A MANUAL
OF THE
OPERATIONS OF SURGERY

FOR THE USE OF

*Senior Students, House Surgeons, and
Junior Practitioners.*

ILLUSTRATED.

BY

JOSEPH BELL, M.D., F.R.C.S. EDIN.,

CONSULTING SURGEON TO THE ROYAL INFIRMARY, AND SURGEON TO THE ROYAL
EDINBURGH HOSPITAL FOR SICK CHILDREN.

Seventh Edition, Revised and Enlarged.

EDINBURGH:

OLIVER AND BOYD, 'TWEEDDALE COURT.

LONDON: SIMPKIN, MARSHALL, HAMILTON, KENT, & CO., LIM.

TO THE MEMORY OF
JAMES SYME, Esq., F.R.C.S. AND F.R.S.E.,
SURGEON TO THE QUEEN IN SCOTLAND,
PROFESSOR OF CLINICAL SURGERY IN THE
UNIVERSITY OF EDINBURGH,
ETC., ETC.,
THIS BOOK IS DEDICATED
BY HIS OLD HOUSE-SURGEON AND ASSISTANT
THE AUTHOR.

PREFACE TO SEVENTH EDITION.

To keep the work up to date has been the Author's aim in this Seventh Edition.

A large part of it has been rewritten, and many new operative procedures added.

The chapter on Eye operations has been revised, and to a great extent rewritten by Mr W. G. Sym, F.R.C.S. Ed., Assistant Ophthalmic Surgeon to the Royal Infirmary of Edinburgh.

2 MELVILLE CRESCENT, EDINBURGH,
July 1892.

PREFACE TO THE FIRST EDITION.

HAVING been asked, year after year, by the members of my Class for Operative Surgery, to recommend to them some Manual of Surgical Operations which might at once guide them in their choice of operations, and give minute details as to the mode of performance, I have been gradually led to undertake the production of this little work.

My aim has been to describe as simply as possible those operations which are most likely to prove useful, and especially those which, from their nature, admit of being practised on the dead body.

In accordance with this plan, neither historical completeness of detail, nor much variety in the methods of performing any given operation, is to be expected. Hence, also, many omissions which would be unpardonable in the briefest system of Surgery are unavoidable. For example, excision of tumours and operations for necrosis are hardly mentioned, because for these no special instructions can well be given; for, while general principles may guide us to *what* should be done, the special circumstances of each case must dictate *how* it is to be done.

In such a work as this, to attempt originality would be undesirable and intrusive; a judicious selection, a faithful compilation, are all that can be expected.

That the selection of operations may sometimes show "Northern Proclivities" is possible; and this is perhaps not unnatural to a scholar and teacher in the Edinburgh School.

An earnest endeavour has been used to make the references correct and copious; for any mistakes or omissions the author would crave indulgence.

The four Plates which precede the letterpress were drawn on wood (from original photographs) by Mr D. W. Williamson, Melbourne Place, and the lines of incision for the various operations were added by the author.

The rough woodcuts scattered through the work were drawn on wood by the author, and for their roughness he, not his engraver, is responsible. He also hopes that the references in the letterpress will be accepted as sufficient acknowledgment of the true ownership, in those few instances in which the idea of the diagram has been borrowed.

It has been thought unnecessary to introduce woodcuts of surgical instruments, as the illustrated catalogues lately published by Weiss, Maw, and others, are sufficiently accurate.

In excuse of the frequent baldness and brevity of the style, the author must point to the size and price

of the work. Its composition would have been easier had its dimensions been greater.

Though intended chiefly to guide the studies, on the dead subject, of students and junior practitioners, the author ventures to hope that the Manual may be useful to those who, in the public services, in the colonies, or in lonely country districts, find themselves constrained to attempt the performance of operations which, in the towns, usually fall to the lot of a few Hospital Surgeons.

JOSEPH BELL.

5 CASTLE TERRACE, EDINBURGH,
July 1866.

CONTENTS.

CHAPTER I.

LIGATURE OF ARTERIES.

	PAGE
Ligature of Arteries—General Maxims—Ligature of Aorta— Iliacs—Gluteal—Femoral—Popliteal—Innominate— Carotids—Lingual—Subclavian—Brachial, etc., .	1-48

CHAPTER II.

AMPUTATIONS.

Amputation—Flap and Circular compared—Special Ampu- tation of Arm and Leg,	49-109
---	--------

CHAPTER III.

EXCISION OF JOINTS.

Brief Historical Sketch—Comparison of Excisions with Am- putations—Special Excisions of the six larger Joints— Excisions of smaller Joints and Bones,	110-151
---	---------

CHAPTER IV.

OPERATIONS ON CRANIUM AND SCALP.

Trephining—Excision of Wens,	152-155
--	---------

CHAPTER V.

OPERATIONS ON THE EYE AND ITS APPENDAGES.

PAGE

Entropium and Ectropium—Ptosis—Tarsal Tumours—On Lachrymal Organs—Mr Bowman's Operation—Pterygium—Strabismus, convergent and divergent—Paracentesis of the Anterior Chamber—Operations for Cataract by Displacement, Solution, and Extraction—Various methods of Extraction—Operations for Artificial Pupil—Iridesis—Corelysis—Iridectomy—Sclerotomy—Excision of Staphyloma—Excision of Eyeball, etc., .	156-177
--	---------

CHAPTER VI.

OPERATIONS ON THE NOSE AND LIPS.

Rhinoplastic Operations from Cheek, Forehead, and elsewhere—Removal of Nasal Polypi—Excision of Cancers of Lips—Cheiloplastic Operations—Operations for Harelip, .	178-193
--	---------

CHAPTER VII.

OPERATIONS ON THE JAWS.

Excision of Upper Jaw—Of Lower Jaw, . . .	194-202
---	---------

CHAPTER VIII.

OPERATIONS ON MOUTH AND THROAT.

For Salivary Fistula—Excision of Tongue, complete and partial—Fissures of the Palate, soft and hard—Excision of Tonsils,	203-215
--	---------

CHAPTER IX.

OPERATIONS ON AIR PASSAGES.

Larynx and Trachea—Tracheotomy—Tubes—Laryngotomy—Laryngectomy—Œsophagotomy,	216-231
---	---------

CHAPTER X.

OPERATIONS ON THORAX.

	PAGE
Excision of Mamma—Paracentesis Thoracis—Excision of Portions of Ribs,	232-237

CHAPTER XI.

OPERATIONS ON ABDOMEN.

Paracentesis Abdominis—Gastrotomy—Gastrostomy—Pylorectomy—Gastroenterostomy—Intestinal Anastomosis—Duodenostomy—Enterectomy—Operations on Liver and Gall Bladder—Operations on the Kidneys—Splenectomy—Ovariectomy—Hysterectomy—Hysterotomy—Operation for Strangulated Hernia—Inguinal—Femoral—Umbilical—Obturator—Operations for the Radical Cure of Hernia—Artificial Anus—Colotomy—Inguinal—Lumbar,	238-296
--	---------

CHAPTER XII.

OPERATIONS ON PELVIS.

Lithotomy—Varieties—Litholapaxy—Lithotrity—Operations for Stricture—Puncture of the Bladder—Phymosis—Amputation of Penis—Hydrocele—Hæmatocele—Castration—Operation for Fistula—Fissure—Prolapsus—Polypi of Rectum—Piles—Excision of Rectum,	297-340
---	---------

CHAPTER XIII.

TENOTOMY.

On Tenotomy for Wry Neck and Club-Foot,	341-345
---	---------

CHAPTER XIV.

OPERATIONS ON NERVES.

Nerve-stretching—Nerve-cutting—Excision of Gasserian Ganglia—Nerve suture,	346-351
INDEX,	353-360

PLATE I.

1. Ligature of Aorta—Sir A. Cooper's incision.
2. Ligature of Aorta—South and Murray's incision.
3. Ligature of Common Iliac.
4. Ligature of External Iliac—Sir A. Cooper's.
5. Ligature of Femoral in Scarpa's triangle.
6. Ligature of Femoral below Sartorius.¹
7. Ligature of Innominate.
8. Ligature of third part of Left Subclavian.
9. Ligature of Axillary in its first part.
10. Ligature of Axillary in its third part.
11. Ligature of Brachial.
12. Amputation of Arm by double flaps.
13. Amputation at Shoulder-joint (1st method), showing portion of skin left uncut till the conclusion of the disarticulation.
14. Amputation at Ankle-joint by internal flap—Mackenzie's.
- 15-16. Amputation of Leg just above the Ankle-joint.
- 17-18. Amputation below Knee—modified circular.
19. Amputation through Condyles of Femur—Syme, and Pl. III. 5.
20. Amputation at lower third of Thigh—Syme, and Pl. III. 6.
 - A. Excision of Head of Humerus.
 - B. Excision of Knee-joint; semilunar incision.

¹ This line is placed too low down; it should be in the middle third of the thigh.

PLATE II.

1. Amputation at lower third of Fore-arm—Teale's.
- 2-2. Amputation at Shoulder-joint by large postero-external flap
—2nd method.
- 3-3. Amputation at Shoulder-joint by triangular flap from deltoid
—3rd method.
- 4-5. Amputation through Tarsus—Chopart's.
- 6-7. Amputation at Knee-joint.
8. Amputation by Single Flap—Carden's, and Pl. IV. 16.
- 9-10. Amputation of Thigh—Teale's.
 - A. Excision of Hip-joint.
 - B-B. Excision of Ankle-joint—Hancock's incisions.

PLATE III.

1. Ligature of Popliteal.
 2. Amputation at Elbow-joint—posterior flap.
 3. Amputation at Shoulder-joint—posterior incision of first method, and Pl. I. 13.
 4. Amputation at Ankle-joint—Mackenzie's, and Pl. I. 14.
 5. Amputation through Condyles of Femur—Syme, and Pl. I. 19.
 6. Amputation at lower third of Thigh—Syme, and Pl. I. 20.
 7. Amputation at Knee—posterior incision.
 8. Amputation of Thigh—Spence's, and at Pl. IV. 18.
 9. Amputation at Hip-joint, and Pl. IV. 20.
-
- A. Excision of Shoulder-joint—deltoid flap.
 - B. Excision of Shoulder-joint by posterior incision.
 - C. Excision of Elbow-joint—H-shaped incision.
 - D. Excision of Elbow-joint—linear incision.
 - E. Excision of Hip-joint—Gross's.
 - F. Excision of Os Calcis.
 - G. Excision of Scapula.

PLATE IV.

1. Ligature of Carotid.
 2. Ligature of Subclavian (3rd stage)—Skey's incision.
 3. Amputation at Wrist-joint—dorsal incision.
 4. Amputation at Wrist-joint—palmar incision.
 5. Amputation at Fore-arm—dorsal incision.
 6. Amputation at Fore-arm—palmar incision.
 7. Amputation at Elbow-joint—Anterior flap, and Pl. III. 3.
 8. Amputation at Arm—Teale's method.
 9. Amputation at Shoulder-joint—1st method, and Pl. III. 3.
 - 10-11. Amputation of Metatarsus—Hey's.
 - 12 13. Amputation at Ankle—Syme's.
 - 14-15. Amputation of Leg—posterior flap—Lee's.
 16. Amputation at Knee-joint—Carden's, and Pl. II. 8.
 17. Amputation of Thigh—B. Bell's.
 18. Amputation of Thigh—Spence's, and Pl. III. 8.
 19. Amputation of Thigh in Middle Third.
 - 20-20. Amputation at Hip-joint, and Pl. III. 9.
-
- A. Excision of Wrist—radial incision.
 - B. Excision of Wrist—ulnar incision.

CHAPTER I.

LIGATURE OF ARTERIES.

Ligature of Arteries.—In a work of this nature there is no room for any discussion of the principles which should guide us in the selection of cases, or of the pathology of aneurism, or the local effects of the ligature on the vessels. One or two fundamental axioms may be given in a few words:—

1. In selecting the spot for the application of the ligature, avoid as far as possible bifurcations, or the neighbourhood of large collateral branches.

2. A free incision should be made through the skin and subjacent textures, till the sheath of the artery is reached and fairly exposed.

3. The sheath must be opened and the artery cleaned with a sharp knife till the white external coat is clearly seen. The portion cleaned should, however, be as small as possible, consistent with thorough exposure, so that the ligature may be passed round the vessel without force.

4. As the artery should never be raised from its bed, it is generally advisable to pass the needle only so far as just to permit the eye to be seen past the vessel. The ligature should then be seized by a pair of forceps and gently pulled through, the needle being cautiously withdrawn. When catgut is used, it is better to pass the unarmed needle till the eye is visible, then thread and withdraw it, thus pulling the catgut through.

5. As a rule, the needle should be passed from the side of the vessel at which the chief dangers exist. This will generally be the side at which the vein is.

6. The ligature should be single, and consist of chromicised catgut or kangaroo tendon. Ligatures of floss-silk are recommended by Messrs Ballance and Edmunds, whose researches on the effects of ligatures on the coats of vessels are of great value. The methods of preparing the material vary, but all agree in principle, that if possible the full strength and pliability of the material be retained, while it is rendered aseptic.

7. Before the ligature is tightened, it is well to feel that pressure between the ligature and the finger arrests the pulsation of the tumour.

8. Mr Teale¹ lays stress, in cases where the artery is tied above and below a wound, on the value of dividing the vessel completely between the ligatures, so as to relieve the tension caused by the elasticity of the arterial coats.

Ligature of the Aorta.—It has been found necessary in a few rare cases to place a ligature on the abdominal aorta; no case has as yet survived the operation beyond a very few days, but they have in their progress sufficiently proved that the circulation can be carried on, and gangrene does not necessarily result even after such a decided interference with vascular supply.

Operation.—The ligature may be applied in one of two ways, the choice being influenced by the nature of the disease for which it is done.

1. A straight incision (Plate I. fig. 1) in the linea alba, just avoiding the umbilicus by a curve, and dividing the peritoneum, allows the intestines to be pushed aside, and

¹ "Address in Surgery," *British Medical Journal*, August 1889.

the aorta exposed still covered by the peritoneum, as it lies in front of the lumbar vertebræ. The peritoneum must again be divided very cautiously at the point selected, which should be midway between the origin of the inferior mesenteric and the bifurcation of the aorta, and the aortic plexus of nerves carefully dissected off, in order that they may not be interfered with by the ligature. The ligature should then be passed round, tied, cut short, and the wound accurately sewed up.

2. Without wounding the peritoneum.

A curved incision (Plate I. fig. 2), with its convexity backwards, from the projecting end of the tenth rib to a point a little in front of the anterior superior spinous process of the ilium. At first through the skin and fascia only, this incision must be continued through the muscles of the abdominal wall, one by one, till the transversalis fascia is exposed, which must then be scraped through very cautiously, so as not to injure the peritoneum, which is to be detached from the fascia covering the psoas and iliacus muscles, and must be held inwards and out of the way by bent copper spatulæ. The common iliac will then be felt pulsating, and on it the finger may easily be guided up until the aorta is reached.

The really difficult part of the operation now begins: to isolate the vessel from the spine behind, the inferior cava on the right side, and the plexus of nerves in the cellular tissue all round. The cleaning of the vessel must be done in great measure by the finger-nail, and much dexterity will be required to pass the ligature without unnecessarily raising the vessel from its bed, especially as the vessel itself may very possibly be diseased, and the aneurism of the iliac trunk for which the operation is required will displace and confuse the parts, and may have set up adhesive inflammation.

Results.—Operation has been performed at least eleven times. By the first method by Sir Astley Cooper and Mr James; by the second by Drs Murray and Monteiro, M'Guire, Heron Watson, and Stokes, and Mr South, and Czerny of Heidelberg, and Mr H. Milton¹ of Cairo. All the cases proved fatal; Dr Monteiro's survived for ten days, and eventually perished from hæmorrhage; the rest all died at shorter intervals.

Ligature of Common Iliac.—*Anatomical Note.*—This short thick trunk varies slightly in its relations on the two sides of the body. As the aorta bifurcates on the left side of the body of the fourth lumbar vertebra, the common iliac of the right side would have a longer course to pursue than that on the left, if both ended at corresponding points. However, this is not always the case, as has been pointed out by Mr Adams of Dublin, as the right common iliac often bifurcates sooner than the left does. With this slight difference, the position of the two vessels is precisely similar, each extending along the brim of the pelvis from the bifurcation of the aorta towards the sacro-iliac synchondrosis for about two inches. Sometimes the division takes place a little higher, even at the junction of the last lumbar vertebra and the sacrum. This variation depends chiefly on the length of the artery, which, as Quain has shown, varies from one inch and a half to more than three inches.

The anterior surface of both arteries is covered by the peritoneum, and each is crossed by the ureter just as it bifurcates into its branches.

The artery of the right side is in close contact behind with its corresponding vein, which at its upper part projects to the outside, and below to the inner side. The

¹ *Lancet*, January 10th, 1891.

artery of the left side is less involved with its vein, which lies below it, and to the inside. The right is in contact with a coil of ileum, the left with the colon. The inferior mesenteric artery crosses the left one, while to the outside of both, and behind them, lie the sympathetic and obturator nerves.

There are no named branches from the common iliac.

Operation.—The chief difficulties to be encountered are—
1. The close proximity of the peritoneum, and specially the risk there is that it has become adherent to the sac of the aneurism; 2. The depth of the parts, and tendency of the intestines to roll into the wound; 3. Specially on the right side, the proximity of the great veins. With these exceptions the passing of the ligature is not so difficult as in some situations, the lax cellular tissue in which the vessel lies generally yielding much more easily than the tough sheath which elsewhere, as in the femoral, requires accurate dissection.

Incision.—(Plate I. fig. 3.)—From a point about half an inch above the centre of Poupart's ligament, a crescentic incision should be made, at first extending upwards and outwards, so as to pass about one inch inside of the anterior superior spine of the ilium, and then prolonged upwards and inwards, as far as may be rendered necessary by the size of the aneurism or the depth of parts. It must extend through skin and superficial fascia, exposing the tendon of the external oblique, which must then be slit up to the full extent visible. The spermatic cord may then be easily exposed under the edge of the internal oblique, and the forefinger of the left hand inserted on the cord, and thus beneath the internal oblique and transversalis muscles, the peritoneum being quite safe below.

On the finger these muscles may be safely divided to the full extent of the external incision. The deep circumflex

iliac artery if possible should not be divided, but may bleed smartly and require a ligature; and in cases where an aneurism has interfered with the circulation, the bleeding both from enlarged arteries and veins may be severe and troublesome.

The peritoneum must then be very cautiously raised from the tumour, and supported, along with the intestines, by copper spatulæ. The surgeon will rarely succeed in obtaining anything like a satisfactory view of the vessel, but can expose it for the ligature by the aid of his finger-nail. An ordinary aneurism-needle will generally suffice for the conveyance of the ligature.

The difficulties may occasionally be much increased by special circumstances, such as great stoutness of the patient, and consequent thickness of the abdominal wall; or large size of the aneurism, which may cause alterations in the relation of parts and adhesion of the peritoneum. The ureter generally gives no trouble, as in pressing back the peritoneum it is adherent to it, and is removed along with it towards the middle line.

Results.—Are not by any means satisfactory,

Sixty-eight cases in all have been collected, with sixteen recoveries.¹

Ligature of Internal Iliac.—Various methods may be used:—

1. By the same incision as for the common iliac. The operator having reached the bifurcation of the vessel, must, instead of tracing it upwards, endeavour to trace it downwards, and the same time inwards, into the basin of the pelvis. To do this his finger must cross the external iliac artery, which will pulsate under the joint of the ungual

¹ *International Encyclopædia of Surgery*, vol. iii. p. 313.

phalanx, while the pulp of the finger is touching the internal iliac,—the external iliac vein, which occupies the angle formed by the bifurcation of the artery, lying between these two points. The ligature should be applied within three-quarters of an inch from the bifurcation.

2. The operation known as Sir Philip Crampton's¹ is partly abdominal and partly lumbar, gets at the artery from behind, with less interference with peritoneum, by an incision commencing at anterior extremity of last false rib, following in a concave direction the line of the crest of the ilium within its inner margin till the anterior superior spine is reached. His brilliant and striking description of the operation is historical.

3. Possibly in these days of disrespect for the peritoneum, an operation on the lines of that used by Dr Dennis of New York for the internal iliac may become general.

Dr Dennis² of New York tied both internal iliacs at the same time for pulsating gluteal tumours by a median incision from umbilicus to pubes. This, after intestines were drawn aside, enabled him to apply catgut ligatures fairly easily. Mr Treves³ has performed the same operation in a boy of sixteen, with success.

Anatomical Note.—This short thick trunk extends backwards and inwards (Ellis); downwards and backwards (Harrison), in front of the sacro-iliac synchondrosis, as far as the upper extremity of the great sacro-sciatic notch, a distance varying in the adult from one and a half to two inches in length. It forms a curve with its concavity forwards, and at its termination divides into, rather than gives off, its two or three principal branches. Its corresponding vein is in close contact behind, as also the lumbo-sacral

¹ *Medico-Chirurgical Transactions*, vol. xvi. p. 161.

² *New York Medical News*, 1886.

³ Treves, *Operative Surgery*, vol. i. p. 213.

nerve, the obturator nerve to its outer side. The peritoneum covers it anteriorly, and it is crossed just at its commencement by the ureter. On the left side it is covered anteriorly by the rectum. Of its anatomical relations, that of the external iliac vein is perhaps the most important, as it is apt to interfere with the passing of the needle.

Results.—This vessel has been tied for aneurism of one or other of its branches, or for wound, about twenty-seven times.¹ Of these eight recovered; in nineteen the operation proved fatal, in most of them from secondary hæmorrhage. In one case the hæmorrhage occurred within twelve hours after the operation. Treves' case which recovered must be added to this list. The circulation of the parts supplied after the ligature is carried on mainly by the lumbar and lateral sacral branches, which become much developed even before the operation, in cases of aneurism.

Ligature of External Iliac.—*Anatomical Note.*—This artery extends from the bifurcation of the common iliac to the centre of Poupart's ligament, where it leaves the abdomen, passing under the ligament, and becomes the common femoral. Its upper extremity is thus not always constant, varying in position from the sacro-lumbar fibro-cartilage to the upper end of the sacro-iliac synchondrosis, or even a little lower down. Thus, though the position of the lower end is at a fixed point, the artery varies in length. In an adult male of moderate stature it is from three and a half to four inches in length. On the surface of the abdomen the position of this vessel would be indicated by a line drawn from about an inch on either side of the umbilicus to the middle of the space between the symphysis pubis and the crest of the ilium. Its relations to neighbouring parts are

¹ *International Encyclopædia of Surgery*, vol. iii. p. 313.

as follows:—The peritoneum lies *in front* of it, separated from it only by a subperitoneal layer of loose fascia, in which the artery and vein lie, which varies much in consistence and amount, and which occasionally gives a good deal of trouble in the operation of ligature. Near its origin it is sometimes crossed by the ureter, and near its termination the genito-crural nerve lies on it. The spermatic vessels cross it, and occasionally a quantity of subperitoneal fat marks its course. *Externally*.—The fascia-iliaca and some fibres of the psoas muscle separate it from the anterior crural nerve, which lies outside of the vessel, and at a somewhat deeper level, hidden amid the fibres of psoas and iliacus. *Internally*.—The external iliac vein lies on the same plane, and to the inner side of the artery, at Poupart's ligament, on both sides of the body. As we trace it upwards we find that on the left side it lies internal to the artery in its whole course, while on the right side it becomes posterior to the artery as it approaches the bifurcation of the common iliac. Lastly, just before the vessel reaches Poupart, the circumflex iliac vein crosses it.

Branches.—The two large branches to the wall of the abdomen, the epigastric and the circumflex iliac, rise a few lines above Poupart's ligament. Their position is unfortunately apt to vary upwards, to the extent of an inch and a half or even two inches, and they are important, as, besides being liable to be cut during the operation, their position very materially modifies the prognosis, as, if too high up, they interfere with the proper formation of the coagulum.

Operation.—Various plans of incision through the skin have been recommended by various operators, the chief difference being with regard to the part of the artery aimed at; the plan known as that of Mr Abernethy, with various modifications, being intended to expose the artery pretty high up, and enable the surgeon to reach it from above;

while the method going by the name of Sir Astley Cooper's exposes the lower part of the artery, and enables the surgeon to reach it from below. Though the latter is in some respects easier, the former method is generally to be preferred, being further from the seat of disease, and especially more out of the way of the epigastric and circumflex arteries.

The higher operation (ABERNETHY's modified).—An incision must be made through the skin about four inches in length, but longer in proportion to the amount of subcutaneous fat, and the depth of the pelvis, extending from a point one inch to the inside of the anterior superior spine of the ilium, to a point half an inch above the middle line of Poupart's ligament. It must be slightly curved, with its convexity looking outwards and downwards.¹

The subcutaneous cellular tissue and the tendon of the external oblique may then be divided freely in the same line. Then at some one point or other (generally easiest below), the internal oblique and transversalis muscles must be cautiously scraped through with the aid of the forceps, till the transversalis fascia is reached; they may then be freely divided by a probe-pointed bistoury (guarded by the finger pushed up below the muscles) to the required extent. The muscles being held aside by the flat copper spatulæ, the fascia transversalis must be carefully scratched through near the crest of the ilium, and thus the operator will be enabled to push the peritoneum inwards, and by the forefinger will easily recognise the pulsation of the artery lying on the soft brim of the pelvis.

A branch of the circumflex iliac artery will very likely be cut in dissecting through the muscles, and must be secured, as also any branches of the epigastric which

¹ The line 3 in Plate I. shows the direction required. It will not be necessary to carry the incision so far up for the external as for the common iliac.

may be divided in the incisions through the abdominal wall (*ut supra*, p. 6).

The operator should then, by pressing the peritoneum and its contents gently inwards, endeavour to see the vessel; if, from the depth of the pelvis, this cannot be done, the sense of touch will be in most cases sufficient to enable him to isolate the artery by the point of his finger-nail, or by the blunt aneurism-needle, from the vein. The ligature should be passed from the inner side to avoid including the vein, and thus there will be less chance of wounding the peritoneum from the convexity of the needle being applied to it. If possible, the genito-crural nerve should not be included in the ligature, but probably such an accident would do no great harm.

It is of much more consequence to avoid injuring the peritoneum. This is sometimes very difficult, from the adhesions which are set up between the peritoneum, the artery, and especially the aneurism, as the result of pressure and inflammation. The accident of wounding the peritoneum has happened to Keate, Tait, Post, and others, and in some cases with perfect impunity. However, the peritoneum should be displaced as little as possible from its cellular connexions, as such displacement increases the risk of diffuse inflammation of that membrane; and the vessel itself should be raised and disturbed as little as possible, lest destruction of the vasa vasorum cause ulceration of the weak coats and secondary hæmorrhage.

The operation from below (Plate I. fig. 4), SIR ASTLEY COOPER's, is thus described by Mr Hodgson:¹—"A semi-lunar incision is made through the integuments in the direction of the fibres of the aponeurosis of the external oblique muscle. One extremity of the incision will be situated near

¹ *On the Arteries and Veins*, p. 421.

the spine of the ilium; the other will terminate a little above the inner margin of the abdominal ring. The aponeurosis of the external oblique muscles will be exposed, and is to be divided throughout the extent, and in the direction of the external wound. The flap which is thus formed being raised, the spermatic cord will be seen passing under the margin of the internal oblique and transverse muscles. The opening in the fascia which lines the transverse muscle through which the spermatic cord passes, is situated in the mid space between the anterior superior spine of the ilium and the symphysis pubis. The epigastric artery runs precisely along the inner margin of this opening, beneath which the external iliac artery is situated. If the finger therefore be passed under the spermatic cord through this opening in the fascia, it will come in immediate contact with the artery which lies on the outside of the external iliac vein. The artery and vein are connected by dense cellular tissue, which must be separated to allow of the ligature being passed round the former."

In comparing the two methods of operating, we find that while the latter is in some respects easier, and the vessel in it lies more superficial, it has certain disadvantages which more than counterbalance its advantages. Thus, first, the epigastric artery is very likely to be wounded. It may be said, Well, if so, the ends can be tied; but this tying is sometimes very difficult; and, as shown in Dupuytren's case of this accident, involves considerable interference with the peritoneum, and a possibly fatal peritonitis. Besides this, by cutting the epigastric you destroy an important agent which would have carried on the anastomosing circulation, and thus greatly increase the risk of gangrene. By this method, also, the artery is exposed too near to the seat of disease; and if found to be enlarged and involved in the aneurism, considerable difficulty may be experienced in

reaching the upper part of the vessel. Again, ligature of the lower third or half of the vessel, which this method implies, is dangerous from the occasional high origin of the circumflex or epigastric, or both, rendering the formation of a clot much more difficult, and secondary hæmorrhage much more likely.

The circumflex iliac vein must also be remembered, as it crosses the artery near the lower end of it, just before it goes under Poupart's ligament.

However, the method may occasionally vary with the individual case. In every case of ligature of the great vessels of the abdomen, the bowels should be carefully evacuated before the operation, and the bladder emptied. A properly managed position, with the shoulders raised and the knees semiflexed, will greatly facilitate the gaining access to the vessel.

In sewing up the wounds in the abdominal walls, advantage will be gained by putting in a certain number of stitches so deeply as to include the whole thickness of the muscles, and in the intervals between these deep ones to insert others less deeply, so as accurately to approximate the edges of the skin. This will both facilitate union and also render the occurrence of hernia less probable. This latter accident did occur in a case, otherwise successful, in which Mr Kirby tied the external iliac.

Both external iliacs have been tied in the same patient with success, on at least two occasions, once by Arendt,¹ with an interval of only eight days between the operations; and a second time by Tait,² at an interval of rather more than eleven months.

This operation is in the great majority of cases performed for femoral aneurism, and naturally secondary hæmorrhage

¹ Velpeau's *Nouv. élém. de Médecine opérative*, vol. i. p. 175.

² Samuel Cooper's *Surgical Dictionary*, p. 157.

is a too frequent result. Wounds of these great vessels generally result in so rapid death from hæmorrhage as to give no time for surgical interference. One case, however, is recorded,¹ in which the external iliac was cut in a lad of seventeen by an accidental stab, and in which Drs Layraud and Durand, who were almost instantly on the spot, succeeded in stopping the bleeding by compresses, till Velpeau arrived, who tied the vessel above with perfect success.

Ligature of Gluteal.—This vessel, though one of the branches of the internal iliac, approaches the surface so nearly as to be occasionally wounded. It is also, though very rarely, the subject of spontaneous aneurism. The principle of treatment and the operation to be selected in any given case depends upon its origin, whether traumatic or spontaneous. For if traumatic, the wound must almost necessarily be accessible from the outside; the neighbouring part of the artery is probably healthy, and hence the case can be treated by the old operation, slitting up the tumour, and tying the vessel above and below the wound. When the aneurism is spontaneous, there is no guide to tell us where the aneurism may have first originated; it may be that it is high up in the pelvis, and that the visible tumour is only its expansion in the direction of least resistance, or the coats of the vessel may be extensively diseased. The only chance is ligature of the internal iliac, and probably the intraperitoneal method is the safest.

1. The old operation, or ligature of the gluteal artery in the hip.

Anatomical Note.—The gluteal is the largest branch of the internal iliac, and leaves the pelvis by the great sacro-sciatic notch just at the upper edge of the pyriformis muscle.

¹ *Cyclopædia of Practical Surgery*, vol. i. p. 277.

After a very short course, it divides into superficial and deep branches opposite the posterior margin of the gluteus minimus, between it and the pyriformis muscles.

Very precise rules have been given to enable the operator to hit on the exact spot where the artery leaves the pelvis. These, though perhaps interesting anatomically, are quite useless in a surgical point of view, for the only reasons which could possibly induce a surgeon to cut down upon the gluteal in the living body, are the existence either of a wound of the vessel or an aneurism. In the first the flow of blood, in the second the tumour, would give sufficient guidance.

In cases of traumatic aneurism the operation should be something like the following:—A free incision should be made into the tumour, dividing it in its long direction; the contents should be rapidly scooped out, and a finger placed on the bleeding point, just at the upper corner of the sciatic notch. This will at once stop the hæmorrhage till the vessel can be secured. This sounds easy enough, and has been done several times with success. Thus, John Bell,¹ by an incision two feet long, as he tells as in his hyperbolical language, was enabled to tie the vessel in the case of the leech-gatherer who had punctured the artery by a pair of long scissors. Carmichael² of Dublin used a smaller incision, removed one or two pounds of clots, and tied the vessel, in a case of wound by a penknife.

Now, though both of these cases were eventually successful, both patients lost during the operation a very large quantity of blood; John Bell's especially could not be removed from the operating-table for a considerable time after the operation. The period at which the great loss of blood took place was the interval after the incision was

¹ John Bell's *Prin. of Surg.*, vol. i. 421. ² *Dublin Jour.*, vol. iv. 321.

made, and before the artery was exposed to view, *i.e.*, the interval in which the surgeon was busy dislodging the clots from the cellular membrane, the sac of the false aneurism.

The procedure devised by Mr Syme to obviate this difficulty, and which was put in practice by him in several very trying cases, is best given in his own terse description of an operation in a case of traumatic gluteal aneurism:—

“The patient having been rendered unconscious, and placed on his right side, I thrust a bistoury into the tumour, over the situation of the gluteal artery, and introduced my finger so as to prevent the blood from flowing, except by occasional gushes, which showed what would have been the effect of neglecting this precaution, while I searched for the vessel. Finding it impossible to accomplish the object in this way, I enlarged the wound by degrees sufficiently for the introduction of my fingers in succession, until the whole hand was admitted into the cavity, of which the orifice was still so small as to embrace the wrist with a tightness that prevented any continuous hæmorrhage. Being now able to explore the state of matters satisfactorily, I found that there was a large mass of dense fibrinous coagulum firmly impacted into the sciatic notch; and, not without using considerable force, succeeded in disengaging the whole of this obstacle to reaching the artery, which would have proved very serious if it had been allowed to exist after the sac was laid open. The compact mass, which was afterwards found to be not less than a pound in weight, having been thus detached, so that it moved freely in the fluid contents of the sac, and the gentleman who assisted me being prepared for the next step of the process, I ran my knife rapidly through the whole extent of the tumour, turned out all that was within it, and had the bleeding orifice instantly under subjection by the pressure of a finger. Nothing then

remained but to pass a double thread under the vessel, and tie it on both sides of the aperture."

The bleeding in this case was thus rendered comparatively trifling, and the patient made a speedy and complete recovery. He returned home within six weeks after the operation.¹

2. In one case, at least, the gluteal artery has been tied with success (for traumatic aneurism) just where it leaves the pelvis, without the tumour being opened. This was in the practice of Professor Campbell of Montreal. The operation was a very difficult one, and while possible only in cases seen very early, and where the tumour is very small, does not appear to have any advantage over the old method. Additional access to the vessel might be obtained by division of a few fibres of the great sacro-sciatic ligament.

Cases of spontaneous aneurism of the gluteal artery should be treated by ligature of the internal iliac. Steven's and Syme's cases of ligature of the internal iliac were of this nature.

Manuals of operative surgery occasionally devote pages to the description of special operations for the ligature of such arteries as the sciatic, epigastric, circumflex ilii, and pudic. They do not require ligature, except in cases of wound either of the vessels themselves or their branches; and, according to the modern principles of surgery in such cases, the ligature should be applied to the bleeding point, rather than to the vessel at a distance above it.

Ligature of Femoral.—Under this head we practically mean cases of ligature of the superficial femoral, for the common femoral, or (as called by some anatomists) the

¹ *Observations in Clinical Surgery*, Syme, pp. 171-3.

femoral, before the profunda is given off, very rarely requires to be tied. If it is wounded, of course the bleeding point must be sought, and the artery tied above and below it, but if an aneurism on the superficial femoral renders ligature of that trunk impossible, experience teaches that ligature of the external iliac gives better results than ligature of the common femoral. Erichsen asserts that out of twelve cases in which the common femoral has been tied, only three have succeeded, the others dying from secondary hæmorrhage. The experience of the Dublin surgeons, Porter, Smyly, and Macnamara, has been more satisfactory, as in eight cases of this operation six were successful.¹ A ninth case was unsuccessful. Reasons to explain the danger are not far to seek, for the numerous small muscular branches, along with the superficial epigastric, circumflex, and pudic trunks, reduce the chances of a good coagulum in the common femoral to a minimum, even without taking into consideration the shortness of the trunk before the great profunda femoris is given off. For the common femoral artery is only from one to two inches in length, and if there are some rare cases in which it is a little later in its bifurcation, there are others in which it divides nearer to Poupart's ligament.

The superficial femoral is the name given to the main trunk between the origin of the profunda and the point at which, passing through the tendon of the adductor magnus, it receives the name of popliteal. During this long course it gives off no branch large enough or regular enough to receive a name, except one, the anastomotica magna, which rises in Hunter's canal, close to the end of the vessel, so in that respect it is peculiarly suitable for the application of a ligature. Again, in the upper part of its course, it is

¹ *Brit. Med. Jour.*, 1867, Oct. 5.

superficial, being covered only by skin and fascia. A short notice of its most important anatomical relations is necessary.

For the first two inches or two inches and a half of its separate existence, the superficial femoral lies in Scarpa's triangle, covered, as we said, only by skin and fascia. This triangle is formed by the sartorius and adductor longus muscles which meet at its apex, and by Poupart's ligament, which defines its base. The artery lies almost exactly in the centre of the space, and at the apex is covered by the sartorius muscle. The spot where it goes under the sartorius is the one selected for the application of the ligature. The femoral vein lies to the inner side of the femoral artery in this triangle, but their mutual relations vary with the portion of the limb; for, on the level of Poupart's ligament, the artery and vein lie side by side on the same plane, but in different compartments of their sheath; as the artery dives below the sartorius, the vein is still on the inside, but on a plane slightly posterior; while, by the time they reach Hunter's canal, the vein has got completely behind the artery. The separate compartments of the sheath in which the vessels lie are much less marked as the vessels go down the limb, the septum between the artery and the vein being in most cases very ill marked, even at the level where the ligature is applied. The anterior crural nerve, which on the level of Poupart's ligament lay outside of the artery and on a plane somewhat posterior, has divided into numerous branches before it reaches the point of ligature. One of its branches requires to be mentioned, and may sometimes be noticed and avoided during the operation, namely, the internal saphenous nerve, which, first lying external to the artery, crosses it in front, reaching its inner side just before it enters Hunter's canal, where it leaves the vessel accompanying the anastomotica magna branch.

Operation of Ligature of the Femoral—Scarpa's space.

—The patient being placed on his back, and being brought very thoroughly under chloroform, the knee of the affected limb should be bent at an angle of about 120° , and supported on a pillow. Having previously ascertained the angle of junction of the sartorius and adductor, the surgeon should make an incision (Plate I. fig. 5) just over the pulsations of the vessel, in the middle line of the space, having its lower end quite over the sartorius muscle, and its upper one, at a distance from two and a half to three and a half inches, varying according to the amount of fat and muscle. The saphena vein can generally be recognised, and is almost always safe out of the way of this incision at its inner side.

The first incision should divide the skin, superficial fascia, and fat, quite down to the fascia lata. The edges of the wound being held apart, the fascia should be carefully divided and the sartorius exposed; its fibres can generally be easily enough recognised by their oblique direction; once recognised, the fascia should be dissected from it till its inner edge be gained, the corner of which should then be turned so that it may be held outwards by an assistant with a blunt hook. The sheath of the vessels is now exposed, and after having thoroughly satisfied himself of the position of the artery by the pulsation, the surgeon should carefully raise a portion of the sheath with the dissecting forceps, and open it freely enough to allow the coats of the artery to be distinctly seen. If the parts are deep, as in a fat or muscular patient, great advantage will be gained by seizing one edge of the sheath by a pair of spring forceps, and committing it to the care of an assistant, while the operator holds the other in his dissecting forceps; there is thus no fear of losing the orifice of the sheath, which without this precaution may easily happen, from the parts being confused with

blood, or the position altered by movements of the patient. Now comes the stage of the operation on which, more than on anything else, success or failure depends. A *small* portion of the vessel must be cleaned for the reception of the ligature, and it must be *thoroughly* cleaned, so that the needle may be passed round it without bruising of the coats or rupture of an unnecessary number of the vasa vasorum by rough attempts to force a passage for it. Hence all compromises, such as blunted instruments, silver knives, and the like, are dangerous, for in trying to avoid the Scylla of wounding the artery, they fall into the Charybdis, on the one hand, of isolating too much of the vessel and causing gangrene from want of vascular supply, or, on the other, expose the vein to the danger of injury by the aneurism-needle in their attempts to force it round an uncleaned vessel.

The needle should in most cases be passed from the inner side, care being taken to avoid including the vein which is on the inner side and behind the vessel; the internal saphenous nerve, if seen, should be avoided. The needle must not be passed quite round the vessel raising it up, still less must the vessel be held up on the needle, as used to be done, as if the surgeon was surprised at his own success, but the needle should be passed just far enough to expose the end of the ligature, which must be seized by forceps and cautiously drawn through. It must then be tied very firmly and secured with a reef knot.

The edges of the wound must be brought into accurate apposition, secured by one or two stitches, and drainage should be provided for.

From the very fact that ligature of the superficial femoral is a remarkably successful operation in causing consolidation of the aneurism and a rapid cure, there is also a corresponding danger that the limb be not sufficiently supplied with blood at first. The limb may very possibly become cold

and remain so for some hours at least after the operation. To avoid this as far as possible, it should be wrapped in cotton wadding, and very great care should be taken that it be not over-stimulated by hot applications, friction, or the like, any of which measures might very likely excite reaction, which would result in gangrene.

Complete rest of the limb and of the whole body must be enjoined; the food must be nourishing and in moderate quantity. The chief danger is from gangrene of the limb, which is especially apt to result when the vein is wounded, or even too much handled during the operation.

When properly performed, and in suitable cases, the operation is very successful. Mr Syme tied this artery for aneurism thirty-seven times, and of these every one recovered. The statistics of Norris and Porta, who collected all the cases in which ligature of the femoral had been employed for *any* cause, show a mortality of somewhat less than one in four. Rabe's table up to 1869, with the additional cases collected by Mr Barwell to 1880, gives 297 cases with 53 deaths.¹ Mr Hutchinson's table, again, of fifty cases collected from the records of Metropolitan Hospitals, shows the very startling result of sixteen deaths out of the fifty cases, or a mortality, in round numbers, of one-third. Let us hope that future statistics will show better results. Antiseptic precautions, early recognition of disease, and improved material used for ligature, should all tend to diminish fatal results.

Certain anomalies have been observed in the distribution of the femoral vessels, of some importance as affecting the possibility of applying, and the result of, ligature; such as—1. A high division of the branches which afterwards become posterior tibial and peroneal. 2. A double super-

¹ *International Encyclopædia of Surgery*, vol. iii. p. 466.

ficial femoral, both branches of which may unite and form the popliteal, as in Sir Charles Bell's well-known case. 3. Absence of the artery altogether, as in Manec's case, where the popliteal was a continuation of an immensely enlarged sciatic.

In such a case the absence of pulsation in front, and the presence of increased pulsation behind the limb, ought to prevent any fruitless attempt at search.

Ligature of the Superficial Femoral below the Sartorius Muscle.—This operation, though once common in France, and though the one recommended by Hunter himself, is now comparatively little used in this country, except in cases of wound; and rightly so; for while it has no advantage over the upper position, it is at once nearer the seat of disease if a popliteal aneurism, and the vessel is more deeply buried under muscles, and has a more distinct fibrous sheath, which requires division.

It is, however, by no means a difficult operation, and is thus performed:—

The limb being laid as before on the outside, and slightly bent, the skin shaved and the pulsation of the artery detected, an incision (Plate I. fig. 6) must be made from the lower edge of the sartorius muscle just as it crosses the vessel, along the course of the vessel, avoiding if possible the internal saphena vein.

The sartorius when exposed must be drawn inwards. The fibrous canal filling the interspace between the abductor magnus and vastus internus is then recognised, and must be fairly opened; the artery is now seen lying in it, and over the vein which is posterior to it, but projects slightly on its outer side; the internal saphenous nerve is lying on the artery. The needle is best passed from without inwards so as to avoid the vein. The anas-

tomotica magna is sometimes a large trunk, and has been mistaken for the femoral in this situation, and tied instead of it.

Ligature of the Popliteal.—This operation is now hardly ever performed for aneurism, ligature of the superficial femoral having quite superseded it, and it is very rarely required for wounds, from the manner in which the vessel is protected by its position.

Before the invention of the Hunterian principle of ligature at a distance, the old operation for popliteal aneurism consisted in cutting into the space, clearing out the contents of the aneurismal sac, and tying both ends of the vessel; from the depth of parts and the close connexion of the popliteal vein, this operation was rarely successful. Mr Annandale has performed it successfully in two cases, in which ligature seemed contraindicated.¹

In cases of hæmorrhage for suppuration of an aneurismal sac, it might possibly be advisable, and there are certain cases of rupture of the artery, without the existence of an external wound, in which attempts have been made to save the limb by tying the vessel.² From the complexity of the parts, the numerous tendons, veins, and nerves crowded together in a narrow hollow, and chiefly from the great depth at which the artery lies, any attempt at ligature is very difficult. It is least so at the lower angle of the space, where, between the heads of the gastrocnemius, the vessel comes more to the surface, but is still overlapped by muscle.

Operation.—The patient lying on his face, a straight incision (Plate III. fig. 1), at least four inches in length, should be made over the artery, and thus nearer the inner than the outer hamstring; a strong fibrous aponeurosis will

¹ *Trans. Edin. Med. Chirurg. Society*, vol. v. p. 35.

² Poland, *Guy's Hosp. Reports*, ser. iii. vol. vi.

require division after the skin and superficial fascia are cut through, the limb is then to be flexed, and the tendons drawn aside with strong retractors; fat and lymphatic glands must next be dissected through, and then the vein and artery, lying on a sort of sheath of condensed cellular tissue, are seen, the vein lying above the artery¹ and obscuring it. The vein must be drawn to the outside, and the thread passed round the artery, which lies close to the bone, on the ligamentum posticum of Winslowe.

It is a very difficult subject to decide what operations should be described in a work of this character, on the vessels of the leg and foot. A very large number of distinct methods of operations on the various parts of the three chief arteries of the leg have been described by surgeons and anatomists, but specially by the latter.

The fact is, however, that these complicated procedures are rarely required, for aneurisms of the arteries of the leg and foot are almost unknown, while in cases of wound of the vessel, or rupture resulting in traumatic aneurism, the proper treatment is not to tie the vessel higher up, but by dilating the wound and clearing out the clots, if required, to secure the bleeding point, and tie the vessel above and below.

Again, a wound of the sole of the foot often gives rise to very severe and persistent hæmorrhage, while the fasciæ and complicated tendons render ligature of the vessel at the spot very difficult; yet ligature of either the anterior or posterior tibial would probably be insufficient; and to tie both these vessels, with possibly the peroneal and interosseous as well, would be a much more severe and dangerous procedure than ligature of the superficial femoral; while probably careful plugging of the wound, combined with

¹ At upper part of space vein is to the outside of the artery, and in lower to its inside.

flexion of the knee, will be found to stop the hæmorrhage sooner than either of the more formidable methods.

A competent knowledge of the anatomy of the part, and of the ordinary methods of checking hæmorrhage, such as ligatures, graduated compresses, with careful bandaging and splints, aided by position, specially flexion of the knee after Mr Ernest Hart's method, will suffice to enable the surgeon to check any hæmorrhage of the foot or leg, without it being necessary to burden the memory with the three positions in which to tie the peroneal, or the various methods, more or less bloody and tedious, by which the posterior tibial in its upper third may be secured.

NOTE.—While, as a matter of surgical principle to guide our practice on the living, I still hold very strongly the opinions here expressed against special operations for ligature of the arteries of the leg, and allow the sentences to stand as in earlier editions of this work, I insert in a note a brief description of the more important ones, in deference to the advice of friends and the urgent request of pupils, as these operations are used by Examining Boards as tests of the operative dexterity of candidates:—

1. ANTERIOR TIBIAL ARTERY IN LOWER HALF OF LEG.—*Anatomical Note.*—This vessel is related on its tibial side to the tibialis anticus, and on its fibular, to the extensor longus digitorum above, and the extensor pollicis below. The anterior tibial nerve lies first on its outer side, then crosses the artery, and eventually reaches its inner side near the foot. *Operation.*—An incision, at least three inches long, parallel with the outer edge of the tibia, and about three-quarters of an inch from it, exposes the deep fascia. This being divided, the outer edge of the tibialis anticus must be found, and will be the guide to the artery, which, surrounded by its venæ comites, lies very deeply between the muscles.

2. POSTERIOR TIBIAL.—*A.* In middle third of leg. Here the artery is separated from the inner border of the tibia, by the flexor longus digitorum, and is covered by the soleus. *Operation.*—An incision at least four inches long, along the inner margin of the tibia, exposes the edge of the gastrocnemius; then divide the tendinous attachment, then expose the soleus, and divide its attachment also; the deep fascia will then be seen; slit it up, and the vessel will be found about an inch internal to the edge of the bone. The nerve is there just crossing it.

Guthrie's, or the direct operation, has the very high authority of the late Professor Spence in its favour. An incision through skin and fascia in the middle of the back of the leg allows the two heads

of the gastrocnemius to be separated to the same extent. The soleus is then to be scraped through in same direction, and its deep aponeurotic surface carefully slit up. The artery and vein are then easily seen.

B. In lower third of leg.—This is an easier and more scientific operation, as it does not involve the division of great tendons. An incision midway between the internal malleolus and the tendo Achillis, parallel with both, will expose the very deep and strong fascia in which the tendons lie. The artery, with its venæ comites, occupies a central position, having the tendons of the tibialis posticus and flexor communis in front between it and the internal malleolus, and the posterior tibial nerve behind it, while the flexor longus pollicis lies still nearer the tendo Achillis.

TABLE illustrating anastomotic circulation after ligature of arteries of lower limb.

1. AORTA.—Epigastric and mammary of both sides.

Hæmorrhoidal and spermatic, with branches of pudic both deep and superficial.

2. COMMON ILIAC.—Internal iliac and branches, with those of the other side, along with the following:—

3. EXTERNAL ILIAC.—Internal mammary and deep epigastric.

Iliolumbar and lumbar branches of aorta, with deep circumflex ilii.

Pudic from internal iliac, with superficial pudic of common femoral.

Gluteal, sciatic, and obturator, with the circumflex and perforating branches or deep femoral.

4. FEMORAL.—External circumflex, with external articular of popliteal.

Perforating, with branches of gluteal and sciatic.

Profunda branches, with anastomotica and articular branches.

Obturator and internal circumflex, with anastomotica and superior internal articular.

NOTE.—The importance of the articular branches of the popliteal explain the danger of gangrene after a sudden rupture or increase in size of a popliteal aneurism.

Ligature of the Innominate.—The performance of this extremely dangerous, in fact almost hopeless operation, is by no means so difficult as might be expected.

The patient lying down with the shoulders raised and head thrown well back, the sternal attachment of the right sterno-mastoid must be very freely exposed. This may be done by an incision (Plate I. fig. 7) along its anterior edge from the upper edge of the sternum, as far as may be necessary; another about the same length along the

upper edge of the clavicle, will meet the former at an acute angle, and will include a triangular flap of skin, which must be carefully dissected up. The sternal, and probably a portion of the clavicular attachment of the right sternomastoid, must then be cautiously divided. This being done, the sterno-hyoid and sterno-thyroid muscles require division immediately above their sternal attachments.

A dense process of cervical fascia (just becoming thoracic) now covers the vessel, binding it on the right side to the right innominate vein, and on the left maintaining the relation of the innominate artery to the trachea. The inferior thyroid veins lie on this fascia, and must be drawn aside, not cut. The fascia is then to be scraped through very cautiously, exposing the root of the right carotid, which being traced downwards, will lead to the innominate. The following parts lie in close relation to the vessel at the point of ligature, and must be avoided:—1. The left innominate vein crosses the artery in front from left to right, and must be drawn down. 2. The right innominate vein and right pneumogastric are in close contact with the artery on the right side; to avoid them the aneurism-needle must be entered on the outside (right of the vessel). 3. The apex of the right pleura and the trachea are in close contact behind, requiring the point of the needle to be kept close to the artery in bringing the thread round.

It might have been expected that the sudden arrest of so large a proportion of the vascular supply of the body, so very near the heart, would cause serious or even fatal symptoms; this, however, is not the case, no serious inconvenience of this sort being experienced; yet hitherto nearly every case has proved fatal, either from secondary hæmorrhage or inflammation of lungs and pleura.

In twenty-one well-authenticated, and in three more doubtful cases, the ligature has been applied; all of these,

except Smyth's, died at periods varying from twelve hours (as in Hutin's case) to sixty-seven days (Graefe's).

A successful case of ligature of the innominate along with the right carotid and (after secondary hæmorrhage) the right vertebral, in a mulatto aged thirty-two, for a subclavian aneurism, has been put on record by Dr Smyth of New Orleans, in the *American Journal of Medical Science* for July 1866.

Another case, successful so far as the operation was concerned, has lately been recorded by Mr Thomson of Dublin. Death resulted on forty-second day from ulceration into the vessels beyond the aneurism, the result of a deep abscess.¹

Mr Mitchell Banks of Liverpool had an even more interesting and successful case in which the innominate was tied with success, patient going out on twentieth day; returning forty-seven days later to have the first part of the subclavian tied for the extending aneurism. He survived the second operation thirty-seven days.²

In four cases the operation was attempted, but the operators had to desist before the application of the ligature, in consequence of the diseased state of the arterial coats. Of these, three died, and one (Professor Porter's of Dublin) case recovered, the patient leaving the hospital with the aneurism nearly consolidated.

Dr Peixotto of Portugal applied a precautionary ligature to the innominate in a case where secondary hæmorrhage occurred from the carotid. The ligature was not tightened beyond what was necessary merely to cause flattening of the vessel. The patient made a good recovery.

Mr R. Barwell has reported twenty-seven most interesting

¹ Mr Thomson's most interesting paper on this subject is full of information down to 1883. *International Encyclopædia of Surgery*, vol. iii. p. 529.

² Jacobson's *Operations of Surgery*, p. 536.

cases in which simultaneous ligature of carotid and subclavian have proved of marked benefit in aortic as well as in innominate aneurisms. Some of them were practically cures.

Professor George Porter of Dublin records an interesting case of subclavian aneurism, in which, after failing to close the axillary artery by acupressure, he applied L'Estrange's compressor to the innominate itself for three days with temporary benefit. The patient eventually died of hæmorrhage.¹

For a very full and interesting account of ligatures of vessels in root of neck we may refer to vol. iii. of the 1883 edition of *Holmes' Surgery*, pp. 119-122, and to vol. iii. of the *International Encyclopædia of Surgery*.

Ligature of Common Carotid.—Though the anatomical relations of the right and left carotid are different at their origin, they so precisely resemble each other in the whole of that part of their course which is at all amenable to surgical treatment, that one description will suffice for both, and the necessary anatomy will be brought out quite sufficiently in the description of each operation.

From its giving off no collateral branches, the common carotid artery may be tied at any part of its course.

It has been tied successfully at the distance of only three-quarters, or, in one case by Porter, hardly to be imitated, one-eighth of an inch from the innominate, and up to an equal distance from its bifurcation. In choosing the part of the vessel for operation, the operator must be guided by the position of the aneurism, if on the vessel itself, but if the aneurism be distant, as in scalp or orbit, he need have regard to position simply as facilitating the operation.

The easiest position in which to apply the ligature is

¹ *Dublin Quarterly Journal*, Nov. 1867.

just above the omohyoid muscle, the vessel being there near the surface.

Ligature above Omohyoid.—Using the anterior border of the sterno-mastoid as a guide, but leaving it gradually above to a little nearer the mesial line, an incision (Plate IV. fig. 1), varying in length according to the depth of fat and cellular tissue in the neck, but with its central point opposite the upper border of the cricoid cartilage, must be made through skin, platysma, and superficial fascia. While making the incision the head should be held back, and the face slightly turned to the opposite side; the parts being now relaxed by position, the edges of the wound must be held apart by blunt hooks or copper spatulæ, and the deep fascia carefully divided over the vessel, which will be recognised by the pulsation. It may be noted here that even in thin subjects the sterno-mastoid edge *invariably* overlaps the vessel, though in many anatomical diagrams the vessel appears to be in part subcutaneous.

The descendens noni may possibly be seen, but this is by no means invariably the case, crossing the sheath of the vessel very gradually from without inwards in its progress down the neck. It must be carefully displaced outwards.

The sheath of the vessel is then to be cautiously opened to the extent of about half an inch. The internal jugular vein, possibly much distended under the anæsthetic, may overlap the artery on its outer side, and will require to be pressed, emptied, and held out of the way. A small portion of the artery being thoroughly separated from the sheath, the aneurism-needle must be passed from without inwards to avoid the vein, and kept as close to the artery as possible to avoid the vagus.

The tendon of the omohyoid muscle, or, in muscular subjects, a portion of its anterior fleshy belly, may be seen

crossing the vessel from above downwards and outwards at the lower angle of the wound.

Ligature of Carotid below the Omohyoid.—An incision in precisely the same direction as the former, but at a slightly lower level, is required, but the dissection is rather more difficult. The edge of the sterno-mastoid when exposed must be drawn outwards; the sterno-hyoid and thyroid inwards; the omohyoid upwards; the sheath opened, and the descendens noni or its branches drawn to the tracheal side. The jugular vein and vagus are both at the outer side, and must be avoided, while the inferior thyroid artery and sympathetic nerve both lie behind the vessel, and may be included in the ligature if care be not taken.

VARIETIES.—*Sedillot's Operation.*—To secure the artery still lower in the neck: An incision two and a half inches long, from the inner end of the clavicle obliquely upwards and outwards in the interval between the sternal and clavicular attachments of the sterno-mastoid; this divides the superficial textures; the two portions of muscle must then be drawn apart. The internal jugular vein lies in the interval, and must be drawn to the outside before the artery can be seen at all, and it is this that makes this operation very difficult and dangerous, especially on the left side, where the vein is close to the artery, and probably even crossing it from left to right. The thoracic duct is behind.

Malgaigne's modification of the above is an improvement: to expose the external attachment of the muscle, to cut it through and turn it to the outside, as in the operation for ligature of the innominate, then to divide or pull inwards sterno-hyoid and sterno-thyroid, thus exposing the sheath. The needle must be passed from without inwards.

Results.—Pilz has collected 600 cases, of which 43·16 per cent. died. The united tables of Norris and Wood give 188 cases, with a mortality of sixty, or nearly one in three. These tables include cases in which the vessel was tied for wounds, and as a preparatory step in the operation of removal of tumours of the jaw, etc. Later statistics give a

very much lessened mortality, due chiefly to the use of animal ligatures.

Of thirty-one cases in which it was tied for pulsating tumours of the orbit, only two died from the operation.¹ Rivington's statistics to a later date give forty-six cases on forty-four patients with six deaths.

Both carotids have been tied in the same patient twenty-five times, at intervals of less than a year; and it is a very remarkable fact that only five of these fifty ligatures proved fatal,—two in which both were tied on the same day, and three in which the operation was performed to arrest hæmorrhage from malignant disease of the face and jaws—from gunshot wound,—and from syphilitic ulceration.

The external carotid, and also most of its principal branches, have been tied for aneurisms, wounds, goitres, enlargement of the tongue, vascular tumours on occiput and other lesions; also as a first stage in the operation of extirpation of the upper jaw, for the purpose of preventing hæmorrhage. However, such operations are rare, and will probably become rarer still, and it is hardly necessary to describe the operations on each *seriatim*.

Aneurism of the external carotid or branches are rare; if idiopathic, ligature of the common carotid will be found at once easier, not more dangerous, and more effectual than ligature of the branch; if traumatic, the aneurism itself should be attacked, and the bleeding point secured by a double ligature. Wounds are common enough, but if accessible at all, the injured vessel should be tied at the bleeding point; if inaccessible (and under this head we may include wounds of the internal carotid), the common carotid must be tied.

No one would think of tying the superior thyroids for

¹ W. Zehender, *Monatsbl. für Augenheilkunde*. 1868.

goitre unless they were so manifestly enlarged, tortuous, and pulsating, as to render the operation so simple (from their superficial position) as to require no special directions; besides this, the cases in which it has been already done have given very little encouragement to repeat it.

As cases may occur in which any diminution of the cerebral supply is contra-indicated, and thus the more difficult ligature of the external carotid may be preferred to the more simple operation on the common trunk, and as the lingual may require ligature near its root, in consequence of obstinate hæmorrhage from the tongue, short directions are given for the performance of both these operations.

1. Ligature of External Carotid.—Head in same position as for the common carotid. A straight incision parallel with the anterior edge of sterno-mastoid, but about half an inch in front of it, must begin almost at angle of jaw, and extend downwards nearly to the level of the thyroid cartilage. Cautiously divide skin, platysma, and fascia; the lower end of the parotid must be pulled upwards, and the veins, which are numerous, cautiously separated. The anterior border of the sterno-mastoid must be pulled backwards, and the digastric and stylo-hyoid forwards and inwards. The superior laryngeal nerve which lies behind the vessel must be avoided.

2. Ligature of Lingual.—To secure this vessel either before it becomes concealed by the hyo-glossus, or after it is under the muscle, a curved incision is necessary, following the line of the hyoid bone, and especially of its greater cornu, but a line or two above its upper border. After the skin and platysma are divided, the posterior belly of the digastric must be recognised, which again will guide to the posterior edge of the hyo-glossus. The edge of the sub-

maxillary gland may very probably require to be raised out of the way. The artery can then be secured, either before it dips under the hyo-glossus muscle, or after it has done so, by the division of a few of its fibres on a director. Care is needed to avoid injury of the hypo-glossal nerve, which lies above the muscle.

The internal carotid artery occasionally, but very rarely, is the subject of idiopathic aneurism. It may, like any other artery, be wounded, especially from the fauces. Traumatic aneurisms, the result of stabs or bullet wounds, occasionally occur, and are most dangerous, tending to point internally.¹ The treatment of either of these lesions is ligature of the common carotid itself, in preference to ligature of the internal carotid. Guthrie's operation for securing the bleeding internal carotid at the injured spot, by dividing and turning up the ramus of the lower jaw, has never been performed in the living body, and is so difficult, dangerous, and unnecessary, as not to merit description.

Ligature of Subclavian.—*Note.*—In consequence of the difference in the origin, and variety in the anatomical relations of the right and left subclavian arteries, in so far at least as their first stage is concerned, it is necessary to give a very brief separate account of each.

Right Subclavian.—The innominate artery divides into the right subclavian and right carotid exactly behind the sterno-clavicular articulation. The right subclavian extends from this point in an arched form across the neck, between the scalene muscles, over the apex of the pleura, till passing under cover of the clavicle, it changes its name to axillary at the lower end of the first rib. For convenience of description, the artery is divided into three parts, which have

¹ Dr Prewitt of St Louis, *Transactions of Amer. Surg. Assoc.*, vol. iv. p. 233.

very various anatomical relations, and differ from each other much in their amenability to surgical treatment by ligature. The anterior scalenus muscle defines the three parts, the first extending to the inner border of the muscle, the second being concealed by the muscle, and the third reaching from its outer border to the lower border of the first rib.

Branches of the Subclavian.—While the deep relations of pleura, veins, and nerves can be noticed under the head of each operation in detail, one anatomical point must never be forgotten as influencing very much the success of all surgical interference with the subclavian arteries—*i.e.*, the branches given off. To give any chance of success in the application of a ligature to such a large vessel, so near the heart, a large portion of artery free from branches is required, that the clot may be long, firm, and undisturbed. The first part of the subclavian gives off the vertebral, thyroid axis, and internal mammary; the second, the superior intercostal; while the third part has in most cases no branch whatever. In these anatomical differences we find the reason for the almost invariable fatality resulting on any interference with the first and second parts, and the comparative safety of ligature of the third part, without requiring to account for the difference on other grounds, such as depth of part, importance of nervous relations, or nearer proximity to the heart.

The second and third parts of both arteries are so similar to each other, that a separate account is not required for the two sides.

Ligature of Right Subclavian.—*First Part.*—*Operation.*—An incision just at upper edge of sternum and right clavicle, extending from inner edge of *left* sterno-mastoid transversely to outer border of right sterno-mastoid through skin, platysma, and exposing sterno-mastoid, to be joined

at an angle by a second incision, which, two, three, or even four inches long, must extend along inner border of right sterno-mastoid. Flap to be raised upwards and outwards. The sternal attachment of the sterno-mastoid must then be cautiously divided, as also part or the whole of its clavicular attachment, according as room is required. The sterno-hyoid and thyroid muscles will then require similar division. The internal jugular will then be seen very prominent,¹ and will require to be drawn inwards or outwards, according to circumstances. The carotid and right subclavian arteries will then be felt lying close together crossed by the pneumogastric and recurrent nerves, the latter turning behind the subclavian. The nerves must be drawn inwards; the cardiac filaments of the sympathetic will then be observed, and drawn outwards. The subclavian vein lies below, concealed by the clavicle, and will probably not be seen during the operation. The needle should be passed round the artery from below upwards, care being taken not to injure the pleura, which lies beneath and behind the artery.

Results.—Eighteen cases, all of which died; mostly of hæmorrhage.

Ligature of Left Subclavian.—*First Part.*—This operation, which has been described by some as impossible, has, I believe, been only once performed on the living body. *Operation.*—Incisions as for the preceding operation, except being on the opposite side. After the skin, platysma, and muscles have been divided, as already described, the deep cervical fascia requires division close to the inner edge of the scalenus anticus. The artery lies excessively deep, and great difficulty is experienced in avoiding injury to the pleura and the thoracic duct.

¹ Butcher, *Op. and Cons. Surgery*, p. 861.

Results.—Once performed by Dr Rodger of New York; death from hæmorrhage on fifteenth day.

Anatomical Note.—The course of the left subclavian in its first stage is much straighter, as its origin is much deeper, than on the right side. The pneumogastric, phrenic, and cardiac nerves lie parallel to its course; the œsophagus and thoracic duct lie behind it, and to its inner side.

Ligature of Subclavian.—*Second Part.*—This very rare operation hardly requires a separate description, as the incisions necessary for ligature of the artery in its third part will, with very slight modifications, be sufficient for the purpose.

It has, however, special elements of danger in it, involved in the unavoidable division of part at least, or probably the whole, of the scalenus anticus. The phrenic nerve, from its position on that muscle, requires special care to avoid dividing it, and in most cases the internal jugular vein is also in the way. The branches of the thyroid axis, which cross the neck, are quite in the line of the incision. The lowest cord of the brachial plexus lies immediately behind the artery, between it and the middle scalenus. The pleura lies just below it. The subclavian vein is generally quite safe, running in front of the scalenus anticus, and at a lower level.

The presence of the superior intercostal branch adds greatly to the danger of ligature of the vessel in this position, from its interfering with a proper clot.

Results.—Dupuytren¹ performed it successfully for a traumatic axillary aneurism. Auchincloss² did it for a large true aneurism, but the patient died sixty-eight and a half hours after the operation. Liston cut through the outer portion of the scalenus with success for an idiopathic aneurism. Thirteen have been collected by Wyeth, with four recoveries and nine deaths.

¹ *Leçons Orales*, iv. 530. ² *Ed. Med. and Surg. Jour.*, vol. xlv.

Ligature of Subclavian.—*Third Part.*—For this comparatively common operation, various methods of procedure have been suggested and employed.

In the dead body, where the axilla is free from swelling, and in thin patients, the artery in this third stage is tolerably superficial, and can be secured with ease. But in very muscular men, with short necks and well-curved clavicles, and specially when the axilla is filled up with an aneurism, and the shoulder cannot be depressed, the operation becomes very difficult.

Operation of Ramsden, Liston, and Syme.—*Position.*—The patient lying on his back with his shoulders supported by pillows, and his head lying back, and drawn to the opposite side; the shoulder of the affected side must be depressed as much as possible.

Incisions.—(Plate I. fig. 8.)—One through skin, superficial fascia, and platysma, along the upper edge of the clavicle, for at least three inches from the anterior edge of the trapezius to the posterior border of the sterno-mastoid, and in muscular subjects freely overlapping the edges of both muscles. Another two inches in length along posterior border of sterno-mastoid meets the first at an angle. On reflecting the chief flap thus made upwards and backwards, the external jugular will be seen, and, if possible, must be drawn to a side; if not, it must be divided, and both ends tied. The lower edge of the posterior belly of the omohyoid must then be sought; this leads at once to the posterior or outer margin of the scalenus anticus. The connexion of the deep fascia to that muscle must then be very carefully scraped through, and by tracing the muscle to its insertion to the first rib, the artery is at once reached, lying behind the insertion. The pulsation of the vessel between the forefinger and the first rib will prove a great assistance; yet care is required, lest one of the branches of the brachial

plexus be secured instead of the artery. The lowest cord lies very close to the vessel. The subclavian vein is not likely to give much trouble, from its being on a lower level, and (unless very much dilated) nearly concealed by the clavicle. The suprascapular artery is also hidden, but the transverse cervical crosses the very line of incision, and may give trouble, being occasionally much enlarged, so much so as even for a time to have been mistaken for the subclavian itself. If possible, both these branches should be saved, as being important means of carrying on the anastomosis for the future support of the limb.

An absorbent gland is occasionally in the way, and has even been mistaken for the vessel and carefully cleaned. Such may be removed without scruple: Liston and Green are reported as having both tied first by mistake one of the cords of the brachial plexus.

Care must be taken not to injure the pleura, which lies immediately behind and below the vessel at the seat of ligature. Various instrumental devices have been invented for passing the ligature. The simplest seems still to be best, a common aneurism-needle with a considerable curve, and with its eye close to its point.

Other methods of operating.—A single curved incision above the clavicle, with its concavity upwards, of about three or four inches long, with its inner end rather higher than the outer (Green, Fergusson).

A linear transverse incision in the same situation (Velpeau).

A single linear incision perpendicular to the clavicle (Roux).

An arched incision (Plate IV. fig. 2) with its convexity outwards, and its base on the posterior edge of the sterno-mastoid, from three inches above the clavicle to the clavicular attachment of the muscle (Skey).

Results.—Dr Wyeth's Tables in 1877 give 251 cases with 134 or 53 per cent. of deaths. Barwell has analyzed some more recent cases with a mortality of 32 out of 90, or 35.5 per cent.

The late Mr Furner of Brighton reported a most interesting case, in which he tied both subclavian arteries at an interval of two years in the same patient, for axillary aneurisms, with success.

Ligature of Vertebral.—This important branch is occasionally tied along with subclavian for aneurisms in root of neck, and has been tied as a treatment for epilepsy in about thirty-six cases by Dr Alexander¹ of Liverpool, with three deaths, but with a hardly satisfactory result on the epilepsy.

Operation is in first stage practically the same as that for ligature of third part of subclavian. After defining and probably dividing part of the clavicular portion of sternomastoid, the operator looks for the scalenus anticus and defines the interval between it and the longus colli. The so-called carotid tubercle of sixth cervical vertebra is a good guide, as the artery may be felt below it. The vein lies in front of the artery, and fibres of the sympathetic are very apt to be wounded or disturbed in the operation.

Ligature of Axillary.—*Anatomical Note.*—This vessel, the next stage in the continuation of the subclavian downwards, may be defined surgically as extending from the clavicle to the lower border of the teres major. From the depth of the vessel at its upper part, the numerous nerves, and the close proximity of the vein, the surgeon has carefully to study the anatomical relations. It, like the subclavian, is commonly divided into three stages, and, also like the subclavian, these stages are defined by the relations of the artery to a muscle, the pectoralis minor. Surgically we may draw a very close parallel between the two vessels, for we find that in the axillary, as in the subclavian, the first stage is very deep, and very rarely amenable to ligature; the second still deeper and more rarely attempted, as

¹ *Dictionary of Surgery*, vol. ii. p. 786.

in both the operation involves division of a deep muscle; while the third stage in each is the one most frequently chosen by the surgeon.

First Stage.—Between the lower edge of the first rib and upper border of the pectoralis minor the vessel is deeply seated, contained in that process of deep fascia called the costo-coracoid membrane, and covered above by skin, platysma, and the clavicular portion of the pectoralis major. It lies on the first intercostal muscle and the upper digitation of the serratus magnus, while the cords of the brachial plexus are on its acromial side, and the axillary vein in close contact with it on its thoracic side, and frequently overlapping the artery.

Operation.—The great desideratum is free access. An incision (Plate I. fig. 9), semilunar in shape, with its convexity downwards, must extend from half an inch outside of the sterno-clavicular articulation to very near the coracoid process, stopping just before it arrives at the edge of the deltoid, in order to avoid injury of the cephalic vein. It must include skin, fascia, and platysma, and the flap must be thrown upwards. The clavicular portion of the pectoralis major must then be divided right across its fibres, which will retract. The arm must then be brought close to the side to relax the pectoralis minor, which must be drawn aside. The artery will then be felt pulsating, but hidden by the costo-coracoid membrane, which acts as its sheath. This must be carefully scratched through, the nerves pulled outwards, the vein avoided and pulled downwards and inwards, and the thread passed round from within outwards. (Manec, Hodgson, and, with slight modification in the incision through the skin, Chamberlaine.)

Ligature has been performed in this position by separating the pectoralis and deltoid muscles, without dividing the muscular fibres (Roux, Desault).

To attempt to gain access between the clavicular and sternal por-

tions of pectoralis major, as has been proposed by some, is almost impracticable in the living body, from the position of the vein, to which, rather than to the artery, this incision leads.

Ligature of Axillary, in its second stage, is not an advisable operation, when it is merely intended to throw a ligature round the artery for an aneurism lower down.

It has been performed at least twice by Delpech, but it is a rude procedure; in his cases, after the muscle was cut, a dive with the finger was made to collect the whole mass of vessels and nerves, and bring them to the surface near the collar-bone; in this position it is said the artery was easily isolated and tied.

In Mr Syme's operation of cutting into large axillary aneurisms, and tying both ends of the vessel, the pectoralis minor may, indeed generally has, to be divided, and must take its chance without any special notice or precaution, in the sweeping, free incisions required.

Ligature of Axillary, in its third stage.—This is an operation very much more common, more easy of accomplishment, and safer in its results than either of the preceding; the artery in this stage being more superficial, in fact almost subcutaneous.

Operation.—The arm being extended and supinated, an incision (Plate I. fig. 10) two and a half or three inches long, must be made in the base of the axilla over the artery, involving at first skin and superficial fascia only; the deep fascia is then exposed and must be carefully scraped through, avoiding injury of the basilic vein, if (as sometimes occurs) it has not yet dipped through the fascia. The vessel can now be felt; the median nerve which lies over the artery, or slightly to its outer side, must be drawn outwards, and the axillary vein, which lies at the thoracic side, but often overlaps the vessel, must be carefully drawn inwards. The ligature must then be passed from within outwards.

When the patient is very fat or muscular, the coracobrachialis muscle may be required as a guide to the vessel; but in general its superficial position renders any guide quite unnecessary, even in the dead body.

Anatomical Note.—While in each stage the axillary artery gives off branches, those arising from the third stage are by far the most important, especially the subscapular, which leaves it at the edge of the muscle of the same name. To avoid these the ligature should be applied as low down on the vessel as possible, and, in point of fact, the operation called ligature of the third stage of the axillary is, anatomically speaking, really ligature of the brachial high up, and where there is room at all, there will be the less chance of secondary hæmorrhage, the greater the distance is between the ligature and the great subscapular branch.

Mr Syme's Operation for Axillary Aneurism.—Description of the operation in his own words:—

“Chloroform being administered, I made an incision along the outer edge of the sterno-mastoid muscle, through the platysma myoides and fascia of the neck, so as to allow a finger to be pushed down to the situation where the subclavian artery issues from under the scalenus anticus and lies upon the first rib. I then opened the tumour, when a tremendous gush of blood showed that the artery was not effectually compressed; but while I plugged the aperture with my hand, Mr Lister, who assisted me, by a slight movement of his finger, which had been thrust deeply under the upper edge of the tumour, and through the clots contained in it, at length succeeded in getting command of the vessel. I then laid the cavity freely open, and with both hands scooped out nearly seven pounds of coagulated blood, as was ascertained by measurement. The axillary artery appeared to have been torn across, and as the lower orifice still bled freely, I tied it in the first instance. I next cut

through the lesser pectoral muscle close up to the clavicle, and holding the upper end of the vessel between my finger and thumb, passed an aneurism-needle, so as to apply a ligature about half an inch above the orifice." ¹

In a similar operation performed by the author for traumatic aneurism, the result of a stab, very little blood was lost, though no incision was made above the clavicle. The patient made a good recovery. ²

Ligature of Brachial.—To arrest hæmorrhage from a wound of the artery itself, no special directions are required, except to enlarge the wound, and secure the vessel above and below the bleeding point. There are, however, rare cases in which for bleeding in the palm (after all other means have failed), or for aneurism lower down the arm, a ligature may be necessary.

Operation.—The biceps muscle, at its inner edge, is the best guide to the position of the incision, or if it be obscured by fat or œdema, a line extending from the axilla, just over the head of the humerus to the middle of the bend of the elbow, will define its course. An incision (Plate I. fig. 11) three inches in length, about the middle of the arm (when you have the choice of position), through skin and superficial fascia, will expose the deep fascia, and probably the basilic vein. Drawing the latter aside, cautiously divide the deep fascia. The artery is then exposed, but in close relation to various nerves; of these the ones most likely to come in the way are—1. The median, which lies in front of, but a little to the outside of the artery, though in some rare cases it lies behind it; 2. The internal cutaneous; 3. The ulnar, both of which ought to be rather to the inside of the artery. Two brachial veins accompany and wind

¹ *Observations in Clinical Surgery*, pp. 148, 149.

² *Edin. Med. Journal*, March 1879.

round the vessel, occasionally interlacing. Pulsation will, in the living body, usually suffice to distinguish the artery from the other textures, and the ligature may be passed from whichever side is most convenient.

Note.—The relation of the median nerve to the vessel varies according to the part of the arm—thus, as low as the insertion of the coracobrachialis it is to the outer side, as has been described, it then crosses the vessel obliquely, and two inches above the elbow it is on the inner side of the artery. Again, the operator must never forget the possibility of there being a high division of the artery. This occurs, Mr Quain has shown, perhaps once in every ten or eleven cases, and may necessitate ligature of both trunks.

In those cases (once much more frequent than at present) where an aneurism has formed after a wound of the brachial at the bend of the arm in venesection, the aneurism may be either circumscribed or diffuse.

If circumscribed, it is advised by some surgeons, specially by the late Professor Colles of Dublin, that the brachial should be tied immediately above the tumour. In most cases of circumscribed, and in all such cases of diffuse aneurism, the preferable operation is boldly to lay open the tumour, turn out all the clots, seek for the wound in the artery, and tie the vessel above and below, dividing it in all cases between the ligatures. A tourniquet above, or, better still, a trustworthy assistant, prevents all fear of hæmorrhage, and such a radical operation exposes the limb to far less chance of gangrene than do any attempts at removing or lessening the tumour by pressure (as recommended by Cusack, Tyrrell, Harrison), and is much more certain than a mere ligature above.¹

Ligature of Vessels in Fore-arm.—Here, as also we found is the case in the leg, it is almost useless to go on

¹ See case of recurrence, Fergusson's *Practical Surgery*, 1st ed., p. 222.

giving exact directions as to the method of throwing a ligature round the vessels in all possible situations.

For below the elbow spontaneous aneurism is almost unknown, and even traumatic aneurisms are extremely rare. It is therefore for hæmorrhage only that the vessels are likely to require ligature, and it is a rule in surgery that to enlarge the wound and to apply a ligature above and below the bleeding point is better practice than to apply a ligature at a distance.

In the case of wounds of the palmar arch, it is extremely difficult, and very apt to injure the future usefulness of the hand, thus to seek for the bleeding point under the palmar fascia, and for *these*, ligatures of radial and ulnar have occasionally been practised. However, as even this has proved ineffectual, and the interosseous has proved sufficient to continue the bleeding, ligature of the brachial at once is preferable to ligature of so many branches in the fore-arm.

The use of graduated compresses, carefully applied, combined with flexion of the elbow over a bandage, will generally prove sufficient to check such hæmorrhage from the palm, without having recourse to either of the above more severe measures.

Note.—As in the lower limb at page 26, and for the same reasons, I here insert a brief account of the methods of tying the ulnar and radial arteries.

1. **LIGATURE OF ULNAR.**—Only admissible in the lower half of its course. *Operation.*—Use the tendon of the flexor carpi ulnaris as a guide, and make an incision along its radial edge, at least two inches in length; expose the deep fascia of the arm and then cautiously divide it; then bending the hand, the flexor carpi ulnaris is relaxed, and the artery is found lying pretty deeply between it and the flexor sublimis digitorum. The ulnar nerve lies at its ulnar side, and the venæ comites accompany the artery. In a tolerably muscular arm, the incision will have to be about an inch inside of the ulnar border of the limb.

2. **RADIAL.**—This artery lies more superficial than the preceding, and may be tied at any part of its course.

A. *Operation in upper part of fore-arm.* Here the artery lies in

the interval between the supinator longus and the pronator radii teres. In a muscular arm, the edge of the former muscle is the best guide; in a fat one, the incision may be made in a line extending from the centre of the bend of the arm to the inner edge of the styloid process of the radius. The deep fascia must be exposed and opened, and the muscles relaxed and held aside. The radial nerve lies on the radial side of the vessel.

B. Operation in lower half of arm. Here the vessel is more superficial, lying in the groove between the flexor carpi radialis and supinator longus. An incision two inches in length, and parallel with these tendons, easily exposes the artery. The nerve is still on its radial side, but is making its way to the back of the hand.

C. Operation at first metacarpal. The artery may be tied easily enough in the triangular space bounded by the extensors of the thumb, on the dorsum of the proximal end of the first metacarpal bone. Skey¹ recommends a transverse,—Stephen Smith² and others, a longitudinal incision. The author has had to secure the radial in its lower third, the superficialis volæ, and the radial again in the triangular space, in a case where division of the artery by a transverse cut had caused a large aneurism to form close above the annular ligament.

TABLE illustrating anastomotic circulation after ligature of arteries of neck and upper limb.

1. Common carotid.

(a) Across middle line: thyroids, linguals, facials, occipitals; also terminal branches of external carotids; also internal carotids by circle of Willis.

(b) Of same side: occipital with vertebral; superior thyroid with inferior thyroid, etc.

2. Subclavian, 3d part.

Suprascapular with dorsal branches of subscapular; posterior scapular with costal and muscular branches of subscapular. Thoracic anastomosis between internal mammary and intercostals, with branches of axillary.

3. Axillary and brachial. Anastomosis varies with the position of the ligature, but is very free between the various muscular branches of these vessels.

CHAPTER II.

AMPUTATIONS.

IN ordinary surgical language the name Amputation is applied to all cases of removal of limbs, or portions of limbs, by the knife, though in strict accuracy it should be restricted to those cases in which a limb is removed *in the continuity of a bone*, its removal *at a joint* being called a Disarticulation.

There are two chief methods in which the knife may be used in severing a limb with the view of leaving soft parts to cover the bone as safely, quickly, and comfortably as possible. These are,—the Flap method, in which two, three, or more flaps of skin and muscles are made either by transfixion or dissection so as to fit over the bone and to each other; and the Circular, in which, by rapid sweeps of the knife round the limb, the soft parts are divided in different layers so as to form a sort of cup-shaped hollow, at the bottom of which the bone is found, and which heals by approximation of its surfaces. Both methods may be used, are suitable in different positions, and also even in the same operation it is possible to unite the advantages of both the flap and the circular method.

In the modified circular, which is best suited for amputation below the knee, and in the long anterior flaps of Teale, Spence, and Carden, we have illustrations of the manner in which the advantages of both the flap and circular methods have been secured without the disadvantages of either. The long anterior flap, not like Teale's to fold upon itself, but

like Spence's and Carden's, to hang over and shield the end of the bones and the face of a transversely-cut short posterior flap, seems to be now the typical method for successful amputations. There may be exceptions, as when the anterior skin is more injured than the posterior, or where an anterior flap would demand too great sacrifice of length of limb, but as a rule it will be found the best method for the patient.

Amputation of the Upper Extremity.—The extreme importance of the human hand, its tactile sensibility, its grasping power, and the irreparable loss sustained by its removal, render the greatest caution necessary, lest we should remove a single digit or portion of one that might be saved. In cases of severe smashing injuries involving the fingers, it is the surgeon's bounden duty not recklessly to amputate the limb with neat flaps at the wrist-joint, but carefully to endeavour to save even a single finger from the wreck, though at the risk of a longer convalescence, or even of a profuse suppuration. While a toe or two, or a small longitudinal segment of the foot, may be comparatively useless, and a good artificial foot, with an ankle-joint stump, certainly preferable, a single finger, provided its motions are tolerably intact, will prove much more valuable to its possessor than the most ingeniously contrived artificial hand.

However, while in cases of extensive smash we endeavour to save anything we can, the case is very much altered when it is only one or two fingers that are injured. Here we find another principle brought into play, and our conservative surgery must be limited by the following consideration. In endeavouring to save a portion of the injured finger or fingers, will the saved portion interfere with the important movements of the uninjured ones? These two

principles—1. Generally to save as much as we can; 2. Not to save anything which may be detrimental or in the way, —will guide us in describing the amputations of the upper extremity.

FIG. I.

Amputation of a distal phalanx.—This small operation is not very often required. In cases of whitlow in which the distal phalanx alone has necrosed, removal of the necrosed bone by forceps is generally all that is necessary. In cases of injury, however, in which nail and distal phalanx are both reduced to pulp, it will hasten recovery much to remove the extremity. There is

no choice as to flap, the nail preventing an

anterior one, so a flap long enough to fold over must be cut from the pulp of the finger in either of two ways (Fig. I. 1):—1. Holding the fragment to be removed in the left hand, and bending the joint, the surgeon makes a transverse cut across the back of the finger, right into and through the joint, cutting a long palmar flap from within outwards as he withdraws the knife.

FIG. II.

Note.—Some difficulty is often felt in making the dorsal incision so as exactly and at once to hit the joint; the most common mistake being, that the transverse incision is made too high, and the knife, instead of striking the joint, only saws fruitlessly at the neck of the bone above. To avoid this, the surgeon should take as a guide to the joint, not the well-marked and tempting looking *dorsal* fold in the skin, but the *palmar* one, which exactly corresponds with the joint between the proximal and middle phalanges, and is only about a line above the distal articulation.— (Fig. II.)

2. Making the long flap by transfixion, it may be held back by an assistant, and the joint cut into.

Amputation through the second phalanx.—If the distal phalanx be so much crushed that a flap cannot be obtained, two short semilunar lateral flaps may be dissected (Fig. 1. 2) from the sides of the second phalanx, which may then be divided by the bone-pliers at the spot required.

In cases of injury which do not admit of either of the preceding operations, it is quite possible to amputate either at the first joint, or even through the proximal phalanx. Patients are sometimes anxious for such operations in preference to amputation of the whole finger. The surgeon should, however, never amputate through either middle or ring finger higher up than the distal end of the second phalanx, unless absolutely compelled by the patient, for the resulting stump, being no longer commanded by the tendons, will prove merely an incumbrance, and may possibly require a secondary operation at no distant date for its removal.

This rule is applicable in cases in which a single finger is injured, and two or three complete ones are left; in cases where all the fingers have been mutilated every morsel should be left, and may be of use.

Amputation of a whole finger.—(Fig. 1. 3)—This is an operation of great importance, from its frequency.

If the third or fourth digits require amputation, it should be performed as follows:—The vessels of the arm being commanded, an assistant holds the hand, separating the fingers at each side of the one to be removed. The surgeon holding the finger to be removed, enters the point of a long straight bistoury exactly (some authorities say half an inch) above the metacarpo-phalangeal joint, and cuts from the prominence of the knuckle right into the angle of the web, then, turning inwards there, cuts obliquely into the palm to a point nearly opposite the one at which he set out.

He then repeats this incision on the other side, makes

tense the ligaments, first at one side and then at the other, by drawing the finger to the opposite side, and cuts them. The tendons being cut, the finger is detached. The vessels being tied, one point of suture is put in on the dorsal aspect, and the fingers on each side tied together at their extremities, with a pad of lint between them.

Note.—While most authorities agree with the direction in the text regarding the palmar termination of the incision, I believe, in most cases, it is not necessary to go so far, and that the incisions may fitly meet in the palm at a point midway between a point opposite to the knuckle, and the centre of the well-marked “sulcus of flexion.”

The so-called racket incision is slightly different from the above, and does not cut so deeply on palmar surface. The dorsal incision begins opposite neck of metacarpal bone in middle line, ending after passing base of phalanx, it then divides into two, which extend obliquely across each third of root of finger, and are united by a transverse incision in the palmar crease or sulcus of flexion.

Modification.—Lisfranc's method is too long in its minute description to give in detail. The principle is to make a semilunar flap at one side (the one opposite the operator's right hand), by cutting from without inwards, then to open the joint from this cut, and, still keeping the edge of the knife close to the head of the phalanx, cutting the other flap from within outwards. This can be very rapidly done, but the last flap is apt to be irregular and deficient, especially in those common cases, in which, after whitlow or suppuration, the tissues are hard and brawny, and the skin does not play freely.

It is quite unnecessary to remove the head of the metacarpal, either for the sake of appearance, or to render healing more rapid, and its removal weakens the arch of the hand; where the cartilage is eroded by disease, the cartilage-covered portion can be scooped off by a gouge or removed entire by pliers, without interfering with the broad end to which the transverse ligament of the palm is attached. If required either for injury or disease, the metacarpal head may be easily removed by a single straight incision from the knuckle upwards, as far as the point at which it may be deemed necessary to saw it through, or better

still, divide it with the bone-pliers. This incision should be made as a first step in the first incision for amputation of the finger, and the finger should not be disarticulated, but kept on, to aid by its leverage in separating the metacarpal head.

Amputation of the index or little fingers.—This operation differs from the preceding only in this, that care must be taken to make a good large flap on the free side of each; making the incision, which begins at the knuckle (Fig. 1. 4), enclose a well-rounded flap, and not allowing it to enter the palm till it reaches the level of the web between the fingers. The metacarpal heads may here be cut obliquely with the bone-pliers, to prevent undue projection.

Amputation of one or more metacarpals.—These operations may be rendered necessary by disease or injury. If the latter demands their performance, no rules can be given for incisions or flaps, they must just be obtained where and how they can best be got. If for disease, a single dorsal incision (Fig. 1. 5) over the bone will allow it to be dissected out of the hand.

N.B.—In no case, except that of the thumb, should any attempt be made to save a finger while its metacarpal is removed. (See *Excisions of Bones*.)

Amputation of first and fifth metacarpals.—Various special operations have been devised for speedy and elegant removal of these bones. Their disadvantages, etc., are fully detailed under *Amputations of the Foot*.

The vascularity and consequent vitality of the tissues of the hand and arm sometimes afford very encouraging and satisfactory results in conservative operations.

The following is an instance of what may be accomplished in a young healthy subject.

A. A., æt. 18, ploughman, was harnessing a vicious horse, when it caught his right hand between its teeth, and gave

a severe bite. On admission, I found the middle and ring fingers completely separated at the metacarpal joints, but each hanging on by a portion of skin, the middle by the skin on its radial side, the ring by that on its ulnar. The back and the palm were both stripped of skin up to the middle of the third and fourth metacarpal bones, which were exposed, but not fractured. As it was important for him to maintain the transverse arch of the hand intact, I determined to make an attempt to save the metacarpals, and finding that the skin on the radial side of the middle, and ulnar side of the ring fingers, was still warm, and apparently alive, I carefully dissected as long a flap as possible from each, and then folded them down, one at the front, the other at the back of the hand. The flaps survived, and the result was admirable, the patient being able in a very few weeks to guide the plough. The sensation in his new palm and back of the hand is very peculiar, they being still the fingers, so far as nervous supply is concerned.

In amputations for injury involving the metacarpals, it is always important to avoid entering the carpo-metacarpal joint, hence if it can be done it is best to saw through the bones at the required level, rather than disarticulate. This rule should be observed even in those cases in which the thumb alone can be saved, for notwithstanding the isolation of the joint between the first metacarpal and the trapezium, it is very important for the future use of this one digit that the motions both of the wrist and carpal joints should be preserved entire.

No exact rules can be given for the performance of these operations, as the size and positions of the flaps must be determined by the nature of the accident and the amount of skin left uninjured.

In the rare condition where the greater part of the metacarpus is destroyed, and yet carpal joints are uninjured, a

most useful artificial hand, preserving the movements of the wrist, may be fitted on, and as much as possible should be saved; but in cases of injury, where the carpus is opened and the hand irreparably destroyed, the question arises, Where ought amputation to be performed? To this we answer, that there appears no conceivable advantage to be gained by leaving all or any of the carpal bones. If successful, it would result only in the retention of a flapping joint, useless from there being no tendons to act upon it, except the tendon of the flexor carpi ulnaris attached to the pisiform, and there are several risks it would run in the inflammation of all the carpal joints, and the almost certain spread of this inflammation to the bursa underneath the flexor tendons, beyond the annular ligament, and up the arm among the muscles.

Amputation at the Wrist-Joint.—This is an operation by no means frequent, and it has the advantages of preserving a long stump, and retaining the full movements of pronation and supination, in cases where the radio-ulnar joint is sound and uninjured, but in practice it is often found that fibrous adhesions limit to a great extent the motions of the two bones on each other, specially in those cases where the radio-ulnar joint has been diseased or injured.

Another advantage is the extreme ease with which disarticulation may be performed on emergency, no saw being required, and the ordinary bistoury of the pocket-case being quite sufficient for cutting the flaps.

Operation.—By double flap. An incision (Plate IV. fig. 3) on the dorsal surface, extending in a semilunar direction from one styloid process to the other, will define a flap of skin only, which must be raised; the joint must then be opened by a transverse incision, and a long semilunar flap of skin and fascia should be shaped (Plate IV. fig. 4) from

the palm. Disarticulation is facilitated by the surgeon forcibly bending the wrist when he makes the transverse cut, and it will be found easier to shape the palmar flap from the outside by dissection, than to do it by transfixion after disarticulation, on account of the prominence of the pisiform on the inner side of the palm.

FIG. III.*

FIG. IV.*

In the thin wasted wrist of the aged, or in any case where the skin is very lax, this amputation may be very easily performed by the circular method. While an assistant draws up the skin as much as possible, the surgeon makes an accurate circular incision through the skin, about an inch below the styloid processes, just grazing the thenar and hypothenar eminences. Another circular sweep just above the pisiform and unciform bones divides all the soft textures, after which the joint may be opened, and, if necessary, the styloid processes cut away with saw or pliers.

Amputation by a long single flap, either dorsal or palmar, may be rendered necessary by accident. The palmar one of the two is preferable; indeed, rather than trust for a covering to the thin skin of the back of the hand, with its numerous tendons, it is better to amputate an inch or two higher up through the fore-arm.

The following amputation by external flap was described (so far as I can discover, for the first time) by Dr Dubrueil, in his work on Operative Surgery:¹—"Commencing just below the level

* FIG. IV. shows dorsal view of incision. FIG. III. shows face of completed stump; R, Radial; U, Ulnar.

¹ *Manual d'Opérations chirurgicales.*

of the articulation, while the hand is pronated, the surgeon makes a convex incision, beginning at the junction of the outer and middle thirds of the arm behind, reaching at its summit the middle of the dorsal surface of the first metacarpal, and terminating in front just below the palmar surface of the joint, again at the junction of the outer and middle thirds of the breadth of the arm. This flap being raised, the wrist is disarticulated, beginning at the radial side. A circular incision finishes the cutting of the skin."—(Figs. III. and IV.)

Amputation through the Fore-arm.—The method of operating must, in the fore-arm, depend a good deal upon the part of the arm where you require to amputate, the muscularity of the limb, and the condition of the skin and subcutaneous cellular tissue.

It must be remembered that a section of the fore-arm involves two bones, not, like the tibia and fibula, in a constant permanent relation in position to each other, but which rotate one upon another to an amount which varies with the part of the limb divided, and which rotation is a very important element in the future usefulness of the stump; again, that two sets of muscles occupy, one the back, the other the front of the limb, that these two are unequal in size, and that the outer sides or rather edges of each bone are subcutaneous; again, that these sets of muscles are comparatively fleshy in the upper two-thirds of the limb, and almost entirely tendinous in the lower third.

Remembering these points, we find that certain things require our attention, and certain difficulties are present in amputation of the fore-arm, from which amputation of the arm, with its single bone and copious muscular covering on all sides, is completely free.

Thus our flaps in the fore-arm must be antero-posterior; lateral flaps are an impossibility. Great care is requisite to cut them at all equal, from the inequality of the muscles on the two sides. In the lower third we cannot obtain available muscular flaps. Lastly, care must be taken lest, from

the ever-varying relations of the two bones to each other in the varying positions of the limb, the surgeon mistake their position and pass his knife between them.

The next question that arises is, Where are we to operate? In cases where we have a choice, is there here, as in the leg, any "point of election"? *No.* As a rule in the fore-arm, the surgeon should endeavour to save as much as possible; especially when nearing the middle of the fore-arm, he should try to save the insertion of the pronator teres, so important in its function of pronating the radius.

Amputation in Lower Third of the Fore-arm.—By two flaps. These antero-posterior flaps must consist of skin only, as the tendons are only in the way, and thus should be made by dissection from without.¹ Making the dorsal one first, the surgeon should enter his knife at the palmar edge of the bone that is further from him, and cut a semilunar flap of skin only, finishing the incision quite on the palmar edge of the inner bone. The two ends of this incision must then be united by a similar semilunar flap of skin on the palmar side. The two flaps having been dissected back, he then clears the bones by a circular incision through tendons and muscles, not forgetting to pass the knife between the bones, and retracting all the soft parts, saws through the bones, at least half or probably three-quarters of an inch higher up. It is generally easiest to saw through both bones at once.

Long Dorsal Flap.—Where it is possible from laxity of the soft parts and the wrist not being much destroyed, to get a long flap from the back of the arm after Mr Teale's method, a very good stump will result. His rule is, "In

¹ As the surgeon will find it most convenient to stand on his own right side of the limb to be removed, the knife will be entered on the palmar side of the radius of the right arm, of the ulna of the left.

tracing the long flap a longitudinal line is drawn over the radius, so as to leave the radial vessels for the short flap (Plate II. fig. 1). At a distance equal to half the circumference of the limb, another line parallel to the former is drawn along the ulna. These are then joined at their lower ends, across the dorsal aspect of the wrist or fore-arm, by a transverse line equal in length to half the circumference of the fore-arm. The short flap is marked by a transverse line on the palmar aspect, uniting the long ones at their upper fourth.

"The operator, in forming the long flap, makes the two longitudinal incisions merely through the integuments, but the transverse one is carried directly down to the bones. In dissecting the long flap from below upwards, the tissues of which it is composed must be separated close to the periosteum and interosseous membrane. The short flap is made by a transverse incision through all the structures down to the bones, care being taken to separate the parts upwards close to the periosteum and membrane." The stump must be placed in the prone position, "to allow the long dorsal flap to be the superior when the patient is recumbent, and thus fall over the ends of the bones."¹

The principal objection to the long dorsal rectangular flap (which makes an excellent covering) is, that unless it can be obtained from over the wrist-joint it requires the bones to be sawn so very high up. This may be avoided, to some extent, by making it shorter and rounded off, as in Carden's Amputation, *q.v.*

Amputation in Upper Two-Thirds.—Where the fore-arm is very fat or fleshy, this amputation can be very easily performed by two equal antero-posterior flaps made by transfixion. In most cases, however, from the comparative

¹ Teale, *On Amputation by Rectangular Flaps*, pp. 46-48.

leanness of the dorsal aspect of the limb, the following method will have the best result. The surgeon must, as in the former case, shape a rounded dorsal flap by dissection from without (Plate IV. fig. 5), embracing the whole breadth of the limb down to the palmar edge of both bones. Then at once he transfixes the two points of this dorsal flap, and cuts out an equal one from the palmar aspect of the limb (Plate IV. fig. 6). Dissecting up the dorsal flap he clears the bones at least half an inch above as before, and applies the saw.

N.B.—This operation should be performed even in cases where only an inch of radius can be retained, as the attachment of the biceps makes a very small stump of fore-arm wonderfully useful.

Amputation at Elbow-Joint.—In cases where it is found impossible to save any portion of the fore-arm, disarticulation at the elbow-joint may be easily performed. This operation was proposed and performed so long ago as the days of Ambrose Paré,¹ was much approved by Dupuytren, Baudens, and Velpeau, had fallen into disuse for a time, but is now again recommended by some excellent surgeons, especially by the late Dr Gross² and Dr Ashhurst,³ both of Philadelphia.

It is tolerably easy to perform, and does not involve any sawing of bones, but the flaps are apt to be cut too short, unless care be taken, from the manner in which the trochlea projects downwards beyond the line of the condyles, so that if the base of an ordinary-shaped flap be made on a level with the condyles, it will prove insufficient to cover the bone. It may be performed either by the circular method

¹ Johnson's folio ed., p. 342.

² Gross's *Surgery*, 6th ed., vol. ii. p. 1103.

³ *International Encyclopædia of Surgery*, vol. i. p. 641.

(Velpéau), oval (Baudens), or by a long anterior and short posterior flap (Textor and Dupuytren). Probably the best method is by a long anterior flap when it can be obtained, thus:—The arm being placed in a slightly flexed position, the surgeon transfixes in front of the joint, in a line extending from the level of the external condyle to a point one inch below the internal condyle (Plate IV. fig. 7); the tissues should be held well forward at the moment of transfixion. The flap should be at least two and a half inches deep at its apex, which must be rounded off. The two ends of this flap may then be united behind by a semilunar incision (Plate III. fig. 2), which will separate the radial attachments. The ulna must then be cleared, and the triceps divided at its insertion.

Modifications.—Dupuytren used to saw through the ulna, leaving the olecranon attached. Velpéau opposed this, but it is again recommended by Gross, who leaves the olecranon, and at the same time improves the shape of the stump by sawing off the "inner trochlea" on a level with the general surface.

Amputation of the Arm.—This amputation is best performed by double flap, and is the typical instance which exhibits all the advantages of two equal flaps made by transfixion, without any of the disadvantages of that method. These advantages are, easiness of performance, rapidity, excellent covering for the bone, with as little sacrifice of tissue as is possible, while the fact that the cicatrix is opposite the end of the bone is hardly a disadvantage in the arm (as it certainly is in the leg), as no weight has to be borne on it. When they can be obtained, anterior and posterior flaps are generally considered most satisfactory, but Mr Spence preferred lateral ones, lest the line of union should be interfered with by the deltoid raising the bone. If the right arm has to be amputated, the operator standing at the inner side raises the anterior muscles with his left hand, and

enters the knife just in front of the brachial vessels (Plate I. fig. 12); keeping as close as possible to the bone, he brings out the knife at a point exactly opposite, then with a brisk sawing motion, cuts a semicircular flap, taking care to bring out the knife more suddenly just at the end, in order to cut through the skin as perpendicularly to the arm as possible. The knife is again entered at the same point, carried behind the bone, and brought out at the same angle, and an exactly corresponding flap cut from the other side of the limb, the flaps are then retracted, the bone cleared by circular incision, and sawn through as high up as it is exposed. In primary cases, where the muscles are firm and developed, the flaps should be cut a little concave.

Modifications and Varieties.—Teale's method may of course be used here as elsewhere. The internal line of incision (Plate IV. fig. 8) should be made just in front of the brachial vessels. This method requires the amputation to be performed higher up than would otherwise be necessary (from the length of the anterior flap), and this disadvantage is not counterbalanced by any special advantage in the posterior retraction of the cicatrix.

In feeble flabby arms, the true circular operation is very easily performed, and with good results. A circular sweep of the knife is made through the skin alone, which is drawn up by an assistant, while the surgeon separates it from the fascia; another circular cut through fascia and muscles exposes the bone, which must then be cleared and cut through at a still higher level.

Amputation at the Shoulder-Joint.—This operation, like that at the hip-joint, can, from the nature of the joint to be covered, and the abundant soft parts in the normal state of the tissues, be performed on the dead in very various ways, by single, double, or triple flaps, by transfixion or dissection, rapidly or slowly. Hence manuals of operative surgery might collect at least twenty different methods, most of which have some recommendation, and all of which are practicable enough.

When, however, we reflect that in the living body, in cases where amputation at the shoulder-joint is required

at all, the severity of the accident, or the urgency of the disease, will, in general, leave no room for selection, we shall see how utterly valueless is any knowledge of mere methods of operating, and of how much greater importance it is that we should simply be thoroughly familiar with the anatomy of the joint.

For example, an accident which necessitates amputation so high up has, in all probability, opened into the joint and destroyed the soft parts on at least one aspect; in such a case the flaps must be cut from the uninjured soft parts only. If an aneurism has rendered amputation through it and through the joint a last resource, the flap must be gained chiefly at least from the outside; a malignant tumour of the humerus will almost certainly prevent any transfixion, and require flaps to be made by dissection, wherever the skin is least likely to be involved. Again, some of the most vaunted and most rapid operations almost require for their success the integrity of the humerus, which has to make itself useful as a lever in disarticulation, while in most cases of accident we are amputating for compound injury of the humerus, almost certainly implying fracture with comminution.

From its proximity to the trunk, hæmorrhage is one of the chief dangers to be apprehended during this operation, especially from the axillary artery. As far as possible to obviate this danger, most plans of operating are based on the principle that the vessels and nerves should be the last tissues to be cut; in some they are not divided till after disarticulation.

While a good assistant, to make pressure on the subclavian above the clavicle, is a most advisable precaution, too much must not be trusted to this pressure above, as the struggles of the patient and the spasmodic movements of the limb, which are so apt to occur under the stimulus

of the knife, are apt to render futile the best efforts at compression.

The operator should trust rather to making the incisions in such a manner that the great vessel be not divided till the hand of an assistant, or in default of a suitable one, his own left hand, is able to follow the knife and grasp the flap.

The bleeding from the circumflex, subscapular, and posterior scapular arteries can easily be arrested by a dossil of lint till the great vessel is tied, and they can be secured.

In cases where proper assistants cannot be had, temporary closure of the axillary vessel could easily be made by carrying a strong silver wire or silk ligature completely round the vessel by a curved needle before the incisions are commenced, and by tying this firmly over a pad of lint.

Pressure on the artery above the clavicle is best made by the thumb of a strong assistant, who endeavours to compress it against the first rib; where the parts are deep and muscular, the padded handle of the tourniquet, or of a large door-key, will do as the agent of pressure.

A brief notice of three of the best methods of operating will be quite sufficient to show what should be aimed at in shoulder-joint amputations:—

1. In cases where the surgeon can choose his flaps, the following method will be found the most satisfactory, as resulting in the smallest possible wound, in having less risk of hæmorrhage during the operation than any other method, and in providing excellent flaps.

It is Larrey's method slightly modified.

Operation.—With a moderate-sized amputating knife an incision of about two inches in length, extending through all the tissues down to the bone, should be made from the edge of the acromion process to a point about one inch below the top of the humerus; from this latter point a

curved incision, enclosing a semilunar flap, should be made on each side of the limb to the anterior and posterior folds of the axilla respectively (Plate IV. fig. 9, and Plate III. fig. 3). These flaps should then be dissected back, including the muscles and exposing the joint. When thoroughly exposed, the joint must then be opened from above, and the bone separated. One small portion of skin lying above the artery, vein, and nerves still remains to be divided (Plate I. fig. 13). This may be done by an oblique cut from within outwards, in such a direction as to form part of the anterior or internal incision, and with the precaution of having an assistant to command the vessels before they are divided. The resulting wound is almost perfectly ovoid, the flaps come together with great ease in a straight vertical line, which admits of easy and thorough drainage. Union is generally rapid. Larrey's success by this method was very remarkable: ninety out of a hundred cases in military practice were saved, notwithstanding the well-known risks of such operations.

2. As good as the former, and nearly as universally applicable, is the method devised by Professor Spence, and practised by him in nearly every case:—"With a broad strong bistoury I cut down upon the inner aspect of the head of the humerus, immediately external to the coracoid process, and carry the incision down through the clavicular fibres of the deltoid and pectoralis major muscles till I reach the humeral attachment of the latter muscle, which I divide. I then with a gentle curve carry my incision across and fairly through the lower fibres of the deltoid towards, but not through, the posterior border of the axilla. Unless the textures be much torn, I next mark out the line of the lower part of the inner section by carrying an incision through the *skin and fat only*, from the point where my straight incision terminated, across the inside of the arm to meet the in-

cision at the outer part. This insures accuracy in the line of union, but is not essential. If the fibres of the deltoid have been thoroughly divided in the line of incision, the flap so marked out, along with the posterior circumflex trunk, which enters its deep surface, can be easily separated from the bone and joint, and drawn upwards and backwards so as to expose the head and tuberosities, by the point of the finger without further use of the knife. The tendinous insertions of the capsular muscles, the long head of the biceps, and the capsule, are next divided by cutting directly upon the tuberosities and head of the bone; and the broad subscapular tendon especially, being very fully exposed by the incision, can be much more easily and completely divided than in the double-flap method. By keeping the large posterior flap out of the way by a broad copper spatula or the fingers of an assistant, and taking care to keep the edge of the knife close to the bone, the trunk of the posterior circumflex is protected. In regard to the axillary vessels, they can either be compressed by an assistant before completing the division of the soft parts on the axillary aspect, or to avoid all risk, the axillary artery may be exposed, tied, and divided between two ligatures so as to allow it to retract before dividing the other textures." ¹

Another, but not so good method of making an external flap, is the following :—(a.) For the right arm.—The patient lying well over on his left side, the surgeon stands to the inside of the arm to be removed. Seizing the deltoid in his left hand, with the right he passes an amputating knife, seven or eight inches in length, from a point a little nearer the clavicle than the middle space between the acromion and coracoid processes; then, transfixing the base of the deltoid, and just grazing the posterior surface of the humerus, thrusts the knife downwards and backwards till it protrudes at the posterior margin of the axilla. When doing this, it is important that the arm be held outwards and backwards, and even upwards, as far as possible to relax the deltoid; without this it will be impossible to make the flap of the full size. The flap must then be cut of as full length as can

¹ Spence's *Surgery*, pp. 800, 801.

be obtained, four or five inches at least. An assistant then holds it upwards, while the surgeon, or (if the arm is very muscular) another assistant brings the arm forwards well across the patient's chest, thus exposing the posterior aspect of the joint. This may have very possibly been already opened during the transfixion; the attachments of muscles must now be divided, the knife passed behind the head of the bone, which is dislocated forwards, and a suitable flap of the tissues in front cut from within outwards. The assistant is to follow the knife with his finger and compress the vessels.

(b.) If the left shoulder is to be amputated, the patient lying on his right side, the surgeon stands behind him, and raising the elbow of the limb to be removed from the side, and pulling it slightly backwards, enters the knife at the posterior fold of the axilla (Plate II. fig. 2), and passing the posterior aspect of the head of the humerus, endeavours to protrude it as near the acromion as possible; the flaps must be cut and the rest of the operation performed in the manner we have just described for the other arm.

3. Where the destruction of tissue has been chiefly below the joint, a very good flap may be obtained from above, composed chiefly of the deltoid muscle, and the skin over it. This may be made by transfixion at its base, but is better obtained by dissection from without.

The surgeon cuts (Plate II. figs. 3, 3) in a semilunar direction (with the convexity downwards) from one side of the deltoid to the other, viz., from the root of the acromion to near the coracoid process; he then raises the large flap upwards and throws it back, opens the joint, disarticulates, passes the knife behind the head of the bone, and cuts out, without attempting to save any flaps below, in a transverse direction. By this means the artery is still almost the last structure to be divided, and can be secured by a ready assistant. In cases where much injury has been done to the floor of the axilla and wall of chest, the deltoid flap must be made large in proportion, and triangular rather than semilunar in shape.

N.B.—The statistics of amputation at the shoulder-joint bring out some interesting facts:—1. That the primary amputations here are far more successful than secondary ones.

Guthrie records nineteen cases of the former out of which only one died, while out of a similar number in which the amputation was secondary, fifteen died. In the Crimea, British surgeons had thirty-nine cases with thirteen deaths; of thirty-three primary, nine died; and of six secondary, four were fatal.

S. W. Gross's¹ statistics confirm this; of one hundred and seventy-eight primary, forty-six died—25·8 per cent.; of ninety-five secondary, sixty-one died—64·2 per cent.

Amputations above the Shoulder-Joint.—Under this head we may group the comparatively rare cases in which, from accident or disease, the removal of portions of the scapula and clavicle, or even the entire bones, is rendered necessary. That it is quite possible to survive such injuries has been frequently shown in cases of accident when the scapula along with the arm has been torn off, and yet the patient recovered.

Encouraged by such cases, Gaetani Bey of Cairo removed the whole of scapula and part of the clavicle in a case where he had amputated at the shoulder for smash. The patient recovered. Heron Watson has had a similar case. Dr George M'Lellan amputated arm and scapula in a youth of seventeen for an enormous encephaloid tumour.

The author amputated upper extremity, including scapula and outer half of clavicle, for a rapidly growing vascular sarcoma, to which the skin was partially adherent. He provided against hæmorrhage as follows:—First, exposing and dividing the clavicle, he passed a long curved skewer underneath the great vessels, making its point project in front. Then with an elastic ligature passed in figure-of-8 manner round both ends of skewer, he entirely compressed the great vessels. This allowed the tumour and arm to be

¹ Gross's *Surgery*, 8vo, 6th ed., vol. ii. p. 1106.

carefully dissected out, with a hæmorrhage certainly less than an ounce. The arm had previously been raised and emptied by an Esmarch bandage. The patient made a good recovery. Mr Chavasse,¹ in his excellent paper on the subject, records forty-four cases of this amputation for new growths.

In Paul Berger's monograph on this subject, he describes the steps of an elaborate operation which can always be done on the dead body, but is by no means universally applicable in the living one. After carefully excising subperiosteally the middle third of the clavicle, he ties both artery and vein with a double ligature, between which they are then divided. He cuts a pectoro-axillary flap, and divides the brachial plexus; next, the arm being drawn forwards, he cuts by dissection a posterior scapular flap of skin, and exposes and divides the trapezius, after which the omohyoid, levator anguli scapulæ, rhomboids, and serratus are easily cut.

Syme amputated with success the arm along with the scapula and outer half of clavicle, in a case in which he had previously excised the head of the humerus for a tumour.²

Gilbert, Mussey, Rigaud, Fergusson, and others, have performed similar operations, secondary to amputation at the shoulder-joint, for cases of caries and malignant tumour. It is impossible to give any exact directions for the incisions which must be planned for individual cases, with two chief aims, to avoid hæmorrhage as far as possible, and to leave abundance of skin. In operations on the scapula, it should be freely exposed by large enough incisions. And if the method of arresting hæmorrhage by the author above described be used, there need be no hurry in planning the flaps or making the dissection. (See *Excisions*.)

¹ *Medico-Chirurgical Transactions*, vol. lxxiii., 1890.

² *Excision of Scapula*, p. 33.

Amputations of Lower Extremity.—Commencing with the most distal, and gradually working our way upwards, we find that partial amputations of the toes are extremely rare. Only in the case of the great toe is such an operation *ever* admissible, for the other toes are so short, and the stumps left by amputation are at once so useless from their shortness, and so detrimental from the manner in which they project upwards and rub against the shoe, that any injury requiring partial amputation of a lesser toe is treated by its complete removal.

Amputation of Distal Phalanx of Great Toe.—This is comparatively rarely required now. It used to be thought necessary for the cure of those not uncommon cases of exostosis of the distal phalanx, but it is now found that most of these can be cured by simply clipping off the exostosis. It is important to save the base of the distal phalanx even if the ungual portion of it requires removal. When necessary, however, and when the choice of flaps is possible, the best plan is by a long flap from the plantar surface (Fig. v. 4), as in the similar operation on the thumb; laying the edge of the knife over the dorsal aspect of the joint, cutting through it, and turning the edge of the knife round close to the bone, so as to cut out a large flap from the ball of the toe.

FIG. v.

Amputation of a Single Lesser Toe—*second, third, or fourth.*—This operation is on exactly the same principle as that described for the corresponding finger; but it must be remembered that the metatarso-phalangeal joint is more

deeply situated in the soft parts than is the metacarpophalangeal; and thus the commencement of the elliptical incision which is to surround the base of the toe must be proportionally higher up (Fig. v. 1). On the other hand, as it is very important to avoid as much as possible any cicatrix in the sole of the foot, the plantar end of the incision need not be carried to a point exactly opposite the one from which it set out, but it will be sufficient if it reaches the groove between the toe and sole. A little more care may thus be required in dissecting out the head of the first phalanx, but this is quite repaid by the cicatrix in the sole being avoided. Early division of the flexor tendons renders disarticulation easy.

Amputation of the First and Fifth Toes.—The incisions are conducted on the same principle as in the other operations, the operator being careful to preserve as much as possible (Fig. v. 2) of the hard useful pad of the inner and outer sides respectively.

Most surgeons are now agreed that in these operations it is best not to remove the head of the metatarsal bone with the toe. Cutting off the large cartilaginous head obliquely with a pair of bone-pliers may prevent an awkward unseemly projection, but it does diminish the strength of the transverse arch of the foot.

Amputation of one or more Toes with their Metatarsals.—It is not necessary to give very particular details regarding such operations, as the surgeon must be guided in the individual cases by the specialties of accident or disease.

One or two guiding principles are important:—

1. Having made up your mind at what point you are to cut the metatarsal, if the amputation be a partial one, or as

to the exact position of the joint, if you intend to disarticulate, commence your dorsal incision (Fig. v. 3) at a point fully half an inch higher up than the selected spot, as free access is of the very last importance.

2. Whenever it is possible, cut the bone through its continuity rather than disarticulate. Specially is this important in the case of the metatarsal bone of the great toe, that the insertion of the tendon of the peroneous longus may be saved. If, however, the terminal branch of the *dorsalis pedis* artery be wounded, it may be necessary to disarticulate the first metatarsal to secure it rather than trust to compression to stop the bleeding.

3. In cutting through the first and fifth metatarsals, remember to apply the bone-pliers obliquely, not transversely, so as to avoid unseemly projection.

4. As far as possible avoid cutting into the sole at all.

The plantar cicatrix is almost a fatal objection to a plan of removing the first and fifth toes and their metatarsals which has much otherwise in rapidity and elegance to recommend it. In the great toe, for example, it is performed as follows:—Seizing the soft parts of the inner edge of the foot in his left hand, the surgeon draws them *inwards*, transfixes just at the tarso-metatarsal joint, and keeping as close as possible to the inner edge of the metatarsal bone, cuts the flap as long as to the middle of the first phalanx; then the soft parts of the foot being drawn as far *outwards* as possible by an assistant, the surgeon enters his knife between the first and second toes, and succeeds in entering his former incision so as to separate the metatarsal bone without removing any skin. All that remains is to open the tarso-metatarsal joint. It is a very neat-looking operation, leaves a very good covering for the parts, and is performed with extreme rapidity. This last is not so much

required in these days of anæsthetics, and the cicatrix in the sole is a very formidable objection to it.

The simplest and shortest rule that can be given for the amputation of a toe, with the part or whole of its metatarsal, is to make one dorsal incision, commencing about a quarter of an inch above the spot at which you intend to divide the bone or to disarticulate, extending downwards in a straight line to the metatarso-phalangeal articulation, and then bifurcating so as to surround the base of the toe at the normal fold of the skin. The soft parts are then to be cleared from the metatarso-phalangeal joint, and the toe still being retained on the metatarsal bone, it should be carefully dissected up, avoiding any pricking of the soft parts below, till the joint is reached, or the spot at which the bone-pliers are to be applied is fully cleared.

Amputation of the Anterior Portion of the Foot at the Tarso-Metatarsal Joint—Hey's Operation.—This operation, which is now comparatively rarely performed, has been invested with a halo of difficulty and complexity which is to a great extent unnecessary.

There is no doubt that the anatomical conformation of the joints involved, especially the manner in which the head of the second metatarsal (Fig. v. c) projects upwards into the tarsus, and is locked between the cuneiform bones, renders disarticulation in the healthy foot rather difficult; but it must be remembered that in cases where for accident we have to deal with previously healthy tissues, it is quite unnecessary to disarticulate, a better result being attained by simply sawing the foot across in the line of the articulation; and again, where we have to operate for disease, the tissues are so matted, and the bones so soft, that complete removal of the metatarsus is much easier than it appears when practising on the dead subject.

Very various plans of incision have been proposed. Mr Hey's original procedure has not been much improved upon. His short account of it has at once surgical value and historical interest:—

“I made a mark across the upper part of the foot, to point out as exactly as I could the place where the metatarsal bones were joined to those of the tarsus. About half an inch from this mark, nearer the toes, I made a transverse incision through the integuments and muscles covering the metatarsal bones (Plate IV. figs. 10, 11). From each extremity of this wound I made an incision (along the inner and outer side of the foot) to the toes. I removed all the toes at their junction with the metatarsal bones, and then separated the integuments and muscles forming the sole of the foot from the inferior part of the metatarsal bones, keeping the edge of my scalpel as near the bones as I could, that I might both expedite the operation and preserve as much muscular flesh in the flap as possible. I then separated with the scalpel the four smaller metatarsal bones at their junction with the tarsus, which was easily effected, as the joints lie in a straight line across the foot. The projecting part of the first cuneiform bone which supports the great toe I was obliged to divide with a saw. The arteries, which required a ligature, being tied, I applied the flap which had formed the sole of the foot to the integuments which remained on the upper part, and retained them in contact by sutures.

“The patient could walk with firmness and ease; she was in no danger of hurting the cicatrix by striking the place where the toes had been against any hard substance, for this part was covered with the strong integuments which had before constituted the sole of the foot. The cicatrix was situated upon the upper part of the foot, and had very little

breadth, as the divided parts had been kept united after being brought into close contact.”¹

Lisfranc's method has, briefly, the following modifications:—Having fixed the position of the articulations of the first and fifth metatarsals with the tarsus, the operator unites them by a curved incision across the dorsum of the foot, with its convexity downwards. He then divides the dorsal ligaments over the articulations, opens the first from the inside, the fifth, fourth, and third from the outside, he then with a strong narrow-bladed knife divides the interosseous ligaments between the sides and end of the head of the second metatarsal and the cuneiforms, thus completing the disarticulation; bending the fore part of the foot downwards, he then keeps the edge of the knife close to the lower surface of the bones, separating the plantar ligaments, and cutting out a long plantar flap of skin and muscles.

In every case it must be remembered that the upper end of the fifth metatarsal projects far up along the outer edge of the foot. Allowance must be made for this projection in commencing the incision. A rule given by Mr Syme to guide the disarticulation of the three outer metatarsals will often be of service; it is this: “Having once entered the joint of the fifth, the knife must be drawn along in a direction of a line drawn towards the distal end of the first metatarsal; for the fourth, the direction must be changed to the middle of the same bone; and to open the third it will be necessary to come across the dorsum of the foot as if intending to reach the proximal end.”

To avoid the difficulties of disarticulation, Skey recommends cutting of the head of the second metatarsal with a pair of pliers. Baudens, Guerin, and others approve of sawing all the bones across in the line desired.

¹ Hey's *Observations*, 3rd ed., pp. 552, 556.

Most surgeons are now agreed that in this operation it is better to make both flaps by cutting from without, in preference to transfixion of the plantar one from within. In cases where, from injury and disease, the plantar flap is deficient in size, it may be necessary to make the dorsal flap longer. However, the long plantar is preferable both from its superior hardness, and also because from its length it permits the cicatrix to be well on the dorsum of the foot, and therefore less likely to be injured by the pressure of the boot in front.

Amputations through the Tarsus.—Various plans of amputating through the tarsus have been devised and described at great length. The most important of these is the operation of removal of the anterior portion of the foot, at the joints between the astragalus and scaphoid, and os calcis and cuboid, well known to the profession by the name of its first describer, Chopart.

It has been to a great extent in cases of disease superseded by the infinitely preferable amputation at the ankle-joint of Mr Syme, and is comparatively rarely practised in this country. Indeed, amputation at the ankle-joint may be said to have taken the place of most of these amputations through the tarsus; for though cases are occasionally met with in which the limitation of the disease or injury may render Chopart's possible, and though at first sight it appears to have an advantage in removing less of the body, still, in many cases of removal for disease of the tarsus, the bones left behind, though apparently sound at the time, are almost sure to become eventually diseased.

In cases performed for injury, however, we find that by suitable and ingenious boots, a Chopart's or Hey's stump may be useful and maintain ankle-joint movements. A very full, scientific, and valuable paper on this subject by Mr

Charles W. Cathcart is published in the *Edinburgh Medical Journal* for March 1888.

Chopart's own manner of operation was briefly somewhat as follows:—

The tourniquet having been applied, the surgeon is to make a transverse incision through the skin which covers the instep, two inches below the ankle-joint. He is to divide the skin, and the extensor tendons, and the muscles in that situation, so as to expose the convexity of the tarsus. He is next to make on each side a small longitudinal incision, which is to begin below and a little in front of the malleolus, and is to end at one of the extremities of the first incision. After having formed in this way a flap of integuments, he is to let it be drawn upwards by the assistant who holds the leg. There is no occasion to dissect and reflect the flap, for the cellular substance connecting the skin with the subjacent aponeurosis is so loose, that it can easily be drawn up above the place where the joint of the calcaneum with the cuboides and that between the astragalus and scaphoides ought to be opened. The surgeon will penetrate the last the most easily, particularly by taking for his guide the eminence which indicates the attachment of the tibialis anticus muscle to the inside of the os naviculare. The joint of the os cuboides and os calcis lies pretty nearly in the same transverse line, but rather obliquely forwards. The ligaments having been cut, the foot falls back. The bistoury is then to be put down, and the straight knife used, with which a flap of the soft parts is to be formed under the tarsus and metatarsus, long enough to admit of being applied to the naked bones, so as entirely to cover them, etc.¹

Chopart's amputation, after an interval of comparative

¹ Roux's *Parallel between English and French Surgery*. Translation abridged from Cooper's *Surgical Dictionary*, p. 106.

neglect, was introduced into this country by Mr Syme in 1829. His method of performance is thus described: "The blade of the knife employed should be about six inches long, and half an inch broad, sharp at the point and blunt on the back. The tourniquet ought to be applied immediately above the ankle, having compresses placed over the posterior and anterior tibial arteries. The surgeon should measure with his eye the middle distance between the malleolus externus and the head of the metatarsal bone of the little toe, which is the situation of the articulation between the os cuboides and os calcis. Placing his forefinger here, he ought to place his thumb on the other side of the foot directly opposite, which will show him where the os naviculare and astragalus are connected. An incision (Plate II. figs 4 and 5), somewhat curved with its convexity forward, is then to be made from one of these points to the other, when, instead of proceeding to disarticulate, the operator should transfix the sole of the foot from side to side at the extremities of the first incision, and carry the knife forwards so as to detach a sufficient flap, which must extend the whole length of the metatarsus to the balls of the toes. The disarticulation may finally be completed with great ease, as the shape of the articular surfaces concerned is very simple, and nearly transverse."¹

Regarding the method of disarticulating at the astragalo-calcaneal joint, and removing all the foot except the astragalus, various plans have been tried. Malgaigne advises an internal flap, thus sacrificing the valuable pad of the heel. Roux, Verneuil, and others endeavour to save the pad. This operation, however, had fallen almost completely into disuse, but was revived by Hancock and still described by Ashhurst under the name—

¹ Syme's *Principles*, 4th edit., p. 145.

Subastragaloid Amputation. In it the flap is made as in Syme's, then the anterior bones removed as in Chopart's, and os calcis grasped by lion forceps and twisted off, its attachment and the insertion of tendo Achillis being cautiously cleared. If flaps are scanty, the head of astragalus may be cut off with a small saw.¹

Tripier's Amputation² is a modification of above, the skin incisions being made as in Chopart's amputation, and then the calcaneum is sawn through on a level with the sustentaculum tali on a plane at a right angle to the axis of the leg.

Amputation at the Ankle-Joint, or Syme's Amputation.—This operation is one of much interest and great practical importance. In our cold variable climate caries of the bones of the tarsus, and strumous disease of the ankle-joint, are very common and very intractable maladies, and for both of these, when far advanced, Syme's amputation is far the best procedure. When properly done, according to the *exact* plan of its proposer, it removes the whole of the diseased parts and not an inch more, is an operation of very slight danger to life, and results almost invariably in a thoroughly useful, comfortable stump. Much of its success depends on the manner in which it is performed, and as many surgical manuals are not sufficiently full, some positively in error regarding this point, and as very many modifications have been devised, diminishing in value and applicability very much in proportion as they diverge from the original description, I think it advisable to describe the operation minutely, and point out in detail the parts of it which seem absolutely essential to success.

¹ *International Encyclopædia of Surgery*, vol. i. p. 654.

² *Ibid.*, p. 655.

Operation.—The foot being held at a right angle to the leg, the point of a straight bistoury, with a pretty strong blade, should be entered just below the centre of the external malleolus (Plate IV. figs. 12, 13), (1), and then carried right across the integuments of the sole, in a straight line (or in the case of a prominent heel, slightly backwards), (2), to a point at the same level on the opposite side. (3.) This incision should reach boldly through all the tissues down to the bone. Holding the heel in the fingers of his left hand, the operator then inserts his left thumb-nail into the incision, and pushes the flap downwards, as with the knife kept close to the bone, and cutting on it, he frees the flap from its attachments. The thumb-nail guards the knife from in any way scoring the flap. (4.) This process is continued till the tuberosity of the os calcis is fairly turned, and the tendo Achillis nearly reached. Shifting his left hand he then extends the foot, and joins the extremities of the first incision by a transverse one right across the instep. (5.) Thus he opens the joint between the astragalus and tibia. (6.) Divides the lateral ligaments, disarticulates, and still keeping close to the bone, removes the foot by the division of the tendo Achillis.

The lower ends of the tibia and fibula are then to be isolated from the soft parts, and a thin slice, including both malleoli, to be removed. If the disease of the joint has affected the lower end of the bone, slice after slice may be removed, till a healthy surface of cancellated texture is obtained. The vessels are then secured.

Dressing of the Stump.—From its peculiar shape and position, the escape of any blood into the stump is much to be deprecated, for as it cannot easily get out, on the one hand it gives pain, and may cause sloughing from its pressure, and on the other it is sure eventually to cause suppuration, and delay union. To avoid such results care must be taken

to secure every vessel that can be seen, and to make provision for thorough drainage by the use of drains of catgut or horse hair in bundles, or if necessary by the insertion of a small rubber drainage tube at the outside of the incision.

Notes.—(1.) If commenced further forward, as in Pirogoff's modification, it will be found difficult to turn the corner of the heel; if further back, the nutrition of the flap is endangered.

(2.) This is very important. In several well-known text-books, even in the last edition of Gross's *Surgery*, the incision is figured passing obliquely *forwards*. This is a fatal error, for besides making a flap far too long, it forces the operator to cut fairly into the hollow of the sole, quite off the prominence of the os calcis, and he finds that it is utterly impossible to free his flap without using great force, and inevitably scoring it in all directions. Sloughing is almost inevitably the result.

(3.) The incision is to stop at least half-an-inch below the internal malleolus. Most surgical manuals, even when they profess to describe Mr Syme's own method of operating, say that the incision should extend from malleolus to malleolus. If this be done, the flap becomes unsymmetrical, too long, and also the posterior tibial artery, on which much of the vascular supply of the flap depends, is cut. When the incision is properly made, the vessel is not cut till after its division into the plantar arteries.

(4.) Scoring the flap. Some may ask, Why do you object to a little scoring, the tissues are thick enough? Yes. One look at an injected preparation will show that the vessels supplying this thick flap come to it from its inner surface, and are inevitably cut across in any scoring of it, and also, that scoring cuts across the vessels, and *must* divide dozens of them.

(5.) Across the instep. Some authors recommend a semilunar anterior flap; this is quite unnecessary, increases bagging, and delays union. It can be required only in cases where the heel flap has been destroyed or lessened by disease, which may so far interfere with the nutrition of the flap as to cause sloughing.

(6.) It is not impossible that a careless operator may (by cutting a little too low) miss the joint and get into the hollow of the neck of the astragalus, where he may cut away for a long time without making much progress.

It is the most perfect stump that can be made, in fact the only one in the lower extremity which can bear pressure enough to support the weight of the body; all the others require the weight to be distributed over the general surface of the limb by means of apparatus. A good ankle-joint

stump can bear the whole weight of the body, as when the patient hops on it without any artificial aid, or without even the interposition of a stocking between the stump and a stone floor. More than this, I have seen a patient who had both his feet amputated at the ankle-joint run without shoes or stockings on the stone passages, without even the aid of a stick, and with very great swiftness.

The reason of this may be found in the nature of the flap itself, originally intended to bear the weight of the body, there being no cicatrix at the part on which pressure is borne. I have noticed that perfection in walking on an ankle-joint stump has a certain relation to the freedom of movement which the pad has over the face of the bone. This ought to be pretty considerable. It is explained by the new attachments formed by the tendons, and is under the control of the patient, being elicited when he is told to move his toes.

The modifications of Mr Syme's original operation have been very various. It will be unnecessary even to name them all. One or two may require notice. Retaining Mr Syme's incisions in their integrity, some operators prefer not to disarticulate the foot, but remove it by sawing through the tibia and fibula at once, while still in connexion with the foot. That most excellent surgeon and first-rate operator, Dr Johnston of Montrose, used to prefer this method.

In cases where the pad of the heel has been destroyed by disease or accident, so as to be partially or entirely unavailable for the flap, the late Dr Richard Mackenzie¹ practised the following operation by internal flap:—"With the foot and ankle projecting from the table with their internal aspect upwards, he entered the point of the knife (Plate I.

¹ *Monthly Journal of Medical Science* for 1849, vol. ix. p. 951.

fig. 14) in the mesial line of the posterior aspect of the ankle, on a level with the articulation, carried it down obliquely across the tendo Achillis towards the external border of the plantar aspect of the heel, along which it is continued in a semilunar direction. The incision is then curved across the sole of the foot, and terminates on the inner side of the tendon of the tibialis anticus, about an inch in front of the inner malleolus. The second incision (Plate III. fig. 4) is carried across the outer aspect of the ankle in a semilunar direction, between the extremities of the first incisions, the convexity of the incision downwards, and passing half-an-inch below the external malleolus.

Precisely the same principle might supply the flap from the outer side in cases where the internal flap as well as the heel was deficient, but probably the nutrition of the external flap would be more doubtful. Neither the one nor the other is nearly so good as the true heel flap, and they are both only very poor substitutes for it when it cannot be had.

The modification invented by Professor Pirogoff involves a much more important principle than any of the preceding. Instead of dissecting the flap from the posterior projecting portion of the os calcis, and removing the tarsus entire, he saws off the posterior portion of the os calcis obliquely, leaving it in contact with the pad of skin, which is retained. Immediately after making the cut which defines the posterior flap and divides the tissues down to the bone, he opens the joint in front, disarticulates, and then putting on a narrow saw immediately behind the astragalus and over the sustentaculum tali, he saws the os calcis obliquely downwards and forwards till he reaches the first incision; then removes the ends of the tibia and fibula, and brings up the slice of os calcis into contact with them.

Advantages.—It is easy of performance, saving the dis-

section from the heel, which some find so hard. It leaves a longer limb. It is said to bear pressure better, and there is certainly not so much chance of bagging of pus, and the mortality is exceedingly small, Hancock's collected cases giving only 8.6 per cent.; in cases of injury it is quite a warrantable operation.

Le Fort has further modified Pirogoff's operation by making longer anterior and heel flaps, and entering the ankle-joint from the front, so to saw the os calcis transversely as to allow the patient to walk on the part of the thick tissue of the heel accustomed to pressure, instead of on the thin tissue of the back of heel, on which he has to press in Pirogoff's operation.

Disadvantages.—It is contrary to sound principle in cases of disease, for it wilfully leaves a portion of the tarsus, in which disease is so apt to return. It leaves too long a limb, for it is found that the shortening in Mr Syme's method is just sufficient to admit of a properly constructed spring being placed in the boot to make up for the loss of the elastic arch of the foot. It brings the firm pad of the heel too much forward, thus tending to lean the weight of the body on the softer tissues behind the heel. It takes much longer to unite and consolidate.

The author has now, in a large number of cases of Syme's amputation for disease, found advantage in leaving the periosteum in the heel flap, *i.e.*, he cuts fairly into the os calcis when dividing the skin of heel, and then using a periosteum scraper instead of the knife, it is quite easy to remove the whole of the periosteum from the bone; this results in a large and more rounded pad of great strength and thickness.

In cases where from disease or injury it is impossible to obtain either a heel flap or a substitute lateral one, the question is, Where should amputation be performed?

It was for a long time the opinion of nearly all the best surgeons, and still is the opinion of many, that amputation of the leg should be performed at what was known as the "seat of election," just below the knee, even in cases where abundance of soft parts could be obtained for an amputation much lower down. The rule in surgery, to save as much of the body as possible in every amputation, was in the leg believed to be set aside by objections which militated strongly against all the other operations in the leg except the one performed just below the knee. Very briefly, these were somewhat as follows:—1. Just above the ankle you have large bones with nothing to cover them except skin and tendons. 2. Higher up in the calf you have plenty of muscle, but it is all on one side, and that the wrong one; it is very heavy, very difficult to dress and keep in position, and then when you have succeeded with it, the muscle wastes away and the stump is flabby. 3. And chiefly, as in all the amputations of the leg, the cicatrices are so much in the way, and the bones are so ill covered, that the patient can never rest his leg on the stump itself, but has either to rest his weight on his patella impinging on the top of a bottle-shaped leg, or just to stick out his stump behind him and kneel on the top of his wooden leg; therefore it is no use to have a stump longer than a few inches; in fact, the longer the stump is the more it is in the way. And more than this, many of the stumps made near the ankle, or through the calf, are not only useless, but positively painful. The skin becomes attached to the bones, the cicatrix never properly firms at all, the patient can hardly bear the pressure of a stocking, far less can he make use of the limb. For these reasons, secondary amputations below the knee used to be of very common occurrence.

Now, this idea has been much modified, and the general consensus of surgeons is that it is best and safest to retain

as much of the limb as possible if only the surface of the bones is well covered by skin, and the cicatrix can be kept off the end of the bones. Instrument makers now make artificial limbs more comfortable, lighter, and more useful, and, as a rule, they prefer a long stump on which to fit them.

A still more important point to be remembered is, that amputation just above the ankle is a much less fatal amputation than that just below the knee (Lister in Holmes' *Surgery*, 3rd ed., vol. iii. p. 716; Gross, 6th ed., vol. ii. p. 1113; Ben. Bell, 6th edit., vol. vii. p. 312).

There is little doubt, however, that the principle so much in vogue in the present day, of one long anterior or posterior flap, instead of two equal flaps, or of circular amputations, has done very much to make amputations at the ankle or through the calf justifiable and useful in bearing the weight of the body.

Amputation just above the Ankle.—Cases admitting of this operation must always be rare, for disease of the tarsus or ankle-joint hardly ever goes so far as to contra-indicate the performance of Mr Syme's greatly preferable operation; and an accident which would require this operation from injury to the ankle would in most cases require an amputation a good deal higher up from the splintering of the tibia so apt to occur.

In a suitable case the plan of the operation should be as follows:—A long anterior flap, slightly rounded at the end, should be cut (Plate I. figs. 15, 16),—from the outside, not by transfixion,—and the anterior muscles dissected up along with it. It should be long enough to fall down over the face of the bones at the point of section, and easily cover the point of the posterior flap, which is to be made by cutting through all the tissues with one bold transverse stroke of the knife. This operation, which is the plan of Mr Teale of

Leeds very slightly modified, is equally applicable at any point of the leg, with this difference only, that the length of the anterior flap must always be carefully proportioned to the mass of the muscular flap behind it has to cover in.

This operation provides a skin covering, without any danger of the cicatrix being pressed on or becoming adherent.

The author has operated many times in this manner, in cases of accident in which the heel flaps had been completely destroyed. All his cases have recovered completely and rapidly, and walked on useful limbs, with the free movement of the knee-joint, the weight being spread over the surface of a bucket leg, not borne only on end of stump.

Sédillot's Amputation of Leg by an external flap.—A longitudinal incision through the skin is made along the *inner* edge of the tibia. The tissues are then drawn to the fibular side of the limb; a slender knife can be introduced close to the *outer* edge of the tibia, made to graze the fibula, and be brought out posteriorly, then made to transfix the limb on the outer side of both bones. The knife being carried downwards is made to cut its way outwards, thus making a broad rounded external flap. A somewhat convex incision on the inner side exposes the bones, which must be cleared and divided, if possible, a little higher up.

In June 1865, Mr Henry Lee¹ described a method of operating which he hoped would unite the benefits of Mr Teale's method to the ease of performance of the old flap from the calf. I append a short account of his method. It is apparently identical in principle and almost identical in description with an operation described by Farabeuf, who emphasizes the importance of abundant length of skin in the posterior flap, which must be well retracted before the calf muscles are divided from without inwards.

¹ *Medico-Chirurgical Transactions*, vol. xlviii.

Lee's Amputation of the Leg by a long rectangular flap from the Calf.—The operation described was performed according to Mr Teale's method, as far as the external incisions were concerned, but the long flap was made from the back instead of from the front of the limb (Plate IV. figs. 14, 15). Two parallel incisions were made along the sides of the leg, these were met by a third transverse incision behind, which joined the lower extremities of the first two. These incisions, which formed the three sides of the square, extended through the skin and cellular tissue only. A fourth incision was made transversely through the skin in front of the leg so as to form a flap in this situation, one-fourth only of the length of the posterior flap. When the skin had somewhat retracted by its natural elasticity, an incision was made through the parts situated in front of the bones, which were reflected upwards to a level with the upper extremities of the first longitudinal incisions. The deeper structures at the back of the leg were then freely divided in the situation of the lower transverse incision. The conjoined gastrocnemius and soleus muscles were separated from the subjacent parts, and reflected as high as the anterior flap. The deeper layer of muscles, together with the large vessels and nerves, were divided as high as the incision would permit, and the bones sawn through in the usual way. The flaps were then adjusted in the manner recommended by Mr Teale.¹

Teale's own method, which is described in detail as a mode of amputating the thigh, p. 99, is applicable in this situation where the anterior soft parts can be obtained.

The patients were able to bear the weight of the body on the end of the stump.

In every case in which the posterior muscular flap is

¹ *Med. Times and Gazette*, June 3, 1865.

utilized it is important, as was long ago insisted on by Mr Hey, that the posterior tibial nerve should be dissected out and removed, so as to prevent it being pressed on by cicatrix or against bone.

In cases of chronic disease, where the muscles are atrophied and condensed, the following posterior flap method may be used with advantage. An incision is made across the front of the leg from the *posterior edge* of the fibula to the *posterior edge* of the tibia, or *vice versa*, according to the limb. The limb is then transfixed behind the bones from the same points, and a long and gently rounded posterior flap cut. The bones are then cleaned, and cut through at a little higher level.

Amputation immediately below the Knee at the "true seat of election."—The principles on which this operation is founded are—1. That a muscular flap is not necessary, skin being perfectly sufficient; 2. That as the muscles retract they must be cut at a lower level than the bones, and as they retract unequally from their varying length, the cuts must be made with due reference to that inequality; 3. That no more of the tibia need be retained than what is just sufficient to retain the attachment of the ligamentum patellæ, and to insure its vitality; 4. That the head of the fibula must be retained in every case, as in a certain proportion the tibio-fibular articulation communicates with the knee-joint.

Operation.—Two equal semilunar flaps of skin must be cut—from the outside, not by transfixion, one anterior and external, the other posterior and internal, their extremities meeting at points about two inches below the tuberosity of the tibia on either side (Plate I. figs. 17, 18). These must be reflected up, and with them a further extent of skin, embracing the whole circumference of the limb, must be dissected up (as if pulling off the fingers of a glove), so as to

expose the bone one inch below the tuberosity. The anterior muscles being very close to their origin, and consequently being able to retract very slightly, must be cut as high as exposed, and the posterior ones about the middle of their exposed surface.

Endless varieties in the shape and relations of the skin flaps at this situation might be described, as required by varying nature of the accidents which render the operation necessary. The principle is the same in all, to save the knee-joint movement if possible.

The bones must then be sawn as high as exposed, with the following precautions:—1. In order to prevent splintering of the fibula, endeavour to saw it along with the tibia, so as to finish it first; 2. To prevent projection of a sharp prominence of the edge of the tibia, enter the saw obliquely a little higher up than where you intend to divide the bone, then withdraw it, and enter the saw again at right angles to the bone, and a line or two lower down. Some surgeons prefer to make this section afterwards with a finer saw or the bone-pliers.

This operation is very frequently required to remedy painful and unhealed stumps, the result of amputations lower down, specially those in which the long posterior flap from the muscles of the calf has been used, and in which primary union had not been obtained. In the above amputation the patient will not be able to rest the weight of his body on the *face* of the stump, but by putting the limb into a well-padded case with soft rounded edges, the weight might be borne partly on the sides of the stump and partly on the lower edge of the patella; and the patient will be able to walk with great comfort, preserving the use of his knee-joint.

Amputation at the Knee-Joint.—This “relic of ancient

surgery," as Mr Skey calls it, has been revived only of late years, and seems in certain cases to be a justifiable and successful operation.

Practised by Fabricius Hildanus and Guillemeau in the sixteenth and seventeenth centuries, it had fallen into disuse till revived by Hoin, Velpeau, and Baudens, on the Continent, Professor Nathan Smith in America, and Mr Lane in London.

The mortality of this operation prior to the introduction of antiseptics was greater than that of amputation of thigh, from the risk of mischief in the joint, half of which was left to take its chance; of later years the mortality is certainly less, though I am not aware of any statistics on the subject since 1882.

It is not possible that this operation can be at all frequent, since the cases in which it is applicable are comparatively rare; for, to be successful, the following conditions are essential:—1. That there be abundant skin in front of the knee-joint to make a long anterior flap; 2. That the patella and articular surface of the femur are healthy. These conditions at once exclude nearly every case of disease or accident. If the joint is diseased some amputation through the thigh must be attempted; if injured and the front of the knee is safe, it may very likely be possible to amputate below the knee. Hence this operation may be useful in cases where, for malignant disease, the *whole* tibia requires removal, and yet the knee-joint is sound, or for gunshot injuries, in which the tibia is splintered, but the soft tissues comparatively uninjured.

Operation.—A long anterior flap should be cut with a semilunar end (Plate II. figs. 6, 7), extending as far as the insertion of the ligamentum patellæ. This flap, including the patella, should be thrown up, the joint cut into, and a short posterior flap made by transfixion.

It is important to retain the patella, if possible, as its

removal endangers the vitality of the anterior flap; it sometimes becomes ankylosed, but in other cases it remains freely mobile, and adds to the value of the stump.

Stephen Smith's¹ method by two equal lateral skin flaps, commencing each at centre of the interarticular line behind, and curving, with a bold convexity outwards, up to meet in front one inch below tuberosity of tibia. The skin should include with it fascia and cellular tissue, and the ligamentum patellæ is cut, thus allowing the patella to remain. When the flaps unite their line of union lies between the condyles opposite to intercondyloid notch. It is thus sunk, and not pressed on by the artificial leg. Brinton modifies this by a suggestion, if possible, to leave in the stump the semilunar cartilages, with all their lateral attachments undisturbed, by separating them from the head of tibia.

Professor Pancoast has practised an amputation at the knee-joint by three flaps, performed entirely by the scalpel, which, he says, results in a good stump. One flap, the anterior one, is longest and semilunar in shape, its convexity passing three inches below the tuberosity of the tibia; the other two are much smaller, and postero-lateral.²

Advantages.—There is a free drain for matter, no tendency to retraction of the flaps, and the weight of the body is borne on skin previously habituated to pressure.

Amputation through the Condyles of the Femur.—In the *London and Edinburgh Journal of Medical Science* for 1845, Mr Syme advocated a method of amputation through the condyles of the femur as specially suitable in case of diseased knee-joint. Amputation at this spot has certain advantages:—1. The shaft of the bone being untouched,

¹ *American Journal of Medical Science*, 1870.

² *Operative Surgery*, p. 170.

there is no injury of the medullary cavity, and hence no fear of inflammation of its lining membrane. 2. There is less risk of exfoliation, the cancellated texture of the epiphysis not being liable to it. 3. Being close to the joint, the muscles are cut through where they are tendinous, thus very much diminishing the risk of retraction and consequent protrusion of the bone. 4. A large broad surface of bone is left to bear the weight of the body, and one which, like the ankle-joint stump, will round off and afford a comfortable pad over which the skin of the flap will freely play.

One objection used to be urged against this mode of operating, the fear lest the thickened, brawny, and often ulcerated textures in the neighbourhood of a diseased knee-joint would not make a good covering. This, however, is no longer a bugbear, as we see in cases of resection, where the diseased joint tissues are taken away, how very soon all swelling and disease departs, once its cause is removed.

Mr Syme's original operation was briefly as follows:—With an ordinary amputating-knife make a lunated incision (Plate I. fig. 19) from one condyle to the other, across the front of the joint, on a level with the middle of the patella, divide the tissues down to the bones, and then draw the flap upwards, then cut the quadriceps extensor immediately above the patella. The point of the blade should then be pushed in at one end of the wound, thrust behind the femur, and made to appear at the other end; it should then be carried downwards (Plate III. fig. 5), so as to make a flap from the calf of the leg, about six or eight inches in length, in proportion to the thickness of the limb; the flap should then be slightly retracted, and the knife carried round the bone a little above the condyles to clear a way for the saw, which should be applied so as to leave the section as horizontal as possible.

This method is now rarely used, as we may select accord-

ing to circumstances from the following much better methods of covering in the bone—either by Gritti or Stokes' osteoplastic method, in which they adopt the principle of Pirogoff's operation, or what is much more generally applicable, the method of Carden and his imitators.

Gritti's Amputation.¹—In this two flaps are formed—an anterior long rectangular one and a posterior short one. The condyles of the femur are divided through their base, and the lower surface of patella is removed by a small saw, and then the surfaces of bone approximated.

Stokes' ² Modification of Gritti's Amputation.—In this "supracondyloid" amputation, the femur is sawn just above the condyles, without going into the medullary canal. The anterior flap is oval, twice as long as posterior, and the patella is brought up after denudation against end of femur.

The flaps should be made large enough to cover in the surface, the inner one being the fuller.

Carden's Amputation at the Condyles of the Femur.³—The operation consists in reflecting a rounded or semi-oval flap of skin and fat from the front of the knee-joint, dividing everything else straight down to the bone, and sawing the bone slightly above the plane of the muscles, thus forming a flat-faced stump, with a bonnet of integument to fall over it.

The operator standing on the right side of the limb, seizes it between his left forefinger and thumb at the spot selected

¹ *Annali Universali de Medicina*, Milano, 1857.

² *Med. Chir. Transactions of London*, vol. liii. p. 175.

³ Carden's (of Worcester) Pamphlet, pp. 5, 6; and *British Medical Journal*, 1864.

for the base of the flap, and enters (Plate II. fig. 8) the point of the knife close to his finger, bringing it round through skin and fat below the patella to the spot pressed by his thumb; then turning the edge downwards at a right angle with the line of the limb, he passes it through to the spot where it first entered, cutting outwards through everything behind the bone (Plate IV. fig. 16). The flap is then reflected, and the remainder of the soft parts divided straight down to the bone; the muscles are then slightly cleared upwards, and the saw applied.

The author long ago (1866) ventured to make a slight change in the method of performing this most excellent operation, for having found the posterior flap, as cut in the method above described, rather scanty in the earlier cases in which he had occasion to perform it, after dissecting back the anterior flap and cutting into the knee-joint, he shapes a slightly convex posterior flap of skin only, at least one and a half inches in length in adult, and allows it to retract before dividing the muscles by a circular cut to the bone, and has had every reason to be satisfied with the change. This modification seems now to be universally adopted. Lister¹ uses this long posterior flap to meet a square anterior one.

Amputation of the Thigh.—Amputation of the thigh has been the favourite battle-ground where flap and circular, antero-posterior and lateral, long and short flaps, double, triple, and conical incisions, have striven with each other; so were an attempt made to describe one quarter of the various methods employed, the history of Amputation would have to be rewritten.

It will suffice merely to describe the *best* modes of ampu-

¹ Holmes' *System of Surgery*, vol. iii., 1883.

tating the thigh through its lower, middle, and upper thirds respectively, and at the hip-joint.

In one word, it may be stated that, with the exception of those amputations performed through the lower third of the bone, the flap method is to be preferred, and the flaps should in almost every case be made by transfixion.

In the lower third, however, the flap method, though exceedingly easy, and capable of very rapid performance, has certain defects; the chief of these being the tendency which the muscular flaps (the necessary result of transfixion) have to cause undue retraction, and hence protrusion of the bone. This is seen specially in the hamstrings, which from the great distance of their origin, and the purely longitudinal direction of their fibres, retract to a very great extent, much more than the anterior muscles can do from the pennate direction of their fibres, and the manner in which they are mutually bound down to each other and to the bone.

Even in this one position, the lower third of the thigh, the methods that may be needed are various, and require separate notice;—for operations here are extremely frequent from the frequency of strumous disease of the knee-joint in our variable climate, and from the fact that compound fractures or dislocations of the knee-joint so very often necessitate amputation.

In cases where the skin over the patella is uninjured and available, the operation by long anterior flap (either by Teale's method, or by Mr Spence's modification of it, which curiously is almost exactly similar to the amputation of Benjamin Bell by a single flap) is suitable enough. But, I believe, preferable to either of these is the operation of Mr Carden, already described. In cases where the knee-joint is injured, and the skin over the patella unavailable, and yet where it is not necessary to go higher up the limb, the modified circular amputation of Mr Syme will be found very suitable.

As it is in this lower third of the thigh that a very large proportion of the cases requiring a long anterior flap is to be found, it affords the best opportunity for comparing in their detail the three almost similar plans of B. Bell, Teale, and Spence—after which Mr Syme's modified circular may be described.

Benjamin Bell's Flap Operation above the Knee (reported in his own words, slightly abbreviated).—"When this operation is to be performed above the knee, it may be done either with one or two flaps, but it will commonly succeed best with one. The flap answers best on the fore part of the thigh, for here there is a sufficiency of the parts for covering the bones, and the matter passes more freely off than when the flap is formed behind. . . . The extreme point of the flap should reach to the end of the limb, unless the teguments are in any part diseased, in which case it must terminate where the disease begins, and its base should be where the bone is to be sawn. This will determine the length of the flap, and we should be directed with respect to the breadth of it by the circumference of the limb, for the diameter of a circle being somewhat less than a third of its circumference, although a limb may not be exactly circular, yet by attention to this we may ascertain with sufficient exactness the size of a flap for covering a stump (Plate IV. fig. 17). Thus a flap of four inches and a quarter in length will reach completely across a stump whose circumference is twelve inches; but as some allowance must be made for the quantity of skin and muscles that may be saved on the opposite side of the limb, by cutting them in the manner I have directed, and drawing them up before sawing the bone, and as it is a point of importance to leave the limb as long as possible, instead of four inches and a quarter, a limb of this size, when the first incision is managed in this manner,

will not require a flap longer than three inches and a quarter, and so in proportion, according to the size of the limb. The flap at its base should be as broad as the breadth of the limb will permit, and should be continued nearly, although not altogether, of the same breadth till within a little of its termination, where it should be rounded off so as to correspond as exactly as may be with the figure of the sore on the back part of the limb. This being marked out, the surgeon, standing on the outside of the limb, should push a straight double-edged knife with a sharp point to the depth of the bone, by entering the point of it at the outside of the base of the intended flap; and carrying the point close to the bone, it must here be pushed through the teguments at the mark on the opposite side. The edge of the knife must now be carried downwards in such a direction as to form the flap, according to the figure marked out; and as it draws towards the end, the edge of it should be somewhat raised from the bone, so as to make the extremity of the flap thinner than the base, by which it will apply with more neatness to the surface of the sore. The flap being supported by an assistant, the teguments and muscles of the other parts of the limb should, by one stroke of the knife, be cut down to the bone, about an inch beneath where the bone is to be sawn; and the muscles being separated to this height from the bone with the point of a knife, the soft parts must all be supported with the leather retractors till the bone is sawn," etc., arteries tied, and dressings applied.¹

Amputation of Thigh by Rectangular Flap—(Teale's).
—I take the opportunity here of describing fully, and as far as possible in his own words, Mr Teale's method of ampu-

¹ B. Bell's *Surgery*, 6th ed., vol. vii. pp. 336-339.

tating, this being the situation where his method is most frequently available. The same principle may be applied to amputations at almost any other part of the body.

After advising the surgeon to mark out the proposed line of incision with ink before the operation, he gives the following directions for fixing the exact size of the flap:—"Supposing the amputation to take place (Plate II. figs. 9, 10) at the lower part of the middle third of the thigh, the circumference of the limb is to be measured at the point where the bone is to be divided.¹ Assuming this to be sixteen inches, the long flap is to have its length and breadth each equal to half the circumference, namely, eight inches. Two longitudinal lines of this extent are then traced on the limb, and are met at their lower points by a transverse line of the same length. The inner longitudinal line should be first traced in ink as near as practicable to the femoral vessels, without including them within the range of the long flap. The outer longitudinal line, which is somewhat posterior, is next marked eight inches distant from the former and parallel to it. These two lines are then joined by a transverse line of the same extent, which falls upon the upper border of the patella, or upon some lower portion of this bone. The short flap is indicated by a transverse line passing behind the thigh, the length of this flap being one-fourth that of the long one; or, assuming the circumference of the limb to be sixteen inches, and the length of the long flap eight inches, the length of the short flap is two inches. The operator begins by making the two lateral incisions of the long flap, through the *integuments only*. The transverse incision of this flap, supposing it to run along the upper edge of the patella, is made by a free sweep of the knife through the skin and tendinous structures down to the

¹ In diagram the amputation is drawn as if for middle third of thigh.

femur. Should the lower transverse line of the flap fall across the middle or lower part of the patella, the transverse incision can extend through the skin only, which must be dissected up as far as the upper border of the patella, at which place the tendinous structures are to be cut direct to the thigh-bone. The flap is completed by cutting the fleshy structures from below upwards close to the bone. The posterior short flap, containing the large vessels and nerves, is made by *one sweep* of the knife down to the bone, the soft parts being afterwards separated from the bone close to the periosteum, as far upwards as the intended place of sawing. . . . In adjusting the flaps, the long one is folded over the end of the bone, and brought, by its transverse line, into union with the short flap, the two corresponding free angles of each being first united by suture. One or two additional stitches complete the transverse line of union. Care is now required in arranging the two lateral lines of union. As the long flap is folded upon itself so as to form a kind of pouch for the end of the bone, it is requisite that it should be held in its folded state by a point of suture on each side. Another stitch on each side secures the lateral line of the short flap to the corresponding part of the long one. A longitudinal line of union thus passes at right angles each end of the transverse line."¹

Mr Teale's account of the resulting stumps is too long to quote entire, but in a few words, we find that by retraction of the short posterior flap, the cicatrix is drawn up quite behind and out of the way of the bone, that a soft mass without any large nerves or vessels is the result of the partial atrophy of the long flap, and that the patient is able to bear one-half, two-thirds, or even in some cases the entire weight of his body on the face of the stump. Such a power

¹ Teale, *op. cit.*, pp. 34, 39.

of support is to be found in no other flap except in Mr Syme's amputation at the ankle-joint.

Spence's Amputation by a long Anterior Flap,¹—The method devised by the late Professor Spence in amputations just above the knee-joint obtains the advantages of Teale's method, and avoids many of its disadvantages. He makes two flaps. The anterior one, which is to fall loosely over and cover in the posterior segment of the stump, must have a breadth fully equal to one-half of the circumference of the limb, and must be gently rounded at its extremity, so as to adjust itself readily to the curve of the cut margin of the posterior half of the stump. The anterior incision begins below, or on a level with, the lower margin of the patella, and when the skin is retracted to a little above the patella, is cut down *obliquely* to the bone, so as to divide the soft parts up to the base of the flap. The posterior incision begins about two fingers'-breadth below the base of the anterior flap, and the assistant retracting the skin, the edge of the knife is carried obliquely up to the bone (in Alanson's manner) and the posterior soft parts divided, the bone is sawn through—or immediately above—the condyloid portion. The results are good, for by these means the end of the bone has a thick covering, including muscular fibres, over it, and the cicatrix is not pressed upon in walking. The stump remains full, mobile, and fleshy, as in Mr Teale's method, without the disadvantage which it has, in requiring the bone to be divided so far above the seat of injury or disease. This is an exceedingly good method of operating in the lower third of the thigh, in muscular patients the very best, and in all cases only equalled in value by Carden's method.

¹ *Edin. Med. Journal* for April 1863.

The next is now hardly ever used, except in cases where the skin over the patella is destroyed.

Modified Circular at lower third of Thigh (Syme's).—Two equal semilunar flaps of skin should be cut (Plate I. fig. 20, Plate III. fig. 6), one anterior, the other posterior, their convexities being towards the knee. The skin and subcutaneous cellular tissue should be raised from the fascia, and then retracted to a further distance of at least two inches; the muscles should then be divided right down to the bone, on a level as high as they are exposed in front, and as low as they are exposed behind. This allows for the different amount of retraction at the two sides of the limb, and leaves the muscles cut on a level; the whole mass of muscles should then be drawn well up, and the bone exposed, and sawn through at a level about two inches higher than where it was first exposed by the anterior incision through the muscles.

In very weak thin flabby limbs this process may be simplified by just at once including the muscles in the skin flaps, and carefully exposing the bone higher up. In performing the retraction the assistant should be cautioned not to overdo it, lest he strip the periosteum from the bone higher than is necessary, and thus cause exfoliation, and greatly delay cure.

Amputation in the middle third of the Thigh.—A very short notice will suffice here. The exact position, shape, and size of the flaps must in every case be modified by the nature of the injury for which the operation is performed, taking the flaps where they can be obtained. As a general rule, a long anterior flap with a short posterior, on the principle described above, should be preferred. In cases where the long anterior cannot be obtained, two equal flaps should be made by transfixion. The flaps should always

be antero-posterior, the lateral flaps introduced by Vermale, and indorsed by Chelius and Erichsen, having the great disadvantage of allowing the bone, which is drawn up by the psoas and iliacus, to project at the upper angle.

Supposing the right thigh is to be amputated, the surgeon, standing on the inside of the leg, should raise the skin and muscles of the front of the limb in his left hand, and entering the knife just in front of the vessels, should transfix the limb, the knife passing in front of the bone, and including as nearly as possible an exact half of the limb (Plate IV. fig. 19); having by a sawing motion brought out the knife and cut a flap of the required length, the knife is re-entered at the same place, and passing behind the bone, the point must be brought out at the angle on the other side. If the flaps are to contract equally the posterior should be cut a little longer, perhaps one inch in an adult thigh, than the anterior. Both flaps being then held back by an assistant, the bone is cleared by a circular turn of the knife, and the saw applied; the vessels are found cut high up in the inner angle of the posterior flap.

In muscular patients it is often better to make the incision through the skin first and allow it to retract before transfixing; this is slower and not so brilliant looking, but avoids redundancy of muscle.

Amputation at the Hip-Joint.—This operation, exceedingly dangerous from the amount of the body removed, the great hæmorrhage, and the risk of shock, is of comparatively modern invention. Though the proportion of recoveries is at present to that of deaths about one to two or two and a half, it is a perfectly justifiable and necessary operation in many cases of disease and injury.

Ashhurst¹ reports 633 cases, of which 393 died, or 64·1

¹ *International Encyclopædia of Surgery*, vol. i. p. 677.

per cent., 82·4 per cent. in traumatic ones, 40·2 in pathological ones; in 20 the result is not given.

Like amputation at the shoulder, amputation at the hip has given rise to very many various methods of performance. Under the heads of single flap, double flap, oval, circular, and mixed flap and circular, at least twenty-five distinct methods have been put on record, and, including modifications, there are thirty-seven or thirty-eight different surgeons who have each their own plan of operation.

The reason of this fearful complexity in its literature depends on this fact, that this amputation has generally been performed for cases of such severe injury of the limb, that no milder amputation was possible, and thus the flaps had to be taken just where the surgeon could get them best. And this will have to be the guiding principle in most amputations at this joint; the surgeon must just cut his coat according to his cloth—get his flaps where and how he can.

In cases, however, where it is possible to have a choice, and to select the flaps, the following is, I believe, both the best and quickest method :—

This is one of the very few operations in which quickness of performance is a desideratum; the use of anæsthetics has, in most other cases, given time for elaboration of flaps and careful dissection; here the risk of loss of blood, specially from the posterior flap, renders rapid disarticulation imperative.

Amputation by double flap, anterior the longer.—In hip-joint amputations, besides the ordinary sponge-squeezers, two assistants are necessary, whose duties are exceedingly important.

The first is to check hæmorrhage. Pressing with a firm pad on the external iliac just as it passes the bone, he must be prepared, the instant the anterior flap is cut, to follow the

knife and seize flap and artery in his hand, and he is to hold it there till all the vessels in the posterior flap are first tied.

The second has to manage the limb, and on the manner in which he performs his duty much of the success and nearly all the celerity of the operation depend. While the surgeon is transfixing the anterior flap, this assistant is to support the limb in a slightly flexed position, so as to relax the muscles; the instant the flap is cut he is to extend the limb forcibly, and at the same time be careful not to abduct it in the least, but to turn the toes inward so as to bring the great trochanter well forwards on a level with the joint; if this precaution be neglected, the operator in making the posterior flap is almost certain to lock his knife in the hollow between the head of the bone and the great trochanter.

If it be the left side, the operator, standing on the outside of the limb, enters the point of a long straight knife midway between the anterior superior spinous process of the ilium and the great trochanter, and passes it as close to the front of the joint as possible, making the point emerge close to the tuberosity of the ischium (Plate IV. fig. 20-20). With a rapid sawing movement he then cuts a long anterior flap, avoiding any pointing of it, and endeavouring to make the curve equal. The fingers of the assistant must be inserted so as to follow the knife and seize the vessel even before it is divided. The flap being raised out of the way, the surgeon, without changing his knife (as used to be advised), opens the joint, divides the ligaments as they start up on the limb being extended and adducted, the round ligament, and the posterior part of the capsule; and then getting the knife fairly behind both the head of the bone and the trochanter, cuts the posterior flap as rapidly as possible. Instantly, on the limb being separated, assistants should be

ready with large dry sponges or pads of dry lint to press against the surface of the posterior flap, till the large branches, chiefly of the internal iliac, which are cut in it, are tied one by one.

The lever invented by Mr Richard Davy, by which the common iliac is compressed from the rectum, has in many cases proved of great service in preventing hæmorrhage, but has dangers of its own in cases of abnormal position of rectum, or even in sudden movements of the patient.

In some cases the abdominal tourniquet will be found of service in checking hæmorrhage during the operation of amputation at the hip-joint. It consists of an arch of steel fitted with a pad behind, which rests against the vertebral column, and a pad in front playing on a very fine and long screw, through an opening in the arch. When it can be borne, screwed down tightly on the aorta just before the incisions are commenced, it checks hæmorrhage admirably without injuring the viscera; but it must be most carefully watched, as in some cases it so interferes with respiration as to be dangerous, and in unskilled hands it may do much harm, even causing rupture of intestine. When this is applied, a method of amputation once practised by Mr Syme, though not so rapid as the double-flap method by transfixion, will be found very easy, and to result in most excellent flaps. He cut an anterior flap in the usual manner by transfixion, then made a straight incision from its outer edge down to about two inches below the great trochanter, thus exposing it fully, and from the lower end of this incision transfixed again, cutting a posterior flap nearly equal in size to the anterior; a few strokes of the knife round the joint finished the disarticulation. The resulting flaps came together with great accuracy, and were not burdened with the great unequal masses of muscles so often noticed in the

posterior flaps which are made by cutting from within outwards *after* disarticulation.

In some cases of amputation where the femur has been badly shattered, it is a good plan to amputate through the upper third of thigh, tie all the vessels, and then, aided by an incision at outer side, dissect out the head of the bone.

Furneaux Jordan's method of amputation has such enormous advantages, especially in cases in which the head of the femur has been previously excised, that it bids fair to become the usual method of amputation at hip-joint:—

“A straight incision was made, and the trochanters and upper part of the shaft were freed from their muscular attachments, after which the capsule was opened; next the shaft was cleared downwards from all its attachments for a considerable distance, and then a few free sawing movements with a long-bladed knife through the thigh from which the bone had been removed ended the operation.”¹

The thigh can thus be divided low down, where it is thinner; little blood need be lost, and the drainage can be well managed. In his own words the principle of the operation is,—Eucleate the bone where it is most thinly covered; cut across the soft parts where they are smallest; do not touch the bulky soft parts at the inner and upper parts of the thigh.

Note.—It is often possible to save the patient much blood in extensive mutilations by emptying the limb to be removed, as far as may be, of the blood it contains. This can be done in many cases by position. If the limb be raised at a right angle to the body, and then bandaged with an Esmarch bandage, it can be rendered bloodless. Before commencing the operation a very tight elastic tube should be wound two or three times round the limb as high as possible below the flaps to prevent the blood from re-entering the limb. A very important recommendation has been made by Mr Duncan of Edinburgh, that the blood lost during and after the operation should be prevented from coagulating by salines, and reinjected into the divided veins of the limb.

In severe cases of smash when both lower limbs have required

¹ *Surgical Enquiries*, second edition, p. 305.

amputation, the author has derived much assistance from the method of managing the operation detailed below :—

Double Primary Amputation of (both) Thighs from railway smash—Rapid recovery.—G., a healthy-looking man, aged twenty-seven, but looking much older, while driving a horse near Granton, caught his foot on the edge of a rail at a point, fell, and both his legs were run over by several loaded waggons. A special engine was procured, his thighs tightly tied up, and he was sent up to hospital at once.

I was in hospital at the time, so with as little delay as possible he was placed on the operating-table, and the necessity for amputation being too evident, I obtained his leave to remove both his legs above the knee; but his pulse was very feeble, and he was intensely nervous, throwing his arms wildly about, panting for breath, and looking very ill, cold, and exhausted.

I determined that by great rapidity he might be got off the table alive, so operated in the following manner:—Fixing the tourniquet firmly near both groins, I first amputated the right leg by Carden's method, and tied the femoral only, wrapped up the stump in a towel wrung out of carbolic solution 1-20, then took off the other limb by Mr Spence's method,—it had been injured higher than the right, so that I could not save the condyles of the femur,—then tied the femoral there, and fixed it up with another towel; then returning to the first, I tied one or two large branches which spouted, and rolled it up again, then back to the left one, doing the same, and getting the tourniquet off both limbs. On going back to the right the surface was nearly dry and glazed, so, asking Dr Maclaren, who assisted me, to stitch it up and insert a drainage-tube, I did the same for the left, so rapidly that the patient was in his bed with his limbs dressed and bandaged in $24\frac{1}{2}$ minutes from the time he entered the hospital gate.

The strictest antiseptic precautions were observed, two engines being used to furnish spray. Of course this great rapidity was due to the fact that everything was ready, the assistants all in hospital, admirably disciplined, and steam had been up in the spray engines. Shock was comparatively trivial; his temperature once, and only once, reached 100° . His stumps healed by first intention, and he was in the garden on the seventh day after the operation.

I have now in three cases found the benefit of this mode of dealing with double primary amputation in avoiding shock, lessening the time needed, and greatly diminishing the number of vessels requiring to be tied. In a previous case of double amputation for railway smash at the knees, the patient was almost pulseless, and had he been kept many minutes more on the table would not have left it alive. He also rapidly recovered.

The case is interesting also as showing that, when the assistants know their work, the strictest adherence to antiseptic precautions need not in itself make either the operation or the dressing tedious, though it can easily be made an excuse for much fussing and many delays.¹

CHAPTER III.

EXCISION OF JOINTS.

Historical.—Beyond a passage ascribed to Hippocrates, but of very doubtful authenticity, and slight allusions in the works of Celsus and Paulus Ægineta, the ancients give us no information whatever on this subject.

Hippocrates says,—“Complete resections of bones in the neighbourhood of joints both in the foot, in the hand, in the tibia up to the malleoli, and in the ulna at its junction with the hand, and in many other places, are safe operations, if that fatal syncope does not at once occur, and continued fever does not attack the patient on the fourth day.”

Celsus and Ægineta both advise the removal of protruding ends of bone in compound dislocations, but without giving any cases.

From the days of these classic fathers of Surgery, we have hardly an indication of any attention whatever having been paid to their hints till quite within the last hundred years.

The first distinct publication on the subject was by Henry Park of Liverpool, in a letter to Percival Pott in 1783. He proposed the removal of the articulating extremities of diseased elbow and knee-joints to obtain cures. He says he was led to this by its having been the invariable custom, for more than thirty years, at the Liverpool Infirmary, to take off the protruded extremities of bones in cases of compound dislocation.

The chief credit, however, in practically elevating ex-

cisions into the catalogue of recognised surgical operations, is owing, British surgeons most cordially own, to two provincial surgeons of France, the Moreaus (father and son) of Bar-sur-Ornain. They took the lead in the most marked manner, having excised the shoulder in 1786, the wrist and elbow in 1794, knee and ankle in 1792, and had followed this up so well that, in 1803, the younger Moreau could boast, "the town has become in some sort the refuge of the unfortunate afflicted with carious joints, after they have tried all the means usually recommended by professional men, or have had recourse to empirical nostrums, or when amputation seemed to them the last resource."

Moreau's papers and cases, which, between 1786 and 1789, he frequently read to the French Academy, were, some violently opposed, others utterly neglected by his compatriots, and many of them lost and buried in the unpublished papers of that body.

And though diseased joints did not decline in frequency, and though injured ones were extremely numerous during these long years of European war, excisions were but rarely performed.

With the exception of the removal of head of humerus after gunshot injury, hardly any British, and but very few French, limbs were saved by excision taking the place of amputation.

The limbs that were saved by Percy by excision of the head of the humerus really owe their recovery and safety to the elder Moreau; for an operation of his, at which he was assisted by that distinguished military surgeon, gave the latter the hint, which he followed so successfully, that by 1795 he had performed it nineteen times, and had indoctrinated Sabatier, Larrey, and others, and elevated it into a recognised operation of military surgery.

So far, however, as the application of the great improve-

ment of the Moreaus to disease went, the French surgeons have little reason to boast, for it is to English Surgery, and especially to one Edinburgh surgeon, that this class of operations owes nearly all its improvement in methods and frequency of performance.

For though (as we shall see under the special heads) here and there one or two cases were performed, it was not till the publication of Mr Syme's monograph on the excision of diseased joints, in 1831, that the importance and value of the discovery were fairly brought before the profession; and the conservative surgery, of which excision as preferred to amputation is the great type, must ever be associated with British surgeons—Syme, Fergusson, Mackenzie, Jones of Jersey, Butcher of Dublin.

On the Continent—Langenbeck, Stromeyer, Heyfelder, Ollier, Esmarch of Kiel, especially in the surgical history of the first Schleswig-Holstein war, have followed up the example, and every decade shows such improvements in early recognition and treatment of joint disease, accurate removal and careful apposition, so that results are so improved both to life and limb that erosion or excision has now to a marked extent replaced amputation as a mode of treatment in joint disease. In private practice especially amputations for disease are almost unknown.

Before proceeding to describe the operations on the various joints, one or two questions may be briefly asked and answered by way of introduction.

In what cases, or sorts of cases, are excisions suitable?

1. In cases of compound injury or dislocation of a large joint, as used by Filkin, Park, White, and other English surgeons long ago. In hospital practice, or in private, where there is every advantage of rest, food, and appliances, such operations are almost invariable. But long and sad experience has shown that, as a general rule in military

practice, with the difficulties of transport, the generally bad sanitary state of the hospitals, and the want often of adequate dressings and attention, excisions are much more fatal than amputations; and, except in elbow and shoulder (*q.v.*), should be avoided, unless a stationary hospital is attainable.

2. Excision for deformity (generally speaking for bony ankylosis) will require for decision the consideration of many points, *i.e.*, the joint affected, the nature of the disease or injury which has caused the ankylosis; and in each case—(1), the state of health of the patient; and (2), his occupation, and the consequent position of limb which would suit him best. As a general rule, such operations on the lower extremity are rarely necessary, except in hip and knee; while in the upper, the elbow-joint is the only one which you will ever be likely to be asked to remedy, or should comply with the request if asked; as the shoulder, even if ankylosed, will (1), from its own weight generally become so in the most favourable position; and (2), from the extreme mobility which the scapula can acquire, its ankylosis will not be so much felt.

The elbow, however, from the frequency of fractures of the condyles of the humerus obliquely into the joint, and from the manner in which these are so often neither recognised nor properly treated, very often becomes ankylosed in the most awkward possible position, *i.e.* nearly straight; and operations undertaken for such deformities are in general both quite safe and very satisfactory. Mr Syme had one case (resulting from a fall, causing a double fracture), in which both arms were thus firmly ankylosed in such a position that the sufferer could absolutely perform none of the commonest duties of life without assistance. Excision of both joints cured him.

The author excised with success for disease the elbow-

joint of a patient whose other arm had required the same operation.

The occupation of the patient must always be taken into consideration when settling the position of an ankylosis, or the necessity or advantage of a resection.

Thus Bryant¹ tells of a painter who wished his arm to be fixed in a straight position, and of a turner whose knee, at his own request, was permitted to stiffen at a right angle, as that position allowed him to turn his wheel.

3. *Excision for Disease of the Joint.*—In our cold climate, so cursed by scrofula, and specially among the children of the labouring poor, such joint diseases are very prevalent, and whether the disease commences in the synovial membrane, the articular cartilages, or the heads of the bones, it frequently so disorganizes the joint as to make it a question what is to be done to preserve the very life of the patient.

The tendency of surgical procedure at present is in the direction of early and active surgical interference with diseased joints, by free incision, drainage, and scraping of abscess cavities or any diseased synovial membrane. If this treatment fail of a cure, then excision is in nearly every case preferred to amputation. Great care is required to put the limb in the position which will be most useful if ankylosis is to follow.

As a general rule, attempts at preservation of the limb without excision are much more justifiable, and longer justifiable in the hip and knee-joints than in the elbow or shoulder; for the results in the lower limb will probably be as good, if the patient survive, if not better, than those obtained by excision, while the danger of the operation is greater; while in the upper limb, the danger to life in operating is less than that of leaving the limb on, and the

¹ *On Diseases and Injuries of Joints*, p. 121.

results obtained by a successful operation, with well-managed after-treatment, are far more satisfactory than the best possible ankylosis.

Another point bearing on this, of very great importance: In children, the most frequent subjects of such disease, excision of the lower limb may, by removing the epiphyses, cause to a very considerable degree disparity in their length, thus rendering them nearly useless, while in the upper such disparity is neither so extensive nor so injurious to the usefulness of the limb, which is not required for purposes of progression.

In the hip-joint, when the constitution of the patient and his surrounding circumstances admit of a long-continued recumbent posture in good conditions for health, expectant treatment will often succeed, but in delicate children early excision of the head of the femur may minimize the risk of tubercular infection, and may greatly shorten the time required.

In deciding upon selection of an Excision as against Amputation, many questions must be considered, chiefly under the heads of the separate joints:—

1. As to the difficulties and dangers of the operations contrasted.

Excisions have the special peculiarity and danger of dealing chiefly with cancellated bone, broadened out, open, with numerous patulous canals for large veins, tending on any irritation or inflammation to set up a diffuse suppuration, and to culminate in phlebitis, myelitis, and other pyæmic conditions, unless antisepsis is successfully managed.

Excisions are performed through degenerate or disorganised, amputations through healthy, tissue.

Excisions require extreme care and absolute rest (*i.e.* in lower limb) for many weeks and months after the operation.

But, on the other hand,—

Amputations remove a portion of the body; excisions a much less one. Amputations are always necessarily nearer the centre than the corresponding excisions, and statistics show that the fatality of operations increases, as a rule, in proportion as they approach the centre.

A successful excision, especially in arm, saves a limb nearly perfect; an amputation at best is only the stump for a wooden one.

On the whole, there is actually very little difference in the mortality of excisions and amputations.

2. As to the results of the operation on the usefulness of the limb, depending on joint involved, age of patient, and amount of bone removed:—

A. *Joint involved*.—These must be noticed separately, but one thing is absolutely certain, that a much higher standard of usefulness, both in equality of length, amount of ankylosis, and position, is needed in the lower than in the upper limb. For a leg hanging like a flail, or shortened by some inches, is not so good for purposes of locomotion as a wooden leg is; while an arm, even though powerless at the elbow, and perhaps much shortened, can be so strengthened and supported by slings and bandages as to give a most useful hand, the complex movements and uses of the fingers of which no mechanism can at all imitate.

B. *Age of Patient*.—It must be remembered that excision in a child may remove the epiphyses by which in great measure the growth of the bone is to be managed, and the limb, especially in the leg, may thus be so stunted as eventually to be of little advantage. After the operation it may have looked excellently well, and yet in a few years later it may be found to be seven or eight inches shorter than its neighbour.

C. *Amount of Bone removed*.—From an erroneous view

of the pathological changes in the bone effected, far too much was removed by many of the earlier operators, especially Moreau and Crampton.

The reason that this is sometimes still the case, is well seen in many preparations. The bones are thickened to a considerable distance, and covered with irregular warty excrescences. These, which used to be considered evidences of disease, are only compact new healthy bone, thrown out like the callus of a fracture in consequence of the irritation.

In a word, what we require to remove is the following:—

1. All the cartilage, dead or alive, healthy or diseased.
2. Only the bone involving the articular extremities, in thin slices, or with the occasional use of the gouge, till a healthy bleeding surface is obtained.
3. The synovial membrane, as precisely and thoroughly as possible, should be gouged or scraped away till a healthy surface is obtained, which should then be swabbed with a 20 grain to the ounce solution of chloride of zinc, and the pouches should be freely drained.

Excision of the Shoulder-Joint.—Before considering the method of operating, a word or two is required on the subject of how much is to be removed, and in what cases the operation should be performed. The shoulder and hip-joints are the only ones in which partial excision is ever admissible, indeed, in the shoulder excision of the head of the humerus only is in many cases found to be all that is necessary, while in all it is much less dangerous to life than when the glenoid cavity also requires to be interfered with.

It is rarely necessary to remove more of the bone than merely its articular extremity (when performed for disease of the joint), and if possible this should be done inside the capsule, *i.e.*, through an incision in the capsule, but without

involving its attachment to the neck of the bone. When the glenoid is also diseased, mere gouging or scraping the cartilaginous surface will not suffice, but the neck must be thoroughly exposed, so that the whole cup of the glenoid may be removed by powerful forceps.

Cases suitable for Excision.—Cases of chronic disease of the head of the humerus (generally tubercular), or of chronic ulceration of the cartilages which have resisted counter-irritation. Cases of gunshot injury of the joint, or of compound dislocation, or fracture involving the joint. Cases of limited tumours affecting merely the head and upper third of the bone, and non-malignant in character. Ankylosis very rarely requires and would not be much benefited by such an operation.

Operation.—Though perhaps not the easiest, the following method is the one followed by the best results. It is suited especially for cases of caries or other disease of the joint, where the head of the humerus is either alone or chiefly affected:—

A single straight incision (Plate I. fig. A.) is made from a point just external to the coracoid process downwards along the humerus for at least three inches. It corresponds almost exactly to the bicipital groove, and has the advantage of avoiding the great vessels and nerves. The long head of the biceps may then be raised from its groove, and drawn to a side so as to be preserved. This is deemed of importance by Langenbeck and others. Mr Syme, however, did not attach much value to its preservation, as it is often diseased. The capsule, which is often much altered, perhaps in part destroyed, is then opened, and the tendons of the muscles which rotate the head of the humerus divided in succession, while the elbow is rotated first inwards and then outwards by an assistant so as to put them on the stretch. As far as possible, these separations of muscles and ligament should

be done subperiosteally. The arm being then forced backwards, the head of the bone can be protruded through the wound, and sawn off either above the surgical neck, or if shaft is diseased at the needed distance. The glenoid must then be carefully examined, and any diseased bone removed by the cutting pliers. One or two small branches supplying the anterior fold of the axilla are the only vessels divided, and may not even require ligature, unless, indeed, from necrosis, or to remove a tumour, a larger portion of the humerus than usual has been removed. If the limit of capsule has been infringed on below, the circumflex vessels may probably be cut, in which case the bleeding may be considerable.

N.B.—In cases of fracture of neck of humerus, or of compound gunshot injury, or where the head has been separated by necrosis from the shaft, or where, as has happened to Stanley and others, the bone broke in the endeavour to tilt the head out, the surgeon will require to seize the detached head with strong forceps, and dissect it out with care.

Other methods of Resection.—When from great thickening and induration of the soft parts, enlargement of the head of the bone, or other reason, the straight incision may be deemed insufficient for the purpose (and we may remark that there are comparatively few cases in which it is insufficient), access may be obtained to the joint by raising a flap from the deltoid (Plate III. fig. A.) Its shape—V-shaped, semilunar, or ovoid—is not of much consequence, for there are no great nerves or vessels to wound on the outside of the joint, and the surgeon should be guided, as in all other operations on the joint, very much by the position of any pre-existing sinuses. This flap being raised upwards towards its base, very free access is gained to the joint.

In these cases, fortunately comparatively rare, in which there is reason to believe that the glenoid is chiefly involved in disease, and yet that the disease can be removed without amputation, access will be gained most easily by an incision (Plate III. fig. B.) on the posterior surface of the joint, corresponding in size and direction to the linear incision in front. This gives a much easier mode of access to the glenoid. I have seen cases in which the glenoid cavity and neck of the scapula were extensively diseased, while the head of the bone was quite sound.

After-treatment is exceedingly simple; for the first day or two the shoulder is to be supported on a pillow with a simple pad in the axilla, if there is any tendency for the arm to drag inwards; after this the patient should be encouraged to sit up and move about with his arm in a sling, the elbow hanging freely down.

Results.—Hodge records ninety-six cases in which this excision was performed for gunshot injury, of which twenty-five proved fatal, and fifty for disease, of which only eight died,—results which are more encouraging than those of amputation at the shoulder-joint for disease; though for injury the mortality is much greater than Larrey's famous statistics of Amputation, *q.v.* p. 66. Sir William MacCormac's statistics of St Thomas's Hospital show a mortality of 10 per cent.

Spence had thirty-three cases, with three deaths. He generally made a counter-opening behind to get rid of discharges, and inserted a drainage-tube.

Gurlt's statistics of excision for gunshot injury give of 1661 cases 1067 recoveries, 27 doubtful results, and 567 deaths, the mortality being 34.70 per cent.

Excision of the Elbow-Joint—*In what cases should it be performed?*—1. For disease of the elbow-joint which has

resisted ordinary remedies, and is wearing down the patient's strength, including caries, ulceration of cartilages, and gelatinous synovial degeneration.

2. For wounds of the elbow penetrating the joint, the prognosis both as to the patient's life and the usefulness of his arm is much better after excision than after endeavours to save the joint without excision. This is especially the case when the wound of the joint is small and punctured, but if the case is seen early and treated by free drainage, with antiseptic precautions, excision may not be required.

3. For ankylosis, in cases where after disease or injury the limb has stiffened in a bad position, especially when, with a straight elbow, the hand is rendered almost perfectly useless.

How much should be removed?—In the elbow-joint, more than any other joint in the body, complete excision is absolutely necessary; any portion of the articular surface being left proves a source of unfavourable result.

The surgeon is apt to err rather in removing too little than too much, especially if he takes care to save the periosteum. When this can be done, it has great advantage in the marvellous reproduction both of the shape and the movements of the joint. For the removal of too little bone is, on the one hand, apt to result in long-standing sinuses, on the other, to induce ankylosis.

In making the section of the bones, the saw ought to be applied to the humerus transversely just at the commencement of its condyloid projections, and to the radius and ulna, at least at a level with the base of the coronoid process of the ulna.

But while removing enough, we must not be led into the error of removing too much. If this be done, as was done by Sir Philip Crampton in his first case, and as happens occasionally of necessity in cases of excision for gunshot wounds or other accidents, much of the power of the arm

is lost as a consequence of the shortening and excessive mobility.

A mistaken pathology sometimes deceives in the examination of the state of the bones, and causes an unnecessary amount to be removed. For in many cases of disease the bones in the neighbourhood of the joint are stimulated to an excessive amount of what is in reality Nature's effort at repair, and while the cartilaginous surfaces are denuded of cartilage, soft, and porous, the bones close by are roughened with a stalactitic-looking growth, projecting in knobs and angles. Now, if this be mistaken for disease and removed, too much will almost certainly be taken away, and the result will be unsatisfactory.

It greatly encourages early and rapid healing if in cases of disease the synovial membrane is cautiously but thoroughly removed by scraping.

Operation.—The back of the joint is of course chosen for the seat of the incisions, both because the bones are there just under the skin, and because the great vessels and nerves lie in front of the joint. The form and number of the incisions vary considerably, and ought to vary according to the nature of the case and the amount of disease or injury.

Though it is now little used, for historical interest I retain the description of the H-shaped incision (Plate III. fig. c.), used first by Moreau, and re-introduced by Mr Syme, and used by him for most of his very numerous cases.

The posterior surface of the joint being exposed, the surgeon, with a strong straight bistoury, makes a transverse incision into the joint just above the olecranon. It should begin just far enough outside of the internal condyle to avoid the ulnar nerve, which the surgeon should protect by the forefinger of his left hand, and should extend transversely across to the outer condyle. From each end of this

incision the surgeon should next make at a right angle two incisions, each about one inch and a half or two inches long, right down to the bone, thus marking out two quadrilateral flaps. These should next be raised from the bones, up and down, as much of the soft parts being retained in them as possible, so as to add to their thickness. The olecranon is thus exposed, and should be removed by saw or pliers by cutting into the greater sigmoid notch; the lateral ligaments must then be cut, if they are not already destroyed by the disease, and the humerus protruded, a proper amount of which is then to be sawn off in a transverse direction. The head of the radius is then easily removed by the bone-pliers, and the ulna also protruded, the attachment of the brachialis anticus to the coronoid process divided, and the bone sawn across just at the base of that process.

Few vessels, if any, will require ligature, and the arm being bent to nearly a right angle, the transverse incision must be very carefully sewed up with sutures closely set and deeply placed, as much of the future success of the joint depends on the completeness of the primary union of this incision. Drainage must be arranged at the inner incision. After careful bandaging with abundance of antiseptic wool or wadding, the limb should be laid on a pillow in a position between a right angle and full extension, with forearm midway between pronation and supination. No splint is necessary; in a few days the patient will be able to rise and walk about.

Passive motion should be begun within a few days.

If properly performed, in a tolerably healthy subject, the surgeon should not be satisfied with any results short of almost perfect restoration of motion in the joint. Flexion and extension to their full extent, with a very considerable amount of pronation and supination, are to be expected, with proper care, in a patient of average intelligence.

Numerous cases are now on record where almost perfect performance of all the duties of life was retained after excision of the elbow-joint.¹

In most cases it is possible, and in nearly all advisable, to excise the joint by means of a less complicated incision. Thus one long vertical incision at the posterior surface, with its centre about midway between the ulna and the external condyle, with a transverse incision at right angles to it, and reaching almost to the internal condyle, has been often practised with a very good result.

But by nearly universal consent a single straight incision is now used, and when it is properly dressed and *drained* gives admirable results.

A single vertical incision (Plate III. fig. D.) as long ago recommended by Chassaignac, is, in most cases, quite sufficient to give access. It is most suitable in cases of ankylosis, where there is little deposit of new bone, or in cases of disease of the joint, accompanied with little swelling or thickening of surrounding tissues. It has the advantage of avoiding the cicatrix of a transverse incision, which doubtless may, if at all a broad one, somewhat interfere with the future flexion of the limb, but, on the other hand, unless care is taken, it does *not* give such free egress for the discharge, and when there is much delay in healing, the vertical incision may leave a cicatrix nearly as troublesome as the other.

The following modification, suggested and practised by the late Mr Maunder, seems to be a step in the right direction when it is practicable. "After a longitudinal incision crossing the point of the olecranon I next let the knife sink into the triceps muscle, and divide it longitudinally into two portions, the inner one of which is the more firmly attached to the ulna, while the outer portion is continuous with the anconeus muscle, and sends some tendinous fibres to blend

¹ See Syme's *Observations on Clinical Surgery*, pp. 55, 57; Hodge on *Excision of Joints*, p. 63.

with the fascia of the fore-arm. It is these latter fibres that are to be scrupulously preserved.

"Two points have to be remembered: first, the ulnar nerve, often unseen, must be lifted from its bed, and carried over the internal condyle to a safe place, and then the outer portion of the triceps muscle with its tendinous prolongation, the fascia of the fore-arm and the anconeus muscle must be dissected up, as it were, in one piece, sufficiently to allow of its being temporarily carried out over the external condyle of the humerus."¹

This method aids in retaining the power of *active* extension of the elbow-joint.

Excision for osseous ankylosis in the extended position of the joint may be sometimes rendered very difficult by the density, firmness, and extensive hypertrophy of the bones, which become fused into one solid mass. Any attempt to isolate the bones, and remove the ankylosed joint entire, by incising the bones as if for disease, will both prove very laborious, and also probably end in doing some damage to the vessels and nerves in front. But by sawing through the ankylosis about its centre, as was pointed out many years ago by Mr Syme, the fore-arm may be flexed, and the bones as easily displayed, cleaned, and removed, as in the operation for disease. In this operation, as there is less thickening of the skin and subjacent textures, and in consequence more risk of deficiency and even sloughing of the flaps made by the H-shaped incision, a single straight incision is amply sufficient.

Partial incisions of the elbow-joint are, as a rule, less successful and more dangerous to life than complete ones, except in cases of excision for ankylosis. Even in gunshot wounds, where the bones were previously healthy, and where uninjured portions might have been left with some hopes of success, this is the case.

Dr Heron Watson devised the following operation for cases of ankylosis, the result of injury:—(1.) A linear incision over ulnar

¹ Maunder's *Operative Surgery*, 2nd ed., p. 123.

nerve at inner side of olecranon. (2.) The ulnar nerve to be carefully turned over the inner condyle. (3.) A probe-pointed bistoury to be introduced into the elbow-joint in front of the humerus, and then behind and carried upwards, so as to divide the upper capsular attachments in front and behind. (4.) A pair of bone-forceps to be next employed to cut off the entire inner condyle and trochlea of the humerus, and then introduced in the opposite diagonal direction so as to detach the external condyle and capitulum of the humerus from the shaft. (5.) The truncated and angular end of the humerus to be divided, turned out through the incision, and smoothed across at right angles to the line of the shaft by means of the saw, whereby (6.) room might be afforded, so that partly by twisting and partly by dissection the external condyle and capitulum are removed without any division of the skin on the outer side of the arm.¹

The mortality from this operation is now very small. Sir Wm. MacCormac's St Thomas's Hospital statistics give a mortality of only 2·4 per cent. All of the cases, more than fifty, in which I have done it have recovered with but one exception, and Mr Syme lost only one during the time I was his assistant.

Professor Spence lost only 16 in 189 cases, or 8·3 per cent.

Gurlt's statistics for gunshot injury give a mortality of over 24 per cent.

Out of 82 cases where the joint was excised for injury in the Schleswig-Holstein and Crimean campaigns, only 16 died; and out of 115 cases in which the joint was excised for disease, only 15 died.

Excision of the Wrist.—Very various methods have been proposed and executed for the purpose of excising this joint. These vary much in difficulty and complexity, in proportion to the endeavours made to save tendons from being cut.

The principles which must guide all attempts at operative interference with this joint are—

¹ *Edin. Med. Journal*, May 1873.

1. To remove all the diseased bone, including the cartilage-covered portions of the radius, ulna, and of the metacarpal bones, as little of these bones being removed as possible, beyond the cartilage-covered portions.

2. To disturb the tendons as little as possible, especially to avoid isolating them from the cellular sheath.

3. To commence passive motion of the fingers very soon after the operation.

It is rarely possible to remove the carpal bones as a whole, from the diseased condition which renders the operation necessary, and the digging out of the various bones piecemeal renders the operation very tedious, especially if the proximal ends of the metacarpal bones are involved and require to be removed, hence this operation was practically impossible till after the discovery of anæsthesia.

In describing the operation elaborated and described by Sir J. Lister, the type of the various plans in which the tendons are saved, and no attempt is made to save the periosteum, is given.

Lister's Operation of Excision of the Wrist-Joint.—Even an abridgment of Sir J. Lister's account of his operation must necessarily be long, because the operation itself is so complicated and prolonged, and guided by such precise principles, as to render much abridgment almost impossible.

A tourniquet is put on, to prevent oozing, which would conceal the state of the bones; any adhesions of the tendons must be then broken down by free movement of all the joints.

The radial incision (Plate IV. fig. A.) is then made. It commences at the middle of the dorsal aspect of the radius, on a level with the styloid process, passes as if going towards the inner side of the metacarpal-phalangeal joint of the thumb, in a line parallel to the extensor secundi inter-

nodii, but turns off at an angle as it passes the radial border of the second metacarpal, and then longitudinally downwards for half the length of that bone. The extensor carpi radialis breviar tendon is divided in the incision. The soft parts at the radial side are to be carefully dissected up, and the tendon of the extensor carpi radialis longior divided at its insertion. The cut tendons, and the extensor secundi internodii tendon and the radial artery can thus be pushed outwards, enabling the trapezium to be separated from the carpus by cutting-pliers. The extensor tendons being relaxed by bending back the hand, the soft parts must be cleared from the carpus as far as possible towards the ulnar side.

The ulnar incision (Plate IV. fig. B.) extends from two inches above the end of the ulna, in a line between the bone and the flexor carpi ulnaris, straight down as far as the middle of the palmar aspect of the fifth metacarpal. The dorsal lip of this incision is then raised, and the tendon of the extensor carpi ulnaris cut at its insertion, and reflected up out of its groove in the ulna along with the skin. The extensor tendons are then raised from the carpus, and the dorsal and lateral ligaments of the wrist divided, the tendons still being

FIG. VI.*

* A-A, Deep palmar arch ; B, Trapezium ; G, Articular surface of ulna ; Dotted lines include the amount removed in Lister's earlier operations ; Unshaded portions are those removed by Lister in cases where the disease is limited to the carpus. (Reduced from Lister's diagram in *Lancet*, 1865.)

left as far as possible undisturbed in their relation to the radius. In front the flexor tendons are cleared from the carpus, the pisiform bone separated from the others though not removed, and the hook of the unciform divided by pliers. The knife must not go further down than the base of the metacarpal bones, in case of dividing the deep palmar arch. The anterior ligament of the wrist being now divided, the carpus and metacarpus are to be separated by cutting-pliers, and the carpus extracted by strong sequestrum forceps. By forcible eversion of the hand, the ends of radius and ulna can be protruded at the ulnar incision; as little as possible should be removed, consistent with removing all the disease. The ulna should be cut obliquely, leaving the base of the styloid process, and removing all the cartilage-covered portion. A thin slice of the radius is then to be cut also with the saw, so thin as to remove only the bevelled ungrooved portion, and leaving the tendons as far as possible undisturbed in their grooves. The ulnar articular facet is to be snipped off with bone-pliers. If the bones are more deeply carious, the diseased parts must at all hazards be removed with pliers or gouge. The metacarpal bones must then be treated in precisely the same way, their ends sawn off and their articular facets snipped off with the bone-pliers longitudinally. The trapezium is then to be seized by forceps and carefully dissected out, the metacarpal bone of the thumb pared like the others, the articular surface of the pisiform removed, the rest of the bone being left if it is sound. The radial incision is stitched closely throughout, and also the ends of the ulnar incision, any ligature being brought out through the centre of the ulnar incision, which is kept open with a piece of lint, which also gives support to the extensor tendons.

The after-treatment is important, the principal specialties being—(1), early and free movement of the fingers; (2),

secure fixing of the wrist to procure consolidation. (1.) By passive motion of the joints of the knuckles and fingers, commenced on the second day, and continued daily after the operation; (2.) By a splint supporting the fore-arm and hand, the fingers being held in a semi-flexed position by a large pad of cork fastened firmly on to the splint and made to fit the palm; this prevents the splint from slipping up the arm, and by a turn of a bandage insures fixation of the wrist-joint. The anterior part of this splint below the fingers may be gradually shortened, allowing more and more passive motion of the fingers, but the patient must wear it for months—indeed, till he finds his wrist as strong without it as with it.

Modifications:—It may be mentioned that a single dorsal incision was preferred by the late Professor Spence and Dr Gillespie. Professor Spence reported sixteen cases without a death.

The so-called subperiosteal methods of Boeckel and Ollier differ little from each other or from Lister's as regards incisions, but in the deeper parts of the work the bones have to be separately relieved of their periosteum and removed by gouge or forceps.

From his own experience the author must express his distinct opinion, that in strumous disease better results are got by careful and repeated gouging and scraping of individual bones and sinuses in the milder cases, while in the more severe and extensive ones amputation at forearm is almost always required at last.

Excision of the Hip-Joint.—Though this operation has greatly grown in favour of late years, still the selection of suitable cases for the operation is greatly modified by the varying opinions of the different schools of surgery. Mr Howard Marsh¹ is very much against excision of hip in any case.

¹ *Diseases of the Joints*, 1886.

Enough here to describe the method of operating, and the amount of the bone which is to be removed.

As in the shoulder-joint, the head of the femur is much more liable to disease, and, as a rule, much earlier attacked than is the acetabulum, but unfortunately the acetabulum does eventually become affected also in probably a much larger proportionate number of cases than the glenoid. Caries of the head, neck, and trochanters of the femur is a very common disease in this variable climate, and generally connected with the strumous taint. After much suffering, abscesses form and discharge, giving considerable pain, and forming a source of tubercular infection, the patient dies of general tubercle, or in cases where the suppuration is profuse and lasting, of waxy degeneration of liver and kidneys. As a result of the abscess and destruction of the ligaments, the head of the bone is apt to be displaced, and under some sudden muscular exertion or involuntary spasm, consecutive dislocation of the femur (generally on to the dorsum ilii) very often occurs.

In such a case the operation of excision of the head of the femur is by no means difficult, and not excessively dangerous, especially in young children.

Operation.—It is hardly necessary, or indeed possible, to lay down exact rules for the performance of this operation, in so far as the external incisions are concerned, for the sinuses which exist ought in general to be made use of.

When the surgeon has his choice, a straight incision (Plate II. fig. A.), parallel with the bone, extending from the top of the great trochanter downwards for about two inches, and also from the same point in a curved direction with the concavity forwards, upwards towards the position of the head of the bone (see diagram), will be found very convenient. The incisions should be carried boldly down to the bone, which will often be felt exposed and bathed in

pus, any remains of the ligamentous structures must be cautiously divided with a probe-pointed bistoury, and then by bringing the knee of the affected side forcibly across the opposite thigh, with the toes everted, the head of the bone is brought to the wound. The head, neck, and if necessary great trochanter should be exposed, and the saw applied transversely below the level of the trochanter, so as to remove it entire. If this is not done, it is apt to interfere with drainage and to be pressed on in the wound, and besides this it is almost invariably diseased along with the head. Chain saws are quite unnecessary, it being in most cases easy to apply an ordinary one to the bone, if it is properly everted.

Great care in the after-treatment is required to prevent undue shortening of the limb, or in the event of a cure to secure the most favourable position for the ankylosis. In all cases counter-extension is necessary, and in most may be best managed by a weight and pulley.

Various forms of hammock swings to support the whole body, and slings of leather or canvas to support the limb only, have been found to aid recovery, and render the patient much more comfortable.

When the acetabulum is extensively diseased the prognosis is much more unfavourable than when it is sound, and the diseased tissue must be got rid of as far as possible by gouging.

Experience and the cold evidence of statistics prove, however, that the prognosis in any case is modified very much for the worse by the presence of any disease of the acetabulum, more than one-half of the cases proving fatal in which it is diseased, whether attempts to remove the disease of the acetabulum be made or not, and that those cases do best in which the head of the femur has been displaced, and lies outside the joint almost like a loose sequestrum among the soft parts.

The results of excision of the hip have as yet been very discouraging, the mortality of the whole series of published cases being, according to Dr Hodge's careful table, very little under 1 in every 2 cases, viz., 1 in $2\frac{5}{3}$. Later statistics are, however, more favourable.

Like all other excisions, the mortality increases very much with the patient's age.

Thus of 103 completed cases in which the age is given, 53 recovered and 50 died, but dividing the cases at the end of the sixteenth year, we find that of the children below this age 43 recovered and 29 died, a mortality of 40·2 per cent ; of the adults, 10 recovered and 21 died, or a mortality of 67·6 per cent.

If we remember the marvellous power of recovery from joint diseases we find in childhood under the influence of good diet, cod-liver oil, and fresh air, we cannot shut our eyes to the fact that such results and such a mortality are by no means encouraging.

From an extensive experience in a special hospital for hip-disease, where fresh air, abundant nourishment, and very excellent nursing are provided, the author is learning more and more to trust to the power of Nature in the cure of even very advanced cases of hip-disease in children, and he believes that operation is comparatively rarely necessary, or even warrantable, except for the removal of sequestra.

Mr Holmes's¹ statistics are interesting. He has operated on no fewer than nineteen cases. Of these seven died, one after secondary amputation at the hip. Another required amputation and recovered. Two others died of other diseases without having used their limb. Of the remaining nine, three were perfectly successful, four were promising cases, and two unpromising.

Professor Spence in 19 cases had 6 deaths, or a mortality of 31·6 per cent.

Culbertson's collection gives out of 426 cases, 192 deaths, or 45 per cent.

¹ *On the Surgical Treatment of Children's Diseases*, pp. 454-6.

Mr Croft, whose skill and success as an operator are well known, has recorded 45 cases of excision of hip in his own practice; of these 16 died, 11 were under treatment, 18 had recovered, of which 16 had movable joints and useful limb; the other two are "potentially cured."¹

Mr Wright, of Manchester, out of 100 cases had 85 recoveries and 15 deaths.

Various other incisions have been devised for gaining access to the joint. The most noticeable are those in which a flap is made instead of a linear incision. Sedillot made a semilunar or ovoid flap, the base of which is just below the great trochanter, and which includes it, the convexity being upwards and the flap being turned down. Gross's modification of this is preferable, being turned the opposite way, the convexity being downwards (Plate III. fig. E.), and the flap thus being turned up.

Many surgeons now believe that the following is the best method of excising the hip in early cases in which no sinuses have yet formed:—

R. W. Parker's Operation by Anterior Incision.—An incision, three inches in length, begins half an inch below and external to the anterior superior spinous process, and runs downwards and inwards. Cutting boldly, the knife passes deeply between the tensor fasciæ femoris on the outside and the sartorius and rectus internally. The capsule of the joint is then opened, and a finger passed in to examine the cavity. The neck is then divided by a narrow saw from above downwards, which allows the head to be lifted out by a sequestrum forceps. The cavity of the joint must then be carefully scraped and cleansed with a chloride of zinc solution, drained, and dressed. This is chiefly suitable in cases of joint suppuration at an early stage. Whenever pus is reached the cavity should be thoroughly irrigated with hot water, 105°–110°, and after removal of the head, the whole cavity and its surrounding sinuses should be most carefully and thoroughly scraped by Mr Barker's flushing gouges, till everything is dry and clean. The cavity should then be packed by aseptic sponges till the

¹ *Clinical Society's Transactions*, vol. xiii. p. 71.

stitches are introduced, by which the surfaces are to be coaptated; no drain is needed. After sponges are removed it must be closed, dressed with dry wool, and union by first intention arrived at. Excellent results are reported by Barker,¹ Bilton-Pollard,² and others.

Results in successful Cases.—Of fifty-two in Hodge's table, thirty-one had useful limbs, six indifferent, three decidedly useless, four died within three years, and of the remaining eight no details are given.

The shortening is always considerable, a high-heeled shoe being required in most cases; a stick is indispensable; in many, crutches are necessary.

Various operations have been devised for the treatment of osseous ankylosis of the hip-joint when in a bad position. All are more or less dangerous. Perhaps one of the least dangerous is the plan of subcutaneous division of the neck of the femur by a narrow saw, proposed by Mr Adams of London. It is sometimes a very laborious operation.

Excision of Knee-Joint.—Within one generation most curious changes have taken place in the estimation this operation has obtained and maintained. Opposed by many when reintroduced by Fergusson and his school, it worked its way into favour and was fashionable. There is now in some schools a great prejudice against it, while in others it still holds its own. Its after-treatment is more important than the method of its performance, and the selection of suitable cases more difficult than either.

Removal of Bone.—In every case the excision of the joint ought to be complete. Some attempts have been made to save one or other of the articular surfaces, but they have proved failures. The patella has frequently been left when it was not diseased, as is often the case, but the results have not been such as to recommend such a practice.

Direction of Section of the Bones.—The bones should be

¹ *British Med. Journal*, 1890.

² *Med. Chir. Trans.*, 1889.

cut transversely, and, as far as possible, be in accurate and complete apposition. A slight bevelling at the expense of the posterior margin will produce an ankylosis of the limb in a very slightly flexed position, which is found to aid the patient in walking.

It has been proposed by some¹ to cut both bones obliquely, so as to obviate the difficulty of making the transverse surfaces parallel. This involves a still greater practical difficulty in keeping these oblique surfaces in position during the after-treatment.

This plan might possibly be valuable in cases where the disease was limited to one or other edge of the bone.

Among the various incisions recommended, the best seems to be the *Semilunar Incision*.

Operation.—The limb being held in an extended position, a single semilunar incision (Plate I. fig. B.) is made, entering the joint at once, and dividing the ligamentum patellæ. It should extend from the inner side of the inner condyle of the femur to a corresponding point over the outer one, passing in front of the joint midway between the lower edge of the patella and tuberosity of the tibia. The flap is then dissected back, dividing at first only skin and cellular tissue. This flap should be carried boldly up as far as the apex of the upper synovial reflexion. When skin is thus out of the way, the whole remaining soft parts, including thickened and diseased synovial membrane with patella, its ligament, and a portion of the quadriceps extensor, should be cut boldly away, exposing the periosteum of the femur; then the ligaments are to be divided, when by extreme flexion of the limb the articular surface of the tibia and femur are thoroughly exposed. The crucial ligaments must then be divided cautiously, and the articular portion of the

¹ Billroth of Vienna and Pelikan of St Petersburg, quoted from Heyfelder by Hodge *On Excision of Joints*, p. 161.

femur cleaned anteriorly by the knife, posteriorly by the operator's finger, so far as possible to avoid injury of the artery. The whole articular surface of the femur must then be removed by a transverse cut with the saw as exactly as possible at a right angle with the axis of the limb. The amount of the femur which will require removal will in the adult vary from an inch to an inch and a half or even more. It *must* involve all the bone normally covered by cartilage; and this being removed, if the section show evidence of disease, slice after slice may require removal till a healthy surface is obtained. Occasionally, if the diseased portion appear limited, though deep, the application of a gouge may succeed in removing disease without involving too great shortening of the limb. Specially in children, it is of great importance to avoid removing the whole epiphysis. The tibia must then be exposed in a similar manner, and a thin slice removed; if the bone be tolerably healthy, even less than half an inch will prove quite sufficient.

This method has an immense advantage in that it provides an excellent anterior flap for the amputation, which may be required in cases where the disease of bone is found too extensive to admit of the excision being practised.

Hæmorrhage must then be stopped, and that as thoroughly as possible, by torsion and sluicing with very hot sterilized water, and any remains of diseased synovial membrane may be scraped or gouged away, and then the flap must be brought accurately together with sutures.

In some rare cases, it may be found necessary to divide the hamstring tendons to rectify spastic contraction of the muscles; but this can generally be done quite well from the original wound.

If there is any difficulty in maintaining in accurate apposition the cut surfaces, wire sutures, or the insertion

of metal pins obliquely through both bones, can be used with excellent effect.

By far the best method of after-treatment is the immediate application of Dr Heron Watson's most ingenious splint—consisting of a well-moulded and padded Gooch splint below and a wire skeleton splint above, both of which are fixed up at the time of the operation in an immobile plaster-of-Paris case by suitable bandages. If the joint has been well scraped, sterilized, fixed, and drained, it needs few subsequent dressings, and these can easily be changed without disturbance by the gap left for the purpose in the upper splint. It allows the limb to be suspended from a Salter's swing.

H-shaped Incision.—The internal incision should commence at a point about two inches below the articular surface of the tibia, and in a line with its inner edge; it should then be carried up along the femur in a direction parallel to the axis of the extended limb, so as to pass in front of the saphena vein, and thus avoid it, for a distance of five inches. The external incision, commencing just below the head of the fibula, must be carried upwards parallel to the preceding for the same distance. Both incisions must be made by a heavy scalpel with a firm hand, so as to divide all the tissues down to the bone. The vertical incisions are then united by a transverse one passing across just below the lower angle of the patella. The flaps thus formed must then be dissected up and down, and the internal and external lateral ligaments divided, thus thoroughly opening the joint and exposing the crucial ligaments. These must be divided carefully, remembering the position of the artery. The bones are then to be cleared and divided, as in the operation already described. This is the method of Moreau and Butcher,¹ and has with some modifications been revived by Ollier.

¹ *Operative and Conservative Surgery*, p. 169.

As historically interesting I retain a description of the ingenious operation in which the *Patella and Ligamentum Patellæ are retained*, though in cases of disease I cannot recommend it. "A longitudinal incision, full four inches in extent, was made on each side of the knee-joint, midway between the vasti and flexors of the leg; these two cuts were down to the bones, they were connected by a transverse one just over the prominence of the tubercle of the tibia, care being taken to avoid cutting by this incision the *ligamentum patellæ*; the flap thus defined was reflected upwards, the patella and the ligament were then freed and drawn over the internal condyle, and kept there by means of a broad, flat, and turned-up spatula; the joint was thus exposed, and after the synovial capsule had been cut through as far as could be seen, the leg was forcibly flexed, the crucial ligaments, almost breaking in the act, only required a slight touch of the knife to divide them completely. The articular surfaces of the bones were now completely brought to view, and the diseased portions removed by means of suitable saws, the soft parts being held aside by assistants." ¹

Results of Excision of Knee-joint:—Holmes's Table of recent cases from 1873–1878—

245 cases; 25 deaths, and 47 failures.

Spence's—33 cases; 22 recovered, 11 died.

Relation of Age to result in Excision of Knee-Joint from Hodge's Tables.

Of 182 complete cases:—

68 below 16 years: 50 recovered—18 died; or 26 per cent. died.

114 above 16 years: 55 recovered—59 died; or 51·7 per cent. died.

Culbertson's table gives: ²—

Of 224 under 15 years—42 died; 18·7

379 over 15 years—136 died; 35·9

¹ Mr Jones of Jersey, *Med. Chir. Trans.*, vol. xxxvii. p. 68.

² *International Encyclopædia of Surgery*, vol. iv. p. 520.

Buck's Operation for Anchylosed Knee-Joint.—The principle of this operation is to remove a triangular portion of bone, which is to include the surfaces of the femur and tibia, which have anchylosed in an awkward position, and by this means to set the bones free, and enable the limb to be straightened. Access to the joint may be obtained by either of the two methods already described. Sections of the bones are then to be made with the saw, so as to meet posteriorly a little in front of the posterior surface of the anchylosed joint, and thus remove a triangular portion of bone; the portion still remaining, and which still keeps up the deformity, is then to be broken through as best you can, either by a chisel, or a saw, or forced flexion. The ends are to be pared off by bone-pliers, and the surfaces brought into as close apposition as possible. The operation is a difficult one, a gap being generally left between the anterior edges of the bones, from the unyielding nature of the integuments behind, and the difficulty of removing the posterior projecting edges from their close proximity to the artery. Of twenty cases on record, eight died, and two required amputation.

Excision of the Ankle-Joint.—*In what cases is it to be done, and how much bone is to be removed?*

In cases of compound dislocation of the ankle-joint, the tibia and fibula are apt to be protruded either in front or behind. When this happens it is a dislocation generally very difficult to reduce, and when reduced to retain in position. In such cases, if there seem to be any chance of retaining the foot, excision of the articular ends of tibia and fibula greatly add to the probabilities in its favour. It may be done without any new wound, and, in general, by an ordinary surgeon's saw.

When the astragalus does not protrude, it seems to

matter little for the future result whether its articular surface be removed or not. When, on the other hand, it protrudes, as a result either of the displacement of the entire foot, or of a dislocation complete or partial of the astragalus itself, there is no doubt that excision either of its articular surface or of the entire bone will give very excellent results. Jäger reports twenty-seven such cases, with only one fatal, and one doubtful result.

In cases of disease of the Ankle-Joint.—Excision has been performed a good many times, and should in most cases be complete. A work like this is not the place to discuss the propriety of operations so much as the method of performing them, but one remark may be permitted. Few points of surgical diagnosis are more difficult than it is to tell whether in any given case disease is confined to the ankle-joint, and whether or not the bones of the tarsus participate. If they do even to a slight extent, no operation which attacks the ankle-joint only has any reasonable chance of success. It may look well for a time, but sinuses remain, the irritation of the operation only hastens the progress of the disease of the bone, and the result will almost certainly be disappointing, amputation being almost the inevitable *dernier ressort*.

Methods of Operating:—

Mr Hancock originated the following method, which does not seem to have been much improved upon:—

Commence the incision (Plate II. figs. B. B.) about two inches above and behind the external malleolus, and carry it across the instep to about two inches above and behind the internal malleolus. Take care that this incision merely divides the skin, and does not penetrate beyond the fascia. Reflect the flap so made, and next cut down upon the external malleolus, carrying your knife close to the edge of the bone, both behind and below the process, dislodge the

peronei tendons, and divide the external lateral ligaments of the joint. Having done this, with the bone-nippers cut through the fibula about an inch above the malleolus, remove this piece of bone, dividing the inferior tibio-fibular ligament, and then turn the leg and foot on the outside. Now carefully dissect the tendons of the tibialis posticus and flexor communis digitorum from behind the internal malleolus. Carry your knife close round the edge of this process, and detach the internal lateral ligament, then grasping the heel with one hand, and the front of the foot with the other, forcibly turn the sole of the foot downwards, by which the lower end of the tibia is dislocated and protruded through the wound. This done, remove the diseased end of the tibia with the common amputating saw, and afterwards with a small metacarpal saw placed upon the back of the upper articulating process of the astragalus, between that process and the tendo Achillis, remove the former by cutting from behind forwards. Replace the parts *in situ*; close the wound carefully on the inner side and front of the ankle; but leave the outside open, that there may be a free exit for discharge, apply water-dressing, place the limb on its outer side on a splint, and the operation is completed.

Skin, external and internal ligaments, and the bones are the only parts divided, no tendons and no arteries of any size.¹

Barwell's method by *lateral incisions* is briefly as follows:—

On the outer side, an incision over the lower three inches of the fibula turns forward at the malleolus at an angle, and ends about half an inch above the base of the outer metatarsal. The flap is to be reflected, fibula divided about two

¹ *Lancet*, Oct. 1, 1859.

inches from its lower end by the forceps, and dissected out, leaving peronei tendons uncut. A similar incision on the inner side terminates over the projection of the internal cuneiform bone; the sheaths of the tendons under inner ankle are then to be divided, and the artery and nerve avoided; the internal lateral ligament is then to be divided, the foot twisted outwards, so as to protrude the astragalus and tibia at the inner wound. The lower end of the tibia and top of the astragalus are to be sawn off by a narrow-bladed saw passing from one wound to the other.¹

Dr M. Buchanan of Glasgow has described an operation by which the joint can be excised through a single incision over the external malleolus.

Results.—So far as can be gathered from cases already published, the results when it has been performed for disease are often unsatisfactory. Sinuses remain, which do not heal, the limbs are useless, and amputation is in the end necessary. The mortality is small—only about 8 per cent., but when done for gunshot injury it rises to 26 per cent. In the last Franco-German war, out of 50 cases 26 recovered, 20 died, and in 4 the result was not given,—a mortality of 43 per cent.

Langenbeck performed it sixteen times during the last Schleswig-Holstein war (in 1864), and the Bohemian war in 1866, with only three deaths. In these cases the operation was subperiosteal.

In all cases of excision of the ankle-joint attempt should be made to save the periosteum.

Excision of the Scapula.—More or less of the scapula has in many cases been removed along with the arm, and even with the addition of portion of the clavicle.

¹ Barwell *On Diseased Joints*, p. 464.

Excision of the entire bone, leaving the arm, has now been performed 42 times with at least 8 deaths; and after previous amputation at shoulder, 14 times with 3 deaths. The procedure must vary according to the nature and shape of the tumour on account of which the operation is performed. Mr Syme operated as follows:—

In the first case, one of cerebriiform tumour of the bone, he “made an incision from the acromion process transversely to the posterior edge of the scapula, and another from the centre of this one directly downwards to the lower margin of the tumour. The flaps thus formed being reflected without much hæmorrhage, I separated the scapular attachment of the deltoid, and divided the connexions of the acromial extremity of the clavicle. Then, wishing to command the subscapular artery, I divided it, with the effect of giving issue to a fearful gush of blood, but fortunately caught the vessel and tied it without any delay. I next cut into the joint and round the glenoid cavity, hooked my finger under the coracoid process, so as to facilitate the division of its muscular and ligamentous attachments, and then pulling back the bone with all the force of my left hand, separated its remaining attachments with rapid sweeps of the knife.” (Plate III. fig. G.)

Mr Syme’s second case was also one of tumour of the scapula; the head of the humerus had been excised two years before.

He removed it by two incisions, one from the clavicle a little to the sternal side of the coracoid, directed downwards to the lower boundary of the tumour, another transversely from the shoulder to the posterior edge of the scapula. The clavicle was divided at the spot where it was exposed, and the outer portion removed along with the scapula.¹

¹ Syme *On Excision of the Scapula*, pp. 13-26, 1864.

The author has in a case of osseous tumour removed the whole body of the scapula, leaving glenoid, spine, acromion, and anterior margin with excellent result and a useful arm.

Large portions of the shafts of the humerus, radius, and ulna have been removed for disease or accident, and useful arms have resulted; but as the operative procedures must vary in every case, according to the amount of bone to be removed, and the number and position of the sinuses, no exact directions can be given.

The author excised the whole ulna, and preserved the periosteum with an admirable result.

For very interesting cases of such resections reference may be made to Wagner's treatise on the subject, translated and enlarged by Mr Holmes, and to Williamson's *Military Surgery*, p. 227.

Excision of Metacarpals and Phalanges.—To *excise* the metacarpal implies that the corresponding finger is left. Except in cases of necrosis, where abundance of new bone has formed in the detached periosteum, the results of such excisions do not encourage repetition, the digits which remain being generally very useless. It is quite different, however, if it is the thumb that is involved; and every effort should, in every case, be made to retain the thumb, even in the complete absence of its metacarpal bone. For the good results of a case in which Mr Syme excised the whole metacarpal bone for a tumour, see his *Observations in Clinical Surgery*, p. 38.

The operation is not difficult, and requires merely a straight incision over the dorsum, extending the whole length of the bone.

In the same way the proximal phalanx of the thumb may be excised, and yet, if proper care be taken, a very useful

limb be left. I quote entire the following case by Mr Butcher of Dublin :—

Excision of Proximal Phalanx of the Thumb.—The thumb of the right hand was crushed by the crank of a steam-engine. The proximal phalanx was completely shattered; its fragments were removed, the cartilage of the proximal end of the distal phalanx, and also of the head of the metacarpal bone, were pared off with a strong knife. The digit was put up on a splint fully extended. In about a month cure was nearly complete, a firm dense tissue took the place of the removed phalanx, and the power of flexing the ungual was nearly complete.¹

Excision of the Joints of the Fingers.—These operations may be performed for compound dislocation, specially when the thumb is injured; no directions can be given for the incisions.²

In cases of disease it is rarely necessary or advisable to attempt to save a finger, but if the metacarpo-phalangeal joint of the thumb be affected, excision should be performed with the hope of saving the thumb. A single free incision on the radial side of the joint will give sufficient access.

Excision of the Os Calcis.—In those comparatively rare cases in which the os calcis is alone affected, the rest of the tarsus and the ankle-joint being healthy, a considerable difference of opinion exists as to the proper course to be followed. By some surgeons it is considered best merely to gain free access to the diseased bone, and then remove by a gouge all the softened and altered portions, leaving a

¹ Butcher's *Operative and Conservative Surgery*, p. 225.

² For an excellent case, see Annandale on *Diseases of the Finger and Toes*, p. 261.

shell of bone all round, of course saving the periosteum and avoiding interference with the joint. This operation requires no special detailed instruction. We find many surgeons supporters of this comparatively modest operation. The author has many times performed this operation with excellent results. Even when nothing but periosteum is left, the new bone becomes strong and of full size.

Excision of the whole of the diseased bone at its joints, with or without an attempt to leave some of the periosteum, has been deemed necessary by others. Holmes, who has had considerable experience, removes the bone at once by the following incisions, without paying any reference to the periosteum:—

Operation.—An incision (Plate III. fig. F.) is commenced at the inner edge of the tendo Achillis, and drawn horizontally forwards along the outer side of the foot, somewhat in front of the calcaneo-cuboid joint, which lies midway between the outer malleolus and the end of the fifth metatarsal bone. This incision should go down at once upon the bone, so that the tendon should be felt to snap as the incision is commenced. It should be as nearly as possible on a level with the upper border of the os calcis, a point which the surgeon can determine, if the dorsum of the foot is in a natural state, by feeling the pit in which the extensor brevis digitorum arises. Another incision is then to be drawn vertically across the sole, commencing near the anterior end of the former incision, and terminating at the outer border of the grooved or internal surface of the os calcis, beyond which point it should not extend, for fear of wounding the posterior tibial vessels. If more room be required, this vertical incision may be prolonged a little upwards, so as to form a crucial incision. The bone being now denuded by throwing back the flaps, the first point is to find and lay open the calcaneo-cuboid joint, and then the

joints with the astragalus. The close connexions between these two bones constitute the principal difficulty in the operation on the dead subject; but these joints will frequently be found to have been destroyed in cases of disease. The calcaneum having been separated thus from its bony connexions by the free use of the knife, aided, if necessary, by the lever, lion-forceps, etc., the soft parts are next to be cleaned off its inner side with care, in order to avoid the vessels, and the bone will then come away.¹

Hancock's Method.—A single flap was formed in the sole, with the convexity looking forwards, by an incision from one malleolus to the other.

Greenhow's Method.—Incisions made from the inner and outer ankles, meeting at the apex of the heel, and then others extending along the sides of the foot, the flaps being dissected back so as to expose the bone and its connexions.²

Mickulicz's Operation.—Removal of os calcis and astragalus with soft parts of heel. Sawn surfaces of tibia and fibula brought in contact with sawn surfaces of cuboid and scaphoid.

This is an ingenious operation, by which in extensive destruction of heel, or in hopeless disease of astragalus and os calcis, the anterior parts of foot are saved and brought in continuation of bones of leg, imitating a bad case of equinovarus. As an operative procedure it is still on its trial. In cases of injury, such as crush or burn, the results will probably be successful and permanent. If done for disease of bones, the risk of return and subsequent amputation is very considerable, and after this procedure the amputation must be one of the leg, not of the foot.

Operation.—A transverse incision across the sole, from scaphoid tubercle to a point behind base of fifth metatarsal; from each end of this cut, an incision down to the bone to

¹ Holmes' *Surgery*, 3rd edition, vol. iii. p. 771.

² *Brit. and Foreign Med. Chir. Review* for July 1853.

the end of each malleolus, which again are united by a transverse incision across and through tendo Achillis. After opening ankle joint from behind, the astragalus is separated from soft parts on dorsum by a periosteum elevator, the calcaneo-cuboid and astragalo-scaphoid joints are opened from above, and the whole parts thus defined are removed. The lower ends of tibia and fibula are sawn across as in Syme's operation, and the scaphoid and cuboid articular surfaces also removed.

The cut surfaces of bone are then to be brought together, and kept together by wires or pegs of bone or metal. The foot, now looking like a marked case of talipes equinus, should be put up in a plaster-of-Paris dressing over a suitable splint, with a window through which the incision can be drained and dressed.

Excision of Astragalus.—A curved incision on the dorsum of the foot extending from one malleolus to the other, and as far forwards as the front of the scaphoid. The chief caution required is to divide all ligaments which hold the bone in place, and dissect it clean on all other parts before meddling with its posterior surface where the groove exists for the flexor longus pollicis tendon near which the posterior tibial vessels and nerve lie.¹ In case of complete or partial dislocation of the astragalus, admirable results follow its complete removal.

Excision of Astragalus and Scaphoid.—An incision similar to the anterior one in Syme's amputation at the ankle. The flap is then turned back from the dorsum of the foot. The joint is then to be opened, the lateral ligaments of the ankle-joint divided, the foot dislocated so as to show the astragalo-calcanean ligaments, and allow them to be

¹ Mr Holmes in *Lancet* for February 18, 1856.

divided. The bones are then grasped with the lion-forceps and pulled forwards, while the posterior surface of the astragalus is very cautiously cleaned, so as to avoid the posterior tibial artery.¹

Excision of Metatarso-Phalangeal Joint of Great Toe.—Butcher performs it by splitting up the sinuses leading to the carious joint, exposing it and cutting off with bone-pliers the anterior third of the metatarsal bone, and the proximal end of the first phalanx. He also cuts subcutaneously the extensor tendons to prevent them from cocking up the toe.² Pancoast prefers a semilunar incision. A lateral incision is usually to be preferred.

The author has performed this excision frequently for disease; when the whole cartilages are removed, and the wound is freely drained, an admirable result is obtained.

In cases of compound dislocation of the head of the metatarsal bone, it will occasionally be found necessary to excise it either by the original, or a slightly enlarged wound.

The author excised one-half of shaft of metatarsal and the corresponding half of proximal phalanx of great toe for exostosis, with antiseptic precautions. The result was a useful toe with a *mobile joint*.

Excision of Metatarsal Bone of Great Toe.—For this operation a quadrilateral flap has been recommended, but this is quite unnecessary. A single straight incision along the inner border of the foot, extending the whole length of the bone, renders it very easy to remove the whole bone from joint to joint. This is an operation, however, which is rarely needed, and which would leave a very useless flail of a toe. The operation, which is at once more commonly

¹ Mr Holmes in *Lancet* for May 1865.

² Butcher, *Operative and Conservative Surgery*, p. 354.

required, and also gives promise of a more satisfactory result, is the one performed for cario-necrosis of the shaft only, and in the following manner:—

A straight incision through all the tissues, including the periosteum, right down to the bone; then with nail or handle of the knife to separate the periosteum from the bone; then with a pair of bone-pliers or a fine saw to divide the shaft from both its extremities and remove it entire.¹

¹ See Butcher, *Operative and Conservative Surgery*, p. 356.

CHAPTER IV.

OPERATIONS ON CRANIUM AND SCALP.

TREPHINING AND TREPANNING are the names given to operations for the removal of portions of the cranium by circular saws which play on a centre pivot. When the motion is given to the saw simply by rotation of the hand of the operator, as is common in this country, it is called *trephining*; when (as used to be the case in this country, and still is on the Continent) the motion is given by an instrument like a carpenter's brace, the operation is called *trepanning*.

The nature of the operation varies according to the nature of the case for which it is performed. Thus (1), it may be performed through the uninjured cranium in the hope of evacuating an abscess of the *diplœe* or *dura mater*, or of relieving pressure caused by suppuration in the brain itself, or by extravasation into the brain or membranes, or for tumours of brain; or (2), it may be required in cases of punctured and depressed fracture, for the purpose of removing projecting corners of bone and allowing elevation of the depressed portions; or (3), it is sometimes used to remove a circular portion of bone in cases of epilepsy in which pain or tenderness is felt at some limited portion of the cranium.

1. *In cases where the cranium and its coverings are entire.*
—There are certain positions where, if it is possible, the trephine should *not* be applied. These are the longitudinal

sinus, the anterior inferior angle of the parietal bone, where the middle meningeal artery is in the way, the occipital protuberance, and the various sutures. These being avoided, a semilunar incision with its convexity downwards, giving abundance of room round the portion to be operated on, is to be made through the skin, and its flaps reflected. The pericranium should then be raised from the centre by a crucial incision for a space large enough to hold the crown of the trephine. The pericranium should never be removed, but carefully raised and preserved, as its presence will greatly aid in the restoration of bone. The centre pin should then be projected for about the eighth of an inch and bored into the bone. On it as a centre the saw is then worked by semicircular sweeps in both directions alternately, till it forms a groove for itself. Whenever this groove is deep enough the pin should be retracted, lest from its projection it pierce the dura mater before the tables of the skull are cut through. Were the cranium always of the same thickness, and even of similar consistence, the operation would always be easy; but in both these particulars different skulls vary much from each other, and thus by a rash use of the instrument the dura mater may possibly be injured. The tough outer table is more difficult to cut than the softer and more vascular *diplöe*, and the inner table is denser than either, but more brittle. In many old skulls, however, the *diplöe* is wanting altogether, and the two tables are amalgamated, and often very thin.

Great care must be taken in every case to saw slowly, to remove the sawdust, and examine the track of the saw by a probe or quill, lest one part should be cut through quicker than another. The last turns of the instrument must specially be cautious ones. When the disk of bone does not at once come away in the trephine, the elevator or the special forceps for the purpose will easily remove it. If the

abscess, extravasation, tumour, or exostosis be then discovered and removed, all that remains is to remove any sawdust or loose pieces of bone, and possibly to smooth off any sharp edges of the orifice by an instrument called the lenticular. This is very seldom required, and now hardly ever used.

2. *In cases of depressed or punctured fracture* the trephine is occasionally required (when symptoms of compression are present) for the purpose of enabling the depressed portion to be elevated. It is unsafe to apply it on the depressed or fractured bone, lest the additional pressure of the instrument should cause wound of the dura mater or brain. It is generally applied on some projecting corner of sound bone under which the depressed portion is locked, and hence it is rarely necessary to remove a complete circular portion. In fact very many cases of such displacement may be remedied more easily by a pair of strong bone-forceps, or a Hey's saw, applied to remove the projecting portion of sound bone. The same precautions must be used as in the operation already described, and the sawing must be done even more cautiously, as it is rarely more than a semicircle that requires cutting.

In former days trephining was a much more frequent operation than it is now, and apparently more successful. The reason of the greater apparent success can easily be found in the fact that it was performed in many cases merely as a precautionary measure against dreaded inflammation of the brain, which probably never would have appeared at all, and that the operation itself is one by no means dangerous. Very numerous applications of the trephine have been made in the same individual—two, four, six, and even in one case twenty-seven disks having been removed from the same skull, and yet the patients have survived.

The most valuable work of Horsley, Ferrier, MacEwen,

and others, on localization and treatment of brain neoplasms, has rendered the operation of trephining not only much more frequent in its performance, but has placed it on a more scientific basis.

Trephining of the Spine.—This operation, first performed by Cline in 1814, has now, by the great exactitude of physiological knowledge, been placed in the rank of possible operations, and has been performed with success by MacEwen and Victor Horsley, John Duncan, and others.¹

Tumours of the Scalp, Removal of.—By far the most frequent are the encysted tumours, or wens. These consist of a thick, firm cyst-wall, which contains soft, curdy, or pul-taceous matter, sometimes almost fluid, at others dry and gritty. They are loosely attached in the subcutaneous cellular tissue, and unless they have become very large, or have been much pressed on, are non-adherent to the skin.

The treatment is thus very simple. They should merely be transfixed by a sharp knife, the contents evacuated, and the cyst seized by strong dissecting forceps and twisted out.

If they have once become adherent, they must be dissected out in the usual manner, after the adherent portion of skin has been defined by elliptical incisions.

In the case of large wens on visible parts of scalp or face, the author avoids scar by the following plan:—

Make a small incision, two lines at most, through skin only, then with a blunt probe separate the cyst from the skin subcutaneously; then, pulling it to the wound with catch-forceps, empty the cyst and gradually pull it out, as if taking out an ovarian cyst. No scar but a dimple will remain.

¹ *Brit. Med. Jour.*, Jany. 28, 1888.

CHAPTER V.

OPERATIONS ON EYE.¹

Operations on the Eye and its Appendages.

Operations on the Lids.—

1. *For Entropium or Inversion of the Lids, often combined with Trichiasis, irregularity of the Ciliæ.*—As in many cases

FIG. VII.*

the entropium seems to depend partly on a too great laxity of the skin of the lid, combined occasionally with spasm of the orbicularis, the simplest and most natural plan of operation is (a) to remove (Fig. VII. a) an elliptical portion of skin, extending transversely along the whole

length of the affected lid, including the fibres of the orbicularis lying below it, and then to unite the edges with

FIG. VIII.†

several points of fine suture. (b) An improvement on this in obstinate cases is proposed by Mr Streatfield (Fig. VIII.) He continues the same incision, but in addition removes a long, narrow, wedge-shaped portion of the tar-

* Fig. VII. a. Elliptical incision for entropium; b. wedge-shaped incision for ectropium.

† Fig. VIII. illustrates Streatfield's operation for entropium.—a. section of skin; b. section of levator palpebrae; c. section of cartilage of lid; d. section of conjunctiva; e. wedge-shaped portion excised.

¹ Revised, and to a considerable extent rewritten, by W. G. Sym, Esq., M.D., F.R.C.S. Ed.

sal cartilage, grooving it without entirely cutting it through, in such a manner that the retraction of the skin bends the cartilage backwards, thus everting to a very considerable extent the previously inverted ciliae.¹ This operation is suitable for the upper lid. Another mode of procedure, applicable to either upper or lower, is to remove a Δ of skin and deeper tissues (if necessary) from the lid, the base, which is turned towards the ciliary margin, being prolonged at each side to nearly opposite the canthus. Stitches being inserted, the edge of the lid is thus somewhat everted.

2. *Ectropium* is the opposite condition from entropium; in it the eyelids are everted and the palpebral conjunctiva is exposed.

If the result of cicatrix, of a burn, or of disease of bone, the treatment must be varied according to circumstances, and in many cases skin must be transplanted to fill the gap.

In the more usual cases resulting from chronic inflammation the following simple operations are required:—1. In mild cases the excision of an elliptical portion of conjunctiva may suffice, the edges must not be left to contract, but should be brought carefully together. 2. In more chronic cases, where all the tissues of the lid are very lax, it is necessary to remove (Fig. VII. *b*) a V-shaped portion of lid and skin, and then stitch it very carefully up with interrupted sutures. 3. Snellen carries each end of a stout silk thread down through the most prominent part of the exposed conjunctiva to emerge on the cheek $1\frac{1}{2}$ inches or so lower down, where the ends are firmly tied over a piece of drainage tubing. Two such stitches may be used, and may be left in for four or five days.

Operation for Ptosis.—(Drooping of the upper eyelid.) Eversbusch proceeds as follows:—The lid being clamped, a

¹ *Ophthalmic Hospital Reports*, vol. i. p. 121.

horizontal incision is made along its whole length through the skin, halfway between eyebrow and lid margin. Under the superficial tissue lies the tendinous attachment of the Levator Palpebrae Superioris to the tarsal cartilage. A silk thread is made to pick up a loop of this, and then both ends are passed down under the skin, emerging on the lid margin about three millimetres from one another. Three such stitches may be passed and the ends firmly knotted in pairs. The skin wound is then carefully stitched, if necessary a small piece being removed.

Tumours of Eyelids.—1. *Encysted tumours ; cysts of the lids ; tarsal tumour.*—Under these and similar names are recognised a very frequent form of disease, chiefly in the upper lid ; small tumours which rarely exceed half a pea in size, convex towards the skin, which is freely movable over them ; they give no pain, and are annoying only from their bulk and deformity.

Operation.—Evert the lid, incise the conjunctiva freely over the tumour, directing the edge of the knife towards the lid margin, insert the blunt end of a probe, or a small scoop, and roughly stir up the contents of the cyst, thus evacuating it. The probe may require to be reapplied once or twice at intervals of two or three days, and in certain rare cases it may be necessary as a last resource freely to cauterize the inside of the cyst with nitrate of silver.

In no case is it ever necessary to excise the tumour from the outside of the eyelid ; when this has been done in error there frequently remains an awkward and unsightly scar.

2. *Fibrous cysts*, frequently congenital, are met with in one situation, just over the external angular process of the frontal bone. These are larger in size than the preceding, ranging from the size of a barley pickle to that of an almond. Their treatment is excision by a prolonged and

careful dissection from the periosteum, to which they almost invariably are adherent. Care must be taken that the site and direction of the incision should be such as to leave no deformity.

Canthoplasty.—*Enlargement of the Palpebral aperture* is a very useful operation in the spasmodic closure of the lids in bad cases of ulceration of the cornea, in gonorrhœal conjunctivitis, and in trachoma. In all these cases the pressure of lid on globe and retention of secretion are injurious.

Operation.—With a straight knife, or (better) with a straight pair of scissors, the skin at the outer canthus is divided. One blade of the scissors is introduced between the lid margins, pushed straight through the skin beyond the outer canthus, and by a sharp snip the bridge of tissue, including the orbicular muscle, is divided. The smart bleeding which results is highly beneficial. Three silk stitches are then used to unite skin to mucous membrane over the raw surface, one being placed in the angle. It is essential for cosmetic reasons that the incision should be straight, and inclined neither up nor down.

Operations on the Lachrymal Organs.—In a system of ophthalmic surgery, various operative procedures might be detailed under this head, authorized and sanctioned by old custom. Excision of a diseased lachrymal gland, and removal of stones in the gland or ducts, need no special directions for their performance, and the operation immediately to be described, under the head of Sir W. Bowman's operation, is applicable in almost every one of the diseased conditions of the lachrymal canal, sac, and nasal duct, to the exclusion of all the older methods.

Sir W. Bowman's Operation.—In cases of obstruction of the punctum, canaliculus, and nasal duct resulting in watery eye,

accumulation of mucus in the canal, and dryness of the nose, great difficulty used to be experienced in the treatment.

The punctum is too small to admit a probe sufficiently large to dilate a stricture of the nasal duct, and the old method of treatment by passing a larger probe or leaden style into the duct by an incision into the sac through the skin is painful, unsightly, unsatisfactory, and not altogether free from danger. Sir W. Bowman found that by slitting up the inferior punctum and canaliculus as far as the caruncula, several advantages were gained:—(1), The swollen, angry, displaced punctum no longer impeded the entrance of the tears; (2), and chiefly when the canaliculus was slit up, the curve, or rather angle which impeded the passage of probes, was done away with, and the nasal duct could be readily and thoroughly dilated. The principle of Bowman's excellent operation is that a stricture of the nasal duct ought to be treated on the same lines as a urethral stricture.

Operation.—The surgeon stands behind the patient, who is seated, and leans his head on the surgeon's chest. The affected lid is then drawn gently downwards on the cheek, so as to evert and thoroughly expose the lower punctum. Into this the surgeon introduces a fine probe of steel gilt, the first inch of which is very thin, especially at the point, and deeply grooved on one side, exactly like a small (and straight) Syme's stricture director.

Keeping the canal relaxed by relaxing his hold on the lid, the surgeon now gently wriggles the probe along the canaliculus, gradually stretching it as the probe advances, so as to avoid catching the sides of the canal before the point of the instrument, till he feels bone with the end of the director, which has then traversed the canal and sac. He then stretches the eyelid, brings the handle of the probe out over the cheek so as to evert the punctum as much as possible, and then with a fine sharp-pointed knife enters

the groove (Fig. ix.), and fairly slits up the punctum and the canal to the full extent. The incision should be as

FIG. ix.*

straight as possible, and through the inner wall of the canaliculus. A dexterous turn of the instrument upwards on the forehead will generally enable it to be passed at once fairly into the nose through the nasal duct, the usual rule being observed of passing it downwards and slightly backwards, the handle of the probe passing just over the supra-orbital notch.

By means of Weber's knife, which consists of a small cutting blade preceded by a short, slightly up-turned probe point, one can perform this little operation with one instrument.

FIG. x.—Weber's Canaliculus Knife.

For several days after the operation the probe will have to be passed, both to prevent the wound in the canaliculus from healing up, which it is too apt to do, and also gradually to dilate the nasal duct if it has been previously strictured. Probes and directors of various sizes are required; in fact, very much the same instruments (in miniature) as are required for the treatment of stricture of the urethra.

* Rough diagram of Bowman's operation, showing the grooved director in the punctum, and the knife in the groove just before it slits up the canaliculus.

Pterygium, the reddish fleshy or membranous triangular growth, with its base towards the inner canthus, and its apex spreading to and often over the cornea, requires a small operation for its removal. In some cases it will be found sufficient merely to raise the lax portion over the sclerotic with forceps, and divide it freely, removing a transverse portion. If it has encroached upon the cornea, the portion interfering with vision must be dissected off with great care and removed.

In some cases, however, it has been found that after removal of a large pterygium, an unsightly retraction of the caruncle and the semilunar fold is apt to take place. To avoid this the pterygium may be carefully dissected up from its apex to near its base, and then displaced laterally either upwards or downwards, its apex and sides being stitched to a previously prepared site of conjunctiva; or it may be included in a lozenge-shaped incision and removed, the sides of the lozenge being then well undermined and brought together by fine stitches.

Operation for Convergent Strabismus.—*Division of the Internal Rectus.*—The original operation of Dieffenbach, which consisted in free division of the belly of the muscle, is now discarded, as it was apt to be followed by very ugly divergent strabismus, with sinking of the caruncle. The operation now employed is performed by pinching up a fold of conjunctiva, and making a small incision in it with scissors, which then are made to snip through the fibres of Tenon's capsule. When this is done the points of the scissors will be found to be quite free. The *tendon* is then raised on a blunt hook, introduced by the same aperture, and the attachment of the muscle divided close to the sclerotic. Several dips with the hook should then be made in order to catch up and divide any stray fibres of

attachment. Some prefer to have the aperture in the conjunctiva quite below the level of the muscle, the operation being thus done subconjunctivally; others place it directly over the attachment. If this method is pursued, a vertical stitch should be inserted.

Operation for Divergent Strabismus may be required for a primary divergence, or such a condition secondary to a too free division of the internal rectus muscle. To remedy a slight divergence, simple division of the tendon of the external rectus may be sufficient. This operation is performed exactly in the same manner as division of the internal (see above); but it must be kept in mind that the tendon lies considerably further back. For the higher degrees, however, advancement of the point of insertion

FIG. XI.*

of the internal rectus must be combined with it. The tendon is laid bare by an incision in conjunctiva, seized with forceps, and divided close to the sclerotic. Behind the forceps two threads of fine but strong silk are now passed through the muscle, the other ends being passed deeply under the conjunctiva as far as the vertical meridian of the cornea (one

* *a* and *b*, Stitches used in operation of advancement of a muscle. *c*, Muscle (the forceps holding it are not shown).

above, the other below), when they are made to emerge. The portion of muscle grasped in the forceps is now cut off, and the stitches simultaneously tied. The eye is thus rotated inwards by the shortened internal rectus muscle.

[For all operations on the globe itself, cocaine is a very useful anæsthetic. It may be applied in the form of 3 or 4 drops of a 4 per cent. solution, instilled from five to two minutes before operation.

The following operations, however, are better conducted under a general anæsthetic:—Iridectomy for glaucoma, evisceration, enucleation, abscission, and sometimes tenotomy and advancement of muscles.]

Paracentesis of the Anterior Chamber.—*Tapping of the Aqueous Humour.*—This very simple operation is in some cases very useful. In cases of deep corneal ulcer where there is danger of the base suddenly yielding to the (perhaps increased) tension of the globe, with resulting injury to iris and lens; of suppurative ulcer of the cornea, with pus in the anterior chamber; of inflammation of Descemet's membrane, with increased tension; of hydrophthalmus; and in some cases of glaucoma, it is beneficial. It is best for the surgeon to fix the eye for himself without a speculum, by placing the tips of the index and third fingers of one hand on the sclerotic above and below the cornea. In this way he can relieve pressure at a moment's notice. He then pushes the point of a "bent broad needle," or keratome, through the cornea, and *slowly* withdraws it as soon as he is satisfied that it has fairly entered the anterior chamber. Should the aqueous humour not flow out spontaneously, it can be made to do so by touching one lip of the incision with a probe in order to make it gape. This draining of the aqueous humour can be kept up by thus opening the original wound with a probe daily, or several times a day,

as required. To facilitate finding the aperture, the puncture should be made opposite some landmark, such as the outer end of the precise horizontal meridian, or some pigment speck on the iris. If pus or lymph is present in the anterior chamber, a somewhat broader keratome must be used (or a cataract knife), and the opening made below.

Saemisch's Operation is performed in cases of ulcer of the cornea with pus in the anterior chamber, in which it is of great value. It consists in dividing the base of the ulcer by means of a narrow knife thrust from cornea outside the ulcerated area, through the anterior chamber, emerging through cornea at the inner side of the ulcer. The whole tissue lying in front is then cut through, and the anterior chamber emptied of pus and lymph. The free division of the base of the ulcer and the thorough relief of tension set up prompt healing of the ulcer.

Cataract Operations.—Here we cannot enter into any discussion of the pathology of cataract and the varieties of it. Enough for our purpose to know that the lens is in some cases hard, in others soft, and that thus in the latter it may be removed piecemeal, and by a small incision, while in the former, removal must be almost entire, and by a larger opening.

In cataract, the lens, which should be transparent, has become opaque, and the object of treatment is to get it out of the line of sight, to prevent it from obstructing, now that it can no longer assist sight.

The operations used for this end may be classed under three heads:—

1. *Operations for the Removal of the Lens out of the Way without its Removal from the Eye.*—These used to be extensively practised under the name couching, and are of two

kinds,—*Depression*, where the lens is simply pushed down from its place by a needle; *Reclination*, in which it is pushed backwards (turning on its transverse axis) as well as downwards. These are relics of old surgery, and very rarely practised by any oculists of eminence, as, though easy to perform, and with very flattering immediate results, the risks of chronic inflammation of the whole globe and injury to the retina are very great.

2. *For Solution*.—**The Needle Operation, or Keratonyxis.**—Suitable (among other cases) especially in congenital cataracts in infants, and in some cases of diabetic cataract.

The principle of this operation is that the lens, once the capsule is freely opened in front and the aqueous humour admitted, is found rapidly to become absorbed and disappear, if the cataract has been a soft one.

Operation.—A needle with a lance-shaped head is to be used. It should be so made that the rounded shaft of the needle is just large enough to play freely in the wound made by the broader point, and yet not so small as to allow the aqueous humour to escape. The pupil has been dilated, the patient is lying on his back, and the globe is fixed by forceps attached to the conjunctiva of the inner side of the eye. The surgeon then enters the needle near to the sclerotic margin of the cornea, carries it fairly on in the anterior chamber, till the centre of the pupil is reached. He then, by bringing forward the handle, projects the point backwards against the anterior capsule, which he freely lacerates with the point and edge in several directions.

In infants, where processes of repair go on very rapidly, the whole lens may be freely broken up. In diabetic cataract, or indeed in all cases of solution, where the patient is adolescent or adult, or the eye at all weak, only a small portion of the lens should be attacked at one sitting.

The needle should then be withdrawn gradually and with great care, that the broad axis of the blade be in exactly the same position in which it entered, *i.e.*, flat and parallel with the iris, lest the iris be wounded, entangled, or prolapsed.

The eye is then to be closed for twenty-four hours, and atropia to be freely used.

Varieties in the Operation.—Some use two needles at once for breaking up the lens. Some surgeons prefer to enter the needle through the sclerotic; this complicates the operation and renders it less certain, as the point of the needle is of course out of sight in its progress between the iris and the lens.

Even in children this operation requires in most cases to be repeated at least once, while in adults it may be required at short intervals for many months.

3. *By Extraction.*—In these operations the lens is actually removed from the eye—

(1.) *By Linear Incision.*—This method is only suited for cases of soft cataract, such as that caused by injury to the lens, or those mentioned under “needle operations.” The needle operation is performed as above, the pupil kept well dilated by atropia, and then, a few days after, the time varying according to rapidity of “ripening,” the lens is removed thus:—The eye being seized by forceps, a moderately-sized keratome is thrust into the anterior chamber through the cornea or corneo-sclerotic junction. Through this opening the soft lens is “wheeled” out along a gutter-like curette, which may be thrust in for the purpose and used to catch the more adherent portions. Great care must be taken to avoid injury to the iris. When the pupil is as clear as it can be made, atropia is again instilled, and the eye dressed.

EXTRACTION OF SOFT CATARACT BY SUCTION.—Mr T. P. Teale, of Leeds, invented an instrument by which the removal of soft cataract is made more easy, through a linear incision by suction, applied through the medium of a hollow curette furnished with an india-rubber tube and mouth-piece.

The curette is of the usual size, but is roofed in (instead of being merely grooved) to within one line of its extremity, thus forming a tube flattened above, but terminating in a small cup. This is screwed into an ordinary straight handle, which is hollow for a short distance, far enough to join with a second tube fixed at right angles to the handle, and into which the india-rubber pipe and mouth-piece, through which suction is to be made, are attached. In many cases it seems to serve its purpose extremely well.

Certain points require attention:—1. That the puncture to admit the curette is large enough; 2. That its end be sufficiently rounded; 3. Its open end must be held in the area of the pupil, and not allowed to pass behind the iris, else there is great risk of the iris being drawn in. Among other advantages claimed by its inventor, the chief seems to be the more thorough removal of the lens than by the ordinary means, and consequently less risk of opaque deposit in the posterior capsule.

(2.) *Extraction of the Hard Lens.*—The old operation consisted of removing the lens through an opening made by cutting a large flap of the cornea—the lens being then caused to escape through the large aperture thus created. The great objection to this method, which gives very good results when it is successful, is that the cutting off from its supply of nutriment of so large a portion of a non-vascular tissue like the cornea is very liable to be followed by supuration. Von Graefe modified this operation in such a way as to reduce the size of the wound, and so to place it that one has all the advantages of an aperture wide enough to permit the passage of the entire lens, without the risk of cutting off the cornea from nourishment. Instead of the incision being semicircular, it approaches to the linear, and the operation received the name of the “modified linear extraction.”

Operation.—The patient is laid on his back, cocain applied, and the speculum introduced. The surgeon stands behind the patient, seizes with forceps a good hold of the conjun-

tiva at the lower border of the cornea, and rotates the eye downwards. The knife, which is long, narrow, pointed, and very keen, is made to enter the anterior chamber, in or just external to the corneo-scleral junction, at a point two millimetres below the tangent to the vertical meridian of the cornea. This point will best be found by first laying the knife across the cornea, so that its edge corresponds to the corneo-sclerotic junction above, noting the point at which the back crosses that junction to the outer side, and then causing the knife to enter at a point just below that. The blade is to be pushed onwards diagonally through the anterior chamber until about one-third of the way across, the point being directed to the centre of the pupil, or even below it, and then turned upwards by depression of the handle, and made to emerge at a point in the corneo-sclerotic junction exactly corresponding in position to that at which it entered. Until this is done not a drop of aqueous should escape. By a series of one or two long sawing movements the knife is now made to cut its way out, the edge being turned slightly forwards as the knife comes out. The iris is next seized opposite the middle of the wound in a pair of small-toothed forceps, drawn out, and a small piece cut off. A cystotome, or small toothed instrument for tearing the capsule, is now introduced, and the anterior capsule of the lens thoroughly lacerated, especially at its upper part. Everything is now ready for the escape of the lens, which is effected by gentle, steady stroking and pressure over the sclerotic and lower part of the cornea. The edge of the nucleus will presently

FIG. XII.—Modified Linear Extraction, showing position of wound and first and second direction of knife.

present in the wound, and must be very carefully and gently assisted in its exit by pressure from behind. When the nucleus has escaped, there usually remains some cortical matter to be removed in a similar way, and by the use of the guttered scoop, the greatest possible care being taken to avoid any undue pressure whereby vitreous humour would be squeezed out and lost. The edges of the incision in iris and cornea are now to be smoothed down, the lips of the corneal wound seen to be in close and neat apposition, and the operation is completed. There are a few modifications which must be noted. Some surgeons prefer to remove the iris opposite the whole length of the corneal incision, others remove no iris at all. The former procedure is unnecessary; the latter, at least as a routine treatment, is unsafe, for iris is apt to be prolapsed into the wound and cause inflammation; besides, the removal of a piece of iris enables one to clear the pupil much more thoroughly. Some surgeons make the incision wholly corneal, others altogether in the junction. Most make it above, a few make it downwards. It is sometimes advisable to introduce a spoon or vectis, or wire loop, behind the lens, and remove it bodily, even though some vitreous is thus lost.

When operating on the left eye some surgeons prefer to stand behind the patient (as when extracting the lens from the right eye), and use the knife with the left hand. Others, who feel less confidence in the steadiness and precision of the movements of the left hand, prefer to stand close to the left side of the patient's chest, and using the knife with the right hand, cut upwards.

It is useful to perform the iridectomy from three to six weeks before the extraction, under the following circumstances:—(a), To prepare the eye, when both lenses are so far cataractous that the patient is very helpless, but neither lens is yet ripe; (b), when the eye has been previously

attacked by iritis; (c), when glaucoma threatens or is present; (d), when the patient has only one eye to "come and go upon."

Operations for Artificial Pupil.—The cases are by no means unfrequent in which it is necessary to remove or destroy a portion of the iris to admit light to the retina. In cases of excessive prolapse of the iris after extraction of the lens, where the iris has formed adhesions to the wound, and still more frequently in cases where central opacities of the cornea have fairly occluded the natural pupil, the only chance for vision is to enlarge the old one, or make a new pupil by removal of a portion of the iris.

Very various operations have been proposed, and exceedingly numerous and complicated instruments invented for this purpose. We can notice here only one or two of the most approved procedures:—

1. *Iridotomy, or Incision through the Iris.*—This operation is suitable for cases in which, the lens being shrunk up or absent, the iris is drawn up to a wound in or near the angle of the anterior chamber, or is firmly adherent to the remains of the capsule. For its success it is necessary that the tissue of the iris should be so far healthy that on its division the contraction of the fibres causes the slit made to spring open *and remain so*.

Operation.—In some cases this object may be gained by passing through the cornea a narrow-bladed knife. This is directed across the chamber and through the iris at the opposite side to the corneal puncture. Halting for a moment to allow the iris to run up the knife instead of being pushed before it, the operator then, by a quick move-

FIG. XIII.—Keratome.

ment, raises the handle of his knife, and the aperture in the cornea being the fulcrum, the blade cuts its way across the fibres. In the majority of cases, however, the combined iris and membrane is too tough for this manœuvre to be successful, and the division must be made with scissors. These are introduced through the wound made by a narrow keratome close to the corneo-sclerotic junction. One blade of the scissors (the blades are shorter than the diameter of the cornea), which is sharp, is pushed through the iris, the

FIG. XIV.

other (which has a blunt point) remains in the anterior chamber. By one quick snip the whole membrane is cut across, and the scissors are then carefully but quickly withdrawn and the eye dressed, to avoid undue escape of vitreous humour. Whichever of these operations is done, it is essential that the direction of incision be *across* the direction of the stretched iris fibres—therefore usually horizontal.

2. *Iridectomy, Excision of a Portion of Iris.*—This is a much more frequent operation, and is done under the following circumstances:—In treatment of (a) glaucoma, (b) chronic or recurrent iritis, (c) staphyloma of cornea, (d) irido-choroiditis; also, (e) as a preliminary to extraction of hard cataract (*v. s.*); and (f) for optical purposes, where the pupil is obscured by effusion, or by opacity of the cornea, or of the lens (congenital cataract).

Operation.—The eye being fixed as usual, a keratome is pushed through the cornea or corneo-sclerotic junction and withdrawn slowly, so as to avoid too rapid escape of

aqueous. A pair of small-toothed curved forceps is introduced, with which the iris is seized close to its pupillary margin, and a portion drawn out of the wound and snipped off. The edges are then smoothed. When the operation is being

done for glaucoma, the following special points must receive attention:—

(a) The whole operation must be performed slowly, to avoid too sudden reduction of tension; (b) the incision must be very peripheral; (c) the piece of iris removed must be large,—at least one-fifth of the whole circumference; (d) the excised piece must be removed quite to the peri-

FIG. XV.*

phery. When the iridectomy is done for visual purposes, as in cases of opacity of the cornea, and it is therefore desirable to have only a small pupil in order to avoid dazzling, a small blunt hook (Tyrrell's) may be used to pick up the pupillary border of the iris in place of the forceps.

3. *Iridesis, or Ligature of the Iris.*—The steps of this operation are exactly the same as in iridectomy, except that the piece of iris is not snipped off, but included in a tight ligature of very fine silk, which is slipped down the forceps or hook with which it was drawn out. The ends of the ligature should be left long, to avoid its accidental disappearance into the cicatrix, or even deeper; the opening in the corneo-scleral junction must, for the same reason,

* A. Iridectomy for Chronic Iritis, or as preliminary to extraction of Cataract. B. Iridectomy for Glaucoma. C. Iridectomy, Optical. D. Iridotomy.

be small. By this method the new pupil can be made very small, it is true, but the operation is not very frequently performed, as it is somewhat dangerous.

Corelysis.—*Freeing of the Pupil*—An operative procedure for separating posterior adhesions of the iris to the lens. In it the surgeon hopes to act, not on the iris, as in the operations for artificial pupil, but only on the bands of false membrane which distort the pupil.

The operation is briefly as follows:—The eye being firmly held by a speculum, and forceps pinching up the conjunctiva, a broad needle is passed rapidly through the cornea at a point which may give easy access to the adhesion to be torn through. This point is generally at the opposite margin of the irregular pupil, so that the needle may pass through the cornea in front of the one side of the iris, then through the orifice of the pupil, so as to reach the back of the other side. The needle is withdrawn gradually, so as to lose as little of the aqueous humour as possible, and then the spatula hook, called after the inventor of the operation, Mr Streatfield, is introduced. It is used first as a spatula, that is, with its blunt, though polished edge, to

FIG. XVI.*

separate the adhesions, and if this is unsuccessful, as a hook (Fig. XVI.), so as to catch and tear them. In cases which resist the instrument used in both of these ways, Mr Streatfield has used very fine canula-scissors to cut the adhesions.¹ Such a further

complication of the operation practically alters its character into an operation for artificial pupil, *q.v.* This operation is

* *a*, iris; *b*, lens; *c*, cornea. The hook is seen applied to the adhesion between lens and iris.

¹ Streatfield on Corelysis, *Ophthalmic Hospital Reports*, vol. ii. p. 309.

somewhat dangerous to lens and iris, and is not altogether satisfactory, as the adhesions very frequently reform; it is not often resorted to.

Sclerotomy.—This operation is useful in cases of glaucoma, in which the tension rises again after the iridectomy has been done, or in which there is tendency to hæmorrhage, and in cases of inflammation of Descemet's membrane.

The operation is conducted like the first stage of iridectomy, except that the incision is made at the very periphery of the anterior chamber, the knife passing through scleral tissue. Either the stabbing knife (angled keratome) or narrow cataract knife (Graefe's) may be used, and in the latter case a bridge of uncut conjunctiva may be left over the centre of the wound.

Abscission of a Staphylomatous Cornea.—There are certain cases in which the whole or greater part of the cornea bulges forward in a great blue projecting tumour. It is very ugly as it protrudes between the lids and prevents their closure; besides this, from its exposure it frequently inflames, even ulcerates, and has a most injurious effect on the other eye. In the cases suitable for operation vision is completely gone, without hope of its restoration by any operative procedure.

The best thing for the patient is to have just enough of the staphyloma removed to enable the remains of the eyeball to form a good stump for an artificial eye. Various means have been suggested for doing this, varying in extent and severity from a mere shaving off the apex of the staphyloma to excision of the whole eyeball.

By far the best method of operating is the one proposed and practised by Mr Critchett.

The object of it is to remove an elliptical portion of the front of the staphyloma, or the whole staphyloma, when it

is possible, and at the same time to prevent as far as possible the escape of the vitreous.

FIG. XVII.*

FIG. XVIII.†

Operation.—Three, four, or five curved needles armed with thread are passed through the base of the staphyloma from above downwards, being each entered a little above the line of the intended upper incision, and brought out a little below the line of the intended lower one (Fig. XVII.)

To remove the included elliptical portion, Mr Critchett pierces the sclerotic with a Beer's knife, just in front of the tendinous insertion of the external rectus. Through this incision a pair of probe-pointed scissors is introduced, and the piece cut just within the points of the needles. On the removal, the needles, which have retained the vitreous by their pressure, are drawn through and the threads cautiously tied.

Union by first intention very often occurs, and an excellent stump is left with a narrow depressed transverse cicatrix¹ (Fig. XVIII.)

Evisceration, and Mules's Operation.—The object of

* The staphyloma with the needles inserted, the lids held asunder by a spring speculum. The elliptical dotted line shows the amount to be removed; the vertical one, the position of the preliminary incision with the Beer's knife.

† Resulting stump after the stitches are inserted.

¹ *Ophthalmic Hospital Reports*, vol. iv. part 1.

this operation is, while removing those parts of an eye which are most liable to inflame themselves, and to set up sympathetic inflammation in the other, to leave at the same time enough to form a better and more mobile stump than if the whole globe were removed. The conjunctiva having been incised all the way round, the whole cornea is removed by one sweep of a knife and snips with scissors, the lens, iris, vitreous, and other contents of the globe are rapidly turned out with a Volckmann's spoon, or with a pledget of damp wool. Catgut stitches inserted through the conjunctiva (not sclerotic) are used to close the gap, and a catgut drain inserted. It is essential that the *whole* of the contents be thoroughly cleared out. In addition, Mules inserts into the cavity a small glass ball, which he calls an "Artificial vitreous."

Extirpation of the Eyeball.—*Enucleation of the Eyeball only.*—A circular incision should be made with curved scissors through the conjunctiva, a little beyond the corneal margin, then, beginning with the inferior rectus, muscle after muscle should be raised on the blunt hook, and divided, after which the optic nerve is cut through with the scissors. The nerve will be found to the nasal side of the apex of the orbit, and should be cut through as far back as possible. Bleeding is readily stopped by pressure.

Extirpation of Orbital Contents.—This may be required for malignant disease, but with a very poor prognosis. The optic commissure should be freely divided, and then, by bold strokes of curved scissors, or curved probe-pointed bistoury, the orbit may be fairly emptied by scooping out its contents. Even the periosteum may require to be scraped off, and the optic nerve divided as far back as possible. The hæmorrhage may be pretty smart, but can generally be easily checked by compresses; if necessary, these can be soaked in the solution of the perchloride of iron.

CHAPTER VI.

OPERATIONS ON THE NOSE AND LIPS.

Rhinoplastic Operations.—The operations for the restoration or repair of lost or mutilated noses are so various, and the minuteness of detail necessary for full description of them so great, that a complete account in a manual such as this is impossible; a brief notice of some of the most important varieties of the operation is all that can be given.

Principles.—1. It is necessary in every case that a suitable edge be prepared on which to fix the flap of skin, however obtained. To be suitable, this edge should be (*a*) made in healthy skin, not in old or weak cicatrices; hence no trace of the original disease should be left; (*b*) it should be made thoroughly raw, by the removal of an appreciable amount of its edge; it should be pared, not merely scraped.

2. It is useless to attempt to restore a nose unless the patient is in good general health, well nourished, and perfectly free from all remains of disease in the nose or its neighbourhood. The flaps which are to form the new nose may be obtained either from (1), the cheeks; (2), the forehead; (3), a distant part either of the patient or of another person.

(1.) *From the Cheeks.*—When the cheeks are healthy, and specially if they are tolerably full and lax, the flaps from the cheeks produce very satisfactory results. As suggested by Mr Syme, the operation consists in the

shaping of two equal flaps (A, A) from the skin of the cheek at each side, having the attachment above. A site for each flap is formed by the careful paring away of the whole thickness of the edge of the cavity of the lost organ (see Fig. XIX.)

FIG. XIX.*

The flaps are then raised from their attachments to the upper jawbone, and approximated in the middle line by several points of metallic suture, and the outer edges stitched to the raw surface on each side at a proper distance from the nasal orifice. If any septum remains of the old nose, it may be made very useful as a fixed point, a straight needle being thrust through one flap close to its outer lower edge, then through the septum, and out at a corresponding point of the other flap. The edges of the wound left in the cheek at each side can generally be, to a certain extent, approximated by silver stitches (B, B), and the triangular portion (C, C), which is necessarily left to heal by granulation, proves an advantage, as by its depression it enhances the apparent height and prominence of the new organ. The cavity should be very gently distended with lint, and may be supported by the blades of a small pair of forceps, applied so as to embrace the nose.

(2.) *From the Forehead.*—The Indian operation may be used in cases where, from disease, the cheeks also have suffered, and are not to be trusted to for flaps.

Operation.—1. It should be decided as to the shape and size of the portion of skin necessary, by fitting on pieces of soft leather or moulding wax. To allow for shrinking, the

* Operation for formation of a new nose from the cheeks; A A, flaps approximated in middle line; B B, outer part of bed of flaps stitched up; C C, triangle at each side left to granulate.

flap should be made at least one-third larger than is at first apparently necessary. The exact boundaries of the flap to be raised should then be marked out on the forehead by lightly pencilling it with nitrate of silver, the mark from which is not effaced by blood, as is sure to be the case with an ink line. Various shapes have been proposed for the flap varying in length of neck, in the shape of the angles, and especially in the arrangements made for the formation of a columna. Some (as Liston) prefer afterwards to provide for the columna separately, by a flap raised from the upper

FIG. XX.*

lip in a subsequent operation. The flap is then to be raised from the forehead, care being taken not to injure the periosteum. The incision is to be carried lower down on the side (generally the left) to which the flap is to be twisted. The flap is then to be brought round (Fig. xx.) and carefully fitted on to the edges previously prepared for its reception. The neck must be left as lax as possible, lest by tight twisting the supply of blood be cut off, and the flaps

thus deprived of nourishment. Both silk and metallic sutures are recommended. Hamilton of Dublin,¹ after a large experience of both, prefers the former.

* Operation for formation of a new nose from the forehead:—*a*, prominence of flap which is to be used as septum; *b*, left-hand corner of flap, which is twisted and fastened at *c*; *d*, one of the tubes or quills over which the nose is moulded.—(*Modified from Bernard and Huette.*)

¹ *The Restoration of a Lost Nose by Operation*, p. 57; an excellent monograph on the subject.

Surgeon-Major Keegan describes¹ a most ingenious method, by which in many cases he has with great success restored the nose, or rather the soft portion of the nose after removal by knife as a punishment. His method presupposes healthy tissues and uninjured skin over the nasal bones. The first stage is to lift and turn *down* in two flaps the skin covering the nasal bones. The inferior borders of these flaps are not interfered with. He then, in usual method, raised from the forehead a suitably sized flap with an oblique pedicle. Immediately on raising it he approximates its edges as far as possible. The forehead flap is now brought down and made to rest on the raw surfaces of the reflected nasal flaps, and the nostrils of the newly formed nose are thus lined inside by the reflected skin surface of these flaps. Edges are pared and carefully united by horse-hair sutures. Any one wishing to do this operation must refer to the original description and diagrams.

There are various risks; sloughing of the whole flap at once, shrinking of it after weeks or even months; certain inevitable drawbacks, as the cicatrix on the forehead, the very various and ludicrous changes of colour to which the new organ is subject,—these cannot be remedied by further operation. Two points generally require a second use of the knife a few weeks after:—(1.) The neck of the flap is sure to be redundant and prominent, but can be pared. (2.) The columna almost always requires improving, and, in Liston's method, to be made. He pared the inner surface of the apex of the nose, and then raised a central flap of the lip in the middle line, about a quarter of an inch broad, and extending from the remains of the old septum to the free border, raising it from the gum, and stitched the free end of it to the prepared apex, bringing together the two divided portions of the lip by ordinary harelip sutures. The

¹ *Lancet*, February 21, 1891.

columna, if redundant, could be shaved down, and it was found that the mucous surface very quickly became like skin on exposure.

For other points with regard to the operation, reference may be made to the works of Treves¹ and Jacobson,² and Hamilton's monograph, referred to above.

Note.—The tongue and groove suture proposed by Professor Pancoast, and recommended by Professor Gross, is said to be specially suitable for such plastic operations. It is very complicated, as it requires one edge to be bevelled to a wedge shape, the other being grooved to include the wedge, thus opposing four raw surfaces, which are retained in contact by being transfixed by fine silk sutures.

(3.) There are certain cases in which neither cheeks nor forehead are available for flaps, and yet the patients press very much for some operation. If they have patience and determination, the Taliacotian or Italian operation may be attempted.³

Without going into detail, the principle of it is as follows :—1. A piece of skin of suitable size was marked out over the left biceps, and defined by two longitudinal incisions, and raised from the subcutaneous cellular tissue, thus being left attached by its two ends only; a piece of linen was pulled below it. 2. After a few days the upper end was also divided, and the flap thus contracted. In a few days more the sides of the old nose were made raw, and the upper free surface of the flap also made raw and stitched to them, the arm being fastened up by a most elaborate series of bandages. 3. After a fortnight in this position, the last attachment of the flap to the arm was severed, and the new nose could then be modelled at pleasure.

¹ Treves' *Manual of Surgical Operations*, vol. ii.

² Jacobson, *The Operations of Surgery*.

³ Sir W. MacCormac's case, *Clinical Society Transactions*, 1877.

The literature of the subject is exceedingly curious, especially the cases in which the new material was obtained from an accommodating friend or servant.

Operative Treatment of Lupus.—We may here notice a mode of treatment which has admirable results. The patient being put deeply under an anæsthetic, the surgeon with a sharp spoon carefully pares away all the diseased tissues, and then destroys the base either by nitric acid or a strong solution of chloride of zinc. The author has done this in a great number of cases with excellent effect.

Nasal Polypi, Removal of.—Of these there are different kinds.

1. *Ordinary Mucous Polypi.*—These grow from the spongy bones, generally the superior one, are non-malignant in their character, soft and vascular, often fill up the whole of both nasal cavities, and frequently hang down behind into the pharynx. The practical point to remember is that, however large and numerous they may be, they *invariably* have their origin from a comparatively limited spot, the edge of the spongy bone, and *always* hang from a narrow neck. Hence the treatment is easy and satisfactory, if the neck be attacked, and not the body of the tumour.

Slightly curved, narrow-bladed forceps should be passed along by the side of the superior spongy bone, with their blades open, till the neck of the polypus is seized. Holding it firmly, the forceps should then be slowly twisted round till the neck is destroyed and the polypus detached. This should be repeated till the patient can blow freely through both nostrils. If attempts are made to seize the body of the polypus, it will break down under the forceps, bleed, and give much trouble.

Various operations by galvano-cautery, wire snares, etc., have been devised, but are not so satisfactory or permanent.

The author entirely agrees with, and for years has operated on, the principle first put on distinct record by Mr Mitchell Banks,¹ though we were both taught it by Professor Syme, that to prevent recurrence the edge of the turbinated should be broken off and removed with the polypi; no harm can ensue, and numerous small polypi are seen attached to the mucous membrane, which would have escaped any snare or cautery, and would inevitably have reproduced all the symptoms had they not been removed.

2. *The Fibrous Polypus*.—This exceedingly formidable malady is fortunately much more rare than the other. It is almost invariably single, is attached to the posterior margin of the nares by a narrow but very strong root, is extremely firm in consistence, may grow to a large size so as to obstruct both nostrils, generally gives rise to severe and frequent hæmorrhages. The hæmorrhage *during* any attempt to remove it is generally of the most severe character, but ceases *immediately* on its complete detachment.

Mr Syme's method of treatment is occasionally successful—By the ordinary polypus forceps described already, he seized the tumour through the nostril, and then with the fore and middle fingers of the left hand introduced behind the soft palate, he attacked the point of attachment, and by his nails, aided by the forceps, detached it from its narrow base.²

But, unfortunately, in a large number of cases of nasopharyngeal polypus this cannot be done with success, and various methods of obtaining access to the origin of the tumour have been devised; all are severe operations, and

¹ *Clinical Surgical Work in Liverpool Royal Infirmary.*

² Syme's *Observations in Clinical Surgery*, p. 132.

attended by much disfigurement. One type of such operation is that devised by NELATON. He attacks the palate, raises two flaps of mucous membrane and periosteum, detaches the soft palate from the hard, and then removes enough of the exposed hard palate by chisel and mallet so as to give access to the tumour.

ANNANDALE'S¹ method is probably less severe. After exposing the anterior nares by turning the lip upwards from the upper jaw by Rouge's method, he divides the bony septum of the nose, splits first the soft parts of the hard palate in the middle line, and then divides the bone by a fine saw through the alveolar margin of upper jaw and whole hard palate. After this is done, he finds the right and left halves of the upper jaw can be so far separated as to allow the tumour to be attacked by strong forceps and periosteal elevator. The jaws are afterwards stitched together by wire.

3. *Malignant Polypi* should not be meddled with unless it is absolutely certain that the whole of the bone from which they grow can be removed also. This is very rarely the case. (See *Excision of Superior Maxilla*.)

Operations on the Lips.

—1. Epithelial cancers of the lower lip are very frequent, and require removal.

If the tumour or ulcer be small, and involves a considerable thickness of the lip, it is most easily removed by a V-shaped incision (Fig.

xxi. A B A). Its shape permits the most accurate apposition of the cut surfaces; and if the lips are full and

FIG. XXI.*

* Diagram of V-shaped incision; A B A, dots showing points for sutures.

¹ *Lancet*, January 1889.

the tumour small, very slight trace of the operation will remain.

Again, if the tumour be more extensive, involving a large portion of the prolabium, and yet not extending deeply into the substance of the lip, it may be very easily removed by a pair of curved scissors, applied in the direction shown in the diagram (Fig. XXII. A B). The skin must then be stitched to the mucous membrane by

FIG. XXII.*

numerous points of interrupted suture.

But if the tumour be at once extensive and deep, mere removal is not sufficient, but some provision must be made for supplying the blank left by the operation.

In cases where a third, or even a half, of the lower lip has thus been removed, it may be found sufficient freely to dissect what is left of the lip from the gums, and thus approximate the cut surfaces in the middle line.

FIG. XXIII.†

as to cause great deformity. The addition of an incision

* Diagram of incision for scooping out a shallow tumour by scissors.

† Diagram of incisions:—C A C, outline of incision for removal; C A D, outline of flap on each side; B, prominence of chin; c c, dotted lines, showing incisions to enlarge mouth, if required.

horizontally outwards, at one or both angles of the mouth, will do away with such risk, and allow the surfaces to come together without puckering; while by stitching the skin and mucous membrane together in the course of these horizontal incisions, we can increase the size of the buccal orifice almost *ad libitum*.

Lastly, when the lower lip has been entirely removed, it is still possible to supply its place in the following manner, which was devised by Mr Syme:—The tumour being fairly isolated by a V-shaped incision (Fig. XXIII.) C A C including the whole thickness of the lip, each of the incisions should be prolonged

FIG. XXIV.*

downwards and outwards, as shown by the dotted lines A D, A D. The flaps thus marked out must be separated from the bone, brought upwards, and approximated in the middle line. Possibly it may be necessary still further to enlarge the buccal orifice by short lateral incisions, c c. Whether these are required or not, silk stitches are to be introduced to unite the skin and mucous membrane along the lines A C. The gap left between D B D must be left to granulate, but in most cases may be very much diminished in size by additional sutures at its outer corners, near D. The granulating surface E E very rapidly heals up,

* Diagram of flaps in position:—A A, corners of flaps brought up and approximated by *silver* sutures; c c, new lip got by lateral incisions, skin and mucous membrane being united by *silk* threads; E E, gap left to granulate.

leaving a dimple on each side, which rather improves the appearance, by adding to the prominence of the chin, B. Many different methods of obtaining and arranging flaps for deformities of lower lips after burns or lupus, or removal of tumours, are described; but the general principle is best illustrated by the one described. The others differ only in details.

Similar operations on the upper lip are much less frequent. Quadrilateral flaps, unilateral or bilateral according to position of gap, are most generally used; and they are, as a rule, taken from the cheek on either or both sides. Care must be taken not to interfere with Steno's duct.

The Operations for Harelip, though all conducted on the same general principles, vary considerably in extent required according to the position and size of the fissure or fissures to be remedied.

1. *For Single Harelip*.—Where the fissure extends only from the prolabium up to the attachment of the lip to the gums: this is very easily remedied, the chief risk being lest the surgeon should not remove enough of the edges of the fissure.

Operation.—Bleeding being controlled by an assistant, the surgeon fixes a pair of spring artery forceps into the mucous membrane and skin at the salient angle at each side of the fissure. Taking one of these in his left hand, he puts the edge to be pared on the stretch, and then with a sharp narrow straight bistoury he transfixes the lip at the point just beyond the upper angle of the fissure, and cuts outwards, being careful to remove the whole thinner part of the lip, and to leave the edge rather concave than convex. If left convex, or even quite straight, there is a risk that, after union has taken place, an angle remain showing the position of the cleft. The same is then to be done on the other side.

The bleeding is then to be controlled by twisting the larger vessels, and if oozing still continue from the smaller ones, a pad of lint should be placed in the wound, and a few minutes' delay given, as, to facilitate immediate union, it is of the greatest importance that all hæmorrhage should have ceased before the edges are brought together.

When the bleeding has ceased, the edges should be approximated by two or more points of interrupted metallic suture inserted very deeply through the tissues, and taking a good hold of the edges of the wound. Accurate fitting of the edges is much assisted by the insertion of horse-hair sutures less deeply placed between each silver wire. These are intended for coaptation, and should not be subjected to any tension. Some surgeons still prefer the old harelip needles secured by a figure-of-8 suture, but the inevitable mark left after them is a decided objection to their use, and they are rarely required. A silk suture inserted through the prolabium is of great advantage, as it keeps the inner surface of the wound closed, which without it is very apt to be kept open by the pressure of the teeth or gums, and in infants by the movements of the tip of the tongue. This silk suture should be invariably inserted first and tied last.

Various methods have been devised to utilize, if possible, the portion of the edge of the lip which is separated during the operation of refreshing the edges, for the purpose of filling up the sort of cleft or gap which is apt to be noticed at the edge of the prolabium. The most ingenious and simplest of these is that proposed by M. Nelaton, for use in cases where the fissure does not extend so far up as the nose. It consists in leaving the two portions which are pared off (Fig. xxv.) the sides of the cleft attached to each other as well as to the free edge of the lip, then pulling them down, so as to bring their bleeding surfaces into apposition, and make a diamond-shaped wound instead of a triangular cleft (Fig. xxvi.) When brought together by sutures a projection is left at the edge of the lip; this, in most cases, disappears; if it does not, it can easily be pared down.

2. When the fissure, though single, extends upwards into the nose, the operation is more difficult, and the result fre-

quently less satisfactory. The first thing to be done is to separate the lips from the gums, so as to make them more freely mobile, and also to get rid of the tucking down of the nasal alæ, which is so common, and causes such a disagreeable deformity. The whole edges of the cleft require refreshing.

3. *Double Harelip*, without bony deformity, and where

FIG. XXV.*

FIG. XXVI.†

the intervening portion of the skin is vertical, does not project, and can be made useful for the new lip. Such cases are not very common, but when they do occur the question

FIG. XXVII.‡

arises, How are they to be managed—in two separate operations or at once? I believe, in every case, at once. The central wedge-shaped portion is not large enough to extend downwards as far as the prolabium, but still should not be removed altogether, as it may be of great use, especially in bearing the columna nasi, and allowing its full development. The edges should be

* Fig. xxv. shows the incision bounding the cleft.

† Fig. xxvi. shows the diamond-shaped wound before the sutures are applied.

‡ Diagram of operation for double harelip:—*a*, stitch through both sides and wedge-shaped portion, which also aids the septum; *b*, other stitches approximating edges.

pared in the same way, and to the same extent as in single harelip, with the addition that the intervening portion should have its edges completely removed, and be left in the form of a wedge, with its apex downwards. The highest suture should be passed through first one side, then the base of the wedge, and then the other side; the second one through both, and the apex of the wedge; and a third should unite the prolabium, not including the wedge. In this variety the silk suture for the mucous membrane inside is very essential.

4. *Double Harelip*, combined with fissures of the hard palate, and projection of a central bone. This is the analogue of the inter-maxillary bone in the lower animals, and bears the two middle incisor teeth, and projects very variously in different cases. In some it projects horizontally forwards in the most hideous manner, in others it lies at an angle more or less oblique; in very few does it maintain its proper position; when projecting forwards, and as the teeth also share in its projection, it entirely prevents approximation of the edges of the fissures by operation, so it must first be dealt with in one of two ways, either—

FIG. XXVIII.*

(1.) It may be at once removed with bone-pliers, the piece of skin over it being saved. This is the best that can be done in cases of old standing after the first year or two, though attempts have been made to break the neck of the projecting portion, and thus permit of its being shoved back. Extended experience has led the author in nearly every case

* Diagram of double harelip, with projecting bone:—*a*, central piece of lip, dotted lines showing incision; *b*, projecting bone bearing teeth, which are generally small and stunted.

to remove the projecting bone, saving all the soft parts, including the periosteum. He is glad to find this method has the very high authority of Mr Rose,¹ to whose excellent and exhaustive work on Harelip and Cleft Palate he refers those wishing further details on the subject.

(2.) By gradual pressure by a spring truss, strapping, or a bandage, it may be forced back. This is possible only in cases where the deformity has been comparatively slight, and the patient has been seen early. The edges must then be pared and approximated as directed above.

One or two points about the operation for harelip require a special notice:—

1. *When to Operate.*—Great differences in opinion exist. Some say not before two or three years, others within two or three days, or even *hours*, after birth.

Probably the safest time is not much earlier than the second month in very strong children, the fifth in weakly ones, up to the commencement of the first dentition; and when once dentition has commenced, it is not so safe to operate till it is over.

Prior to dentition the operation is attended with rather more risk, but again, if delayed, there is great risk that the teeth do not come in properly.

2. With regard to the most delicate part of the operation, *the management of the prolabium.*—Some are satisfied, and I believe rightly, with careful apposition by a silk suture after a *sufficient* amount of the edges has been removed; others have proposed various plans to obviate any risk of an angle remaining.

Malgaigne proposes to retain a small portion of the parings of the edge to make a flap at each side; Lloyd a single one from the long half of the lip, and brings it up under the opposite one, securing it with a stitch.

¹ Rose on *Harelip and Cleft Palate*, 1891.

Occasionally in young children, and especially in cases where there has been much tension, the stitches cut through early and the wound gapes. The author has found admirable results from an immediate repetition of the suturing, thus bringing together surfaces covered with granulations. A secondary union of these granulations takes place, and union may be perfect, with the minimum of scar, in a week.

One caution must be given to the nurse after an operation for bad harelip on a young child. The respiration is very apt to be interfered with, the child being accustomed to breath through a large cleft which was never closed, now has little room through the nasal fossæ, perhaps obscured with blood, and the lips now come into absolute contact. If respiration is noticed to be difficult the nurse must, for some hours or even days, see that the lower lip is pulled down and opened.

CHAPTER VII.

OPERATIONS ON THE JAWS.

1. **Excision of the Upper Jaw.**—With regard to the morbid conditions for which this operation is undertaken, it may be sufficient here to observe, that in no case can the operation be called justifiable in which the disease extends beyond the upper jaw-bone and the corresponding palate-bone, for unless the morbid growth be entirely removed, recurrence is inevitable, and no advantage is gained by the operation. If both upper jaws are involved, both may be removed in whole or part. It is undertaken for the removal of tumours of the antrum and of the alveolar margins, in all which cases the section or its removal must be made through healthy bone, and wide of the disease, so as to insure that the whole is removed. There are other cases in which the whole or part of the upper jaw has been removed for the purpose of giving access to disease behind, for example, to naso-pharyngeal polypi with extensive attachments.

In describing the operation for the excision of the entire upper jaw, we have to consider—(1), what incisions through the soft parts will expose the tumour best, and with least deformity; (2), what bony processes require to be divided, and where. Very various incisions have been recommended by various authors; some describing three, in various directions, forming flaps of different sizes, while others, again, are satisfied with a very small division of the upper lip into the nose, or even attempt removal of the bone without any

incision through the skin at all. These discrepancies depend in great measure on different views of what constitutes excision of the upper jaw, the more complicated ones contemplating removal of the whole bone anatomically so called, including the floor of the orbit, while the less complicated ones are suitable for cases in which a much less extensive removal is required.

To remove the whole bone, an incision (Fig. XXIX. A) of the skin must extend from the angle of the mouth upwards and outwards in a slightly curved direction with its convexity downwards, as far on the malar bone as half an inch outside of the outer angle of the eye. The flaps must then be raised in both directions, the inner one specially dissected off the bones, so as to expose thoroughly the nasal cavity. It is of great importance thoroughly to display the floor of the orbit, so that the attachment of the orbital fascia may be accurately cut through, the inferior oblique muscle divided at its origin, and the eye and the fat of the orbit cautiously raised from its floor.

FIG. XXIX.*

Three processes of bone then require attention and division.

(1.) The articulation with the opposite bone in the hard palate. To divide this, one incisor tooth at least must be drawn, the soft palate divided by a knife to prevent laceration, and the thick alveolar portion sawn through in a longitudinal direction from before backwards.

* Diagram of operations on the jaws :—A, incision for removal of the whole upper jaw; B, incision for removal of alveolar portion and antrum; C, incision for removing the larger half of lower jaw; the opposite side is the one supposed to be operated on, and the incision is crossing the symphysis and turning up at a right angle.

(2.) The articulation with the malar bone at the upper angle of the incision through the skin. This must be notched with a small saw in a direction corresponding to the articulation, and then wrenched asunder by a pair of strong bone-pliers.

(3.) The nasal process of the upper jaw must now be divided by the pliers, one limb of which is cautiously inserted into the orbit, the other into the nose. If the disease extend high up in this process, it may be necessary partially to separate the corresponding nasal bone, and thus reach the suture between the nasal process and the frontal bone. The pliers must now be inserted into the groove already made by the saw on the hard palate, and the separation continued to the full extent backwards. A comparatively slight force exerted on the tumour either by the hand, or (when the tumour is small) by a pair of strong claw forceps, will suffice to break down the posterior attachments of the bone and remove it entire. The necessary laceration of the soft parts behind is so far an advantage, as it lessens the risk of hæmorrhage from the posterior palatine vessels.

The hæmorrhage from this operation was at one time much dreaded, but is rarely excessive; very few vessels require ligature, except those divided in the early stages in making the skin flaps; the hollow left should be stuffed with iodoform gauze.

The incisions recommended for this operation have been very various, and a knowledge of some of them may occasionally be useful, on account of specialities in the shape and size of the tumour. Liston "entered the bistoury over the external angular process of the frontal bone, and carried it down through the cheek to the corner of the mouth. Then the knife is to be pushed through the integument to the nasal process of the maxilla, the cartilage of the

ala is detached from the bone, and lip cut through in the mesial line; the flap thus formed is to be dissected up and the bones divided."¹ Dieffenbach made an incision through the upper lip and along the back or prominent part of the nose, up towards the inner canthus, from whence he carried the knife along the lower eyelid, at a right angle to the first incision as far as the malar bone.

Langenbeck makes a U-shaped flap with its convexity downwards, beginning at the junction of the nasal cartilage with the nasal bone, and ends over the middle of the malar bone. This does not give free access if whole bone is to be removed.

In cases where the tumour is of moderate size, Sir W. Fergusson found² it sufficient to divide the upper lip by a single incision exactly in the middle line, this incision to be continued into one or both nostrils, if required. The ala of the nose is so easily raised, and the tip so movable, as to give great facilities to the operator for clearing the bone even to the floor of the orbit.

In cases where the tumour is larger, or the bones more extensively affected, Sir W. Fergusson preferred an extension of the foregoing incision (Fig. XXIX. B) upwards along the edge of the nose almost to the angle of the eye, and thence at a right angle along the lower eyelid, as far as may be necessary, even to the zygoma. The advantages claimed for such procedures are that the deformity is less and the vessels are divided at their terminal extremities.

2. Excision of the Lower Jaw.—Removal of portions, greater or smaller, of the lower jaw, for tumours, simple or malignant, are now operations of very frequent occurrence, while in some few cases the whole bone has been removed at both its articulations.

¹ *Operative Surgery*, p. 265.

² *Lancet*, July 1, 1865.

The operative procedures vary much, according to the amount of bone requiring removal, and also the position of the portion to be excised.

(1.) *Of a portion only of one side of the body of the bone.*—This is perhaps the simplest form of operation, and is frequently required for tumours, specially for epulis.

Incision.—If the parts are tolerably lax and the tumour small, a single incision just at the lower edge of the bone, of a length rather greater than the piece of bone to be removed, will suffice; this will divide the facial artery, which must be tied or compressed,¹ while the surgeon, dissecting on the tumour, separates the flaps in front, cutting upwards into the mouth, and then detaches the mylohyoid below, and clears the bone freely from mucous membrane. He then, with a narrow saw, notches the bone beyond the tumour, at each side, and, introducing strong bone-pliers into the notches, is enabled to separate the required portion. The wound is then stitched up, and a very rapid cure generally results with very little deformity, as the cicatrix is in shadow. If from the size of the tumour more room is needed, it can easily be got by an additional incision from the angle of the mouth joining the former.

To prevent deformity, which is apt to result from the centre of the chin crossing the middle line, it is often a wise precaution to have a silver plate prepared fitting the molar teeth of both jaws on the sound side, and thus acting as a splint. Such a precaution may be required in any operation in which the lower jaw is sawn through.

¹ Temporary compression of the facial can be easily managed, in cases where it is of much importance to avoid loss of blood, by passing a needle from the outside through the skin above the vessel, then under the vessel, and out again through the skin below. A figure-of-8 suture can then be thrown round both ends of the needle, and the artery thus thoroughly compressed.

N.B.—There are certain cases in which the epulis is small and confined to the alveolar margin, in which the base of the jaw is retained entire and the tumour is removed without any incision of the skin. The mucous membrane on both sides being carefully dissected from the affected part, the bone may be sawn as before, but only through the alveolar portion, the grooves of the saw converging as they penetrate, then by a pair of strong curved bone-pliers the affected alveolar portion is to be scooped out without injuring the base. This proceeding, which has been practised by Syme, Fergusson, Pollock, the author in many cases, and others, leaves no deformity, but, it must be owned, is much more liable to the risk of recurrence of the disease, and for this reason is strongly condemned by Gross.

Note.—In this, as in all other operations on the jaws, the very first thing to be done is to draw the teeth at the spots at which the saw is to be applied.

(2.) *Excision of a portion involving the Symphysis.*—Free access is of importance. The best incision is probably one which (Fig. XXIX. C) commences at the angle of the mouth opposite the healthy portion of jaw, extends down to the place at which the saw is to be applied, and then along the base of the jaw past the middle line to the other point of section. The flap is to be thrown up and the bone cleared. The next point to be noticed is, that when, in clearing the bone behind, the muscles attached to the symphysis are divided, the tongue loses its support, and unless watched may tend to fall backwards, embarrassing respiration and even perhaps choking the patient. The tongue being confided to a special assistant, must be drawn well forwards. Various plans have been devised for keeping it in position, as stitching it to the point of the patient's nose; putting a ligature into its apex, and fastening it to the cheek by a

piece of strapping, and transfixing its roots with a harelip needle, used to stitch up a central incision in the chin. The tendency to retraction very soon ceases, new attachments are formed by the muscles, and after the first five or six days there is very little risk of the tongue giving rise to any untoward consequences by its displacement.

(3.) *Disarticulation of one or both Joints.*—When the portion of bone implicated involves disarticulation for its complete removal, the difficulty of the operation is much increased. The remarkably strong attachments of the joint, especially the relation of the temporal muscle to the coronoid process, and the close proximity of large arteries and nerves, especially the internal maxillary artery and the lingual nerve, render this disarticulation very difficult.

The chief points to be attended to seem to be (1), that the incision through the skin should extend quite up to the level of the articulation; (2), that the bone should be sawn through at the other side of the tumour, and freely cleared from all its attachments, before any attempt be made at disarticulation, for by means of the tumour great leverage can be attained, so as to put the muscles on the stretch, and allow them to be safely divided; (3), that the articulation should always be entered from the front, not from behind, and the inner side of the condyle should be very carefully cleared, the surgeon cutting on the bone so as to avoid, if possible, the internal maxillary artery; (4), free and early division of the attachment of the temporal muscle to the coronoid process, or if necessary the coronoid may be snapped across with bone-pliers.

Disarticulation of the entire bone has been very rarely performed.¹ If necessary, it can be performed without any incision into the mouth, by one semilunar sweep from one

¹ Syme, *Contributions to the Path. and Practice of Surgery*, p. 21; Carnochan of New York, *Cases in Surgery*.

articulation to the other, passing along the lower margin of each side of the body, and just below the symphysis of the chin.

Disarticulation of the Ramus without opening into the cavity of the Mouth.—That this operation is possible, though it may not be often required, is shown by the following case by Mr Syme. It was a tumour of the ramus, extending only as far forwards as the wisdom-tooth :—

“An incision was made from the zygomatic arch down along the posterior margin of the ramus, slightly curved with its convexity towards the ear, to a little way beyond the base of the jaw. The parotid gland and masseter muscle being dissected off the jaw, it was divided by cutting-pliers immediately behind the wisdom-tooth, after being notched with a saw. The ramus was then seized by a strong pair of tooth-forceps, and notwithstanding strong posterior attachments, was drawn outwards, its muscular connexions divided and turned out entire. There was thus no wound of the mucous membrane of the mouth, the masseter and pterygoid muscles were not completely divided, and the facial artery was intact.¹

Fergusson² taught that even the very largest tumours of the lower jaw may be successfully removed without opening into the orifice of the mouth at all by division of the lips. A large lunated incision below the lower margin of the bone, with its ends extending upwards to within half an inch of the lips, will give free access, and yet avoid both hæmorrhage and deformity, as the labial artery and vein are not cut, and there is no trouble in readjusting the lips. Some tumours of lower jaw can be removed without any wound of skin.

It may be noted that when the jaw is being removed for a new growth no attempt should be made to save periosteum.

¹ *Contributions to the Path. and Prac. of Surgery*, pp. 23, 24.

² *Lancet*, July 1, 1865.

If for necrosis, the periosteum and any small remains of bone must be saved if possible. In a case lately operated on by the author, where he has had to remove the whole lower jaw, except one condyle and a bit of the ramus, the periosteum was saved, and a small substitute was reproduced, but even with it respiration was so embarrassed as to render tracheotomy necessary.

Operations for Closure of the Jaws.—These may be rendered necessary either from disease of the temporo-maxillary articulation at one or both sides, or as a result of cicatrices from disease.

Two methods are most used,—

1. When the joint is ankylosed one or both condyles may have to be excised. Access to the joint can be obtained either by a horizontal incision along lower border of zygoma, or by a vertical one from the lower margin of zygoma downwards as far as is necessary, with perhaps a horizontal one along zygoma if more room is needed. The parotid gland, and especially the branches of the facial, must be protected as far as possible. The masseter needs to be reflected to display the capsule, the knife must be kept close to the bone, and the neck is to be divided either with a chisel or a fine saw. Passive motion must be early and freely exercised, and much care, and perhaps the use of a powerful screw-gag will be required, if the results are to be satisfactory.

2. Where ankylosis is extensive and old cicatrices are present, Esmarch's operation is the best. This consists in the removal at one or both sides of a wedge-shaped portion of the horizontal ramus of the jaw. The narrowest part of the wedge is uppermost, and should be at least half an inch, while the base should include at least one inch and a half of the lower border. The wedge should be taken out in front of the masseter and of the adhesions. Early and extensive passive movement is needed.

CHAPTER VIII.

OPERATIONS ON MOUTH AND THROAT.

Salivary Fistula, Operation for.—After a wound or abscess of the cheek, in which the parotid duct is implicated, a salivary fistula is very apt to remain. The saliva thus discharges in the cheek, giving rise to considerable annoyance, as well as injury to the digestion. It is by no means easy to cure this. Perhaps the best operation is the one of which a rude diagram is given (Fig. xxx.) The duct (c) communicates with the fistula (d). One end of a thread, either silken or metallic, should be passed through the fistula, and then as far backwards as convenient through the cheek into the mouth; the needle should then be withdrawn, the thread being left in. The other end being threaded, should then be re-inserted at the fistula, and carried forwards in a similar manner; the needle should be again unthreaded in the mouth and withdrawn; the two ends should then be tied pretty tightly inside, and allowed to make their way by ulceration into the cavity of

FIG. XXX.*

* Rough diagram of operation for salivary fistula:—A, section of cheek close to buccal orifice; B, section of zygoma, muscles, etc.; C, the duct of the parotid; D, the fistulous opening of the cheek; E E, the thread knotted inside the mouth; F, the palate.

the mouth. A passage will thus be obtained for the saliva into the mouth, and every possible precaution should be taken to enable the external wound to close. In some cases it may be necessary after the internal orifice is quite patent to pare the edges of the outer opening and unite them by sutures.

Excision of the Tongue, for malignant disease of the organ, may be either complete or partial. Complete excision affords a hope of permanent and complete relief from the disease, but it is an operation of difficulty and danger. It may be performed in either of the following methods. The first insures very free access to the deeper parts and renders complete removal a certainty.

1. *Syme's method of Excision*.—The patient being seated on a chair, chloroform was not administered, so that the blood might escape forwards, and not pass into the pharynx. The operation is thus described:¹—

“Having extracted one of the front incisors, I cut through the middle of the lip and continued the incision down to the os hyoides, then sawed through the jaw in the same line, and insinuating my finger under the tongue as a guide to the knife, divided the mucous lining of the mouth, together with the attachment of the genio-hyoglossi. While the two halves of the bone were held apart, I dissected backwards, and cut through the hyoglossi, along with the mucous membrane covering them, so as to allow the tongue to be pulled forward, and bring into view the situation of the lingual arteries, which were cut and tied, first on one side, and then on the other. The process might now have been at once completed, had I not feared that the epiglottis might be implicated in the disease, which extended beyond the reach of my finger, and thus suffer injury from the knife if used with-

¹ *Lancet*, Feb. 4, 1865.

out a guide. I therefore cut away about two-thirds of the tongue, and then being able to reach the os hyoides with my finger, retained it there while the remaining attachments were divided by the knife in my other hand close to the bone. Some small arterial branches having been tied, the edges of the wound were brought together and retained by silver sutures, except at the lowest part, where the ligatures were allowed to maintain a drain for the discharge of fluids from the cavity." The patient was able to swallow from a drinking-cup with a spout on the day following the operation, and was able to travel upwards of 200 miles within four weeks of the operation.

2. *By the Ecraseur*.—Nunneley of Leeds has recorded cases in which he made a small incision through the skin, and mylohyoid and geniohyoid muscles, and through this passed a curved needle bearing the chain of the ecraseur completely round the base of the tongue. In one case the chain was unsatisfactory, but strong whipcord was introduced as it was withdrawn, and tied with all possible force. The organ eventually sloughed away, with a cure which lasted at least for some months.

Sir James Paget operates as follows:—

The patient is placed under the influence of chloroform, and the mouth held widely open. The tongue is then drawn forwards, the mucous membrane and soft parts of the floor of the mouth, including the attachment of the genio-hyoglossi to the symphysis, being divided close to the bone. The steel wire of an ecraseur is then passed round its root as low down as possible, slowly tightened, and the tongue thus divided through its whole thickness in a very few minutes. The bleeding is slight, being almost entirely from the parts cut with the knife. Recovery has been rapid in the recorded cases.¹

¹ *Med. Times and Gazette* for Feb. 10, 1866.

To Dr George Buchanan of Glasgow the credit is due of the invention of the operation of removal of the half of the tongue in the median line. In at least one instance the cure after five years was still permanent.

The author in nine cases removed the affected half of the tongue by means of the thermo-cautery, first splitting it in the middle line, and then cutting through the base with a curved platinum knife at a low red heat. In one only was there any trouble from hæmorrhage, and all made good recoveries. But the separation of the slough caused by the burn rendered the wound so putrid as to interfere with the patient's comfort and delay healing.

A much better method is the following, now well known to the world as Whitehead's operation:—

Mr Walter Whitehead,¹ of Manchester, has had a very large experience of an operation devised by himself, in which, after pulling the tongue well forward by a string previously introduced near its apex, and the mouth being held open by a gag, he detaches the organ from jaw and fauces by successive short snips with scissors, and then in same manner divides the muscles, tying or twisting the vessels as they bleed. His success has been very great by this method, though others who have tried it have sometimes found bleeding troublesome. The author has entirely discarded the thermo-cautery in favour of this method, from the greater simplicity of the after-treatment and much greater comfort of the patient, and has had no trouble from bleeding.

In cases of removal of one-half of the tongue by Whitehead's method, after oozing has ceased, the author invariably tries to stitch up as much as possible of the mucous membrane of the floor of the mouth to the tongue, and also near the apex to unite the mucous membrane of the lower

¹ *Transactions International Medical Congress*, 1881, vol. ii. p. 460.

surface to that of the dorsum; it is wonderful what a small wound may thus be left to granulate.

For those extensive cases of disease in which not only the whole tongue but the lymphatic glands under the jaw require removal, the following method presents many advantages:—

Kocher's Operation.—After a preliminary tracheotomy, the pharynx is stuffed with an antiseptic sponge secured by a string. An incision is then made, commencing a little below the tip of the ear, extending along the anterior border of the sterno-mastoid muscle, as low as the hyoid bone, past the body of it, and then upwards along the anterior belly of the digastric muscle. The resulting flap is turned upward, and the lingual artery tied before it goes under the hyoglossus muscle. After this the glands connected with the tongue and the tongue itself can be easily removed without hurry or hæmorrhage. It is easy to tie the other lingual artery either from the original wound or from the other side.

Dr Kocher recommends that the wound be left open to granulate under an antiseptic dressing. The trachea tube can be kept in till the wound is so far healed as to insure against any risk of infection by lungs or stomach.¹

Regnoli's method² is interesting historically. A semi-lunar incision along the base of the jaw, from one angle to the other, detaches the muscles and soft structures, and is thrown down; the tongue is then drawn through the opening, and can be freely dealt with either by knife or ligature. After removal the flap is replaced.

For practical purposes, in cases where the glands are unaffected and the tongue fairly mobile, Whitehead's operation gives best results. In the more serious cases, where the

¹ *Deutsche Zeitschr. f. Klin. Chir.*, Bd. xiii., 1880.

² *Gross's Surgery*, vol. ii. p. 472.

only chance lies in careful dissection of the whole tongue from the hyoid bone, and the glands must be dissected out, probably Kocher's method is the safest and most scientific.

Fissures in the Palate.—The operations requisite for the cure of fissures in the soft and hard palates are so complicated in their details, that a small treatise would be required thoroughly to describe the various procedures, and the author would refer with pleasure to Mr Rose's admirable monograph.¹

Different cases vary so much in the nature and amount of their deformity, that at least five different varieties have been described. It is sufficient here merely to describe the absolutely essential principles of the operations for the cure of fissures of the hard and soft palate respectively.

In all operations on the palate, two conditions used to be considered requisite for success:—1. That the patient should have arrived at years of discretion, at twelve or fourteen years at least; that he be possessed of considerable firmness, and be extremely anxious for a cure, so as to give full and intelligent co-operation. 2. That for some days or weeks prior to the operation the mouth and palate should have been trained to open widely, and to bear manipulation without reflex action being excited. Professor Billroth of Vienna,² Mr Thomas Smith³ of London, and many others, have made it now the rule to perform this operation in childhood, under chloroform, with the assistance, in the English cases, of a suitable gag invented by Mr Smith. Though it has been performed at four weeks, there is no doubt in young children the operation is not free from danger to life, and Mr Rose's rule not to operate under

¹ *On Harelip and Cleft Palate*, 1891.

² Langenbeck, *Archiv* ii. p. 657. ³ *Med. Chir. Trans.* for 1867-8.

three years is certainly a wise one. The effect of the operation on the voice of the child has been very encouraging, as much more improvement takes place than in cases where the operation is performed late in life.

Fissure in the soft palate only appears as a triangular cleft, the apex of which is above, the base being a line between the points of the bifid uvula, which are widely separated. To cure this it is required—

1. That the edges of the fissure should be brought together without strain or tightness. In small fissures this can generally be done easily enough; but where the fissure is extensive, some means must be used to relieve tension. For this, Sir William Fergusson long ago proposed the division of the palatal muscles, the levator, tensor, and palato-pharyngeus muscle of each side. The incisions in the palate for this purpose certainly aid apposition, but many surgeons entertain doubts whether the division of the muscles has much to do with the good result, and believe that the simple incisions in the mucous membrane, in a proper direction, are all that is required (see Fig. XXXI.)

FIG. XXXI.*

2. That the edges of the fissure be made raw, so as to afford surfaces which will readily unite. Complicated instruments, such as knives of various strange shapes, have been devised for this purpose; an ordinary cataract knife, very sharp, and set on a long handle, is perhaps the best.

* Diagram of staphyloraphy, chiefly to illustrate the passing of the threads:—*a*, the first thread; *b*, the second. The dotted line at edge of fissure shows amount to be removed; the other dotted line showing size and position of the incision through the mucous membrane above.

It greatly facilitates the section if the parts are tense, so the point of the uvula should be seized by an ordinary pair of spring forceps, and drawn across the roof of the mouth, while the knife should enter in the middle line, a little above the apex of the fissure, and make the cut downwards as in harelip.

3. That sutures should be inserted to keep the edges in apposition, yet not so tightly as to cause ulceration. They may be either of metal, silver being preferable, or of silk-worm gut which has been soaked in a solution of carbolic acid, or in cases where the cleft is wide, of fine silk also sterilized. Horse hair is an excellent suture for cases where there is not much tension, as when soft palate only is involved. The metallic sutures are now generally preferred. Some dexterity is required in their introduction, and various instruments have been devised; the best seems to be a needle with a short curve fixed on a long handle, which should be entered on the (patient's) left side of the fissure in front, and brought out on the right side.

If silk sutures be used, the chief difficulty, that of passing the thread through the second side from behind forwards, can be avoided in the following manner.¹ A curved needle is passed through one side of the fissure, and then towards the middle line, till its point is seen through the cleft. One of the ends of the thread is then seized by a long pair of forceps, and drawn through the cleft; the needle is then withdrawn, leaving the thread through the palate, and both ends are brought outside at the angle of the mouth. Another needle is then passed through a corresponding point at the opposite side of the palate, till its point again appears at the cleft; this time a double loop of the thread is also brought out through the cleft by the forceps into the mouth. If then the single thread of the first ligature which is in the cleft be

¹ Holmes' *Surgery*, vol. ii. pp. 504-513.

passed through the loop of the second one also in the cleft, it is easy, by withdrawing the loop through the palate, to finish the stitch (see Fig. xxxi.) The first stitch should be inserted at the apex of uvula and not tied, but used to put it on the stretch and to avoid the necessity of catching it with forceps. All the stitches should be passed and their position approved before any one be tied, and it is most convenient to secure them from above downwards. To prevent confusion, each pair of threads after being inserted should be left very long, and brought up to a coronet fixed on the brow, which is fitted with several pairs of hooks numbered for easy reference. This will prevent twisting of the threads or any mistake in tying.

Fissure of the Hard Palate.—This may vary in extent from a very slight cleft in the middle line behind, up to a complete separation of the two halves of the jaw, including even the alveolar process in front, and sometimes complicated with harelip.

To close such fissures by operation is difficult, as the breadth of the cleft is so great as to prevent the apposition of the edges when prepared, without such extreme tension as quite prevents any hope of union. Through the researches of Avery, Warren, Langenbeck, the late Sir William Fergusson, Mr Thomas Smith, Professor Rose, Professor Annandale, and others, such fissures can now be closed by operation conceived with scientific accuracy and generally followed by success.

Operation.—In addition to the usual paring of the edges of the cleft, an incision is made on each side of the palate, extending “from the canine tooth in front to the last molar behind,”¹ along the alveolar ridge (Fig. xxxii.) The whole

¹ *Edinburgh Medical Journal* for Jan. 1865, Mr Annandale's instructive paper on “Cleft Palate.”

flap between the cleft and this incision on each side is then to be raised from the bone by a blunt rounded instrument

FIG. XXXII.*

slightly curved. With this the whole mucous membrane and as much of the periosteum as possible should be completely raised from the bone, attachments for nourishment of the flap being left in front and behind where the vessels enter.

The flaps thus raised will be found to come together in the middle line, sometimes even to overlap, and when united by suture, form a new palate at a lower level than the fissure, experience having shown that in cases of fissure the arch of the palate is always much higher than usual. The higher the arch of the palate, the more likely it is that the flaps will come easily and satisfactorily into position without tension.¹ The flaps do not slough, being well supplied with blood, unless they have been injured in their separation. If the flaps seem scanty and tension is likely to be great, only a portion of the cleft should be attacked at once, though in ordinary cases the operation should be done at one sitting.

The edges must be carefully united by various points of metallic suture, and the fissure of the soft palate closed at the same sitting, unless the patient has lost much blood, or is very much exhausted with the pain. The stitches may be left in for a week, or even ten days, unless they are exciting much irritation. The patient must exercise great self-control and caution in the character of his food and his manner of eating for ten days or a fortnight after the operation.

* Diagram of fissure of hard palate :—*a*, anterior palatine foramina ; *b*, posterior palatine foramina with groove for artery ; *c*, incisions requisite to free the soft structures.

¹ Mr Howard Marsh, *Lancet*, 1888.

Mr Davies-Colley¹ has described an ingenious modification which he says is suitable for cases of very young children, or where the gap is too large for the usual operation, or where the usual operation has failed. It is too long to quote entire, but its principle is—1. The section of a triangular flap containing all the soft parts of the *wider* side of the palate. Its apex is at the incisor teeth, and its base is left attached just behind posterior border of the hard palate. 2. The other side of palate, a half ellipse of the soft parts should be raised with its attached margin left close to the cleft, it should then be folded back as on a hinge, and fixed with a suture or two to the already described first side. The other triangular flap is then brought across the cleft and its tip fixed by suture as nearly as possible to the anterior end of the second flap's gap. Two raw surfaces are thus opposed to each other and unite.

Excision of Tonsils.—The operation to which this name is generally given is only the shaving off of a redundant and projecting portion in cases of chronic enlargement. When properly performed it is a very safe, and in adults a very easy operation, but in children it is sometimes rendered exceedingly difficult by their struggles, combined with the movements of the tongue and the insufficient access through the small mouth.

Many varieties of guillotines have been devised for the purpose of at once transfixing and excising the projecting portion; some of them are very ingenious, and we have the authority of many eminent throat specialists that they do their work, *cito, tuto, et jucundé*. The author is still old-fashioned enough to believe that the best and safest method of removing the redundant portion is to seize it with a

¹ *Brit. Med. Journal*, 1890.

volsellum, and then cut it off by a sawing motion of a probe-pointed curved bistoury; cutting from above downwards, and being careful to cut parallel with the great vessels.

The ordinary volsellum is much improved for this purpose by the addition of a third hook in each blade, placed between the others, with a shorter curve, and slightly shorter; this insures the safe holding of the fragment removed, and prevents the risk of its falling down the throat of the patient.

If both tonsils are enlarged they should both be operated on at the same sitting, and the pain is so slight that even children frequently make little objection to the second operation. Bleeding is rarely troublesome if the portion be at once fairly removed, but if in the patient's struggles the hook should slip before the cut is complete, the partially detached portion will irritate the fauces, cause coughing and attempts to vomit, and sometimes a troublesome hæmorrhage.

The plentiful use of cold water will generally be sufficient to stop the bleeding, though cases are on record in which the use of styptics, or even the temporary closure of a bleeding point by pressure, has been necessary.

M. Guersant has operated on more than one thousand children, with only three cases of any trouble from hæmorrhage, while four or five out of fifteen adults required either the actual cautery or the sesqui-chloride of iron.¹

Excision of Tonsil for Malignant Disease.—Excision of malignant disease of the tonsil is a very serious operation, attended with risk to life and still greater risk of recurrence. It has been attempted through the mouth, but more frequently and more safely from the neck. Preliminary tracheotomy will be necessary, and the use of a Trendelenburg's tampon. The

¹ Holmes' *Diseases of Children*, p. 555.

jaw of the affected side may need division behind the last molar, or access may be gained by an elaborate dissection involving the structures behind the ramus; the dissection must be made cautiously, vessels tied as exposed, and nerves avoided. In a lucky case the tonsil may be shelled out, but in most malignant tumours glands and adjacent parts are matted together.

Mr Butlin's¹ careful researches on the statistics of the operation show that its results have been most unsatisfactory.

¹ *On the Operative Surgery of Malignant Disease.*

CHAPTER IX.

OPERATIONS ON AIR PASSAGES.

Operations on the Larynx and Trachea.—The great air passage may be opened at three different situations, and to the operations at these different places the following names have been given:—

Laryngotomy, when the opening is made in the interval between the cricoid and thyroid cartilages, through the crico-thyroid membrane.

Laryngo-tracheotomy, when the cricoid cartilage and the upper ring of the trachea are divided.

Tracheotomy, when the trachea itself is opened by the division of two, three, or more rings.

Of these the last, *tracheotomy*, is by far the most frequent, important, difficult, and dangerous, and requires a very detailed description. Tracheotomy in a fat child under a year old, in urgent dyspnoea, is one of the most difficult of operations. In the dead body of an adult it is of absolute simplicity. Chassaignac¹ says “the only really rational operation for the opening of the air passages by the surgeon is tracheotomy.”

Tracheotomy.—*Anatomy.*—Between the cricoid cartilage and the level of the upper border of the sternum, the middle line of the neck is occupied by the upper portion of the

¹ *Leçons sur la Trachéotomie*, p. 10.

trachea. Its depth from the surface varies, gradually increasing as the trachea descends, and varying very much according to the fatness, muscularity, and length of the neck. It is, however, almost subcutaneous at the commencement below the cricoid, and on the level of the sternum it is in most cases at least an inch from the surface, in many much deeper. Again, its length varies, even in the adult, from two and a half to three, or even four inches. This is important, as affecting the simplicity of the operation, which, as a rule, is easier the longer the neck is.

The trachea has most important and complicated anatomical relations—some constant, others irregular.

1. The carotid arteries and jugular veins lie at either side, but, where these are regular in their distribution, do not practically interfere in a well-conducted operation.

2. The thyroid gland lies in close relation to the trachea, one lobe being at each side (Fig. xxxiii. B B), and the isthmus of the thyroid crosses the trachea just over the second and third cartilaginous rings. Mr Parker¹ states that in children the isthmus is generally higher up on the crico-tracheal membrane or first tracheal ring. In fat vascular necks, or where the thyroid is enlarged, it may occupy a much larger portion of the trachea. The position of the isthmus practically divides the trachea into two portions in

FIG. XXXIII.*

* Rough diagram of larynx and trachea:—A, crico-thyroid space, *laryngotomy*; B B, dotted outline of thyroid isthmus and lobes, defines the upper and lower positions for *tracheotomy*; C, thyroid—D, cricoid cartilages; E, dotted outline of thymus gland in child of two years; F F, outline of clavicles and jugular fossa.

¹ *On Tracheotomy*, p. 37.

which it is possible to perform tracheotomy. Both have their advocates, but the balance of authority which used to support the operation below the thyroid seems rather now to favour the high operation. A separate notice of each will be required immediately.

3. The *muscles* in relation to the trachea are the sterno-hyoid and sterno-thyroid of each side. The latter are the broadest, are in close contact across the trachea by the inner edges below, but gradually diverge as they ascend the neck. In thick-set, muscular necks, however, they are in close contact for a considerable distance, and require to be separated to give access to the trachea.

The *arteries* are in most cases unimportant; no named branch of any size ought to be divided in the operation. However, occasionally very free bleeding may result from the division of an abnormal *thyroidea ima* running up the trachea to the thyroid body from the innominate, or even from the aorta itself.

The *veins* are very numerous and irregularly distributed. There is generally a large transverse communicating branch between the superior thyroid veins just above the isthmus. The isthmus itself has a large venous plexus over it. Below the isthmus the veins converge into one trunk (or sometimes two parallel ones) lying right in front of the trachea.

4. The last anatomical point which may give trouble in normal necks is the thymus, which is present in children below the age of two, and covers the lower end of the trachea just above the level of the sternum. Where this is not only not diminished, but enlarged, as it sometimes is in unhealthy children, it may give a very great deal of trouble, rolling out at the wound and greatly embarrassing proceedings.

Abnormalities are very various and sometimes very

dangerous: vessels crossing the trachea, as the innominate did in Macilwain's case,¹ or where two brachiocephalic trunks are present, as recorded by Chassaignac.² One of the most frequent dangers to be guarded against is a possible dilatation of the aorta or aneurism of the arch. This may very possibly, as happened in one case to the author, give rise to suffocative paroxysms from its pressure on the recurrent laryngeal nerves. Tracheotomy may be deemed necessary, and there is a great risk, unless proper precautions be taken, of wounding the aorta, where it passes upwards in the jugular fossa. In the author's case the vessel had actually to be pushed downwards by the pulp of the forefinger while the trachea was opened, the knife being guided on the back of the nail of the same finger.

The Operation.—In a work of this kind it would be utterly impossible to go at all into the subject of what diseases, injuries, etc., warrant or require the operation. It is enough to describe the various methods of operating, their dangers and difficulties.

1. *The Operation above the Isthmus of the Thyroid.*—A spot about a quarter or half of an inch in vertical diameter between the cricoid cartilage (Fig. XXXIII.) and thyroid isthmus.

Advantages.—It is near the surface, the vessels are few and comparatively small. It is most suitable in cases of aneurism, or other tumours pressing on the recurrent laryngeal nerve.

Professor Spence³ gave his sanction to the high operation in adults with thick short necks when the operation is

¹ *Surgical Observations*, p. 335. See also Harrison *On the Arteries*, vol. i. p. 16.

² *Leçons sur la Trachéotomie*, p. 9.

³ *Lectures on Surgery*, 3rd ed., vol. ii. p. 900.

performed for ulceration or papilloma of larynx, or for spasm from aneurism, the low operation in his opinion being still retained for cases of croup or diphtheria. Within the last ten years opinion of the majority of surgeons has gradually come round to approval of the high operation in most cases even of croup and diphtheria.

Disadvantages.—The space is too small, and in all cases in children requires very considerable disturbance of the thyroid isthmus, or actual division of it. This division can easily and safely be done, if necessary, between two ligatures, and experience shows that by a blunt director or raspatory the isthmus can easily be pushed downwards. It is doubtless too near the point where the disease is—so much so, that in cases of croup or diphtheria the wound is made directly over and into false membrane. When this is found to be the case, the incision must be enlarged and the membrane scraped away. There is no doubt the operation is easier and the trachea is more accessible.

A straight incision being made in the middle line about one inch and a half in length, expose the upper ring by careful dissection, if possible draw aside the veins, and depress the thyroid isthmus, divide the rings thus exposed, and introduce the tube.

Bose's Method.—Bose's method of doing the high operation is much praised by that most competent authority, Mr Arthur Barker. The usual incision in middle line is carried rapidly down to the deep fascia. This fascia attached to the thyroid cartilage above splits below and laterally to invest the thyroid body and isthmus along with their vessels. The simplest way to carry the isthmus of the thyroid downwards without wounding its delicate vessels is to make a transverse incision one-third of an inch long through the deep fascia at the upper border of the cricoid cartilage, and then pass a director or blunt hook well

behind it, and peel it off the front of the tracheal rings till enough of the latter has been exposed. The steadying of the trachea with a sharp hook renders the incision of it easy.¹

The Operation below the Isthmus.—This is more difficult in its performance, and may be required in some cases. Considerable coolness and a thorough knowledge of the anatomy of the part are absolutely required.

The patient being in the recumbent posture, the shoulders should be well raised, and the head held back so as to extend the windpipe, and thus bring it as near as possible to the surface. A pillow, or the arm of an assistant, behind the neck will be of service.

N.B.—Be careful lest too great extension by an anxious assistant, accompanied by closure of the mouth, should choke the patient (whose breathing is of course already much embarrassed) before the operation be begun.

Chloroform may generally (and in most cases a very small quantity is required to produce narcosis) be given, and, if well borne, renders the operation very much easier than it would otherwise be. An incision must then be made exactly in the median line of the neck, from a little below the cricoid cartilage, almost to the upper edge of the sternum; at first it should be through skin only, then the veins will be seen, probably turgid with dark blood; the larger ones should be drawn aside, if necessary divided, the bleeding stopped by gentle pressure. The deep fascia must then be cautiously divided, great care being taken to keep exactly in the middle line, and the contiguous edges of sterno-thyroid muscles separated from each other by the handle of the knife. A quantity of loose connective tissue, containing numerous small veins, must now be pushed aside, the thyroid

¹ *Archiv f. Clin. Chir.*, Bd. xiv., quoted in Barker's *Surgical Operations*, p. 241.

isthmus pressed upwards, still with the handle of the knife. The forefinger must then be used to distinguish the rings of the trachea. Unless greatly pressed by urgency, it is most important to see the tracheal rings before opening it; and if a director or raspatory is used, as recommended by Whitehead,¹ to split the fascia and expose the trachea, the operation may be practically bloodless once the skin has been divided. If there be much convulsive movement of the larynx and trachea, they should be fixed by the insertion of a small sharp hook with a short curve, just below the cricoid cartilage, and this should be confided to an assistant. The surgeon should then, with the forefinger of his left hand, fix the trachea, and open it by a straight sharp-pointed scalpel, boldly thrusting it through the rings with a jerk or stab, the back of the knife being below, and divide two or three of the rings from below upwards. Any attempt to enter the trachea slowly with a blunt knife or trocar will probably be unsuccessful, as the rings, especially in children, give way before the knife, which merely approximates the sides of the trachea without opening it. There is also a risk of separating the mucous membrane from the wall and pushing it before the knife or tube.

Question of Hæmorrhage.—It is often a question of some importance, and one which sometimes it is not easy to settle, how far attempts should be made completely to arrest the venous hæmorrhage before opening the trachea.

On the one hand, if not arrested, besides the risk of weakening the patient, we have to dread the much more serious complication of the admission of blood into the trachea. And this is very serious in a patient whose respiration has already been much impeded, whose lungs are probably engorged, and who has certainly, by the mere existence of a wound in his trachea, lost the power of coughing

¹ *Lancet*, 1887.

properly ; it must never be forgotten that a quantity of blood so trifling as to be at once ejected by a single cough in the case of a healthy chest, may be a fatal obstacle to respiration in one already weakened by disease. Thus any well-marked arterial hæmorrhage from cut branches, or from the isthmus of the thyroid, must certainly be arrested prior to opening the trachea. Besides this, blood once having entered the bronchi is apt to extend into their smaller ramifications and prove a cause of death, by acting as a local irritation, and setting up intra-lobular suppurative pneumonia. The author has found this to be the case both after tracheotomy and still more frequently in suicide by cut throat.

But, *on the other hand*, it is equally true that there is almost always a considerable amount of oozing from small venous radicles divided during the operation, which depends simply on the great venous engorgement resulting from the obstruction to the respiration, so that while to attempt to tie every point would be simply endless, we may be almost certain that the oozing will cease whenever the trachea is opened, and respiration fairly improved. Slight pressure on the wound is generally sufficient to stop the bleeding till the venous engorgement has disappeared.

Of late years many tracheotomies have been done bloodlessly, by use of the thermo-cautery for division of the soft parts, but the subsequent sloughing of the wound is a great objection to this method.

In cases of extreme urgency, all such minor considerations as suppression of venous oozing must be ignored, and the trachea simply opened as rapidly and freely as possible. I had once to perform the operation after respiration had entirely ceased, and no pulse could be felt at the wrist, with no assistance except that of a female attendant. Merely feeling that no large arterial branch was in the way, I cut

straight through all the tissues, opened the trachea, and commenced artificial respiration. The patient eventually recovered.

Question of Tubes, etc.—Once the trachea is opened, the next question is, How is the opening to be kept pervious? For the moment the handle of the scalpel is to be inserted in the wound, so as to stretch it transversely; this will probably suffice to allow of the escape of any foreign body. But where, to admit air, the wound is to be *kept* open, how is this to be done? It used to be advised that an elliptical portion of the wall of the trachea be removed; this, though succeeding well enough for a time, was unscientific, as the wound always tended to cicatrize, and ended, of course, in permanent narrowing of the canal of the trachea. I have never seen a case in which this expedient was required; but such a case is recorded by Sir J. Fayrer at Calcutta.¹ Not much better is the proposal to insert a silk ligature or a pair of hooks in each side of the wound, and by pulling these apart thus mechanically to open the wound. These also are evidently merely temporary expedients.

Various canulæ and tubes have been proposed. The ones recommended by the older surgeons had all one great fault: they were much too small, and were many of them straight, and thus liable to displacement. The smallness of their bore was their greatest objection, and Mr Liston conferred a great benefit on Surgery by his insisting upon the introduction of tubes with a larger bore, and with a proper curve so as thoroughly to enter the trachea. The tube ought to be large enough to admit all the air required by the lungs, without hurrying the respiration in the least.

There is a mistake made in the construction of many of the tubes even of the present day; the outer opening is large and full, while for convenience of insertion the tube

¹ *Clinical Surgery in India* (1866), p. 143.

tapers down to an inner opening, admitting perhaps not one-half as much air as the outer one does.

Durham, Bryant, and Parker have each their own variety of tube—lobster tail, ball and socket, and angular. Each case requires the tube to be selected for itself with special care to avoid pressure, which is apt to take place on the tracheal wall.

It must be remembered that for some days there is great risk of the tube becoming occluded, by frothy blood or mucus, especially in cases of croup, and in children. To prevent this a double canula will be found essential, providing only that it be remembered that the inner canula, not the outer merely, is to be made large enough to breathe through, and that the inner should project slightly beyond the outer one.

The inner one can thus be removed at intervals and cleansed, by the nurse, without any risk of exciting spasm or dyspnoea by its absence and reintroduction.

After-treatment.—The after-treatment of a case in which tracheotomy has been performed demands great care and many precautions. For the first day or two the constant presence of an experienced nurse or student is always necessary to insure the patency of the tube. The temperature of the room should be equable and not less than from 60° to 65°, and it seems of importance that the air should be kept moist as well as warm. The steaming in a secluded cot may be overdone, and really add to the weakness; a sponge soaked in warm boric solution near the wound is often sufficient protection.

A piece of thin gauze, or other light protecting material, should be placed over the mouth of the tube, to prevent the entrance of dust or germs.

In cases where the operation has been performed for some temporary inflammatory closure of the air passage,

retention of the tube for a few days may suffice. It may then be removed, but it must be remembered that the wound will generally close with great rapidity, so that it is as well to be quite sure of the patency of the natural passage before the artificial one is allowed to close by the removal of the tube. A competent assistant should be present for some hours after removal in case of danger; and if symptoms return it is generally better to pass a MacEwen's tube through the larynx for a few days, rather than reintroduce the tube by the wound.

In cases where from long-standing disease or severe injury the larynx is rendered totally unfit for work, and the tube has to be worn during the rest of the patient's life, care must be taken (1), lest the tube do not fit accurately, in which case it may ulcerate in various directions, even into the great vessels,¹—in such cases tubes made to move easily in a collar, as Durham's or Bryant's, are absolutely necessary, and the patient should possess at least two; (2), lest the tube become worn, and thus the part within the windpipe fall into the trachea and suffocate the patient.²

Intubation of Larynx.—This method of treatment of membranous laryngitis is still *sub judice*. Dr MacEwen in 1880³ recommended the insertion of long tubes like gum elastic catheters from the mouth into the larynx, and his suggestion was followed by Mr Annandale. In America, Dr O'Dwyer⁴ suggested the use of short metallic tubes, which are introduced by a special carrier into the larynx, and which by their shape are self-retaining, and are to be removed for

¹ Mr John Wood, *Path. Soc. Trans.*, vol. xi. p. 20.

² South's *Chelius*, vol. ii. p. 400; and case recorded by Spence, in *Edin. Med. Journal* for August 1862.

³ *British Medical Journal*, 1880.

⁴ *New York Medical Journal*, 1885.

cleaning by a special instrument. This operation has been practised to a very large extent in America,¹ and to a much less extent in this country.²

Dr Waxham has collected 661 cases, with 181 recoveries.

Laryngotomy.—As a temporary expedient in cases of great urgency, where proper instruments and assistants are not at hand, laryngotomy is occasionally useful, though from the want of space without encroaching on the cartilages of the larynx, and from its close proximity to the disease, laryngotomy is by no means a suitable or permanently successful operation.

In the adult, especially in males with long spare necks, the operation itself is exceedingly easy to perform. The crico-thyroid space (Fig. XXXIII. A) is so distinctly shown by the prominence of the thyroid cartilage, and is so superficial, that it is quite easy to open it in the middle line with a common penknife, there being merely the skin and the crico-thyroid membrane to be cut through, with very rarely any vessel of any size. The opening can then be kept patent by a quill or a small piece of flat wood. This simple operation has in many cases, where a foreign body has filled up the box of the larynx, succeeded in saving life, and even in cases of disease it is sometimes useful in giving time for the subsequent performance of tracheotomy.

Easy as it appears and really is, cases are on record in which the thyro-hyoid space has been opened instead of the crico-thyroid, such operations being of course perfectly useless, to relieve dyspnoea.

The incision is best made transversely.

Supra-Thyroid Laryngotomy, or Sub-Hyoid Pharyngotomy, is occasionally used with a view of giving access to

¹ *American Medical Association Journal*, 1888.

² Hunter Mackenzie, *Edin. Medical Journal*, 1892.

upper part of larynx, and specially to epiglottis, for removal of growths. It is done by a transverse incision, in which skin, fascia, sterno-hyoid, and thyro-hyoid muscles, thyro-hyoid membrane, and mucous membrane are divided in order to expose the epiglottis.¹

Laryngo-Tracheotomy.—This modification consists in opening the air passage by the division of the cricoid cartilage vertically in the middle line, along with one or two of the upper rings of the trachea.

It seems to combine all the dangers with none of the advantages of the other methods of operating. It is close to the disease, involves cutting a cartilage of the larynx, and almost certain wounding of the isthmus of the thyroid; and it is not easy to see what corresponding advantages it has over tracheotomy in the usual position.

Thyrotomy is an operation by which the larynx is opened in the middle line by a vertical incision, and its halves separated, while any morbid growths are excised from the cords or ventricles. The merits and dangers of this operation have been discussed at length by Mr Durham² and Sir Morell Mackenzie.³ As intra-laryngeal surgery advances, the cases requiring thyrotomy will diminish in number. If performed for foreign body, it is safer to perform a preliminary laryngotomy; but if for growths of the larynx, unknown difficulties may present themselves, and it is wiser to perform a preliminary tracheotomy and to plug the upper part of trachea.

Laryngectomy, or Excision of the Larynx, first performed by Dr Heron Watson in 1866, has been lately frequently performed for carcinoma and sarcoma. Each case presents

¹ Solis Cohen, Ashhurst's *Encyclopædia of Surgery*, vol. v.

² *Med. Chir. Transactions of London*, 1872.

³ *British Med. Journal* (Nos. 643, 644), 1873.

its own difficulties, which vary according to the amount and extent of the disease for which it is done.

There is a question as to when and where the preliminary tracheotomy should be performed; some operators, such as Mr Butlin, prefer to do it at least ten days before the operation. Others prefer a low tracheotomy, done immediately before the operation, lest the earlier and higher operation should have caused infiltration and matting of the parts (Gussenbauer).

The trachea must be divided and tamponed by a Trendelenburg canula, after which the larynx must be carefully dissected out. A successful case, reported admirably¹ by the late Dr Foulis, gave a great impetus to the operation in this country, especially as phonation was so good with the use of Foulis's modification of the artificial larynx of Gussenbauer. The operation is thus performed:—

Laryngectomy.—Longitudinal incision through the skin in middle line, from hyoid bone to first or second ring of the trachea, with a transverse one at the level of the hyoid, allows flaps to be drawn outwards and downwards, exposing the larynx. The soft parts are best separated by getting fairly through the deep fascia, and then using an elevator or periosteum scraper. Be careful not to loosen the connexions more than is absolutely necessary from the upper part of the trachea. If the disease be malignant, and has penetrated the cartilages, of course a more extensive removal of parts must be undertaken; but if the disease be entirely intralaryngeal, the larynx can be thus cleared with little bleeding, and the extrinsic muscles may be divided close to their insertions, and then thrown back with the skin flaps. All bleeding being stopped, the thyro-hyoid membrane and

¹ *Lancet*, 1877-1878.

muscles require division, and the box of the larynx can thus be drawn forwards, and its posterior attachments severed. Some operators leave the epiglottis if it is healthy, but there seems to be no advantage in this, as it increases the risk of recurrence, and is of no use,—indeed, interferes with the insertion of an artificial larynx. The lower parts must then be divided, either through trachea, if cricoid is diseased, or by leaving a small ring of cricoid. In either case, the upper end of air-passage must be very carefully secured by deep and superficial stitches to the skin.

More than ninety cases were collected by Solis Cohen¹ in 1884, since which date many more have been performed. The mortality is very great, and the risk of recurrence is also very great.

Unilateral Laryngectomy, or excision of one-half of the larynx, was first performed by Billroth in 1878, and in suitable cases is a much less fatal operation than complete laryngectomy. Some of the cases have recovered, and lived for years with considerable power of speech.

Œsophagotomy.—This operation is not very frequently required, and has as yet been performed mainly for the removal of foreign bodies impacted in the œsophagus, and interfering with respiration and deglutition. To cut upon the flaccid empty œsophagus in the living body would be an extremely difficult and dangerous operation, from the manner in which it lies concealed behind the larynx, and in close contact with the great vessels. When it is distended by a foreign body, and specially if the foreign body has well-marked angles, the operation is not nearly so difficult. It has now been performed in sixty-five cases at least, of which thirteen have proved fatal.

Operation.—Unless there is a very decided projection of

¹ *International Encyclopædia of Surgery*, vol. v. p. 757.

the foreign body on the right, the left side of the neck should be chosen, as the œsophagus normally lies rather on the left of the middle line. An incision similar to that required for ligature of the carotid above the omohyoid should be made over the inner edge of the sternomastoid muscle; with it as a guide, the omohyoid may be sought and drawn downwards and inwards, the sheath of the vessels exposed and drawn outwards, the larynx slightly pushed across to the right, the thyroid gland drawn out of the way by a blunt hook, the superior thyroid either avoided or tied. The œsophagus is then exposed, and if the foreign body be large, it is easily recognised; if the foreign body be small, a large probang with a globular ivory head should then be passed from the fauces down to the obstruction; this will distend the walls of the œsophagus, and make it a much more easy and safe business to divide them to the required extent. The wound in the œsophagus should be longitudinal, and at first not larger than is required to admit the finger, on which as a guide the forceps may be introduced to remove the foreign body, or, if necessary, a probe-pointed bistoury still further to dilate the wound.

For some days or even weeks the patient must be fed through an elastic catheter introduced through the nose and retained, or by an ordinary stomach-tube through the mouth. In introducing the latter there is always a risk of opening the wound. If it has been for a recent foreign body and the wound is a clean cut, it may be stitched with fine catgut, but as a rule the outer wound should only be lessened in size by a stitch or two at each end, then the central portion should be kept open by a large drainage-tube, and no special stitches need be inserted in the œsophageal wound.

CHAPTER X.

OPERATIONS ON THORAX.

Excision of Mamma.—When the whole breast is to be removed, two incisions, enclosing an elliptical portion of skin along with the nipple, must be made in the direction of the fibres of the pectoralis muscle. The distance between the incisions at their broadest must depend upon the nature of the disease for which the operation is performed, and the extent to which the skin is involved; in every case the whole nipple should be removed. The incisions should, if possible, be parallel with the fibres of the pectoralis major, and extend across the full diameter of the breast. During the operation the arm should be extended so as to stretch both skin and muscle. The lower flap should be first raised and dissected downwards, with care that the cuts are made in the subcutaneous fat, and wide of the disease; the upper flap is then thrown upwards, and the edge of the gland raised, so that the fibres of the pectoralis are exposed below it. These should be cleanly dissected, so as to insure removal of the whole gland.

Any bleeding during the operation can easily be checked by the fingers of an assistant, and if the arteries entering the gland from the axilla be divided last, they can be at once secured.

Great benefit results from the free use of drainage-tubes in most cases; for this purpose a dependent opening in the lower flap is often made.

It may be laid down as an absolute axiom that in cases of malignant disease of the breast, the whole breast is diseased,¹ and the smallest piece left behind may induce a so-called recurrence, which is really an inefficient removal. Also it is equally certain that the female breast is not, as generally described, a regular disc, but it has projecting lobules in various directions which are often left behind. Sir Astley Cooper long ago showed this, and an excellent paper by Mr Roger Williams² confirms it by many authorities. This being the case, the ordinary incision described above is by no means the best for giving free access; and it will be found safer to remove in every case all the skin lying above the tumour, and from that as a centre to make three or four radiating lines of incision to the circumference, thus allowing flaps to be turned down with great freedom and as far as is necessary. Of course the fascia and glands should also be dissected out.

I may also refer to Mr Banks'³ excellent papers on the subject of free removal, and above all to the admirable work done by Mr H. J. Stiles on the anatomy of the breast and on tumours of it, and also on the method of recognising whether a removal has been complete or not.⁴

Surgeons now operate even when the axillary glands are diseased, and by a very free dissection and removal, even in hopeless-looking cases, life may be prolonged. To insure the removal of the lymphatic vessels as well as the glands, it is best not to separate the breast at its axillary margin, but keep it attached by the tail of lymphatics surrounded by fat, which will lead up to the glands. Section of the great pectoral muscle will aid the dissection.

² *Manchester Medical Chronicle*, June 1892.

³ *British Medical Journal*, 1882 and 1887.

⁴ *Edinburgh Medical Journal*, June 1892.

More than twenty years ago the author¹ pointed out that, in many cases, the ordinary incision bounding an ellipse, including the nipple, was by no means the best mode of insuring free removal of possibly infected skin, and recommended incisions radiating from the nipple, and bisecting the flaps made by the original elliptical ones. These can be brought together easily; but even if they do not come together, it is of less importance compared with having risk of return, and it is wonderful how much of an immense gap will heal by granulation and cicatrization, and if delayed, skin grafting will hasten matters.

Paracentesis Thoracis, for the relief of pleurisy, acute and chronic, and empyema, is an operation of extreme simplicity.

The proper selection of cases, the settling of the suitable position for the tapping, and the choosing of the suitable time for it, are more difficult, and not within the scope of the present work. Among the earlier authorities on this subject are the late Dr Bowditch of Boston, Dr Hughes and Mr Cock,² and the late Dr Warburton Begbie.³

Where is it to be performed? Not *above* the sixth rib, else the opening is not sufficiently dependent; very rarely *below* the eighth on the right side, and the ninth on the left. The intercostal space occasionally bulges outwards if fluid is present, and this bulging, if present, acts as an aid to diagnosis. As the intercostal artery lies under the lower edge of the upper rib in each space, the trocar should be entered not higher than the middle of the space; and because the artery is largest near the spine, and also the space is there deeply covered with muscle, the tapping

¹ *Edinburgh Medical Journal*, 1871.

² Both in *Guy's Hospital Reports*, second series, vol. ii.

³ *Edinburgh Medical Journal* for June 1866.

should never be *behind* the angle of the rib. A common site for puncture is the sixth space in front of the posterior axillary fold; but the more frequent spot selected is in a position considerably behind this, *an inch* or two below the angle of the scapula, between the seventh and eighth, or between the eighth and ninth ribs.

The operation is usually performed for diagnostic purposes by a sterilized hypodermic syringe, and after diagnosis is verified by a suitable hollow needle, varying in thickness according to the nature of the contents, attached either to an ordinary aspirator or to any of the special instruments made for this purpose.

The original instrument of Dr Bowditch has not been much improved upon for use in more chronic cases, where the quantity of fluid is large, and especially if it is thick and curdy.

It consists of a powerful syringe, which fits accurately to the trocar with which the puncture is made. There is a stop-cock between the trocar and syringe, and another at right angles to the syringe. The trocar being introduced, it is held firmly in position by an assistant, by means of a strong cross handle; the first stop-cock is then opened, and the syringe worked slowly till it is filled with fluid through the trocar, the other delivery stop-cock being closed. The first is then closed and the second opened; the syringe is then emptied through the second into a basin. By a repetition of this process, the fluid can be removed at pleasure, without any risk of the entrance of air.

In Empyema mere puncture is rarely of any value except for diagnosis, and the case must be treated by free incisions and drainage with strict antiseptic precautions. By incision the foetid, thick, and caseous pus can be easily and thoroughly evacuated, and the cavity can be well drained. A free incision is made along the upper edge of the lower rib of

the space selected till the intercostal muscles are exposed and divided close to the rib, then the pleura is opened by a director, or if it is thickened, by a knife, the wound in it is then to be dilated by dressing forceps, and in an adult by the operator's forefinger, which can so far explore the cavity. The drainage-tube, as large as possible, furnished with a shield, is then inserted. Washing out should not be done unnecessarily, as it has risks of its own. Free drainage generally suffices. One opening is enough in a child; two may be needed in adults.

Excision of Portions of Ribs.—To insure free drainage and to prevent pressure on the tube, the thorax is now generally opened in bad cases of empyema by removing a portion of a rib; and in very bad cases, where the lung is contracted, healing is hastened by removal of portions of several contiguous ribs,—three, four, or even six having been occasionally thus treated. Make a free incision on the rib that is first to be removed in its direction, raise the periosteum with a scraper, exposing at least an inch; continue the separation of the pleural periosteum by a curved elevator, and when it is separated divide the bone either with saw or bone-pliers, protecting the pleura with the elevator. On removal of the cleaned portion, the knife must then divide cautiously the pleural periosteum, thus reaching the pus. The opening can be enlarged, the cavity freely examined by the finger, and drained, and more ribs, if necessary, may be treated in the same manner.

*Estlander's*¹ *Operation.*—In cases of old empyema with greatly thickened pleura and unexpanded lung a suppurating cavity is left which with its rigid walls can contract no further. To enable this to heal, the ribs and the thickened pleura

¹ *Rev. Mensuelle de Médecine et Chirurgie*, 1879.

must be resected. From five to six or even eight ribs may require partial resection. Esthlander does it by cutting transversely over the centre of an intercostal space, and from this wound he exposes and resects the two ribs which bound the space, so far as required. The periosteum and pleura must also be removed; if the periosteum is left it forms new bone and does away with the good of the operation. Various modifications are devised. Godlee¹ makes a large flap of skin and soft parts; Jacobson² smaller and more numerous flaps. The number of ribs to be dealt with and the amount of bone removed depends on the size, shape, and relations of the cavity.

CHAPTER XI.

OPERATIONS ON ABDOMEN.

Paracentesis Abdominis.—To withdraw fluid from the abdominal cavity is an exceedingly simple operation in itself, though certain precautions are necessary to render it safe.

Trocar.—The usual instrument used to be a simple round canula with a trochar, the point of which should be very sharp, and in the shape of a three-sided pyramid. It should be about three inches in length, and a quarter of an inch in diameter. It may for convenience have an india-rubber tube fixed to its side or end, for the purpose of conveying the fluid to the pail or basin, but any other additions or alterations have not been improvements. Lately surgeons have been diminishing the size of the tube so as to withdraw the fluid more slowly, and taking many precautions to insure the wound being kept aseptic.

Where to Tap.—In the linea alba, midway between the umbilicus and pubes, or rather nearer the umbilicus. Here there are no muscles nor vessels, the opening is a dependent one, and the bladder is quite out of the way of injury.

N.B.—It is a wise precaution, in every case where there is a possibility of doubt as to the state of the bladder, to pass a catheter. I have myself known at least one case in which a surgeon was asked to tap an over-distended bladder as a case of ascites.

The Operation.—As there is great risk of syncope coming on during the operation, from the sudden relief to the pres-

sure on the organs, a broad flannel bandage should be applied to the belly, the ends of which are split into three at each side, and crossed and interlaced behind. An assistant should stand at each side to make gradual pressure by pulling on the ends of the bandage, thus assisting the flow, and maintaining the pressure. A hole should be cut in the bandage at the spot where the puncture is to be made, and the trocar inserted by one firm push, without any preliminary incision, unless the patient is inordinately fat. As the trocar is withdrawn, the canula should be pushed still further in. The surgeon should be ready at once to close the canula with his thumb, if the flow begins to cease, lest air should be admitted. If the flow ceases from any cause before all the fluid seems to be evacuated, the trocar should *not* be reintroduced, lest the intestines be wounded, but a blunt-headed perforated instrument fitting the canula should be inserted.

When all the fluid that can be easily obtained is evacuated, the canula is withdrawn, and a pad of lint secured over the wound by strapping.

Exploratory puncture of abdominal cysts or tumours is now a comparatively rare operation, its advantages being few and its dangers many. A thoroughly sterilized small aspirator needle may be used when it seems absolutely necessary to establish a diagnosis.

In the last decade, Surgery has made immense strides in the invention and performance of operations on the abdominal viscera. Much of this is owing to the labours of the gynecologists on ovarian and uterine tumours. Their magnificent results have given confidence in dealing with the peritoneum; the discovery of less irritating antiseptics than carbolic acid, and the growth of intelligence in the use of simple cleanliness and the disuse of drugs, have all helped to make results of surgical interference more

promising, and thus hardly any abdominal organ has been spared, and many new operations have been devised. In a work of this class, no detailed account of all these operations can be attempted, and the author would not advise any young surgeon to attempt to perform on the living body the operations now described without a much more elaborate study of authorities and prior operation on the dead subject. Still, as many of them are in the mouths of the profession, and some, by too sanguine examiners, are occasionally and most foolishly used as tests of successful or unsuccessful cramming, a short definition or explanation of some of the more important ones is now given.

1. **Gastrotomy**—*To open the Stomach to remove a Foreign Body.*—This is done either by an oblique incision, extending from a little below and to left of xiphoid for three or four inches, about an inch below the level of the costal cartilages, or by a straight incision along the outer edge of the left rectus muscle. All bleeding should be stopped before the peritoneum is opened. This should be done by a small aperture carefully enlarged on a director. The wall of the stomach and the foreign body will then be recognised. It is well, after exposing the stomach and selecting the spot for incision nearest to or most suitable for the extraction of the foreign body, to pass two guiding sutures through the muscular and serous coats. By these the stomach is brought up close to the wall, or to the sponge which should be inserted between it and the wall. The line of incision in the viscus will bleed less if it is made in a direction from one curvature across to the other. The viscus is then opened between the loops, and the surgeon gets a finger in to feel for the foreign body, which is then to be removed with as little pain and injury to the parts as possible. The wound in the viscus, unless it has been injured by much

handling, should then be at once sewed up by Lembert's sutures and returned to the abdominal cavity. M. Labbé, in his successful case, fastened the wall of the viscus to the wound by eight sutures before opening it. In any case, the stomach should be kept empty for a day or two. A typical example is that by Dr Bell of Davenport, who removed a bar of lead one pound in weight and ten inches in length, by an incision four inches in length from the umbilicus to the false ribs. The opening into the stomach was as small as possible, and required no sutures.

2. Gastrotomy for the Treatment of Disease of Œsophageal Orifice or of Pyloric Stricture.—In cases of non-malignant stricture of either aperture of the stomach, the organ is reached as above, and then incised either at its narrow end for pyloric stricture, or at its cardiac end for Œsophageal stricture or foreign body, and then fingers are inserted, first one and then a second, and the stricture thus dilated; considerable force and patience are required; the wound is then sewn up accurately, the viscus returned, and external wound also closed. This operation is chiefly associated with the name of the late Professor Loreta of Bologna, who did it in numerous cases, with good results in some.

Gastrotomy for Foreign Bodies in the Lower End of the Œsophagus.—Dr Richardson¹ of Harvard removed a plate with false teeth which stuck at cardiac end of stomach by introducing his whole hand into the stomach. Other cases have been recorded.

3. Gastrostomy.—The formation of a mouth in the stomach wall in cases of stricture of Œsophagus causing starvation is yearly becoming more frequent and more successful. It is now generally performed in two stages,—1. By an oblique

¹ *Lancet*, October 1887.

incision, as in gastrotomy, along the edges of the left costal cartilage, the peritoneum is exposed, opened, and stomach sought for. It is often found with difficulty, being contracted, and possibly bound down by the carcinomatous contractions. A portion is brought to the surface and carefully stitched by two rows of sutures to the most convenient part of the wound, the rest of which is then stitched up. After four or five days, when the edges are presumably safely adherent by inflammation, a hole, about the size of a No. 3 catheter, is carefully made in the stomach wall by a trocar and canula, through which a No. 2 catheter can be introduced. This is gradually enlarged, and a suitable tube fitted, through which, in successful cases, the patient can feed himself. He masticates his food so as to use his saliva, and spits it all, food and drink, into a glass funnel connected with the tube. In many cases death from starvation has been averted, and some have lived for months and years. The mortality in the earlier cases was very great, chiefly because the operation was delayed too late. The earlier the operation is performed after diagnosis is made the better chance has the patient of recovery. We owe to Mr Howse the method of doing this in two stages. For excellent details of the whole operation, see Holmes' *Surgery*, edition of 1883, vol. i. pp. 801-4; and an admirable pamphlet by Professor Senn¹ of Chicago.

4. **Pylorotomy**—*Removal of a Diseased, Ulcerated, or Cancerous Pylorus, and subsequent attachment of the Duodenum to a portion of the wound left in the Stomach, the rest of which is sewn up.*—An oblique incision over the tumour, wherever it is most easily felt, or even one in mesial line, first exposes the peritoneum; all bleeding must then be

¹ *Chicago Medical Recorder*, 1892.

checked (Billroth and Wölfler make their incisions almost transverse). The peritoneum is next opened, the tumour examined, and if suitable for removal, brought out at the wound. The pylorus and tumour must then be freed from their attachments to the greater and the lesser omentum. This must be done in separate portions by division between double ligatures of finest carbolised silk. The stomach must next be incised in its lesser curvature, see Fig. xxxiv. *c*,

FIG. xxxiv.*

and stitches inserted so as to be ready to close this portion of the wound. The rest of the stomach must then be carefully severed and cleansed, and the stitches at *c* secured. The duodenum is next to be severed, see Fig. xxxiv. *a*, from the disease, and secured accurately by stitches to the lower part (*b*) of the now diminished wound in the stomach. The stitches must be as close and accurate as possible, so as to render the whole wound impervious to fluids. This very tedious and difficult operation, which may be modified according to the position of the ulcer or cancer, will be easily understood by the diagrams.

* Rough diagram of incisions in pylorectomy.

The above operation owes most of its successes, which are not many, to the work of Billroth and his assistants.

FIG. XXXV.*

In cases where it is impossible from adhesions, the following—

5. **Gastroenterostomy** has been devised and adopted. It

FIG. XXXVI.†

is to make a permanent opening between the greater

* Stitches after pylorotomy.

† Gastroenterostomy.

curvature of the stomach and the jejunum, in cases where the pyloric cancer cannot be excised.

The operation is on the same lines as the preceding, but, instead of excision of pylorus, incisions about one and a half inches in length are made in greater curvature of stomach, and in the nearest loop of intestine, and the edges of these apertures united by sutures. Mr Barker had a successful case,¹ which may be consulted as possibly a typical one of that form of operation.

Senn's Method of Intestinal Anastomosis by the Use of Bone Plates.—This mode of operation, which is equally suitable for any portion of the canal, simplifies and shortens the operation. Oval plates are cut by a fine saw from the dense layer of an ox's femur. They are from two and a half to three inches in length, an inch in breadth, and quarter of an inch thick. After decalcification, purification, and careful drying under pressure, an opening is made by drill and file in the centre, five-eighths of an inch long and a sixth of an inch broad, and at the ends and sides of these oval openings² perforations for needles are made. The plates are kept in absolute alcohol, and before use are washed in a two per cent. solution of carbolic acid. The plates are threaded with silk or chromicized³ gut. A suitable portion of stomach and intestine, or intestine and colon, having been selected according to the nature of the case, incisions are made in each, bone plates inserted, and sutures tied so as to bring with certainty and rapidity the serous coats into approximation. For the very elaborate and precise directions as to mode of suturing, the works referred to must be consulted. Other materials than bone have been tried, such as catgut

¹ *British Medical Journal*, Feb. 1886.

² *Intestinal Surgery*, Chicago, 1889.

³ Jessett, *Surgery of Intestines*; Beatson, *Lancet*, Oct. 1890.

hanks, india-rubber tubing, cartilage, and rawhide plates,—the latter were found very useful.

Duodenostomy.—The idea is, in cases of gastric or pyloric cancer, to cut down on the duodenum by practically the same operation as for pylorotomy, but, instead of excising, to stitch the anterior wall of the duodenum to the wound, and treat it as the stomach is treated in gastrotomy. The patient is then to be fed with peptonised food, or food which he himself has chewed. This operation is not likely to prove useful, and gastro-enterostomy will probably take its place.

Enterectomy, or cutting out a portion of the intestine, and uniting the divided ends by suture, has most commonly been done in cases of gangrene of bowel after a strangulated hernia. **Laparo-enterectomy** is perhaps a more accurate name for those cases in which a portion of bowel has been removed by an incision in the abdominal wall for cases of stricture or tumour, or inseparable adhesions of bowel. In either case the operation is difficult and tedious, requiring—(1), careful management of the mesentery involved; (2), careful stitching the bowel surfaces to each other. Various sutures have been devised, and most ingenious instruments to clamp the bowel on each side during the operation, and to keep in good position the ends to be sutured. Full details of all these may be found in the works of Treves, Arthur Barker, and Senn.

It is enough here to point out that, as to the sutures, all are agreed that in all these operations on intestinal tract the great object is to bring the serous surfaces into the closest possible apposition, and for this end deep sutures may be passed through the muscular coat also, so as to double in the two opposite margins, and bring their serous surfaces flat together; while, at the same time, it is of great im-

portance *not* to include the mucous coats, lest the contents of the intestine should enter the track of the thread, and thus in time contaminate the peritoneum. In stomach operations this is especially important, from the well-known power of the gastric juice to digest other substances and surfaces except the mucous one.

Operations on the Liver and Gall-bladder.

Incision for Hepatic Abscess or Hydatids.—This may be done either in one stage, or in two at an interval of a few days. A. At one operation. An incision of sufficient length, probably from three to four inches, is made over the most prominent part of the swelling to the front. The peritoneum is exposed and divided, and liver can be recognised. After carefully packing the wound at its edges, the swelling may then be punctured by a fine trocar, and after the contents are reached, the knife, followed by a finger, enlarges the wound without risk of hæmorrhage. After evacuation and cleaning the liver wound must be carefully and firmly sutured to the external wound, the cyst or abscess thoroughly emptied and drained. Antiseptic dressings and pads are required. B. In two stages. In this method, after the organ is exposed, the edges of parietal peritoneum are stitched to the edges of the wound, which is plugged with dry gauze dressings. After three or four days adhesions will have taken place between the visceral and parietal surfaces of peritoneum, and the organ can be incised without risk of any leakage into the peritoneal cavity.¹

Operations on Gall-bladder, either for wound, dropsy, empyema, or gallstones. Probably there is no surgical area in which greater progress has been made during the

¹ Jacobson, *The Operations of Surgery*, p. 794.

last lustrum than that of the gall-bladder. This we owe in great measure to Mr Lawson Tait¹ and Mr Mayo Robson.²

The great object of operative treatment is the removal of the offending material—bile, pus, or calculus—with at the same time absolute prevention of the escape of bile into the peritoneal cavity.

Aspiration of the gall-bladder, which has been recommended by Dr Harley and others, is much more dangerous and less satisfactory than abdominal section and incision or excision. The whole question is most admirably treated, historically and practically, in Mr Greig Smith's excellent work on abdominal surgery.³

Cholecystotomy.—Incision of the gall-bladder. The best parietal incision is one made vertically over the most prominent part of the tumour, or if there is no marked tumour the tip of the cartilage of the tenth rib. After dividing the wall in the usual way, the peritoneum must be most cautiously opened, and the gall-bladder explored by forefinger. If the cyst is large the walls will probably be thin, and it will require careful handling, not only to prevent escape of contents into the peritoneum, but also to avoid injury of the edges; a trocar must be used to diminish the tension of the contents, and thus enable the cyst to be drawn out into the wound before it is opened. The finger, after a small opening has been made, explores the contents. If there are stones present they must be cautiously removed by suitable forceps, and then the opening of the gall-bladder must be sutured to the edges of the parietal wound. Tait approves a continuous suture, including skin, parietal peritoneum, and

¹ *Edinburgh Medical Journal*, 1889-90.

² *On Gallstones and their Treatment*, 1892.

³ Mr Greig Smith's *Abdominal Surgery*, 4th edition, p. 611.

cyst wall. The gall-bladder should then be drained by a large rubber drainage-tube stitched to the wall, which may be left so long as to drain all the bile into a bottle at the bedside.

Note.—So much depends on the precise details of the technique of this and many of the other operations on liver and kidneys, that no surgeon should think of performing them without a thorough study of the special monographs above cited, or still better, without seeing a master in this art at work.

Cholelithotriety.—It is not always an easy matter to remove gallstones even after incision of the gall-bladder. The stone may be large or adherent, the walls of cyst and ducts are friable, so, rather than risk a peritoneal biliary fistula, which would be almost certainly fatal, a lithotriety may have to be done. Tait, Mayo Robson, and others, record such cases, some crushed by finger and thumb or padded forceps through the walls, others nibbled at by forceps through the ducts.

Cholecystectomy, or excision of the gall-bladder, is recommended by some, as Langenbach, in preference to cholecystotomy, as being less dangerous to life and less liable to biliary fistula. The less danger seems doubtful, for indeed the balance of evidence seems now the other way. It will probably be reserved for cases in which the gall-bladder has been so contracted and diseased that it cannot be attached to the wall after it has been incised, or where fistulæ prevent operation by the same incision as in cystotomy; but after it has been exposed the gall-bladder must be separated from the liver by fingers or scissors, till it is attached only by the cystic duct, which must be isolated, tied with silk, and then cut across.

Cholecystenterostomy.—This operation aims at the

establishment of a fistula between the gall-bladder and the intestine. This operation has been done at least seven times; the communication being with colon, duodenum, and small intestine in two, two, and three cases. One died soon after the operation, two of cancer at longer intervals; four recovered.¹

Operations on the Kidneys.

1. **Nephrotomy.**—Incision of a diseased or cystic kidney.

Operation.—An incision slightly oblique in the space between ribs and ilium, extending forwards for three or four inches, as in lumbar colotomy, but about an inch behind it. It is extremely important to recognise and define accurately the position of 12th rib before beginning operation, and give plenty of room in the incisions in skin. Divide skin, fat, and fascia; expose posterior border of external oblique and outer border of latissimus dorsi; divide them as far as necessary; then divide internal oblique and transversalis fascia, so as to expose outer border of quadratus lumborum, and the lumbar aponeurosis. Mr Greig Smith² suggests that if quadratus cannot be retracted to give sufficient room the encroaching fibres may be divided by strokes of scissors. Now, keeping behind the line of the colon, the peritoneal fat will be seen, and kidney may be felt, incised, and drained. In cases of enlargement the incision may have to be further forward, and in cases of abscess pointing, the position where it is red and near the surface should be selected.

2. **Nephro-lithotomy.**—The first stages of this operation are as in the preceding, but possibly more room may be needed, and can be got by dividing fibres of the quadratus.

¹ Delagenière's *Monograph*, 1890, quoted by Mayo Robson, *op. cit.*

² *Op. cit.*, p. 530.

The kidney must be then carefully felt all over, first by the finger, and then by the insertion of needles, till the stone is felt or struck. When found, the organ above it should be incised sufficiently to allow the finger to enter. The finger can then lacerate the renal tissue sufficiently to give egress to the calculus, which can be lifted out either by finger or forceps. There is less risk of a fistula in opening through the renal tissue than when the pelvis of the organ is incised.

3. Nephrectomy.—Excision of a kidney may be done either—(a) by lumbar method, (b) abdominal.

a. Lumbar Nephrectomy.—The selection of a suitable case is sometimes difficult, and the operation by either method is dangerous, the lumbar being somewhat the less dangerous of the two. In malignant disease nearly 70 per cent. are fatal; for strumous kidney the mortality is 36 per cent.¹; also see Newman's statistics.² Various incisions are advised, probably the best is one recommended by Morris.³ In this the usual incision for nephrectomy is carried up as near to 12th rib as the pleura allows (half an inch at least below it), and extended forwards for four and a half inches; a second incision, longitudinally downwards, starts about an inch anterior to the posterior extremity of the first.

The kidney is now to be raised and separated by the finger if possible. The ease with which that can be done varies according to adhesions from inflammation. The pedicle then must be divided in two halves by passing an aneurism needle with strong silk thread through its centre. Each half must be securely tied, and then cut; and great care must be taken to stop all bleeding. The

¹ Greig Smith, *op. cit.*, p. 575.

² *Surgical Diseases of Kidney*, 1888.

³ *International Encyclopædia of Surgery*, vol. v. p. 1089.

wound must be drained, and if possible the portion of ureter left rendered aseptic.

Thornton recommends that if the ureter is thickened or ulcerated, its divided end should be fixed in the wound of the parietes. If peritoneum has been opened accidentally, the wound in it should be stitched with catgut.

b. Abdominal Operation.—By an incision at the outer edge of the rectus of the side to be removed. The middle part of the incision will probably correspond to the umbilicus. The intestines must be drawn forwards, and the outer layer of the mesocolon opened, so as to allow two or three fingers into the cellular tissue behind the peritoneum till the renal vessels are reached, which can then be tied at leisure, and the organ removed.

As regards the selection of operation. Newman's statistics show that the mortality in lumbar nephrectomy is 30·5 per cent., in ventral 50·8 per cent. This must be partially discounted, by remarking that the larger and possibly the worst kidneys are chosen for the ventral operation, and also that the ventral method enables the surgeon to obtain valuable information as to the condition of the other kidney. In lean subjects either operation is much easier than in fat ones.

Nephrorraphy, or fixation of a movable kidney or a floating kidney.—The exact pathology of these two conditions, which, though allied, are not identical, is still *sub judice*. But practically there are a certain number of kidneys which by their mobility cause severe and intense symptoms, justifying operative interference.

After exposing the kidney by an incision almost identical with that used by Bryant in lumbar colotomy, it is forced as far as possible by an assistant towards the wound. The fatty tissue, and even the fibrous capsule of the kidney

should be freely exposed and irritated by an aseptic finger. Three or four sutures of chromicized gut or silk-worm gut should then be inserted in capsule, or even through renal tissue, and through the margins of the incisions. The wound should be kept open and mechanically irritated by a large rubber drainage-tube till suppuration begins. Mortality has been small—138 cases, 4 deaths.¹

Splenectomy.—The spleen has been successfully removed frequently in cases of wound or protrusion after injury. Ashhurst² has collected twenty-one such operations, all successful. When disease has caused the removal, the mortality has been very great. So far as I can discover, all the cases in which it has been removed for leucocythæmia have died, while out of some thirty-three for other diseases collected by Wright of Manchester sixteen have recovered. Bryant's dictum is excellent. "Splenectomy in leucocythæmia is physiologically unsound and surgically unsafe." The operation in traumatic cases has generally been performed through the original wound or by extension of it.

For disease the middle line of the abdomen is generally selected, but if the diagnosis is certain the outer edge of the left rectus is more convenient. Great care must be taken to avoid and stop bleeding from adhesions, and in lifting up the organ to avoid rupture of its capsule, or too sudden tearing of the splenic vein. The pedicle must first be clamped, and then carefully tied in many portions, each having been carefully divided between two pairs of pressure forceps; after every one of these has been separately secured, then the whole lot may be surrounded by a moderately tight ligature to lessen the shock of the arterial pulse.³ Hæmor-

¹ Greig Smith, *op. cit.*, 527.

² *International Encycl. of Surg.*, vol. v. p. 1103.

³ Greig Smith, *op. cit.*, 642.

rhage has caused most of the deaths, but shock is sometimes most alarming.

Ovariectomy.—For the pathology of ovarian disease we must refer to Sir Spencer Wells' work on the subject, and to Mr Alban Doran's excellent work on *Pathology of the Ovaries and Tubes*, 1884.

Even the modifications in the method of operating which have been devised are so various and numerous, that if collected from the medical journals of the last ten years they would fill a large volume. Besides this, the operation of ovariectomy is one attended by so many complications, that individual cases vary from each other as much as do individual cases of hernia and tracheotomy; and as the specialities of each case require to be met by specialities of treatment, there is hardly any operation in surgery which requires greater readiness of invention, or more individual sagacity in the operator.

To lay open the abdominal cavity from the sternum to the pubes, and rapidly dissect out of this cavity an enormous tumour with a narrow neck, the operator's only embarrassment being the peristaltic movements of the bowels, and his only care being to tie the neck of the tumour firmly with strong string, sew up the wound, and trust to Nature, was an operation very easy to perform, and requiring free cutting rather than dexterity, and rashness more than true surgical insight.

Such were most of the ovariectomies prior to 1857, though Clay of Manchester had twenty-one cures out of thirty-three operations prior to 1850.

An ovariectomy in 1892 is a very different business, varying in certain important particulars.

(1.) Instead of the incision extending from sternum to pubes, it is now made as short as possible.

(2.) Instead of being removed entire, the cyst is now emptied with the greatest possible care (prior to its removal), and none of the contents allowed to enter the peritoneal cavity.

(3.) The pedicle is treated with great care, so that it may not either bleed or putrefy. By very few is the clamp now used. The more usual method is to transfix the pedicle, and tie it with extreme care in two or more portions. Dr Keith, however, uses the cautery, and regards it as a point of chief importance to thoroughly heat the clamp so as to dry the part of the pedicle between its blades, with a result in private cases of a mortality of 2 per cent.¹ The cautery should not be heated beyond a dull red heat, and be applied slowly.

Besides these three important and cardinal points, there are other minor matters almost equally essential; these are—(1), the proper management of the adhesions and the thorough prevention of all hæmorrhage from them; (2), the stitching up of the external wound, including the peritoneum; (3), the treatment of the patient during the first few days of convalescence.

Operation in a typical case, after the method of Sir Spencer Wells and Dr Thomas Keith.—The patient having had her bowels gently opened on the previous day, and being as far as possible in her usual state of health, should be warmly clad in flannel both in body and limb, and laid on an operating table of convenient height, in or near the room she is to occupy. No carrying from ward to operating theatre and back again is admissible. It will be found both cleanly and convenient to have a large india-rubber cloth over the whole abdomen, cut out in the centre so as to expose so much of the tumour as is necessary, but gummed on

¹ Greig Smith, *op. cit.*, p. 126.

or otherwise secured to the sides of the abdomen, and thus protecting the clothes, and hanging down over the edge of the table; this will prevent all wetting of the clothes and unnecessary exposure of the patient's person, and can be easily removed after the operation. Chloroform or ether being administered, the bladder is evacuated by means of a catheter, and the patient's head and shoulders are elevated on pillows. An incision is then made in the linea alba, between the umbilicus and pubes, for about two to three or four inches in length at first, according to circumstances, through all the tissues down to and through the peritoneum. Care is necessary in dividing the peritoneum, on the one hand, not to divide too much, in which case the cyst-wall will be penetrated, and the contents effused into the peritoneal cavity; or, on the other hand, too little, in which case the peritoneum may be mistaken for the cyst, and separated from the transversalis fascia under the idea that adhesions exist. Once the peritoneal cavity is opened, the incision through the peritoneum must be extended to the full length of the external wound by a probe-pointed bistoury.

The cyst-wall is now exposed. The anterior portion of the cyst-wall is now visible, and if the surgeon finds it contains fluid, he now pierces it with a large trocar,¹ to which

¹ *Description of Sir Spencer Wells' Trocar.*—"It consists of a hollow cylinder six inches long, and half an inch in diameter, within which another cylinder fitting it tightly plays. The inner one is cut off at its extremity, somewhat in the form of a pen, and is sharp. The sharp end is kept retracted within the outer cylinder by a spiral spring in the handle at the other end, but can be protruded by pressing on this handle when required for use. When thus protruded it is plunged into the cyst up to its middle; the pressure on the handle is taken off, and the cutting edge is retracted within its sheath. The fluid rushes into the tube, and escapes by an aperture in the side, to which an india-rubber tube is attached, the end of which drops into

is attached an india-rubber tube, by means of which the effused fluid can be easily got rid of in any direction, or, as Dr Keith prefers, a large exhausting aspirator. During the escape of the fluid from the cyst it becomes flaccid, and should be gently and steadily pulled out of the wound by Wells' forceps. In cases where the cyst is multilocular, and thus only a portion of the contents of the tumour is at first evacuated, the operator should, by partially withdrawing the trocar, without removing it entirely from the cyst, endeavour to pierce and evacuate the other cysts, still through the original opening in the first one.

While doing this, great care must be taken lest he pierce the external wall of the tumour, and let any of the contents escape into the abdominal cavity; to guard against this the punctures should be made by the right hand, while the left, reinserted into the abdomen, supports the cyst-wall.

The tumour having been as far as possible emptied of its fluid contents, must now be dragged out of the wound, care being still taken lest any of its fluid contents escape into the peritoneal cavity. In favourable cases the pedicle is now brought easily into view. This may vary very much in length and thickness. It is sometimes entirely absent, the tumour being sessile on the broad ligament of the uterus; sometimes it is thick and strong, sometimes long and slender. The manner in which it is treated has varied in the most remarkable manner. At present two chief methods are used. 1. The clamp and cautery as used

a bucket under the table. The instrument is furnished at its middle with two semicircular bars, carrying each four or five long curved teeth like a volsellum. These teeth lie in contact with the outer surface of the cylinder, but can be raised from it by pressing two handles. When the cyst begins to be flaccid by the escape of the fluid, these side volsellums are raised, and the adjoining part of the cyst is drawn up under the teeth, where it is firmly caught and compressed against the side of the tube."

by Keith. In this the pedicle is flattened out at a convenient distance between the two strong blades of the clamp and compressed by it. The tumour is then cut off with scissors about half an inch from the clamp. The clamp is then protected below by wet cloths, and the large cauteries are rubbed up and down the blades of the clamp till the line of pedicle is smooth and level, and the "stump terminates in a thin gray margin of dry translucent texture."¹

2. The ligature. Silk is now most in use, though some operators use specially prepared catgut. Many methods of tying are used, but Tait's Staffordshire knot seems to be the favourite method. His own description is—"An ordinary handled needle, armed with a long piece of the silk required, is passed through the pedicle and then withdrawn so as to leave a loop on the distal side. This loop is then drawn over the ovary or tumour, and one of the freed ends drawn through it, so that one end is above, while the other is under the retracted loop. Both ends being seized in the hand, they are drawn through the pedicle, against which the thumb and forefinger of the left hand are pressed, as a fulcrum, till complete constriction is made. A simple hitch is then made and tightened, and that is followed by another, as in ordinary ligature tying. He claims for this knot that while it ties the pedicle in two halves these halves are compressed really into one surface, the two halves are equally well compressed, and from the mechanical arrangement of the knot very great constricting force can be employed."²

The toilet of the peritoneum is of great importance, and one of the chief factors in the success of any operator is his instinctive knowledge of how much or little cleansing the

¹ Greig Smith, *op. cit.*, p. 143.

² *Ibid.*, p. 144.

peritoneum requires, and whether or not he should use drainage.

Keith's glass tubes are now generally in use, and a safe maxim seems to be—"When in doubt, drain."

The wound is now to be sewed up by several points of interrupted suture, some inserted very deeply through all the tissues, including even the peritoneum, others in the intervals of the first, including little more than the skin. They may be either of iron, silver, platinum, telegraph-wire (Mr Clover's copper, coated with gutta-percha), or silk. It seems of very little consequence which is used. Sir Spencer Wells, after many trials, uses silk, as being removed with least pain to the patient, and really causing no more supuration than the metallic ones do, if only removed early enough, viz., about the second or third day, by which time the union of the wound should be firm. Bantock, Greig Smith, and others, use silk-worm gut.

The after-treatment should be very simple. Except under special circumstances stimulants are rarely necessary, and indeed, to avoid vomiting, as little as possible should be given by the mouth during the first twenty-four hours. The patient should be allowed to suck a little ice to allay thirst, and opiate and nutritive enemata will be found quite sufficient to keep up the strength in ordinary cases. The urine should be drawn off by the catheter every six hours. The room should be kept quiet, and the temperature equable, so long as there is no interference with a plentiful supply of fresh air.

Some of the specialities and abnormalities involving special risks may now be briefly noticed:—

1. *Adhesions*.—These vary much in amount, in position, in organization, and danger.

a. In amount.—In certain cases no adhesions exist, while in others, omentum, intestines, tumour, uterus, and ab-

dominal wall may be all matted together in one common mass.

b. In organization.—Occasionally they are so soft and friable as to break down under the finger with ease, and so slightly organized as not to bleed at all in the process, while again they may be so firm and close as to require a careful and prolonged dissection, and so vascular as to require many points of ligature to be applied to large active vessels.

c. There are special *dangers* connected with the presence of these adhesions, and varying much in different cases. Thus adhesions to the intestines can generally be separated with comparative ease, and seem, as a rule, to require the application of fewer ligatures than those which unite the tumour to the abdominal wall. Soft and recent adhesions are easily separated by the use of a sponge, others require to be peeled off by fingers, and some larger and older ones need division between two pairs of forceps. Adhesions to the wall are sometimes so firm as to be quite inseparable, and thus to necessitate some of the cyst-wall being left adherent. In Sir Spencer Wells' cases, adhesions to the liver and gall-bladder occasionally occurred, requiring careful dissection to separate them, and yet the patients all survived, while pelvic adhesions, especially to the bladder and uterus, on more than one occasion prevented the completion of the operation.

Vascular adhesions to the wall which require many ligatures certainly add to the dangers of the case, while adhesions to the anterior wall of the abdomen render the operation, especially its first stages, much more difficult, preventing the cyst from being recognised.

2. *The condition of the pedicle* is of great importance. If short and thick, the transfixion and ligature will require great care and caution that every bleeding point be secured,

and it may make even the use of the cautery more difficult.

Dr Keith for a time operated with antiseptic precautions, but has now for some years entirely given up the use of the spray, which he believes has especial dangers in abdominal surgery.

Removal of Uterine Appendages.—This operation is associated in this country with the name of Lawson Tait, in whose papers every information as to suitable cases, treatment, and results will be found. Enough here as to the operation to say that it varies much according as the appendages are normal or diseased. The operation is easy in the one case, most difficult in the other. I give a short abstract of Mr Greig Smith's¹ admirable description. A mesial incision between umbilicus and pubes, from $1\frac{1}{2}$ to 2 inches in length, exposes linea alba, and after its division the subperitoneal fat. Bleeding is stopped by pressure forceps, peritoneum opened and divided. Two fingers are then inserted under the omentum down to the fundus uteri, and then used as forceps, one on each side of the broad ligament, till ovary, mesovarium, and oviduct are felt and lifted out of wound and spread out; the pedicle is pierced by blunt needle, and tied in two halves by Tait's Staffordshire knot. The parts to be cut away are then removed by snips of scissors, the pedicle examined for bleeding, then dropped into abdomen, and the same is done on the other side. Wound is sewn up after all is cleansed. If, however, parts are inflamed and adherent, it is a more serious business, and one of two courses may have to be selected. Tait trusts to his skilled and experienced sense of touch, and does the dissection and separation of parts with his fingers unaided by sight, and trusts to sponge packing and styptics to check

¹ *Op. cit.*, pp. 198-209.

the bleeding. Other surgeons regard this as unscientific, and suggest opening the pelvis with a more free incision, and even the raising of the intestines to give space.

Hysterectomy for Myoma by Abdominal Incision.—1. If pedunculated, a free incision in middle line below umbilicus allows the whole hand to be inserted and the tumour examined. If removal is indicated, the incision is extended upwards sufficiently far to allow tumour to be removed without straining the edges of the wound.¹ Tait's screw inserted deeply into the tumour makes an excellent handle with which to raise the tumour, adhesions are then to be separated, and pedicle sought for. Its treatment is the most important point, and varies with its size, length, and thickness; ligatures—single, double, or more numerous—applied either round the whole pedicle or by transfixion, or to each bleeding point. Some surgeons use elastic ligatures in cases where, from amount of uterine tissue included in the pedicle, shrinking of it may be expected. 2. Where whole or part of uterus has to be removed, clamps and transfixion pins will then be required to arrest hæmorrhage in the pedicle,² which is often enormous in size. Each case must be dealt with on its own merits, and will tax the ingenuity and courage of the surgeon.

Vaginal Hysterectomy for Malignant Disease.—Only the principle which should guide the operator can be given here. The reader may be referred to Mr Greig Smith's³ work, or to Mr Alban Doran's work on Gynæcological Operations.⁴

Parts must be most carefully rendered aseptic by frequent and careful washings. The patient is put in position for perineal

¹ Keith, *British Medical Journal*, Dec. 1887.

² See Greig Smith, *op. cit.*, p. 263.

³ *Op. cit.*, p. 224.

⁴ P. 318.

lithotomy, the uterus is to be seized by powerful volsella, and the surgeon then dissects the vaginal mucous membrane from the cervix by scissors. While the bladder is carefully protected and defined, the operator keeps as close to the uterus as possible in his dissection, and when the peritoneum is reached opens it with his forefinger or pair of sinus forceps. The uterus has then to be hooked down, and broad ligaments and uterine vessels secured, either by ligatures as in an ovariectomy, or if the ligatures cannot be safely fixed, by the use of temporary pressure, by forceps or clamps. Either of these, if used, should not be left *in situ* too long, in case of sloughing. No suturing of peritoneum or vaginal wall is needed.

Puerperal Hysterotomy or Cæsarean Section.—An incision in middle line of abdomen passing the umbilicus at its left, and not reaching the pubes by at least two inches. The gravid uterus is then made to bulge forward, the edges of the parietal wound being protected by flat sponges. The uterus is then to be incised opposite the first wound, beginning at its upper end by an incision sufficiently long to admit a finger. On this finger as a guide the rest of the incision is rapidly made by scissors. The child is then to be extracted head first if possible. Its umbilical cord must be divided between two pairs of forceps; child handed over to an assistant, while the surgeon waits till the uterus contracts and the placenta is expelled. If extraction is delayed or hæmorrhage is excessive, possibly the uterus may have to be removed by Porro's method, *q. v.* If all goes well, is the uterus wound to be stitched or not? Of late years sutures in two rows, superficial and deep, are used; deep ones are to bring together as much muscular surface as possible, while the superficial ones are so arranged as to invaginate and bring together serous surfaces of peritoneum.

Porro's Operation is a Cæsarean section followed by removal of the body of the uterus, with ovaries and oviduct. The Cæsarean section having been finished, instead of delivering the placenta it may be left attached, and the uterus is at once hooked out of the abdomen through the wound in parietes, and wound is protected by sponges. The uterus is then to be constricted by a wire which can be tightened by a *serre-nœud*, and then cut off about an inch above the constriction. The stump is then to be brought out to the lower corner of the abdominal incision, fixed by pins of transfixion or by the clamp. It must be trimmed, and as far as possible reduced in size, and its central mucous membrane scraped out, rubbed, and dried with boracic powder, and dressed with absorbent wool. Some surgeons advise the wire to be daily tightened up till the pedicle comes away; but others, especially Greig Smith,¹ from whose admirable work this abstract is chiefly taken, finds this unnecessary.

Operation for Strangulated Inguinal Hernia.—The great rule to be remembered with regard to this, as well as all other operations for hernia, is, that the earlier it is performed the better chance the patient has. Once a fair trial has been given to the taxis, aided by proper position of the patient, the warm bath, and specially chloroform, the operation should be performed.

The patient should be placed on his back with his shoulders elevated, and the knee of the affected side slightly bent. The groin should then be shaved, and the shape and size of the tumour, with the position of the inguinal canal, carefully studied. The surgeon should then lift up a fold of skin and cellular tissue, in a direction at right angles to the long axis of the tumour, and holding

¹ *Op. cit.*, p. 296.

one side of this raised fold in his own left hand, commit the other to an assistant. He then transfixes this fold with a sharp straight bistoury, with its back towards the sac, and cuts outwards, thus at once making an incision along the axis of the hernia without any risk of wounding the sac or bowel. Any vessel that bleeds may now be tied. This incision will be found sufficiently large for most cases; if not, however, it can easily be prolonged either upwards or downwards. The surgeon must now devote his attention to exposing the neck of the sac, and in so doing, defining the external inguinal ring. The safest method of doing so is carefully to pinch up, with dissecting forceps, layer after layer of connective tissue, dividing each separately by the knife held with its flat side, not its edge, on the sac, and then by means of the finger or forceps raising each layer in succession and dividing it to the full extent of the external incision. It is not always an easy matter to recognise the sac, especially as the number of layers above it, which are described in the anatomical text-books, are often not at all distinct.

The thickness of the connective tissue of the part varies immensely; sometimes six layers or even more can be separately dissected, while, again, one only may be found before the sac is exposed.

If small and recent, the sac may be recognised by its bluish colour, and by the fact that it is possible to pinch up a portion of it between the finger and thumb, and thus to rub its opposed surfaces against each other.

If large and of old standing, it is sometimes so thin as not to be recognisable, or again so enormously thickened, and so adherent, as to be defined with great difficulty.

If it is small, *i.e.*, when the whole tumour is under the size of an egg, it ought to be thoroughly isolated, and its

boundaries everywhere defined. If large, and specially if adherent, the neck alone should be cleared.

The sac thus being reached, the external abdominal ring should be clearly defined, and the finger passed into it, so as if possible to determine the presence or absence of any constriction in it. If it feel tight, the internal pillar of the ring should then be cautiously divided on the finger by a probe-pointed narrow bistoury, in a direction parallel to the linea alba.

At this stage the question comes to be considered as to whether the sac should or should not be opened. Much has been said and written on both sides.

Not to open the sac avoids the risk of peritonitis, and of injury to the bowel; but, on the other hand, exposes the patient to the danger of the hernia being returned unreduced; for in many cases the stricture is to be found in the sac itself, and adhesions very rapidly form between coils of intestine in the sac and the inner wall. Again, not to open the sac prevents us from discovering the condition in which the bowel is; it may possibly be gangrenous, in which case such a return *en masse* would be almost necessarily fatal.

A general rule or two may be given here:—

1. The sac should be opened in every case where there is any reason for doubt about the condition of the bowel, where there has been long-continued vomiting, or much tenderness on pressure.

2. Even in cases in which there is every reason to believe the bowel is perfectly sound, the sac should be opened, unless the whole contents can be easily and completely reduced out of the sac into the belly, as in cases where this cannot be done there probably exist either a stricture in the neck of the sac itself, or adhesions of the bowel to the sac. We should endeavour to avoid opening the sac in cases of old scrotal hernia of large size, where the symptoms have

not been urgent, especially in large unhealthy hospitals, as the risk of peritonitis is so great. Antiseptic precautions considerably diminish the risk of opening the sac, and each decade the number of cases in which the sac is not opened diminishes, so that now it is rare to find it left unopened.

If the sac then is not to be opened, the rest of the operation is very simple. Endeavour to reduce the bowel out of the sac, and then return the sac itself, unless the hernia is of old standing, and adhesions prevent its reduction. A few silver stitches to close the wound and a carefully adjusted pad are now all that is requisite.

If the sac is to be opened, how can it be done with least danger to the bowel?

If the hernia is small, and it is possible to define it all, the sac should be opened at its lower end, as *there* a small quantity of serous fluid which intervenes between the sac and the bowel will be found. Where this is present, there is no danger of wounding the bowel, as the sac can be easily pinched up; but this is by no means invariably the case, so great care should always be taken. A small portion of the wall being thus pinched up should be divided in the same manner as the layers of cellular tissue were divided in exposing the sac. A few drops of serum will then escape, and the glistening surface of the bowel be exposed; the finger should then be introduced at the opening, and the incision enlarged by a probe-pointed bistoury. If the hernia is small the sac should be slit up to its full extent; if large, only a sufficient portion of the neck should be opened. As soon as the opening in the sac is large enough to admit the point of the operator's forefinger, it should be inserted so as to protect the intestines, and the remainder of the sac slit up on it as a guide.

The sac thus opened, the next step is to divide the constriction, wherever it be. It is most likely to be found at

the neck of the sac, just where it protrudes through the internal ring in an oblique hernia, or through the tendons of the transversalis and internal oblique, where the hernia is direct. Now, this constriction might be divided in any direction were it not for the risk of wounding the epigastric artery, and also of injuring the spermatic cord, which is in close relation to the neck of the sac of an oblique hernia.

Wound of the epigastric artery is the chief danger, for in *all* cases it is close to the neck of the sac. Were its position in relation to the neck of the sac constant, it might be easily avoided by an incision in the opposite direction; but as this relation varies according to the nature of the hernia, an element of danger is introduced. Thus, in oblique inguinal ruptures, where the sac passes out through the internal ring (Fig. xxxvii. 1 R), the artery will always be found to the inside of the neck of the sac; while in direct herniæ, where the bowel has made its escape through the triangle of Hesselbach (Fig. xxxvii. +), and passed through the conjoint tendon straight to the external ring, the epigastric artery will be found on the outside of the neck of the sac. In recent herniæ the differential diagnosis is comparatively easy, but in those of old standing and large size, in which the obliquity of the canal has been much diminished, it is almost impossible to tell of what kind the hernia originally was, and consequently to determine in which direction it is safe to incise the neck of the sac.

Such being the case, the best rule is to incise the neck of the sac directly upwards, *i.e.* in a line parallel with the linea alba, and also to cut it very cautiously bit by bit, in every case, if possible, with the finger inserted as a guide to the position of a vessel and a protection to the gut.

The spermatic vessels lie sometimes behind, sometimes on either side of the sac, and in very old herniæ may

be separated from each other so as really to surround the sac. The cut directly upwards is also the safest for them.

All constrictions being overcome, it is not sufficient merely to push back the gut into the belly. Its condition must be carefully examined, and it must be decided whether the constriction has caused gangrene or not. To examine this properly, it is generally best to pull down an inch or two more of the gut, so as thoroughly to bring into view the constricted portion, as it is most likely to be fatally nipped.

It is not always easy to decide as to the condition of the bowel. Certain points must be observed:—

(1.) *Colour*.—There may be very great alteration in the colour of the bowel from congestion, and yet no gangrene. It may be dark red, claret, purple, or even have a brownish tint, and yet recover; where it is black, or a deep brown, the prognosis is unfavourable.

(2.) *Glistening*.—So long as the proper glistening appearance of the bowel remains, there is hope for it, even when the colour is bad; if it has lost it, and especially if, instead of being tense and shining, it is dull and flaccid and in wrinkles, the bowel is almost certainly gangrenous.

(3.) *Thickness*.—If much thickened, and especially if rough on the surface, the bowel has probably been forming adhesions to the sac, or to contiguous coils, and the prognosis is less favourable.

(4.) *Smell*.—The peculiar gangrenous odour on opening the sac is very characteristic. In cases where ulceration and perforation have occurred, the odour is fæcal.

1. If, then, the bowel is tolerably healthy-looking, though discoloured, it should be returned gradually, not *en masse*, into the abdomen, the wound sewed up, and an antiseptic pad put on, with a bandage.

2. If there are adhesions of bowel to sac or to a neigh-

bouring coil, or of omentum to sac, the stricture should be freely divided, the protruding coils of intestine should be emptied of their contents, but no rash attempt made to force their return. Especially is this rule to be observed with protruded, swollen, or adherent omentum, for considerable risks attend any attempt at excision of the protruded portion—risks of hæmorrhage, peritonitis, and ulceration of the contiguous bowel.

If the bowel be returned, or even the continuity of the canal restored by the cutting of the stricture though the bowel be not returned, no great risks accrue from the retention of a piece of omentum in the sac, in a position which it may possibly have already occupied for years.

3. If the bowel is absolutely gangrenous, even in a very small portion of its length, no reduction should be attempted, but the gangrenous portion should be kept outside, with the hope that adhesive inflammation may be set up, so as to glue the bowel to the abdominal wall, prevent fæcal extravasation, and form a temporary artificial anus. If the gangrenous portion be very full of fæces or flatus, incisions may be made into it. This should be avoided in cases where the patient is already much prostrated, as I have seen cases in which the opening of the bowel seemed to inflict a fatal shock.

Enterectomy or excision of the gangrenous portion has been gradually gaining in favour. The divided ends of bowel and edges of omentum must be brought together by suture, or intestinal anastomosis managed by decalcified bone plates. The great practical difficulty in each case is the personal equation. Can the patient, who is presumably exhausted and collapsed, as a result of the presence of gangrenous bowel, bear the extra exposure and shock of a prolonged operation on the intestinal canal, or has he not a better chance of recovery by the establishment of an artificial anus,

which can be afterwards dealt with by operative procedure.

Cases of gangrene of even large portions of bowel are by no means necessarily fatal. They may recover with an artificial anus, the remedy of which by surgical means we must notice in its proper place.

Operation for Strangulated Femoral Hernia.—While the general principles guiding treatment and ruling the conduct of the operation are the same as in inguinal, there are some differences in points of detail which render a brief separate description necessary.

A single word on the anatomy. Tracing a femoral rupture from within outwards, we find that its first stage is to push its way through the weak point of the arch formed by Poupart's ligament, that is, the spot called the crural arch, bounded on its outer side by the sheath of fascia which surrounds the femoral vein; above by Poupart's ligament; on its inner side by the curved fibres of Poupart's ligament, which, curving backwards, are inserted into the ilio-pectineal line, have a sharp falciform edge, and have been dignified by the special name of Gimbernat's ligament (Fig. xxxvii. G.); and below by the os pubis itself. This arch or ring thus bounded is, in the normal state of parts, filled by a layer of fibrous texture, a little fat, and occasionally a small gland. These parts are pushed forwards in the descent of the hernia, and in a small recent one may be said to form a sort of inner covering; in a larger and older one they are split by the hernia, and, while forming a constriction round its neck, leave the fundus of the sac, so far as they are concerned, quite uncovered.

A femoral hernia may stop there, satisfied with merely coming through the ring, and, if sudden and recent in a healthy, well-knit subject, such a rupture is exceedingly dangerous, the constriction being very severe, and the consequent gangrene of the bowel very rapid if unrelieved. In most cases, however, it makes its way still further out, and the next covering it gains is from the cribriform fascia. This is the layer of fibres, pierced (as its name implies) with orifices for the passage of veins and lymphatics, which stretches between the two curved edges of the saphenous opening. It varies much in strength; when the rupture has been slow and gradual, it will certainly add a covering of greater or less thickness, but where the hernia is large and old we must not expect to find many traces of the cribriform fascia, at least over the fundus of the tumour.

The ordinary superficial fascia of the part, with its fat, nerves, veins, and lymphatics, and the thin skin of the groin, are the only

remaining coverings. It is very remarkable how exceedingly thin all the so-called coats become in large femoral hernia of long standing, especially in thin old people.

Operation.—Various incisions are recommended. In most cases a single incision, vertical in direction, and on the inner side of the swelling, is quite sufficient. The one which gives freest access and exposes the sac best, if it is large, is shaped like a T, the horizontal limb of which is oblique, the direction of the obliquity varying on the two sides. The horizontal incision should be made just over Poupart's ligament, and parallel to it, the centre of the incision corresponding to the neck of the sac, and its length varying according to the size of the tumour and the depth of the parts; the other should extend downwards from the centre of the former, as far as is necessary to display the whole sac. The first should be made by pinching up and transfixing the skin, the second by ordinary incision, to the same depth as the first. The small flaps thus made must now be thrown back; any vessels that have been divided are to be tied. Now, with great care and caution the surgeon is to pinch up and divide any layers of condensed cellular tissue which may still cover the sac, till it is thoroughly exposed to its full extent, and remove any glands which may intervene.

The neck of the sac being exposed, it may be possible in some very exceptional cases to give the patient the benefit of the minor operation, which consists in leaving the sac unopened. In such a case (to be described immediately), the surgeon passes his finger along the neck of the sac as far as possible into the ring, and then with a probe-pointed bistoury very cautiously nicks the upper edge of Gimbernat's ligament in one or more places, being careful to feel for any pulsation before dividing a single fibre. He may then be able to empty the sac of its contents, and return the bowel and omentum, still retaining the sac outside.

On the other hand, where it is determined to open the sac, the pinching up of the sac must be managed with great care, to avoid injury of the bowel. There is generally a little fluid to be found at the fundus, which will protect the bowel. As an illustration of the kind of difficulty sometimes met with, Liston tells us that in one case in which he operated "there was no possibility of pinching up the sac, either with the fingers or forceps; it contained no fluid, and was impacted most firmly with bowel; very luckily the membrane was thin; and, observing a pelleton of fat underneath, I scratched very cautiously with the point of the knife in the unsupported hand, until a trifling puncture was made, sufficient to admit the blunt point of a narrow bistoury."¹ If the sac contain bowel and omentum, it is safer to open it over the omentum than over the bowel. When a small opening is made, an escape of the contained fluid takes place, and then the sac should be slit up as far as its neck by a probe-pointed bistoury, guided by the finger, introduced to protect the bowel, whenever the opening is sufficiently large. The forefinger must now be cautiously insinuated into the neck of the sac, the nail being directed to the bowel, the pulp to the crescentic margin of Gimbernat's ligament, and any constriction very cautiously divided. The bowel should then be drawn down a little, the constricted point carefully examined, and then returned or not, according to its condition.

Two points require a brief separate notice:—

1. In what direction is the crural arch to be divided? Not outwards certainly, on account of the vein, nor downwards, as the bone prevents that direction. Is it to be upwards or inwards? Not upwards, for such an incision would endanger the spermatic cord or round ligament, besides greatly weakening the abdominal wall by the division, partial or complete, of Poupart's ligament. Inwards

¹ *Operative Surgery*, p. 462.

then it must be; and little more need be said about it, were it not for the occasional existence of an abnormal course and distribution of the obturator artery.

FIG. XXXVII.*

The usual origin of this vessel is from the internal iliac, in which case (Fig. XXXVII. NO) it never comes near the sac at all. In certain cases (1 in $3\frac{1}{2}$) it rises from the epigastric, and in a very few (1 in 72) from the external iliac. If rising from either of the two last, it most commonly passes downwards at the outer side of the hernia, in which case (Fig. XXXVII. SO) no harm can possibly result; but in a few

* Rough diagram of abnormal course of obturator and its relation to the neck of a hernia. Parts seen from the inside: H, femoral hernia; A, femoral artery; V, femoral vein; E, epigastric artery; O, obturator from epigastric (dangerous); SO, obturator from epigastric (safe); NO, normal course of obturator; IR, internal inguinal ring; SpC, spermatic cord and its vessels; G, Gimbernat's ligament; +, in triangle of Hesselbach.

rare cases, perhaps 1 in every 60 of those operated on, the vessel winds round the hernia (Fig. xxxvii. o), crossing at its inner side, and thus may be (and has actually been) divided by rash incision. With due care, however, and by cutting a very little at a time, even this danger may be avoided.

2. Under what circumstances is it possible or justifiable to reduce a femoral hernia, without previously opening the sac? Only in certain very select cases, where the hernia is recent, the constricting parts lax, the general symptoms very mild, and where there is reason to believe the bowel has completely escaped injury by compression or the taxis. There are both difficulties and dangers in this so-called minor operation:—1. *Difficulties*, For it is not easy to divide the constriction without the assistance of the finger in the sac, and it is not easy to reduce the contents with the sac unopened, except through a much freer opening than is necessary when the bowel has been fairly exposed. 2. *Dangers*, Of reducing sac and viscera, together with the strangulation still kept up by tightness in the neck of the sac; or of supposing the sac is emptied while a knuckle of bowel still remains in it, and is strangulated; or, lastly, of reducing the intestine which has already become gangrenous. It is very remarkable how very soon gangrene may come on, in a case of a small recent femoral hernia, in which the fibrous tissues constricting the neck of the sac are tense and undilatable. A protrusion for eight hours has been sufficient to destroy the life of a knuckle of bowel.

A note here on a certain condition very frequent in femoral herniæ, which may occasionally give a good deal of trouble. Symptoms of strangulation have been well marked, yet when the sac is opened nothing is to be seen except a mass of omentum, perhaps tolerably healthy-looking. To reduce this *en masse* would be very unsafe; it is necessary carefully to unravel it, and disengage the

knuckle of bowel which is almost certainly included in it, and which has given rise to the symptoms of strangulation.

Operation for Strangulated Umbilical Hernia.—The operation is practically the same, whether the hernia is a true umbilical one, or one which with more strict accuracy might be called ventral. True umbilical hernia is a disease of infancy and childhood, being almost always congenital, and the viscera protrude through the umbilical aperture. This rarely requires operation, as it may generally be returned with ease, and even cured by a proper bandage and compress. Ventral hernia, commonly called *umbilical*, is generally a protrusion of viscera through a new preternatural aperture in the fibrous tissues close to the navel, may often attain a large size, is liable to strangulation, and is not easily palliated or cured.

In either case the operation requires a very brief description. If the hernia is small, under the size of a hen's egg, a crucial incision through the thin skin which covers it will thoroughly expose the sac when the flaps are dissected back. The forefinger should then be inserted in the round opening, and the edges cautiously incised in several directions, each incision, however, being very small.

If the rupture is large, a single linear, or a T-shaped incision, exposing the base of the tumour, will be sufficient to allow the requisite dilatation of the opening to be made. It is not at all necessary in every case to open the sac of the peritoneum. If required, it must be done with great caution, as the sac is generally very thin. In cases where the hernia is chiefly omental, the sac should be opened, lest a knuckle of bowel be enclosed and strangulated in the omentum.

In umbilical herniæ of old standing with a large ring there is a great tendency to protrusion of large quantities

of bowel during operation which will need careful management. In one remarkable case, the author was called to a small cottage in the country to operate on a case which had burst. Several feet of distended colon projected from the wound, and was in immediate contact with the blankets. After washing and returning, an elaborate radical cure was made, and the patient recovered.

Obturator Hernia is an extremely rare lesion, and a large proportion of the recorded cases were discovered only after death. When diagnosed during life and strangulated, some have been reduced by taxis, and only a very few cases have been operated on, some with success. It is not likely that a diagnosis could be made, except in very emaciated patients, in whom pain at the obturator foramen was a prominent symptom, and in whom it could be ascertained positively that the crural ring was empty. An incision over the tumour, sufficient to allow the pectineus muscle to be exposed and divided, is necessary. The hernia may then be reduced without opening the sac, if recent; if of long standing, the sac must be opened. One case is recorded by Dr Lorinzer, in which, after strangulation for eleven days, he opened the sac and found the bowel gangrenous. The patient had a faecal fistula, but survived the operation for eleven months.

Mr Oubr 's¹ well-known and classical case was one of the earliest recognised and operated on. Dr Charles Frith² has published a valuable monograph on this hernia, in which he has collected 25 cases which were recognised during life. Of these 17 required operation and 8 were reduced by taxis, but of the whole 25 only 5 recovered.

¹ Holmes' *Surgery*, 3rd ed., 1883, vol. ii. p. 837.

² *British Medical Journal*, April 1890.

In cases of obstruction unexplained by hernia in the more usual situation, a mesial laparotomy which allows the abdominal apertures to be examined from within may, and in several cases has been followed by the recognition and reduction of an obturator hernia. In most cases the operation has been delayed too long. It should be routine practice in cases of obstruction, not inflammatory, and not accounted for by a hernia, to open the abdomen early.

Other forms of hernia—lumbar, sciatic, and perineal—are so rare, and the treatment of each case must necessarily vary so much in its circumstances, as not to require or admit of any detailed account of the operations requisite for their relief.

Operations for the Radical Cure of Hernia.—The inconveniences and discomfort caused by even the best-adjusted trusses or bandages, the unsatisfactory support they afford, and the risk of their slipping and allowing the hernia to escape, have given rise to many attempts to cure hernia by operation.

Even to enumerate these would be quite beyond the limits of the present volume; suffice it to classify a few of the most important of them according to the principle involved in each, and then give a very brief account of the method of operating which seems to be at once the most scientific, least dangerous, and most permanently useful.

The question at issue is briefly this. We have, in a hernia, the following condition:—The walls of a great cavity are at one or more points specially weak, the contained viscera have protruded, either by extension and stretching of a natural opening, or by the formation of a new breach in the walls, and, in protruding, they have brought with them as a covering a serous membrane, ex-

tremely extensible, highly sensitive to injury, and, when injured, certain to resent it by severe, spreading, and dangerous inflammation.

Do we desire to remedy this protrusion, we may act—

1. On the intestines themselves; but for all surgical purposes they are out of our reach. We cannot do more than, by diminishing their contents, diminish their volume, and by position and rest reduce to the utmost their tendency to protrude. This includes the medical and prophylactic treatment of hernia, or rather of the tendency to hernia.

2. We may try what can be done with the *sac* which the intestines have pushed down before them. Can it be obliterated? If it can, perhaps the intestines may be retained in their cavity. Very many plans of dealing with the *sac* have been tried.

To cause obliteration of its cavity many methods have been proposed:—By ligature of it along with the spermatic cord, involving loss of the testicle, either by gradual separation, by sloughing, or by immediate removal; by cutting into it, and then stitching it up; by constricting it with wire, as in the *punctum aureum*; by pinching *sac* and coverings up, by passing needles under them as they emerge from the external ring, as Bonnet of Lyons did; by constricting *sac* alone with a double wire, by subcutaneous puncture, as Dr Morton of Glasgow has done; by severe pressure from the outside with a strong tight truss and a pad of wood, as proposed by Richter; by setons of threads or candle-wicks, as proposed by Schuh of Vienna; by injection of tincture of iodine or cantharides, as by Velpeau and Pancoast; by the introduction into the *sac* of thin bladders of goldbeaters' skin, which were then filled with air, and were intended to excite inflammation, as in the radical cure of hydrocele; or by the still more severe method of Langenbeck, consisting in exposing the *sac* by a

free incision at the superficial ring, separating it from the cord, and passing a ligature round the sac alone, leaving the ligatured portion in the scrotum either to become obliterated or to slough out. Schmucker of Berlin varied this by cutting away the constricted portion below the ligature.

3. We have now only the canal left to act upon; and the operations on the canal may be divided into three great classes:—

(*a.*) Those in which the operator attempts to plug up the dilated canal; (*b.*) those in which he tries to constrict it, by reuniting its separate sides by subcutaneous suture; and (*c.*) where under strict aseptic precautions both sac and canal are cut down upon by open method of operating, and so stitched up as mutually to help and support each other.

(*a.*) Attempts to plug the canal have, in most cases, been made by invagination of the skin of the scrotum and its fascia. These have been very numerous, and are now really of little more than historical interest, as they are rarely, if ever, performed. I retain in small type a brief historical account of some of the more important methods.

Dzondi of Halle, and Jameson of Baltimore, incised lancet-shaped flaps of skin, and endeavoured to fix them by displacement over the ring. Gerdy invaginated a portion of scrotum and fascia into the enlarged canal, by the forefinger pushed it up, and secured it in its place by a thread passed from the point of his finger first through the invaginated skin, then through the abdominal walls, endeavouring to include the walls of the inguinal canal, causing the point of the needle to project some lines above the inguinal ring; the same process being effected with the other end of the thread on the other side of the finger, and the two ends which have been brought out near each other on the abdominal wall, being tied tightly over a cylinder of plaster. The ensheathed sac was then painted with caustic ammonia to excite inflammation, and a pad put on over all.

Signoroni modified this by fixing the invaginated skin by a piece of female catheter, retained in its place by transfixion by three hare-lip needles, tied by twisted sutures.

Wützer of Bonn, again, modified this, by substituting a complicated instrument, consisting of a stout plug in the inguinal canal, held in position by needles which are passed through the anterior wall of the canal in the groin. Compression between plug and compress, with the intention of causing adhesion between skin, fascia, and sac, is then managed by means of a screw. The plug is retained for about seven days.

Modifications of this method have been tried by Wells, Rothmund, Redfern Davies, and Syme, all aiming in the direction of simplicity. J. Fayrer when at Calcutta had a very large experience of Wützer's method, and also a plan of his own. Out of 102 cases by the latter method, 77 were cured, 9 relieved, 14 failed, and 2 died.¹

Now, what results follow these operations? At first they are almost invariably successful, but the complaint is that, in most cases, the rupture recurs. The principle is to plug up the passage by the mechanical presence of the invaginated skin, the plug being retained in position by adhesive inflammation between it and the edges of the dilated ring. But the ring is left dilated, or, indeed, generally its dilatation is increased; and as, on continued pressure from within, the new adhesions give way, or, as often happens, a new protrusion takes place in the circular *cul-de-sac*, necessarily left all round the apex of the invagination, the still lax ring and canal offer no resistance to the protrusion.

(b.) The principle of constriction of the canal by reuniting its separated sides by subcutaneous suture. This is the principle of the various methods introduced by the late Mr Wood of King's College, and described by him in his most able and exhaustive work.²

He sutured the sides of the dilated canal on the following principles and methods:—

1. *For Inguinal Hernia*.—To stitch together the two sides of the canal with safety requires attention to several points

¹ *Clinical and Pathological Observations in India*, pp. 44, 325.

² *Wood On Rupture*, 1863.

- (1.) That it be done nearly, if not entirely, subcutaneously. (2.) That the protruding bowel should be kept out of the way, and not be transfixed by the needle. (3.) That the spermatic cord should be protected from injurious pressure.

When a large old hernia in an adult is the subject of operation, it is thus performed by Mr Wood:—The pubes being shaved, and the patient put thoroughly under the influence of chloroform, the rupture is reduced, and the operator's forefinger forced up the canal so as to push every morsel of bowel fairly into the abdomen. An assistant then commands the internal ring by pressure, to prevent return of the rupture.

An incision is made in the scrotum over the fundus of the sac, large enough to admit a forefinger and the large needle used in the operation; the edges of the skin are to be separated from the fascia below for about one inch all round. The forefinger is then to be passed in at the aperture and pushed upwards, invaginating the detached fascia before it, and it must be made to enter the inguinal canal far enough to define the lower border of the internal oblique muscle stretched over it. A large curved needle (unarmed) is then passed on the finger as a guide, through the internal oblique tendon, the internal portion of the ring, and the skin of the abdomen; it is then threaded with wire and withdrawn. Again, the needle (now threaded) is guided by the finger and pushed through Poupart's ligament and the external pillar of the ring as before; while by a little manipulation its point is made to protrude through the same opening in the skin as before, a loop of wire is now left there, and the needle, still threaded, is again withdrawn. The next stitch, still guided on the finger, takes up the tendinous layer of the triangular aponeurosis covering the outer border of the rectus tendon close to the pubic spine; the point of the needle is then turned obliquely, so as to

protrude through the original puncture in the skin a third time, the needle is then freed from the wire and withdrawn, thus leaving two ends and one intermediate loop of wire all at the one opening. These are so arranged that when they are tightened they draw together the sides of the canal; they are then secured over a compress of lint. The compress is removed and the stitches loosened, at dates varying from the third to the seventh day.

Mr Wood's results were exceedingly good, so that he could report in his admirable article on Hernia,¹—"In the last two hundred cases operated on by my subcutaneous wire method not one has been attended by any serious or unpleasant symptom."

In congenital herniæ, and small ruptures in children and young boys, Mr Wood used rectangular pins in the following manner:—The scrotum being invaginated (without any incision through the skin) as far as possible up the canal, a rectangular pin, with a slightly-curved spear-pointed head, is passed through the skin of the groin to the operator's forefinger; guided by it, it is brought safely down the canal, and brought out through the skin of the scrotum just over the fundus of the hernial sac. A second pin is passed from the lower opening (still guided by the finger) in an upward direction, transfixing in its course the posterior surface of the outer pillar of the superficial ring, its point being brought out through, or at least close to, the first puncture made by the first pin. The pins are then locked in each other's loops—the punctures and skin protected by lint or adhesive plaster,—and the whole is retained by lint and a spica bandage. The pins should generally be withdrawn about the tenth day.

Mr Spanton² proposed a method of operating somewhat on the principle of Mr Wood's, but differing in that a screw is used, which by a series of ingenious manipulations is made to pucker up and approximate the pillars of the rings. It is to be left *in situ* for about a week, till sufficient inflammatory hardness has glued the parts together.

¹ *International Encyclopædia of Surgery*, vol. v. p. 1139, 1885.

² *British Medical Journal*, 1880.

(c.) In the present day, however, the open method with strict antiseptic precautions has almost entirely superseded any other mode of operating. Among the best of these are the varying methods of Barker, Macewen, Ball, and Banks.

Barker's Operation.—When the sac of the hernia has been reached and opened, and its contents have been reduced into the abdomen in the usual way, the next point is to separate the structures of the cord from the neck of the sac. This is best done by inserting the index finger into the opening in the latter, and catching its edge between finger and thumb, while with the other thumb-nail the structures of the cord are peeled off the sac from a limited distance. In doing this all disturbance of the structures of the cord should be avoided as far as possible. Sometimes the thumb-nail may be replaced by the blunt point of an aneurism needle. Be this as it may, eventually the latter instrument is carried under and close to the neck of the sac; and when it is quite certain that it does not include anything but the latter, it is threaded with strong carbolized silk and withdrawn. The two ligatures so introduced are now separated for about half an inch above and below the opening in the sac, and the upper parts are tightly tied as high up as possible, but not cut short; then the sac is divided between them. The pillars of the ring having been exposed by dissection, the left forefinger is introduced into the canal, and so through the internal ring, and made to press its anterior wall forwards. One of the silk threads belonging to the upper stump of the sac is now carried up the canal inside the internal ring, and through the abdominal wall above, and external to the external ring, by means of one of the handled needles, and then the other is similarly passed through the abdominal wall about half an inch to the inner side of the first. These sutures are then knotted tightly, and by this

means the stump of the sac is drawn up into the abdomen and fixed there, and at the same time the internal ring is closed more or less. The needle is now again armed with silk, and is passed from within outwards through one of the walls of the canal high up, the cord being protected as before by the left index-finger. It is then withdrawn still threaded, but leaving one end of the silk through the tendon, and is then made to puncture the other wall at a corresponding point, where it is unthreaded and withdrawn. The piece of silk so introduced is not knotted yet, but is used to draw forward the two pillars, and act as a guide for the introduction of three or four similar stitches lower down. All of these should, if possible, include a portion of the conjoined tendon as well as the two pillars of the external ring. They should, of course, all pass across in front of the cord, and the lowest should not close the ring too tightly upon the latter. When all are in place they are firmly knotted, beginning at the highest, and thus the canal is closed firmly throughout.

The lower part of sac is removed by some operators, but this seems unnecessary, and may cause suppuration in the scrotum; and really its presence does not in any way favour the redescend of the hernia. The skin should then be neatly sutured and the wound drained.¹

Dr Macewen² carefully separates the sac from the entire inguinal canal and from the abdominal aspect of the internal ring; fastens a stitch in the fundus, throws the whole sac into a series of folds, transfixing them with the same stitch carried through one after the other up to the ring, threads the free end of the stitch in an eyed needle, and passes it through the abdominal wall an inch above the upper border of the internal ring, the skin at that point being pulled up

¹ *Manual of Surgical Operations*, pp. 335-7.

² *British Medical Journal*, 1887.

so that it is not included. While traction is made on that thread, pulling the sac into the ring, so that its distal extremity is furthest backward and upward, the conjoined tendon is pierced by a ligature, so as to leave a loop inside; the lower end of that stitch is then carried through Poupart's ligament from within outwards, the upper end through the transversalis, internal and external oblique muscles. Similar stitches may be introduced lower if necessary. The free end of the ligature through the sac is then fastened by passing it several times through the external oblique muscle, and the other stitches are tied, closing the internal ring. Chromicized catgut is used for these sutures, and to unite the skin. A decalcified bone drainage-tube is laid in the lower angle of the wound. No truss is used. He states that the principle of the operation may be applied to femoral hernias, but gives no details.

Ball's¹ method differs from Macewen's to a slight extent. After sac is emptied and isolated it is gradually twisted by strong forceps, making four or five revolutions till it is quite tight. A strong catgut ligature is then tied round the twisted neck and cut short. The twisted sac is kept in the ring by two stout silk sutures passed through it and each pillar of the ring at different levels, which are tied over leaden plates. The fundus of the sac is cut off in front of these sutures.

Mr Banks² dissects out the sac, opens it, replaces bowel, ties and cuts away adherent omentum, pulls the sac well down, ligatures it as high in the canal as possible, and removes it. Finally, the pillars of the ring are brought together by two or three sutures of thick strong silver wire, which are left in position. In femoral hernia the cleaning and removing

¹ *British Medical Journal*, 1887.

² *Medical Times and Gazette*, 1884.

of the sac constitute the whole operation. In ventral and umbilical hernia the sac is used as a plug to stop the aperture. He considers "freshening" the edges of the canal with the idea of securing union to be "utter nonsense." He encourages his patients to wear light trusses afterward.

2. *For Femoral Rupture.*—Cases suitable for operation are less frequent; but should such a one be met with, Mr Wood proposes the following operation on the same plan as the preceding. The hernia being fully reduced and the parts relaxed by position, an incision about an inch long should be made over the fundus of the tumour, and its edges raised so as to admit the finger fairly into the crural opening. The vein is then to be pushed inwards, and the needle passed through the pubic portion of the fascia lata of the thigh, and then through Poupart's ligament, appearing on the skin of the abdomen, a wire is then passed through the eye of the needle and hooked down, appearing through the wound, it is then withdrawn, and the needle again passed through the pubic portion of the fascia lata, but about three-quarters of an inch to the inside of the first puncture, then through Poupart's ligament again, and protruded through the same orifice in the skin; the other end of the wire is then hooked down as before, leaving a loop above, at the needle orifice, and two ends at the wound in the skin below. Both loops and ends must be managed as before. The account given of the open method applies to femoral hernia also, but cases are much less frequent.

3. *For Umbilical Rupture.*—The principle involved in Mr Wood's operation for umbilical rupture is precisely the same as for inguinal and crural. It consists in stitching the two edges of the tendinous aperture by wire; the needle is passed on a sort of small scoop or broad grooved director, which at once invaginates the skin and protects the

bowel. Two stitches are thus inserted on each side. For the ingenious method by which they are introduced subcutaneously, I must refer to the detailed description in Mr Wood's monograph. The wires are thus twisted and tightened over a pad of lint or wood, drawing together the edges of the opening in the tendon.

In cases of umbilical hernia in adults in whom the operation for strangulation has been performed, cutting away the redundant portion of sac and walls, and by careful apposition of the edges of the ring by numerous and carefully adjusted sutures, sometimes is followed by excellent results. An admirable description of such an operation is given by Mr Treves.¹

Operations for Artificial Anus.—In children the condition known as imperforate anus may sometimes be remedied by exploratory operations in the perineum, guided by the protrusion caused by the distended intestine.

In male children the author has twice had to operate when only an exceedingly fine fistulous opening existed connecting the imperforate rectum with the urethra in perinæum; by tracing and laying open the fistula he succeeded in reaching the bowel, opening it freely, drawing it down as far as possible, and stitching the mucous membrane to the skin with excellent results.

In female children the imperforate rectum not unfrequently opens by a similar small opening into the vagina, through which canal the meconium and afterwards fæces escape. In such cases the author has now operated more than a dozen times in following manner:—Bending a soft metal bougie into a hook shape, it can be passed into vagina and through aperture into the imperforate rectum. By now curving the handle the blunt point can be felt in the anal

¹ Treves' *Operative Surgery*, vol. ii. p. 532.

region, and acts as a guide on which it is easy to cut. By cutting cautiously all the tissues except the *cul-de-sac* of mucous membrane may be divided, and with a little care the bowel can be so separated from its cellular tissue as to be brought down to the skin level, when it can be opened crucially, and stitched to the edges of the skin.

There are other cases, however, in which the rectum, as well as the anus, seems to be deficient, and in which, from the want of protrusion, there is no warrant for attempting an operation there; in these the only chance of life that remains is in an attempt to open the bowel higher up.

In adults, again, absolute closure of the rectum and anus, and complete obstruction, may be the result of malignant disease, or even, very rarely, of simple organic stricture.

In such cases, where the patient is tolerably strong and yet evidently doomed from the complete obstruction, an attempt at the formation of an artificial anus is warrantable, and in many cases affords great relief, and prolongs life for months.

Without going into all the various positions proposed for such operations, I select the two most warrantable, which have borne the test of experience. These are—1. Colotomy in the left loin. This is applicable in the case of adults with rectal obstruction. 2. Colotomy in the left groin applicable in many cases in adults, and also most suitable in cases of imperforate anus and deficiency of rectum in infants.

1. Colotomy in the Left Loin, generally known by the name of *Amussat's Operation*.—The patient is laid upon his face, a pillow placed under the abdomen, rendering the left flank prominent. Nearly all the best authorities recommend that Bryant's oblique incision should be used instead of the transverse one recommended originally by Amussat. The exact point where the bowel is to be found most easily is fixed by

Allingham's dissections to be directly in line above a point marked on the skin about half an inch behind the middle of the crest of the ilium as measured between its anterior and posterior spines. The oblique incision should begin about an inch in front of and above this point, and pass obliquely upwards and backwards towards the angle formed by the spine and last rib for as great a distance as may be needed in each given case. In a thin patient three inches may suffice, in a fat one four or even six may be required. Some fibres of the latissimus dorsi, the posterior fibres of external and internal oblique, will require division, and the lumbar fascia will then be exposed and opened, allowing the anterior edge of the quadratus lumborum to appear. This may require partial division, and the transversalis fascia will be exposed. It is then to be pinched up and divided, as in the operation for strangulated hernia. The muscular wall of the colon uncovered by peritoneum may in some cases be easily recognised from its

FIG. XXXVIII.*

distension. But there are other cases in which the bowel is not so easily recognised. If it is empty the subperitoneal fat must be well separated and the bowel felt for by the finger in the angle between the anterior surface of the quadratus and the psoas.

The colon when brought into view may be recognised by its thick coat, and possibly by the presence of a longitudinal band. When recognised and brought to the wound the colon should be kept in position while it is stitched to the wound by numerous points of suture. These should unite the skin, the muscular coat of the bowel if possible not

* Diagram of an artificial anus, showing small sutures which unite the edges of the gut and the skin, and the large ones stitching up the wound beyond.

opening into its lumen. The ends of the wound are also to be sutured by deep sutures passing through all the divided structures of the wall.

The bowel may then *at once* be opened if there is urgency at the projecting point, the wound in it need not be larger than to admit a finger; or, if there is no urgency, some hours or days may be allowed to elapse before the bowel is opened, in the hope that the wound may be nearly healed by first intention and the bowel united to the edges.

Various plans have been suggested for the closure of the portion of bowel left below the opening, such as Mr P. Jones'¹ plan of detaching the mucous membrane from upper portion and adjusting it over the lower one.

When the distension has been great there is generally a rush of fluid fæces, which must be provided for, special care being taken lest any get into the cavity of the peritoneum.

Inguinal Colotomy.—This method, which has been generally preferred in cases of imperforate anus and deficient rectum in newly-born infants, has of late years been recommended most strongly as a substitute for lumbar colotomy in cases of malignant disease. It has the one great preliminary objection that it implies a free opening of the peritoneum, but in ease of performance, and especially in the more manageable position of the artificial anus, there are counterbalancing advantages, and statistics show that in competent hands the operation is wonderfully free of immediate danger to life. There are various modifications in the methods of its performance, which are fully described in the excellent monographs of Allingham (Junior),² Cooper

¹ *British Medical Journal*, 1886.

² *Colotomy, Inguinal, Lumbar, or Transverse*. By Herbert Allingham. 1892.

and Edwards,¹ and in papers by Dr Harrison Cripps,² and in Mr Greig Smith's work,³ where he describes the operation under the name of cœlio-colotomy. Sufficient here to describe the methods of Allingham, Harrison Cripps, and Ball.

1. Allingham's Operation.—An incision through skin and cellular tissue, not above two inches in length, one and a half inside of the left anterior superior spine of the ilium and parallel with Poupart's ligament; muscles are divided till the areolar tissue and peritoneum are reached and divided. Once peritoneum is opened the deeper structures are divided with scissors on the finger to the full extent of the skin wound. When peritoneum is divided it is secured by clip forceps on each side, and a flat sponge secured by a string is inserted into the abdomen to keep intestines out of the way and to catch any blood. The parietal peritoneum is then to be carefully sewed to the skin by interrupted sutures. Then the sigmoid flexure is looked for, and generally bulges into the wound. If not, it must be sought for and hooked up into the wound. It must then be examined by the fingers till a piece with a sufficient mesentery, to allow of a good knuckle of gut being pulled through the wound, the mesentery of which is to be transfixed by a silk suture behind the bowel, and by this means fixed to the wound. The prominent piece of gut is now fixed by several sutures which are passed through only the serous and muscular coats of bowel. The gut is then covered by green protective antiseptic dressing pad and bandage. Next day, if necessary, or if all goes well, in then a few days, the gut is opened by scissors, redundant walls pared away till it is

¹ Cooper and Edwards on *Diseases of Rectum and Anus*, 1892.

² *British Medical Journal*, 1889.

³ *Op. cit.*, p. 473.

nearly on a level with the skin, and thus a good spur and a double-barrelled opening is left. In cases where the sigmoid mesentery is long, and there is a tendency to prolapse, Mr Allingham describes what he calls his supplementary operation, which implies the cutting away of the redundant portion of the gut, assisted by a toothed clamp of his own invention.¹

Mr Allingham gives a table of 60 cases of this operation, with the gratifying result that only 6 died within three months of the operation.

2. Mr Harrison Cripps' Operation.—He makes his incision higher than usual. As a guide "I take an imaginary line from the anterior superior spine to the umbilicus; the incision, two and a half inches long, crosses this at right angles an inch and a half from the superior spine. Half the cut is above and half below the imaginary line." After reaching the peritoneum it is divided and wound slit up on a finger. After hooking up the bowel and recognising it, he draws out as much as will come down, passing it in below as it comes out above. Two provisional ligatures about two inches apart are then passed through the longitudinal muscular band opposite to the mesenteric attachment. Peritoneum and wall are then to be stitched to each other at the edges, and the bowel secured to wound in wall. The threads should all be inserted before any are tied. The subsequent treatment is the same as in operation described above.

3. Dr C. B. Ball's Method.—Dr Charles B. Ball² prefers the left linea semilunaris in which to operate, as it freely exposes

¹ *Op. cit.*, p. 72.

² Dr C. B. Ball, *Transactions of Academy of Medicine in Ireland*, 1887, p. 1845.

the sigmoid flexure; it is made without cutting muscle, the parietes are thinner there than elsewhere, and no vessel of importance need be wounded. The deep epigastric artery is quite safe if the lowest limit of the incision does not pass a line drawn from the umbilicus to the middle of Poupart's ligament. A loop of bowel above the upper limit of the cancer should be drawn out, emptied upwards, clamped above and below, and then carefully sutured to the abdominal wall *before* it is opened. After opening, the loops of sutures in the bowel are to be drawn out, divided, and fixed. Then superficial sutures should be very carefully inserted, so as to apply the mucous membrane to the skin all round the opening, the clamps should then be removed, and the sutures at each end of the wound, which include the peritoneum, tied. Mr Greig Smith¹ has modified this in the direction of simplicity. An incision, preferably vertical, between umbilicus and anterior superior spine, site selected according to supposed position of structure. Incision not to be more even in a fat person than three inches long. A loop of colon is to be pulled through, and a pair of sinus forceps is to be pushed through mesentery, avoiding vessels; a glass rod follows the forceps, and is placed across the wound as near its lower end as possible. No sutures are required. Dressings for three days: if there is distension, aspiration of the gas, open bowel on third day. No cutting or trimming of wound is needed, but glass rod may be left for a fortnight.

Operation for the Removal of an Artificial Anus, in cases where the bowel is patent below.—After the operation for hernia in a case where the bowel is gangrenous, the only hope of the patient's recovery, unless enterectomy has been

¹ *Op. cit.* p. 481.

performed, consists in the formation of adhesions between the bowel and the external wound, and the presence, for a time at least, of an artificial anus. If adhesions do form, and the patient recovers, it becomes a matter of great importance for his future comfort that the canal of intestine should be re-established, and the fistulous opening allowed to close. This, however, is by no means easy, as even when the portion of intestine destroyed has been very small, a septum or valve remains which directs the contents of the bowel outwards, and so long as it exists is an effectual obstacle to any of the faecal contents passing into the distal portion of the bowel. The septum or *éperon* is formed by the mesenteric side of the two ends of the bowel. To destroy this without causing peritonitis is the aim of the surgeon, and it is not an easy matter to accomplish. To cut it away would at once open the peritoneal cavity, so the mode of treatment now adopted in the rare cases where it is necessary has been till lately that recommended by Dupuytren. The principle of it is to destroy the *éperon* by pressure so gradual as to cause adhesive inflammation between the two surfaces, and thus seal up the cavity of the peritoneum, before the continuance of the same pressure shall have caused sloughing of the septum. This is managed by the gradual approximation by a screw of the blades of a pair of forceps, to which Dupuytren gave the name *Enterotome*. The process, which extends over days and weeks, has to be carefully watched lest the inflammation go too far.

Plastic operations are occasionally required to close the opening after the passage is restored. Mr John Duncan¹ describes a successful case.

Resection and circular suture of the intestine is gradually

¹ *Edinburgh Medical Journal*, 1873.

taking the place of Dupuytren's operation, but the mortality is very great, about 50 per cent.¹ Mr Makin's² admirably devised and successful operation is typical of the method. His researches into 39 cases give a mortality of 38 per cent. in such cases.

CHAPTER XII.

OPERATIONS ON PELVIS.

Lithotomy.—However interesting and even instructive it might be, any history of the various operations for the removal of calculi from the bladder would be quite out of place in a manual such as this. It will be sufficient here to describe the operations recommended and practised in the present day.

There are three different situations in which the bladder may be entered for the purpose of removing a calculus:—

1. The perineum, where access is gained through the urethra, prostate, and neck of the bladder.
2. Above the pubes, where the portion of bladder not covered by peritoneum is opened from above.
3. From the rectum.

1. **Lithotomy through the Perineum**, by far the most frequent position for the operation.—Very various methods for its performance have been devised, differing in the nature and shape of the instruments employed, the direction and size of the incisions, the nature of the wound; but all resemble each other in certain very cardinal and important particulars. Thus all agree that it is absolutely necessary to enter the bladder at *one* spot—the neck of the bladder; and that to do this safely the urethra must be opened, and some instrument previously introduced by the urethra is to be used as a guide for the knife. But an instrument in the

urethra and bladder is surrounded for at least an inch of its course by the prostate; and thus the knife, gorget, or finger, which, guided by the instrument in the urethra, is intended to cut or dilate the entrance to the bladder for the purpose of allowing the calculus to be removed, cannot do this without also cutting or dilating this prostate gland. Experience has proved that much of the success of the operation depends upon the position and amount of incision made in this prostate gland. But it might be asked, Why can we not enter the bladder by one side, avoiding altogether its neck and this prostate gland? For this, among other reasons, that the bladder normally contains, and so long as the patient lives must contain, a certain quantity of a very irritating fluid. It is surrounded by the loose areolar tissue of the pelvis, into which, if any of this fluid escapes, abscesses will form and death probably ensue; this result will almost certainly follow any opening made into the bladder except at one spot.

FIG. XXXIX.*

This spot is the neck of the bladder. Why does urinary infiltration not occur there? Because the fascia of the pelvis (which when entire can resist infiltration) is prolonged forwards at the neck of

the bladder over the prostate (Fig. XXXIX. PF), for which it forms a very strong funnel-like sheath. So long as this sheath is not cut where it covers the sides of the prostate, urinary infiltration of the pelvis is impossible, the urine

* Diagram of section of prostate seen from the inside:—PF, pelvic fascia or prostatic sheath; RR, ring which must be cut; L, position of incision in the lateral operation; DD, position of incisions in the bilateral operation.

being carried forwards and fairly out of the pelvis in this urine-tight funnel.

But it may now be said, If this be the case, we are very much limited in the size of the incision we may make into the bladder. We cannot remove a large stone, for the prostate ought not to be larger than a good-sized chestnut, and any cut we might make through a chestnut without cutting out of its side must be very small. Very true; but fortunately the sheath of the prostate, unlike the rind of the chestnut, is very freely dilatable, and will allow the passage of a very considerable stone.

Again, an inquirer might ask, If it is so dilatable, why should we run the risk of cutting the prostate at all? Why should we not introduce instruments gradually increasing in size into the membranous portion of the urethra, and thus dilate prostate and neck of bladder? For this reason, that the urethral canal passing through the prostate is itself lined immediately outside of the mucous membrane by a firm membranous sheath (Fig. XXXIX. RR), which resists dilatation to the utmost. Experience tells us that any attempts to dilate or even forcibly to tear this ring of fibrous texture are both ineffectual and dangerous, while a clean cut into it and through it into the substance of the prostate is at once effectual and comparatively safe.

In a word, we can describe the relation of the prostate to the operation of lithotomy somewhat in this manner:—Its fibrous sheath surrounding the urethra must be cut freely. The gland substance may be cut and freely dilated by the finger. Its fibrous envelope must, as far as possible, be preserved intact, but this interferes the less with the operation, as it is comparatively freely dilatable.

The firm lining of the urethra, which must be cut, is specially strong at its base, forming a tough resisting band just at the aperture of the bladder, which, unfortunately, is

often so high up in the pelvis in tall patients, or in cases in which the prostate is much enlarged, as to be almost out of reach of the finger, and so far up the staff as perhaps to escape division. You will be warned of such an occurrence by the urine in the bladder failing to make its appearance; and if any attempt be made to dilate the opening and introduce the forceps without further incision of the base of the prostate, the result will very likely be fatal, generally from pyæmic symptoms depending on a suppurative inflammation of the prostatic plexus of veins (Fig. xxxix.) In fact, upon a recognition of this fact is founded the aphorism, "that cases in which the forceps have been introduced before the bladder fairly begins to empty its contents are generally fatal."

We have thus traced the necessary guiding principles as to our incisions from the bladder outwards through the prostatic portion of the urethra. We have next to discover

FIG. XL.*

what sort of an opening is necessary in the membranous portion of the urethra consistent with the fulfilment of the same conditions, namely, freedom of escape for the urine, and room enough to remove

the stone. Both of these are gained at once by a free incision of the membranous portion, dividing especially those anterior fibres of the great sphincter muscle of the pelvis, the levator ani, which embrace the membranous

* Diagram of muscles of membranous portion of urethra seen from the inside :—ss, section of os pubis; u, urethra; g, Guthrie's muscle, compressor urethræ; w, Wilson's muscle, levator urethræ.

portion, under the special names of compressor (Fig. XL.) and levator urethræ (Guthrie's and Wilson's muscles).

The principles which guide the position and size of the preliminary incisions which enable the urethra to be opened are very simple:—(1.) The wound in the perineum should be large enough to give free access to the urethra, and easy egress to the stone; (2.) It should be conical, with its base outwards, so as to favour escape of urine and prevent infiltration; (3.) It should not wound any important organ or vessel; that is, it must avoid the rectum, the corpus spongiosum, especially the bulb, if possible, the artery of the bulb, and in every case should leave the pudic artery intact.

So far for broad general principles, which must guide all methods of successful lithotomy.

The Lateral Operation.—*Operation of Cheselden.*—(1.) *Instruments required.*—A staff with a broad substantial handle, and a longer curve than the ordinary catheter requires, furnished with a very deep and wide groove, which occupies the space midway between its convexity and its left side. The one used should invariably be large enough to dilate fully the urethra.

A knife, with its blade three or four inches in length, but sharp only for an inch and a half from its point, its back straight up to within a sixth of an inch of its point, and there deflected at an angle to the point, which again curves to the edge. The angle from the back to the point permits the knife to run more freely along the groove in the staff.

A probe-pointed straight knife with a narrow blade may occasionally be useful in enlarging the incision in the prostate, when this is required by the size of the stone.

Forceps of various sizes and shapes, some with the blades

curved at an angle to reach stones lying behind an enlarged prostate, all with broad blades as thin as is consistent with perfect inflexibility, the blades hollowed and roughened in the inside, but without the projecting teeth sometimes recommended, which are dangerous from being apt to break the stone.

A scoop to remove fragments or small stones, sometimes useful with the aid of the forefinger in lifting out a large one.

A flexible tube of at least half an inch calibre, and about six inches long, rounded off and fenestrated above, fitted at its outer end with a ring and two eyelet-holes for the tapes, with which it is tied into the bladder.

Prior to the operation the patient's health should be attended to, the stomach and bowels regulated, and any disorder of the kidneys or bladder as far as possible alleviated. If his health has been good and habits active, three or four days' confinement to his room on low diet, with a full purge the evening before the operation, is all the preparatory treatment that is necessary.

It is of the utmost importance for the safety of the operation and the patient's comfort after it, that the rectum be completely unloaded before the operation, and the bowels so far emptied as to permit three or four days after the operation to elapse without any movement of the bowels being necessary. If there is any doubt as to the effect of the laxative, a large stimulant enema should be administered on the morning of the operation.

Position.—Much depends on the proper tying up of the patient. He should be placed with his breech projecting over the edge of a narrow table, with head slightly raised on a pillow, but the shoulders low. The hands are then to be secured each to its corresponding foot, by a strong bandage passing round wrist and instep, or by suitable

leather anklets, the knees should be wide apart, and on exactly the same level, so that the pelvis may be quite straight. An assistant should be placed to take charge of each leg.

The staff is next introduced and the stone felt; if there is little water in the bladder, a few ounces may be injected, but this is rarely necessary, for the patient should be ordered to retain as much water as possible, and when he cannot retain it, injection of water may do harm, and will probably not be retained, but at once come away along the groove in the staff. The staff is then committed to a special assistant, who must be thoroughly up to his duty, and attend to the staff alone.

Some surgeons direct the assistant to make the convexity of the staff bulge in the perineum, to enable the groove to be struck more easily. It will be, however, safer both for the rectum and the bulb, if the staff be hooked firmly up against the symphysis pubis, as advised by Liston. The same assistant can also keep the scrotum up out of the way.

If the perineum has not been previously shaved, this is now done.

The operator sits down on a low stool in front of the patient's breech, his instruments being ready to his hand, and then steadying the skin of the perineum with the fingers of his left hand, enters the point of the knife in the raphe of the perineum, midway between the anus and scrotum (one inch in front of anus—*Cheselden, Crichton*; one and a quarter—*Gross, Skey, and Brodie*; one and three-quarters—*Fergusson*; one inch behind the scrotum—*Liston*), and carries the incision obliquely downwards and outwards, in a line midway between the anus and tuberosity of the ischium. The length of the incision must vary with the size of the perineum and the supposed size of the stone, but there is

less risk in its being too large, so long as the rectum is safe, than in its being too small. Its depth should be greatest at its upper angle, where it has to divide the parts to the depth of the transverse muscle of the perineum, and least at its lower angle, where a deep incision is not required, and would be almost sure to wound the rectum.

The forefinger of the left hand is now to be deeply inserted into the wound, and any remaining fibres of the levator ani in front are to be divided, the edge of the knife being directed from above downwards. The left forefinger being still used to push its way through the cellular tissue, the groove in the staff is now felt in the membranous portion of the urethra covered by the deep fascia of the perineum. Now comes the deeper part of the incision. Guided by the finger-nail of the left hand, the surgeon introduces the point of the knife into the groove of the staff. He then takes hold of the staff for a moment to feel that it is held up properly against the os pubis, and in the middle line, and also that the knife is fairly in the groove. Giving the staff back again to the assistant, and keeping the rectum well out of the way by the left hand, he now steadily directs the knife along the groove of the staff till the bladder is fairly entered, and the ring at the base of the prostate completely divided. When this is the case a gush of urine takes place, following the withdrawal of the knife.

When making the deep incision, and in the groove of the staff, the blade of the knife should lie neither vertical nor horizontal, but midway between the two, so as to make the section of the left lobe of the prostate in its longest diameter, that is, in a direction downwards and backwards (Fig. XXXIX. L).

The knife is now withdrawn, and the left forefinger inserted. In most cases it will be long enough to reach the bladder and touch the stone, and may then be freely used

by gradual pressure to dilate the wound; this may be done very freely when necessary for a large stone, if only the ring of fibrous tissue surrounding the urethra be first cut and the bladder fairly entered. Whenever the stone is felt by the finger, the assistant may withdraw the staff.

When the operator has thus felt the stone and sufficiently dilated the wound, the next step is to introduce the forceps; this should be done under the guidance of the finger, and with the blades closed. When the stone is felt the blades should be opened very widely, slightly withdrawn, and then pushed in again, the lower one, if possible, being insinuated under the stone. The blades must be made fairly to grasp and contain the stone in their hollow, for if they only nibble at the end of an oval stone, extraction is impossible. Extraction should then be performed slowly, with alternate wriggings of the forceps from side to side, so as gradually to dilate, not to tear, the prostate, and the operator must remember to pull in the axis of the pelvis, not against the os pubis or the promontory of the sacrum.

If there is much resistance, it may possibly be caused by the stone having been caught in its longer axis, and this may be remedied by careful manipulation by means of the finger and forceps. If the stone is still too large to be extracted without greater force than is warrantable, there are still various expedients (see *infra*, p. 306).

In most cases, however, the stone is removed rapidly enough by the single incision. The finger, or a sound, must then be introduced to feel if any more stones are present. The closed forceps make a very effectual instrument for this purpose. Much information may be gained from the appearance of the first stone, the presence or absence of facets. Its smoothness or roughness enables us to form a pretty certain opinion; yet the bladder should always be carefully searched; and if the stone has been friable or broken in ex-

traction, should be washed out by a current of water. Where the calculi are very numerous, or where many fragments have separated, the scoop will be found useful, both for detecting and removing them. All the stones being extracted, there is in most cases little or no bleeding (see *infra*, Hæmorrhage). The tube already described may now be inserted and tied into the bladder. It may be retained for forty-eight or seventy-two hours, according to circumstances. Care must be taken lest it be closed up by coagula during the first hour or two after the operation. In children the tube is not necessary, and from their restlessness might possibly do harm, but in adults (though it is omitted by some surgeons) experience shows it is a valuable adjunct in the after-treatment.

Having thus traced the course of an ordinary uncomplicated case of lithotomy by the lateral operation, a brief notice is suitable of some of the obstacles and difficulties, some of the dangers and bad results which may be met with, and the best methods of overcoming them.

1. *Large size of the stone*, as an obstacle to extraction. When, either from the enormous size of the stone, generally to be made out before the operation, or from some congenital or acquired deformity of the pelvis, it is obvious beforehand that the calculus cannot pass through the bony pelvis entire, a choice of two courses remains, either—

- (1.) The high or supra-pubic operation (*q.v. infra*); or
- (2.) Crushing of the calculus in the bladder, and removal piecemeal. Instruments of great strength have been devised for this latter operation. The risk to the bladder is very great, and fragments are apt to be left behind; these are sure to form nuclei of new calculi.

2. *Peculiarities in the position or relations of the stone in the bladder*:—

- (1.) It may lie in a sort of pouch behind the prostate,

and thus be out of the reach of the forceps. This may be remedied by the use of curved forceps, or, better still, by the finger in the rectum to tilt up the stone into the bladder.

(2.) It may lie above the pubis in the anterior wall of the bladder. Pressure on the hypogastrium, or the use of a strong probe as a hook, will generally suffice to dislodge it.

(3.) The stone may be encysted. This is extremely rare, and, as Fergusson says, we hear more of these from bunglers who have operated only several times, than from those who have had large experience.

3. *An enlarged prostate* is at once a source of difficulty and of some danger.

The distance of the bladder from the surface may be so very much increased by enlargement of the prostate as to render even the longest forefinger too short to reach the stone or even the bladder. This renders the introduction of the forceps more difficult and uncertain, the dilatation more prolonged, and the extraction more dangerous. If very large, the groove of the staff may not reach the bladder, and thus the deep incision may fail of cutting the ring at the base of the gland, and the urine may thus not escape, and all the dangers of laceration of the ring may result. Such cases may be well managed by the insertion of a straight deeply grooved staff into the insufficient incision, and fairly into the bladder, and on this, pushing a cutting gorget through the uncut portion of the gland. This insures a sufficient yet not dangerous incision, which we cannot so safely perform with the knife, as the parts are so far beyond the reach of the guiding forefinger.

Under the head of risks after lithotomy we may class the following :—

1. Sinking, or shock. In the very aged or very young, or after a very prolonged or painful operation, shock may

now and then kill the patient within a few hours. Since the days of chloroform this result is extremely rare.

2. Hæmorrhage seems to be a very infrequent risk. The transverse perineal artery, which is always cut in the operation, is small, and rarely bleeds much. If the bulb is wounded, as no doubt frequently occurs, the flow from it can easily be checked. The pudic is so well protected from any ordinary incision as to be practically safe; and if wounded by some frightfully extensive incision, it can be compressed against the tuberosity of the ischium.

There is an abnormal distribution of the dorsal artery of the penis, in which, rising higher up than it ought, and coursing along the neck of the bladder, and the lateral lobe of the prostate, it may be divided. This may give trouble, and even result in fatal hæmorrhage. Fortunately it is rare. The author has met with one case in a boy of eleven, in whom a very severe hæmorrhage was not to be explained. The patient recovered without another bad symptom.

Again, a general oozing may often appear a few hours after the operation, when the patient is warm in bed, apparently from the substance of the prostate. If raising the breech and the application of cold fail to arrest it, it may be necessary to plug the wound. This is done by stuffing it with long strips of lint round the tube. Great care must be then taken lest the tube become occluded.

3. Infiltration of urine may occur as a result of a too free incision of the vesical fascia (in adults), and still more frequently of a too small external wound.

Here it should be noticed that in children it is fortunately of very little consequence to preserve the integrity of the prostatic sheath of vesical fascia. In them the prostate is so exceedingly small and undeveloped, that even the forefinger could not be introduced into the bladder without a complete section of the prostate. Probably from the blander

nature of their urine, and the greater vitality of their tissues, this is of less consequence, as it is rarely found that any bad effects result from this section.

Among other risks we find peritonitis, inflammation of neck of bladder, inflammation of prostatic plexus of veins, resulting in pyæmia, suppression of urine, and other kidney complications. For the symptoms and treatment of these there is no place in a mere manual of surgical operations.

Wound of Rectum and Recto-Vesical Fistula.—Such wounds were not uncommon, and in many cases unavoidable, before the days of chloroform, from the struggles of the patient; now they are comparatively rare, and should be still rarer. They probably occur in more cases than the surgeon is aware of, and heal up without his knowledge; we may arrive at this conclusion from the fact that small wounds are found in *post-mortem* examinations of cases in which no such complication has been thought of.

They occasionally heal without giving any trouble, but, at other times, as the external wound contracts, a communication forms between rectum and the urethra, in which the contents are apt to be interchanged in a most disagreeable manner, flatus passing per urethram, and urine per rectum.

When it is evidently not going to heal spontaneously, the septum between the external orifice of the wound and the communication with the gut should be laid open, as in the operation for fistula *in ano*.

There are certain modifications and varieties in the method of operating for stone through the perineum, which deserve at least a brief notice :—

1. *The bilateral operation.*—Though he was not the inventor, Dupuytren's name is justly associated with this operation. The principle of it is to divide both sides of the prostate equally, so as to give more room for extraction of a large stone, without the necessity of much laceration, or the risk of cutting through the prostatic sheath of fascia.

The operation.—A semilunar incision is made transversely across the perineum, extending from a point midway between the right tuber ischii and the anus, upwards, crossing the raphe nearly an inch above the anus, and then curving downwards to a corresponding point on the opposite side. The skin, superficial fascia, and a few of the anterior fibres of the external sphincter, are thus divided, and the groove of the staff sought by the forefinger. The membranous portion of the urethra is then laid open in the middle line, and the beak of a double lithotome caché securely lodged in the groove. It is then pushed into the bladder with its concavity upwards, and when fairly in it is turned round, its blades protruded to the required extent, and withdrawn with its concavity downwards, thus dividing both lobes of the prostate in a direction downwards and outwards (Fig. xxxix. D D). The operation is finished in the usual manner. Though it is a comparatively easy operation, and theoretically may be proved to have many advantages, experience has shown that the results are not so favourable as those of the ordinary lateral operation.

2. *Buchanan's medio-lateral operation* on a rectangular staff.—The staff is bent at a right angle three inches from the end, and deeply grooved on its left side. This is introduced into the urethra so that the angle projects the membranous portion of the urethra close to the apex of the prostate, and the terminal straight portion enters the bladder parallel to the rectum. The angle projects in the perineum, so that the operator with his left forefinger in the rectum is enabled, by a stab with a long straight bistoury (held horizontally and with the cutting edge to the left side), at once to enter the groove, and, by following the groove, the bladder. Whenever the escape of urine shows that the bladder is fairly reached, the knife is withdrawn so as to make a lateral section of the prostate, and then, with the finger still in the rectum, to make an incision in the ischio-rectal fossa, of sufficient size to allow the stone to be easily withdrawn.

The inventor claims for this method that it is easier, that there is less risk of hæmorrhage, wound of the rectum, and infiltration of urine.

3. *Allarton's operation of median lithotomy* suits admirably for stones known to be small, but is quite unsuitable for large ones. Probably in most cases it should be superseded by lithotrity.

Operation.—A large curved staff with a central groove is to be held firmly hooked up against the symphysis pubis, and then steadied by the left forefinger in the rectum. The operator pierces the raphe of the perineum with a long straight bistoury about half an inch above the verge of the anus, enters the groove of the staff, and cuts inwards, almost, but not quite, into the bladder. In withdrawing the knife the wound in the urethra is enlarged upwards towards the scrotum. A ball-pointed probe is then passed on the staff into the bladder, the staff is withdrawn, and the finger, guided by the probe, is used to dilate the neck of the bladder, to an extent sufficient for the removal of the stone by a small pair of forceps.

In this operation the prostate is hardly incised at all. The results are not better than those of the lateral operation.

It will be noted that in the above account of lateral lithotomy the authorities quoted are the dead, not the living. Our great surgeons of the past so perfected the operation that no change is even suggested. The change now is in the selection of the operation, and the supra-pubic is now taking the place of the lateral in the comparatively few cases, an ever lessening number, in which lithotomy is done at all.

2. Lithotomy above the Pubes, or the High Operation.—

In cases where, from the known size of the stone, or from the deformity of the bones of the pelvis, it is impossible that the stone can be extracted entire in the usual manner; in cases where the prostate is very much enlarged, or where there is any real or supposed likelihood of inflammation of the neck of the bladder, the supra-pubic operation is warrantable. Its performance is easy, it does not involve any wound of the peritoneum if properly performed, and there is no risk of hæmorrhage. In more than one case this operation has been attended by wound of peritoneum and subsequent escape of intestines through the wound, even when dressed antiseptically and performed under spray.

Its performance has been made more easy and certain by the introduction of the method of distending the rectum by an elastic bag filled with air or tepid water. This throws the bladder upwards, rendering it more accessible. Care must be taken that this distension be not overdone, as cases are on record in which the rectum has been ruptured. If the bladder cannot be easily distended with fluid, a curved sound should be introduced, and by depressing its handle, the end can be projected forwards, so as to show above the pubes.

Operation.—The patient lies on his back, with his head and shoulders slightly raised, so as to relax the abdominal muscles, and his legs hanging down over the edge of the

table. If his bladder can bear it, it should be fully distended, either by voluntary retention of the urine, or by injection with tepid water. A vertical incision is then made in the middle line, separating the recti muscles from below upwards, care being taken to push the peritoneum well out of the way, which is easily done by the finger in the loose cellular tissue of the part. The anterior wall of the bladder is then exposed, uncovered by peritoneum; it must be opened with great care, also in the middle line, while the wound in the parietes is held aside by retractors. The wall of the bladder should be transfixed by a curved needle, and thus held in position before it is opened. The stone is then removed by a pair of straight forceps, generally with great ease. In some cases, in children and in young adults with healthy urine, the wound in bladder may be at once stitched; in others it is safer to leave a drainage-tube in it, and dress it with antiseptic wool or gauze. When compared with the lateral operations the statistics of the supra-pubic operation used to be discouraging, the mortality being one in three and a half to one in four. But in the improved methods the results are gradually improving, and there is little doubt that at present this operation is gaining ground.

The late Mr George Bell, a most successful lithotomist, proposed to perform this operation in two stages. In a case of greatly enlarged prostate, where the bladder had been punctured above the pubes by a country surgeon for retention of urine, he dilated the track of the canula by means of sponge-tents gradually increased in size, and then succeeded in extracting through the dilated opening several large calculi. The case recovered, and may encourage similar attempts.

Mr Annandale has proposed a method of performing the supra-pubic operation which is ingenious and precise, but

requires a considerable amount of dexterity for its safe performance. He first seizes the stone with a lithotrite, and then raises it up so as to be easily felt and removed by the supra-pubic operation.

The following are interesting historically rather than practically :—

3. Operations through the Rectum.—(a.) *Sanston's Recto-vesical Operation.*—The principle of this operation consisted in laying the two canals, the rectum and the urethra, into one. A large staff, grooved on its convexity, being inserted into the urethra, the operator, with the forefinger of his left hand in the rectum as a guide to the knife, pierces the anterior wall of the rectum, reaches the groove of the staff just in front of the prostate, and cutting outwards divides the rectum, the anterior fibres of levator ani, and the sphincter, as well as the skin of the perineum in the middle line. Entering the knife again into the groove of the staff, it is to be pushed right onwards into the bladder, dividing the prostate, and avoiding if possible the seminal vesicles and ducts; the stone is then very easily removed.

Though this operation was supposed to lessen the risk of pelvic infiltration it is *not* found to do so, and it adds the additional inconvenience of almost inevitable rectal fistula, through which the urine escapes. It is certainly a very easy operation, but the mortality is found to be greater than in the ordinary lateral operation.

(b.) *Lithotomy through the Rectum above the Prostate.*—The presence of a small portion of bladder beyond the prostate in close relation to the rectum renders it possible, in cases where the prostate is not enlarged, to enter the bladder and remove a stone of moderate size, without interfering with the peritoneum, prostate, or neck of the bladder.

This ingenious but difficult operation was performed for the first time by Drs Sims and Bauer in 1859.

I quote the brief notice of the operation by Dr Sims from the *Lancet* of 1864 (vol. i. p. 111):—

“The patient was placed on the left side, and my speculum was introduced into the rectum, exposing the anterior wall of the rectum, just as it would the vagina in the female. A sound was passed into the bladder. The doctor entered the blade of a bistoury in the triangular space bounded by the prostate, the vesiculæ seminales, and the peritoneal reduplication. He passed the finger through this opening, felt the stone, and removed it with the forceps without the least trouble. The operation was done as quickly and as easily as it would have been in a female through the vaginal septum. After the removal of the stone, Dr Bauer kindly asked me to close the wound with silver sutures, which I did, introducing some five or six wires,

with the same facility as in the vagina. There was no leakage of urine. The patient recovered without the least trouble of any sort. The wires were removed on the eighth day, and on the ninth day the patient rode in a carriage with Dr Bauer a distance of four or five miles, to call on, and report himself to, our distinguished countryman, Dr Mott."

The chief risks in this operation seem to be the chance of wounding the peritoneal *cul-de-sac*, as the amount of free space between it and the prostate seems to vary much in individuals and in races. Dr Marion Sims mentioned to me in conversation that he believed this operation impossible in the negro race, from the greater projection downwards of the peritoneal reduplication. An enlarged prostate would be an insuperable objection. The use of silver wire, to close up the wound at once, diminishes very much any risk of rectovesical fistula.

Litholapaxy and Lithotrity.—The great majority of bladder calculi should be recognised early enough to be dealt with without a cutting operation. Lithotrity, or the removal of calculi by breaking them up in the bladder, used to be performed in stages only, a certain time being spent and a certain amount of work done at any given sitting. Litholapaxy, the name given by its distinguished inventor, Dr Bigelow of Boston, is an operative procedure in which under an anæsthetic, by powerful lithotrites, and aided by an exhausting apparatus, stones even of large size are crushed and removed at one sitting. The old rules as to certain sizes of stone and duration of operation are now little regarded, and comparatively few stones in adults are now treated by lithotomy.

In what cases is litholapaxy suitable? Sir Henry Thompson,¹ whose authority is probably the highest attainable, says, "There is for myself no hesitation in advising that for all stones, both great and small, hard and friable, cited at all ages after puberty has been passed, the one-sitting operation, with instruments always conformable to the requirements of the case and in fairly practised hands,

¹ Holmes' *System of Surgery*, vol. iii. p. 307.

is by far the most successful procedure which has yet been employed in the history of surgery."

Even in the case of male children litholapaxy has been lately used with great success by Dr Keyes,¹ Dr Keegan² and Dr Freyer.³ Their cases show that the urethra of a boy will admit an instrument quite capable of crushing a moderate sized stone.

The *urethra* should be capacious enough to let the instrument pass easily and painlessly.

The *bladder* should be large enough to contain four ounces of water at least, should not be much inflamed, and, on the other hand, should not be paralyzed. Paralysis or want of tone in the bladder prevents the thorough evacuation of its contents, and still more the expulsion of the fragments of stone.

A good instrument should, as far as possible, combine strength with lightness. The curved portion of the fixed blade should be fenestrated to allow escape of the fragments and thorough closure of the instrument.

The movable blade must be so arranged as to combine perfect ease of movement up and down in seeking for the stone, with a powerful, slow, and gradual approximation in crushing it. This can be managed by an ingenious arrangement, which leaves the movable blade under the control only of the operator's thumb till the stone is found, and yet by touching a spring, gives him the advantage either of a fine screw or of a rack and pinion movement for crushing the stone.

Operation.—The patient being prepared by a free evacuation of the bowels, and the urethra having been previously fairly dilated, he is asked to retain his urine as long as

¹ *Lancet*, 1885.

² *Lancet*, 1890.

³ *British Medical Journal*, 1891.

possible, or, if he cannot do so, a few ounces of tepid water may be injected per urethram.

He is then laid on a sofa or table, the breech being well raised by pillows, the shoulders low, the thighs and knees bent up and separated. The instrument, well warmed and oiled, is then introduced with the blades closed. When fairly into the bladder the search for the stone begins.

In a work of this size it is impossible to describe in detail the various procedures of the operation, suffice it here to give the principles. The patient being in position and under the anæsthetic, the largest evacuating tube that his urethra will admit after the meatus is incised is inserted, the urine is drained off, and the rubber evacuator which is afterwards to remove the fragments is attached to the washing bottle, and boric solution is gently forced into the bladder. By alternate movements of the bulb the bladder is filled and emptied, and thus washed several times. Two or three ounces at least of fluid are left in the bladder and the tube is withdrawn.

Now the lithotrite has to be used to crush the stone. With great gentleness, and at first with its blades closed, and by slow movement of blades, first on one side, and then, if necessary, on the other, the stone is grazed, then the male blade is opened as far as may be deemed necessary, then a pause is made to allow currents of displaced urine to settle, and then blade is again slowly closed, when probably the stone is caught. It is then to be fixed by screwing the blade down slowly on it, and crushed if possible in the centre of the viscus, and it probably breaks into four or five fragments. Each of these must again be seized and crushed. After ten minutes of this work the lithotrite may be withdrawn, and the evacuating catheter reintroduced. The aspirator, charged with warm boracic solution, is attached, connecting tap opened, and a small portion of the solution

sent into the bladder. This on its return washes out some of the fragments. This is repeated in a few seconds, always giving a pause between each filling and emptying of the bladder. After obtaining all the debris that will come, it may be necessary to use the lithotrite again, and again repeat the washing out. For most full and interesting details of the operation, I would refer to Sir H. Thompson's paper referred to above, and the interesting article on Calculus by Dr Keyes, and on Lithotrity by Dr Hingston, both in the *International Encyclopædia of Surgery*, vol. vi.

Operations for Stricture of Urethra.—Under this head many manipulations and operations might be described; the very instruments devised being exceedingly numerous and complicated. Enough here to detail a few of the more simple and practical procedures under the different heads of—1. *Dilatation* gradual and forced. 2. *Internal Division*. 3. *External Division*.

1. **Dilatation.**—Under this head we have—

a. Vital Dilatation.—The passing of a succession of bougies, gradually increasing in diameter, at intervals of three or four days, for the purpose of exciting an amount of interstitial absorption in the new material constituting the stricture, sufficient to remove it. Passing a bougie, though certainly often very difficult, perhaps should hardly come into the category of surgical operations, yet to preserve a certain completeness in the account of stricture, a very brief description may be here inserted.

The recumbent posture is in most cases to be preferred. The patient should lie flat on his back, with the knees slightly bent and separated, and the head and shoulders slightly raised on a pillow. The operator standing on the patient's left side, raises the penis in his left hand, and with

the right introduces the instrument, previously warmed and oiled, into the meatus. He then pushes it very gently onwards, at the same time stretching the penis with the left hand, just so far as to efface any wrinkles in the mucous membrane, till the point reaches the bulbous portion. The axis of the instrument, which at first for convenience was over the left groin, has now gradually been approaching the middle line. When this is reached, the instrument should be raised from the abdomen, and the handle cautiously carried in the arc of a circle first upwards and then downwards, till, when the instrument is fairly into the bladder, the handle is depressed between the patient's thighs. While this is being done the operator's left hand should be withdrawn from the penis, and the points of the fingers applied to the perineum.

In cases of difficulty certain points may be remembered:—

(1.) That the point of the instrument may in the first inch or two be occasionally entangled in a lacuna in the roof, especially when a small instrument is used; hence the beak should be at first maintained against the inferior wall of the canal.¹

(2.) That the handle should not be depressed too soon; if it is, there is a risk of a false passage being made through the upper wall.

(3.) The opposite error may force the point out of the urethra between the membranous portion and the rectum, and onwards into the substance of the prostate gland.

And certain cautions may be given:—

(1.) In every exploration of an unknown urethra the surgeon should commence with an instrument of medium size, certainly not less than No. 7 or 8.

¹ Holmes' *Surgery*, vol. iii. p. 213.

(2.) In cases of difficulty occurring in the urethra behind the scrotum, invariably use the forefinger of the left hand in the rectum as a guide.

(3.) Expression of pain on the part of the patient is no indication that a false passage is being made, nor its absence that the instrument is in the passage, for it was a remark of Mr Syme, that passing an instrument through a stricture is generally more painful than making a false passage through the walls of the urethra.

An instrument may be passed, while the patient is erect, with the following precautions:—The patient should stand with his back against a wall, his arms supported on the back of a chair on each side, heels eight or ten inches apart, and four or five inches from the wall; his clothes thoroughly down, not merely opened. The bougie should then be held nearly horizontal, with its concavity over the left groin of the patient, the penis being raised in the surgeon's left hand. Introduced thus for four or five inches, the handle is gradually raised into the middle line of the abdomen, and to the perpendicular; it is then to be lightly depressed, and, as the point enters the bladder, brought down towards the operator until it sinks beneath the horizontal line.

b. Forced Dilatation.—Under this head we might describe at great length mechanical contrivances to force or rupture a stricture. A word or two on a few of the most important:—

(1.) Conical bougies of steel or silver.

(2.) Mr Wakley's method, on which many others have been founded. He passed a small bougie or wire into the bladder, over which were slipped straight tubes of varying size, with perfect certainty that they could not leave the urethra.

(3.) Mr Holt's method.¹—The principle of it is to rupture the stricture at once, so that a No. 12 catheter can immediately be passed into the bladder.

¹ *The Immediate Treatment of Stricture.* By Bernard Holt, F.R.C.S., London. Third edition, 1868.

He attained this object by means of an instrument composed of two grooved blades, united about one inch from their apex, into a conical sound, which at its apex is about the size of a No. 2 bougie. This is passed into the bladder, and the grooved blades are separated to any extent that is desired by passing down between them a straight rod equal in size of a No. 8, 10, or 12 bougie. To guide this properly it is made hollow, and it is passed down over a central wire which lies between the grooved blades of the instrument, and is welded to the apex. A great improvement is effected on Mr Holt's later instruments by this wire being made hollow, and fitted with a stilette, for by this means we can with certainty ascertain whether or not the instrument has been passed into the bladder. This instrument, which is an improvement upon one invented by Perrève nearly fifty years ago, has been used on very many occasions by Mr Holt and others with success. The risk to life, if the case be properly managed, is trifling, but, like every other means of treating stricture, it has the objection that the stricture is liable to recur, unless bougies be passed at intervals for months and years.

Sir Henry Thompson introduced and described¹ another very ingenious instrument for the same purpose, constructed on somewhat similar principles. He now rarely uses it, relying more on internal urethrotomy.

All these methods of forcible dilatation are now comparatively little used in this country, though still used to a considerable extent in France. The following method of internal division has been gaining ground:—

2. Internal Division of Stricture is a mode of treatment which, once much disparaged, has of late years been much more used, especially in resilient strictures. Very

¹ Holmes' *System of Surgery*, 1st edition, vol. iv. p. 399.

numerous instruments have been invented, and division can be performed in either of two ways:—

(1.) *From before backwards.*—This method, to be at all admissible, requires a guide to be previously passed; a lancet-shaped blade may then be slipped down a groove in this guide till the stricture is divided. This is least objectionable in cases of stricture close to the meatus.

Probably the best instrument on this principle is that of Mr Reginald Harrison. Its anterior portion is small enough to penetrate a tight stricture; behind this is a broader portion, equal to No. 10 bougie, with a shoulder. In the broad portion a lancet-shaped knife is concealed, which, projected by a spring in the handle, runs along a groove in the narrow portion, the amount to which it may be projected being regulated by a screw.

(2.) *From behind forwards.*—To make the incision thus, it is of course necessary that the stricture should be so far dilatable as to admit an instrument the point of which is large enough to contain the blade by which the stricture is to be divided. This will be found to be at least equal in size to a No. 3 or No. 4 catheter. In many instruments it is much larger.

Civiale's instrument for internal incision of the urethra from behind forwards has the very high recommendation of Sir H. Thompson.¹ It consists of a sound with a bulbous extremity (as large as a No. 5 bougie) which contains a small blade, which can be made to project for such a distance as the operator wishes. It is passed through the stricture with the blade concealed, till the bulb is carried about one-third of an inch or more beyond the stricture; the blade is then projected, and the incision made by drawing it slowly but firmly outwards towards the meatus, with

¹ Holmes' *System of Surgery*, 3rd edition, vol. iii. p. 221.

the blade towards the floor of the urethra, till the stricture is divided in its whole extent. Sir H. Thompson recommends this to be used in cases *where it is not that the stricture is of very small calibre, but that it is undilatable*, that prevents the cure. Many modifications of above have been devised by Lund, Teevan, and other surgeons, on similar principles.

3. Mr Syme's Operation of External Division.—Mr Syme held that no stricture through which the water can escape should be called *impermeable*, for by patience and care the surgeon should always be able to pass a slender director through the stricture on which it may be divided with ease and certainty. The old operation of "perineal section" for so-called impermeable stricture is very different, being difficult, dangerous, and uncertain in its results.

Operation.—A director is passed into the stricture. Mr Syme's directors are of different sizes, the smallest being in diameter less than an ordinary surgical probe. They are made of steel, are grooved on the convexity, and have this peculiarity, that while the lower half is small, the upper is of full size (No. 8 or 10), the difference in calibre occurring quite abruptly. The presence of this "shoulder" on the staff enables the operator to ascertain exactly the position of the stricture, and also to tell when it is fully divided without the necessity of withdrawing the instrument.

This being fairly in the stricture, the patient is put in the position for lithotomy, an assistant holds the staff in his right hand, drawing up the scrotum with his left.

The surgeon then makes an incision in the middle line over the stricture for the necessary distance, from above downwards, till he exposes the urethra, and feels exactly

the shoulder of the staff. Care must be taken not to go past the urethra at either side. When he distinctly feels the outline of the staff, he takes it in his left hand, and a short sharp-pointed bistoury in his right. It should be held firmly in the palm of the hand, with the back of the blade resting on the forefinger, the pulp of which guides the point to the groove, and guards it when making the incision; the knife is to be placed on the groove beyond (*on the bladder side*) of the stricture, and brought forwards, slowly cutting through *the whole* stricture; till the shoulder of the staff is reached. It requires strength and precision to divide thoroughly the indurated stricture, which is apt to elude the knife.

The shoulder of the staff can now be passed through the stricture if the operation is complete; if not, the incision must be extended, always in the middle line, and guided by the groove. When thoroughly divided, the staff is now to be withdrawn, and a full-sized catheter with a double curve passed into the bladder. This should *not* be furnished with a stop-cock or plug, lest the bladder should by inadvertence be allowed to be too full, and extravasation into the cellular tissue of the urethra take place along the side of the instrument.

The catheter should be tied in, and left for two, sometimes for three days, when it can generally be removed with safety, and a bougie should be passed at intervals of three or four, till the wound is healed. To prevent recurrence of the stricture, it is a wise precaution to pass an instrument at intervals for many months after the cure is apparently complete.

In certain cases, where the stricture is far back and the urinary symptoms severe, Mr Syme found advantage from the introduction of a shorter double-curved catheter (only about nine inches long) through the wound into the bladder,

where it should be left for three days. This seems to diminish the risk of rigors, and other symptoms of fever, which are apt to occur when the urine is allowed for the first time to pass over the wound.

Perineal Section is an operation both dangerous and difficult; as Sir Astley Cooper used to say, "the surgeon who performs it requires to have a long summer's day before him."

No director or guide can be passed. A full-sized catheter must be passed as far as possible *up* to the stricture, and held firmly in the middle line. The patient must be tied up in lithotomy position on a table in the very best light that can be obtained. The perineum being shaved, an incision must be made in the middle line from over the point of the catheter to the verge of the anus, if the stricture extend far back.

The urethra should then be opened over the catheter, the edges of the mucous membrane held to each side by silk threads passed through them; and the surgeon now endeavours to pass a fine probe into the opening of the stricture; if this can be done, it is comparatively easy to slit the stricture up. If not, the surgeon must simply seek for the remains of the urethra by slow, cautious dissection in the middle line. If successful, a catheter must be secured in the bladder in the usual way.

A stricture near the orifice, or, as it is not uncommon, involving merely the meatus, can be treated with great ease in the above manner by division on a grooved probe. When quite close to the orifice, with a well-defined hardness, as of a ring round the urethra, it may be divided subcutaneously by a tenotomy knife or other narrow-bladed instrument. It is not necessary to keep a catheter in the bladder in cases where the stricture has been in front of the scrotum.

Mr Wheelhouse uses a straight steel staff grooved to within an inch of its point, which terminates in a comma

shaped tip with an abrupt shoulder turned from the grooved side. This is thrust downwards into the urethra till the point bulges in the middle line of the perineum at the stricture. While an assistant holds it, the surgeon can easily force a narrow-bladed scalpel through the skin of middle line of perineum into the groove. The wound is enlarged, its edges seized with fine forceps, and carefully sponged, when the surgeon can generally see the opening of the stricture at the bottom of the little hollow. A probe-pointed grooved director can be then passed into the stricture, on which it can be divided, and then a catheter can be run into the bladder on the guidance of a slender gorget or director, which replaces the probe. "The operation requires a good light and infinite patience.¹"

Cock's² Operation for Stricture.—In this the urethra is opened *behind* the stricture without a guide. It is a difficult operation, but has one enormous advantage, that it secures perfect rest for the diseased portion of the urethra, and deals with a portion of the canal which is healthy, often dilated, and is accessible. It should be reserved for very bad cases of impermeable stricture with induration, numerous sinuses, and frequent perineal extravasations.

The patient tied up in lithotomy position, the operator's left forefinger in the rectum touches the apex of the prostate gland. A broad double-edged knife with a sharp point is plunged steadily in middle line of perineum till its point is felt in close proximity to the tip of the left forefinger, while by an upward and downward motion of each edge the vertical mesial wound in soft parts is made as large as is necessary. The urethra is thus opened in membranous portion, knife withdrawn, but with left finger still in rectum,

¹ Treves, *op. cit.*, vol. ii. p. 630.

² *Guy's Hospital Reports*, 1866.

a probe-pointed director is passed into the bladder on which a No. 12 gum-elastic catheter straightened on its stylet is slipped into the bladder, cut short, and tied in with tapes.

"It is not such an easy operation as it appears, and it is a severer operation than the size of the wound would suggest"¹

Puncture of the Bladder.—A patient and dexterous use of the catheter prevents this operation from being often required; still, circumstances may arise in which it is found impossible to enter the bladder *per vias naturales*. In such a case the bladder may be punctured from the outside by a curved trocar and canula, in either of two situations.

1. *From above the Pubis.*—This operation is a very simple one, and when the bladder is distended need not imply a wound of the peritoneum.

Operation.—A preliminary incision, varying in length according to the amount of fat, should be made above the pubis exactly in the middle line; the edges of the recti should be separated, the peritoneum pushed out of the way and upwards by the finger, and a curved trocar plunged into the distended bladder obliquely backwards. The canula should be retained for a day or two, and then a flexible catheter with a shield inserted instead. Such instruments have been worn for years. Supra-pubic aspiration is in suitable cases an excellent method of relieving retention, as it can be repeated frequently in a small area; but it must be remembered that in cases of old stricture with hypertrophied and diseased walls and with septic urine, the leaking of even a single puncture may have most serious results.

2. *From the Rectum.*—Except in cases of enlargement of the prostate, it is both easy and safe to puncture the bladder from the rectum. The well-known triangular space un-

¹ Jacobson, *op. cit.* p. 890.

covered by peritoneum, with its apex in front close to the prostate, and bounded on either side by the vasa deferentia and vesiculæ seminales, can be easily reached by a curved trocar. This should be guided by one, or, still better, by two fingers, into the rectum, with its concavity upwards, and the point should be pushed upwards by depression of the handle whenever it is fairly behind the prostate. The trocar may then be withdrawn, and the canula retained for at least forty-eight hours by a suitable bandage. Mr Cock of Guy's Hospital, had a special canula for the purpose,

FIG. XLI.*

which expands at its extremity after its introduction, and thus is not apt to slip.¹ Some surgeons insist that the surgeon should be able to ascertain the existence of fluctuation between the finger in the rectum, and the other hand above the pubes. This is exceedingly difficult to elicit when the bladder is very much distended, and from the constrained position of the finger in the bowel. This operation is much more rarely performed now than twenty years ago used to be the case. The probable explanation is that the bolder use of anæsthetics and improved instruments render it less frequently necessary.

Phymosis.—Elongation of the prepuce, with contraction

* Diagram of puncture of the bladder:—B, bladder; SP, symphysis pubis; Sc, scrotum; b, bulb; pr, peritoneum; P, prostate; R, rectum; S, sacrum and coccyx.

¹ *Med. Chir. Trans.*, vol. xxxv.

of its orifice, in most cases congenital, sometimes so extreme as to cause difficulty in micturition, and frequently preventing the uncovering of the glans.

Operation.—In all well-marked cases, the following is required. The elongated prepuce should be pulled forwards by a pair of catch-forceps, and a circle of skin and mucous membrane removed by a single stroke of a bistoury, or by sharp scissors. Care should be taken lest the glans be in-

FIG. XLII.*

cluded in the incision, as has happened in *at least* one instance. The skin will then be found to retract very freely beyond the glans, but the mucous membrane is found still to cover the glans, and its orifice is still constricted. It must then be slit up (Fig. XLII. *b b*) on the dorsum of the glans, with probe-pointed scissors, as far as the corona, and the

glans will then be thoroughly exposed. The edges of mucous membrane and skin should then be stitched to each other by at least five or six fine silk or catgut sutures, any bleeding points having been first carefully secured. The angles will in time round off, and a wonderfully seemly prepuce be obtained. This operation may be done as a method of cure for obstinate enuresis in cases in which the prepuce is very long and redundant, even when it is not too tight. The author has done this in more than fifty cases with excellent results.

Varieties.—When the prepuce is narrowed at its orifice without

* Diagram of operation for phymosis :—*a*, glans penis ; *b b*, mucous membrane exposed by retraction of the skin, and slit up ; *c d*, sutures introduced and ready to be tied, uniting the skin and mucous membrane.

being redundant in length, a milder operation will prove sufficient. The principle is the same as in the former, but the amount of incision is less, and nothing is removed. Two methods are possible:—

1. *By scissors.*—The blunt point of a pair of scissors is introduced through the preputial orifice, the other blade being outside, and the skin and mucous membrane are divided for about half an inch; the skin being then retracted, the mucous membrane is still further divided by one or two additional snips, and then the edges of skin and mucous membrane are stitched together by one or two points of suture.

2. *By knife.*—A director being introduced within the prepuce, a narrow-bladed knife is guided along it, and pushed through the prepuce from within, and then made to divide skin and mucous membrane from within outwards. Stitches as before.

N. B.—Be careful lest the director pass into the meatus urinarius, and the glans be split up.

Again, some surgeons prefer two lateral incisions instead of one dorsal one. In this case skin and mucous membrane should be divided by scissors for about a quarter of an inch, and then a single stitch inserted in the angle of junction. This has been further modified by Cullerier, who proposed the division of the tight mucous membrane only, in three or four points. He used a pair of scissors with one sharp and one probe-pointed blade, the sharp one thrust in between skin and mucous membrane, the blunt one between the mucous membrane and the glans.

Amputation of the Penis.—This exceedingly simple operation is performed by a single stroke of an amputating knife, drawn along from heel to point, while the penis is stretched in the operator's left hand. As there is more risk of redundancy than of deficiency of the skin, no attempt is made to save it. Numerous vessels in the corpora cavernosa require ligature. Amputation of the penis may be done bloodlessly by the thermo-cautery even close to its root. Transfix the root of corpora cavernosa by a needle; above this pass two or three turns of an elastic ligature; then slowly divide at a low red heat the skin and corpora cavernosa below the needles; split the urethra after dividing its mucous membrane with a knife. The author has done this several times with ease and rapid healing.

The chief risk is stricture of the orifice of the urethra.

To prevent this, several modifications of the operation have been introduced.

FIG. XLIII.*

1. *Ricord's Method*.¹—After the amputation the surgeon seizes with forceps the mucous membrane of the urethra, and with a pair of scissors makes four slits in it, so as to form four equal flaps, and with a silk ligature stitches each of these to the skin. Contraction of the cicatrix will thus tend to open rather than close the urethral orifice.

2. *Teale's Method*.²—He slits up, by a bistoury on a director, the urethra and skin over it for about two-thirds of an inch, and then stitches the one to the other, thus making it a long oval dependent orifice (Fig. XLIII.)

3. *Miller's proposed Method*.³—"A narrow-bladed knife is first used to transfix the penis between the spongy and cavernous bodies close to the root; the knife having been carried forwards for an inch and a half, its edge is turned perpendicularly downwards, and the urethra and skin flap are divided, the cavernous bodies and dorsal integument being then cut perpendicularly upwards where the knife was originally entered for transfixion. A button-hole is afterwards made in the lower flap, through which the corpus spongiosum and urethra protrude, while the flap itself is turned upwards, and attached dorsally and laterally, so as to cover in the exposed cavernous structure."

Mr Jacobson⁴ recommends a similar flap operation, but makes his flap from above, resembling in miniature the upper skin flap in an amputation of thigh. The urethra,

* To illustrate Teale's operation:—*c*, section of penis; *b*, thread inserted uniting mucous membrane and skin; *a*, thread tied.

¹ *Medical Times and Gazette*, vol. xix. p. 354.

² *Miller's System of Surgery*, p. 1255.

³ *Ibid.*, p. 1256.

⁴ *Op. cit.*, p. 907.

previously isolated, is drawn through a hole in it. It hastens healing, but has a tendency, it must be feared, to increase the risk of tightness of the new meatus.

In cases where the disease is deep, the corpora cavernosa should be removed by careful dissection, and any portion of corpus spongiosum and urethra that can be saved should be brought out through a perineal section in middle line, just in front of anus.

Hydrocele.—The very simple operation necessary for hydrocele is thus performed:—The surgeon supports the tumour in his left hand so as to project it forwards, and make the scrotum as tense as possible in front. Having carefully ascertained the exact position of the testicle, which can generally be easily enough done by a finger accustomed to discriminate the difference between a soft solid and a bag tensely filled with fluid, aided by the peculiar sensation of the testicle when squeezed, the surgeon enters a trocar and canula about an eighth of an inch in diameter into the distended cavity of the tunica vaginalis, near the fundus of the swelling. When it is evident the instrument is fairly entered, and not till then, the trocar is withdrawn, and the fluid allowed completely to drain off. When it ceases to flow the surgeon places his forefinger over the end of the canula to prevent the entrance of air, till he fits into its orifice a suitable syringe containing two drachms of the tincture of iodine, made according to the Edinburgh Pharmacopœia: the tincture of the British Pharmacopœia is not sufficiently strong. Having injected this cautiously into the cavity, the canula is withdrawn, and the surgeon, seizing the now flaccid scrotum in his right hand, gives it a thorough shake, so as to spread the iodine over as much as possible of the inner wall. When properly performed this very simple procedure very rarely fails to produce a radical

cure. In cases where in consequence of great hardness and thickness of the sac it cannot be expected to contract, it may be necessary to incise it, and with antiseptic precaution cause it to heal by granulation. It may in severe cases be necessary to excise the thickened sac.

Hæmatocele.—When the contents of the sac of the tunica vaginalis are found to be grumous instead of simply serous, or when, as often happens, only pure blood escapes when the fluid is nearly evacuated, it is found that simply evacuation and injection are very rarely sufficient to effect a cure.

After they have been fairly tried, the sac of the hæmatocele should be laid open in its full extent; any large vessels which bleed should be tied, and the cavity then stuffed with iodoform gauze. When this can be removed, which will be after two or three days, the edges of the wound should be brought closely together, and the cavity will then rapidly heal up from the bottom, and be obliterated by secondary union of granulations.

In cases where the walls of the cavity are enormously thickened, or even, as sometimes happens, almost bony in consistence, an elliptical portion may be removed with advantage.

Excision of Testicle.—This operation is rarely required except for tumours of the testicle. Hence the size of the incision necessary must vary much with the size of the tumour; and the amount of skin to be removed (if any) on the amount of adhesions it has formed to the tumour.

One or two points must be attended to in every case of extirpation of a testicle:—

1. The incision should commence over the cord just outside of the external ring, and be continued fairly over the tumour to its base.

2. As to removal of skin, some surgeons advise that none

should be taken away, others that a considerable quantity can be spared. There is certainly less risk of secondary hæmorrhage if a portion be removed, than when a flaccid, empty bag is left. The author invariably removes a very large quantity of skin if the tumour is large, as there is much more rapid healing, and the resulting scrotum is much more comfortable for the patient.

3. The cord should be exposed at the beginning of the operation, raised from its bed and given to an assistant, who should compress it gently, not from any fear of its escape into the abdomen, but to prevent hæmorrhage. If the tumour has been very large and heavy, the cord will have been much stretched, and if divided too high up, may really give trouble by its elasticity, unless the above precaution is taken. The cord then having been divided close to the tumour, the latter is removed, care being taken not to include the sound testicle in the removal. All the vessels are then to be tied or twisted, and the spermatic artery is to be secured alone, not, as used to be the case, included in a common ligature with the other constituents of the cord. Secondary hæmorrhage is very apt to occur, unless care be taken and time be given, from small scrotal branches which may have escaped notice during the operation.

Operations on the Anus and its Neighbourhood.—Fistula in Ano.—While much might be written on the pathology of fistula, and a good deal even on its diagnosis, a very few words will suffice to describe the simple and effectual operation for its relief.

Dismissing at once all so-called palliatives, drugs, unguents, pressure, and injections, as mere waste of time, and holding that the only method of cure consists in laying the fistula fairly open, the question narrows itself into this: What is the best method of laying it open? Prior to the

discovery by Ribes of the great principle that the internal orifice of the sinus is always within an inch or an inch and a half of the orifice of the anus, the operations for fistula were most unnecessarily severe; the gut used to be divided as far up as the sinuses extended; and large portions of the anus used to be excised bodily along with the sinuses. It is now a much simpler and more satisfactory operation.

Operation.—A common silver probe bent to the required shape is passed into the external opening, or, if there are more than one, into the largest and oldest one. The forefinger of the left hand being introduced into the rectum, the probe is passed through the internal orifice, and its point brought out by the anus. The portion of tissue raised by the probe can then be easily divided with the certainty that the fistula is laid fully open. Anal fistulæ have been divided by the elastic ligature, but it seems slower in action and more painful than the knife, with no counterbalancing advantages.

The author has for last few years operated almost exclusively by a long knife which is continued into a steel probe. The probe is passed up the fistula, then into the bowel, and is hooked out at the anus, and in being simply pushed on the knife cuts the fistula—*tuto, cito, et jucunde*, the patient rarely knowing that more has been done than an exploration.

In cases where, from the hardness and density of the parts it is impossible to pass the probe and bring it out at the anus, a strong probe-pointed bistoury may be passed in by the external orifice till its probe-point can be felt by the finger in the bowel at the internal opening. Supported by the finger it can then be made to cut outwards till the whole septum is divided.

In cases where there has been much undermining of the skin by putrid sinuses, they should be freely divided and their sides scraped by Volkmann's spoon; but it is rarely if ever necessary to divide the external sphincter in more than one place.

Fissure of the Anus, Ulcer of the Anus, resemble each other alike in the exceeding annoyance which they

give to the sufferer, and in the simplicity of the treatment needed.

Operation.—Once the presence of either is determined by the finger in the anus, a sharp-pointed curved bistoury should be introduced, transfixing the base of the fissure or ulcer, and then guided on the finger, completely dividing it, so as to change the ragged ulceration into a simple wound which will rapidly heal. Some surgeons treat this condition by divulsion; under chloroform the two thumbs are introduced into the anus and then forcibly separated.

Prolapsus Ani, Operation for.—Complete prolapsus, in which the whole gut is involved, as seen in the very young and the very aged, is suited for palliative rather than radical treatment.

Cases of prolapsus of the mucous membrane only, as is not uncommon in connexion with or as a result of hæmorrhoids in adults, give opportunity for operative interference.

We may act on either the skin or mucous membrane, or both at once.

1. *The skin* is often found loose, and arranged in radiating folds round the anus. In such cases, as recommended first by Dupuytren, some of these projecting folds may be removed. Again, it may be prolapsed in a great loose ring or circular fold round the margin, forming an exaggerated external pile; in such a case the loose fold may be fairly excised with curved scissors, as recommended by Hey of Leeds.

The first of these methods is apt to be insufficient, the second again has the risk of removing too much.

2. If the protrusion is chiefly mucous membrane exposed

in folds, or a ring, which is generally outside, one or two methods of treatment may be tried:—

a. By ligature, as recommended by Mr Copeland. Raising a longitudinal fold of the mucous membrane, he passed a ligature round it as if it were a pile. There is less chance of the ligature slipping if a double thread be used and its base thus transfixed. Three, four, or even more folds may be thus treated.

b. When the mucous membrane has been so long exposed as to have lost many of its characters, and to resemble leather in its toughness, excision will be found less painful and much more rapid than ligature.

A longitudinal fold at each side of the anus should be pinched up and excised by a pair of probe-pointed curved scissors.

There is always a certain amount of risk of hæmorrhage following such an operation. The risk is lessened and the result improved by stitching up the wound in the mucous membrane before the protruded portion of bowel is returned.

Polypi of the Rectum.—Pedunculated growths varying in consistence, shape, and size, but resembling each other in having a distinct stalk, and in frequently being protruded at stool.

Operation.—Invariably by ligature, which may be single round the stalk, if the tumour be globular and with a distinct narrow stalk, or by transfixion, if (as sometimes happens) the tumour be of uniform thickness throughout, like a worm.

Hæmorrhoids or Piles.—In the treatment of piles it is the differential diagnosis that is troublesome and occasionally difficult; the operative interference required is

generally very simple, if the nature of the case be rightly determined.

External Piles.—Operation.—The apex of the soft flabby excrescence should be seized by a pair of catch-forceps, and it should be cut off close to its base with a knife, or, what is better, a pair of curved scissors. Any little vessel which jets may then be secured. If, instead of numerous individual tumours, a ring of skin round the anus be involved, the whole of it should be shaved off, but not very close to its base, lest too great contraction of the anal orifice should ensue.

If the surgeon, after excising a pile or piles, will take the trouble to stitch up the wound with catgut, he will find the cure much more rapid and less painful than when this is omitted.

Internal Piles.—The chief modes of treatment are—Ligature, the clamp and cautery, and incision.

1. *Ligature.*—The patient should be directed to sit over hot water, and strain till the whole of his piles are fairly protruded. The surgeon should then under an anæsthetic overdistend and thoroughly paralyze the sphincter by his forefingers, the piles can then be more easily dealt with, and he will transfix the base of each separately with a curved needle bearing a strong double thread. The needle being cut off, the threads should be very firmly tied, each isolating its own half of the pile. The tying should be exceedingly tight, so as to cause instant and complete strangulation and death of the tumours. All the piles should be tied at the same sitting. If the piles are very small they may be secured without transfixion in a single noose after being seized by a hook or forceps. There is greater risk of the noose slipping than when the base has been transfixed. Many surgeons make a preliminary incision through the mucous membrane for the ligature to lie in.

The strangulated masses must then be returned into the bowel, and the patient kept in bed or on a sofa till the ligatures separate, which is generally not till the fourth or fifth day. A certain amount of urinary irritation, showing itself sometimes in strangury, sometimes in complete retention, occasionally follows this operation.

2. *Clamp and Cautery*.—This method, introduced and practised by Mr Henry Smith, consists in clamping each pile separately with a steel and ivory clamp, and then burning off the pile, either with an ordinary cautery iron, or by a Paquelin's thermo-cautery, at a low red heat. It is not free from risk of hæmorrhage.

3. By *Incision*, with precautions as in Whitehead's operation, which is scientific in principle. He has had 300 cases without a death. It is performed as follows:—

Whitehead's Operation.¹—After thoroughly paralyzing the sphincters by over-dilating them with two thumbs, the area of piles will then prolapse. The line of junction of mucous membrane and skin is then carefully cut with scissors, and by the aid of forceps carefully dissected from the external and part of the internal sphincters, which must be cleanly exposed till all the hæmorrhoid area of the bowel can be drawn down outside the anus. The mucous membrane *above* this area must then be transversely divided by snips with scissors, each vessel being twisted as divided, and the exposed edge of mucous membrane is then, bit by bit, stitched to the margin of the skin by silk sutures. When the operation is finished, all is dusted with iodoform, returned into anus, and dressed with oiled lint secured by a T bandage.

This operation is by no means easy, and is not free from risk of stricture after such complete removal of mucous membrane.

¹ *British Medical Journal*, July 1887.

There are certain cases in which the lower inch or two of the rectum are found red and congested, and in which every stool is followed by the loss of a certain quantity of florid arterial blood, and yet no distinct hæmorrhoidal tumour is to be seen. In such cases the ligature is not applicable, and relief is obtained by the application of pure nitric acid, or other potential caustics, to the bleeding surface, as recommended by Houston, Lee, Smith, Ashton, and others. These cases are comparatively rare, and whenever it can be applied, the ligature is much simpler, safer, and more certain.

Venous Piles.—When a sudden effusion of blood has occurred into one of the varicose veins or sinuses of a congested anus, an oval or rounded tumour is felt, very tense, shining, and painful. To slit it freely up with an abscess lancet, and evert the clot inside, at once relieves all the symptoms.

Excision of the Rectum.—*Kraske's Method.*¹—Placing the patient on his right side, he makes an incision from the middle of the sacrum to the top of the coccyx down to the bone. He then detaches the soft parts on the left to the border of the sacrum and coccyx, divides the left sacral and coccygeal ligaments up to the level of the third sacral foramen, clears the other side of the coccyx, and removes it with bone forceps. Then the rectum is well exposed, and the diseased portion may be removed entire; if enough room is not given, then the sacrum can also be removed by chisel or saw up to level of third sacral foramen if necessary. When it is possible, he saves the anus and its sphincter, and then unites the lower end of the portions of rectum which is left to the anus. Out of eight cases so treated, four recovered, and in two of them the anal sphincter maintained its function nearly unimpaired.

A less severe method of operating in cases where disease is within reach consists in dividing the bowel from the

¹ *Berliner Klinische Wochenschrift*, Nov. 28, 1887.

anus to the tip of coccyx by a linear incision, then by defining the anus by a horseshoe-shaped incision it is possible to dissect the bowel from its attachments, aided by ligatures passed through the walls of the anus, till the diseased portion is fairly isolated. It can be separated by curved scissors, and vessels secured. It is rarely possible to unite the end of bowel to skin, but it is not necessary, as the parts heal by granulation, and a fairly useful anus results.

CHAPTER XIII.

TENOTOMY.

For convenience sake I group under this one head certain operations used for the relief of distortion, in which muscles or tendons are divided subcutaneously. Since the discovery of the principle by Delpech, and the application of it by Stromeyer, Dieffenbach, Little, and countless successors, it has been used for very many cases for which it is totally inapplicable, *e g.*, for the division of the muscles of the back in spinal curvature. Still there remain several deformities for the relief of which subcutaneous tenotomy is a most important remedy; chief among these are Wry Neck and Club-foot.

Operation for Wry Neck.—*Subcutaneous section of the sterno-mastoid.*—In what cases of wry neck is this operation suitable? In those only in which the muscles are the starting-point of the mischief. These are sometimes congenital, more frequently they commence in childhood. In cases where the distortion depends on disease of the cervical vertebræ, or is secondary to curvature of the spine, division of the muscle is worse than useless.

Operation.—A tenotomy knife, which should be sharp-pointed, narrow in the blade, with a blunt back, should be introduced through the skin a little to one side of the sternal portion of the affected muscle, passed along with its flat edge between the skin and the tendon, till it has fairly crossed the tendon; the blade should then be turned so that

by a gradual sawing motion the edge may be made to divide the tendon about an inch above the sternum. Some surgeons recommend that two knives be used, a sharp-pointed one to divide the skin, and a probe-pointed one for the division of the tendon. A distinct snap will then be felt or heard, and the position of the head will be at once much improved. Exercise, warm bathing, and rubbing, will generally suffice to complete the cure, without it being necessary to call in the aid of the instrument-maker with his expensive apparatus.¹

Operations for Club-Foot.—The following are the tendons which *may* require division in the cure of club-foot, and the operations for their division.

1. *The tendo Achillis.*—There are very few cases of true club-foot which can be successfully treated without division of the tendo Achillis. While in talipes equinus it is generally the only disturbing agent, in talipes varus and valgus it invariably increases and maintains the deformity, which the tibiales or peronei seem to originate.

Operation.—The foot being held at about a right angle with the leg, the operator should pinch up the skin over the tendon, introduce the knife flatwise, a little to one side of the tendon, till its point is nearly projecting at the other, then turn the edge on the tendon and cut inwards with a sawing motion till the tendon gives way with a distinct snap, and the foot can be completely flexed with ease. In this and in the operations which follow, two knives, one sharp and the other probe-pointed, are used by many surgeons. By dividing the tendons with a blunt knife the risk of hæmorrhage is diminished, but by using a second instrument the subcutaneous nature of the operation is endangered.

¹ Syme's *Pathology and Practice of Surgery*, p. 220.

Dr Little¹ recommends that the tendon should be divided from before backwards. There is more risk by this method of wounding the skin, and thus losing the subcutaneous character of the operation.

2. *Tibialis posticus*.—Next in frequency and importance to that of the tendo Achillis, division of this tendon is more difficult to perform. It may be performed either above or below the ankle.

(a.) *Above the Ankle*.—The blade of a tenotomy knife should be entered perpendicularly at the posterior margin of the tibia, half an inch or an inch above the internal malleolus, so as to pass between the bone and the tendon of the *tibialis posticus*, the blade directed towards the latter; the assistant should now evert the foot, the operator pressing the blade against the tendon.²

(b.) *Below the Ankle close to the attachment to the Scaphoid*.—This is the better position of the two when the position of the tendon can be made out, which is not always the case, especially in cases of old standing.

Raising the skin just over the astragalo-scapoid joint, the knife should be entered with its blade downwards, and across the tendon, and should be made to cut on the bone, while an assistant everts the foot till the tendon gives way with a distinct snap.

3. *Tibialis anticus* may in like manner be divided either just above the ankle, or at its insertion. When it requires division it can generally be made so prominent as to render its division comparatively easy.

4. *Peronei*.—These do not often require division, cases of talipes valgus being usually paralytic in character. If necessary they can be cut as they cross the fibula.

¹ Holmes' *Surgery*, vol. iii. p. 573.

² Miller's *System of Surgery*, p. 1339; Holmes' *Surgery*, vol. iii. p. 571.

5. *The plantar fascia* may require division; when this is the case, it is so prominent as to render the operation very easy, if conducted on the principles mentioned above.

6. *Section of plantar fascia and ligaments of sole of foot.*—In many cases of aggravated club-foot these structures require division. Professor Buchanan of Glasgow¹ recommends a very thorough and drastic division subcutaneously, which includes plantar fascia, adductor pollicis, and adjoining half of flexor brevis, tendon of tibialis posticus close to its insertion, and deep ligaments of astragalo-scaphoid joint. This incision divides also internal plantar nerve and artery, but apparently without doing any harm. Professor Buchanan describes the results as being most fortunate.

It is now the practice to treat aggravated cases of club-foot by removal of one or more tarsal bones, or by the removal of a wedge-shaped portion of the tarsus. No precise directions can be given as the procedure must vary with the amount and character of the distortion. Mr Davy² has had large experience of it, and is practically its inventor. In suitable cases, and with antiseptic precautions, the author can bear testimony to the ease with which it is performed and its excellent results, but it should be kept as a last resource in neglected and severe cases. It can hardly ever be necessary in an infant.

Operative treatment of Genu Valgum.—During the last decade, hundreds, perhaps thousands, of limbs have been operated on by chisels and saw for the purpose of remedying distortions, which time and suitable bandaging might have been trusted to cure.

Macewen's operation in suitable cases and with absolute antiseptic precautions is an excellent one. He makes a

¹ *British Medical Journal*, vol. ii., 1888.

² *Med. Chir. Transactions*, 1885.

wedge-shaped cut with a chisel into the lower end of the femur on its inner side, just above the level of the epiphysis. The exact spot is found at the intersection of two lines, one from the upper border of patella, one longitudinal, half an inch in front of the attachment of the adductor magnus. The bone is cut till it can be either broken or bent into shape. This operation can be done either on femur or tibia, or on both bones. It is rarely necessary before the age of 5, but in cases of severe deformity in which the bone is fairly ossified it may be of great value.

CHAPTER XIV.

OPERATIONS ON NERVES.

Nerve-Stretching.—Surgical literature in last ten years is full of cases in which nearly every nerve in the body, even including the optic nerve for blindness, has been stretched for all manner of diseases with varying success. The results have been rather unsatisfactory, and this operation is now less frequently performed. One or two examples may suffice to illustrate the operative procedure:—

1. Stretching of the great sciatic either for sciatica, sclerosis, or locomotor ataxia.

Operation.—A line drawn from the centre of the space between the tuberosity of the ischium or the great trochanter to a corresponding point between the condyles of the femur will give the direction. A free incision in this line three or four inches in length—the nerve lies just below the femoral aponeurosis, beneath the edge of gluteal fold, requiring no muscular fibres to be divided. It must be raised from its bed and boldly stretched or elongated into a loop. Symington's experiments have shown that in the average adult dead body 130 lbs. are required to break the nerve; the amount of force used safely by the surgeon has been estimated between 20–30 lbs.

2. The facial has been stretched for spasm. The trunk is easily reached by an incision extending from near the external auditory meatus to the angle of the jaw, which

enables the parotid to be pushed forward and the edge of the sterno-mastoid pulled backwards.

Neurotomy and Neurectomy.—Chiefly performed for neuralgia of the fifth nerve.

a. This is a very easy operation if directed at the terminal branches only of the nerve, where they make their exit from the frontal, supra-orbital, and mental foramina. The author has done it in very numerous cases, and with great relief, if care be taken to destroy the nerve in the foramen to some extent; a sharp-pointed thermo-cautery does this easily and safely.

b. The more severe and radical operation of cutting out a portion of the trunk of the fifth nerve just after it has left the skull, and destroying Meckel's ganglion, has been done pretty frequently, chiefly by American surgeons, in various ways.

1. *Carnochan's Operation.*—Exposing the whole front wall of antrum, its cavity is opened into from the front by a large trephine. The lower wall of the infra-orbital canal is cut away by a chisel, the posterior wall of the antrum by a smaller trephine, the nerve thus isolated is traced up to and past Meckel's ganglion, which is removed close to the foramen rotundum by cutting the nerve by curved blunt-pointed scissors.

Chavasse¹ has published an interesting account of the whole subject of neurectomy of second division of fifth nerve. The results have not been at all permanent.

Professor Rose of King's College has published a most brilliant series of operations in this situation, in which he has succeeded in attacking the Gasserian ganglion itself. By his courtesy I have the advantage of seeing the proof-sheets of

¹ *Medico-Chirurgical Transactions*, 1834.

his most recent publication on the subject,¹ from which I give the following abstract of the method of removing the Gasserian ganglion. This very formidable operation is done in six stages:—

(1.) A flap of skin and subcutaneous fat is defined by an incision, beginning about half an inch below the external angular process of the frontal bone, along the zygoma down in front of the ear over the parotid region to the angle of the jaw, and then forward along the horizontal ramus as far as the facial artery. This flap is to be dissected forward, avoiding Stenson's duct, protected by layers of gauze, and fixed in temporary position by a catgut suture to the chin.

(2.) *Section of Zygoma and Coronoid Process, and Detachment of Masseter and Temporal Muscles.*—Zygoma is denuded of periosteum; two holes are drilled at its root, and two others through the zygomatic process of malar bone. Two saw cuts, one between each pair of holes, allows the zygoma to be thrown downwards and backwards along with the masseter, so as to expose the coronoid process, which is to be divided obliquely downwards and forwards, and then thrown upwards with the temporal muscle.

(3.) *Search for the Foramen Ovale.*—After scraping through loose tissue and fat, the external pterygoid is seen, and on it the internal maxillary artery passing on to the sphenomaxillary fossa between the heads of the muscle. This must now be exposed, and divided between a double ligature. The inferior dental and gustatory nerves are then seen passing downwards from the lower border of the external pterygoid. Then by scraping away the external pterygoid by raspatories, the under surface of the greater wing of the sphenoid is exposed and the outer pterygoid plate. The

¹ *The Surgical Treatment of Neuralgia of the 5th Nerve (Tic Douloureux)*, 1892.

foramen ovale is then to be brought into view, a matter often of difficulty from its varying relations to the base of the outer plate; sometimes it is behind and external to it, sometimes directly behind it.

(4.) *Opening the Base of Skull.*—Having found foramen ovale, and traced to it the trunk of the lingual and dental nerves, the skull is now to be opened by a trephine, large enough to remove a $\frac{1}{2}$ -inch disc, with a stem long enough to clear the cheek, serrated obliquely on outer side, and with a reversible centre pin, one end blunt, it is used to remove a disc of bone of which the foramen ovale is the centre. In one case Mr Rose made a second trephine opening in the great wing of the sphenoid anterior and a little external to the foramen; after which both trephine openings were united by removing the intervening bridge of bone by a careful use of the chisel and mallet.

(5.) *Removal of the Ganglion.*—The trunk of the third division is now to be secured by a ligature, and traced up to the ganglion, which should be loosened from its resting-place in the apex of the petrous portion of temporal bone. Two hooks will be required,—one blunt pointed, to pass round the nerves and isolate them, the other with a sharp edge on its concave aspect, to be used for cutting them through. The nerves having been thus divided, the soft ganglionic tissue is to be pulled away piecemeal by forceps or a small curette.

(6.) *Reposition of displaced Structures and Closure of Wound.*—After the bleeding is stanchd and wound washed with 1 to 40 carbolic solution, the coronoid process may either be sutured or removed, the zygoma accurately replaced and fixed by silver wire inserted in the holes already drilled, and skin wound most accurately replaced and sutured by a continuous fine catgut suture. If asepsis has been attended to, union without suppuration may be expected.

2. *Pancoast's Operation.*—Expose the coronoid process

by a free incision, divide it at its root and throw it up, then expose and tie internal maxillary artery, after which the upper portion of the external pterygoid is to be detached from the sphenoid, thus exposing the nerve leaving foramen ovale; the second portion is deeper and not so easily got at.

The Spinal Accessory occasionally may be divided before it enters the sterno-mastoid in cases of spasmodic wry neck, with great advantage. This operation is not a difficult one. After defining the inferior border of the digastric, and the sterno-mastoid edge being once fairly exposed, the nerve is easily put on the stretch, and a piece should be cut out at least half an inch in length.

Dr Keen¹ describes a more serious and difficult operation as required in certain cases of spasmodic wry neck which division of spinal accessory had failed to cure. He divides the posterior division of the first, second, and third cervical nerves. The first is to be sought for in the sub-occipital triangle, and the third and second are to be got in a somewhat complicated dissection involving both the trapezius and complexus muscles.

Nerve Suture is a most important surgical procedure. It may be either immediate, done at the time of the dividing accident, or secondary, done for symptoms of paralysis, both motor and sensory, at a later date. The earlier secondary suture is done the better chance there is of a good result. A careful dissection, aided by free incision, is necessary to find the divided ends; the upper often has a bulbous termination. After being found, lifted from their bed, and stretched, the two ends must be refreshed by being snipped

¹ *Annals of Surgery*, 1891.

across by sharp scissors, as little as possible being removed; the divided ends are then to be sutured by several sutures of carbolized or chromicized catgut, which must take a good hold both of nerve and its sheath. If possible, primary union must be obtained and free drainage insured, as both presence of clot and suppuration of wound are most detrimental to the chance of healing.

For much valuable information on the whole subject of Nerve Surgery, Mr A. A. Bowlby's excellent works may be referred to,¹ and also paper by Dr Nicaise.²

 — of the iliac, 4.
 — of the iliac, external, 8.
 — of the iliac, internal, 6.
 — of the innominate, 27.
 — of the lingual, 34.
 — of the popliteal, 24.
 — of posterior tibial, 26.
 — of the subclavian, 35-40.
 — of vertebral, 41.
 — of the vessels in fore-arm, 47.
 Lingual, ligature of, 34.
 Lips, operations on the, 185.
 Lisfranc on amputation, 53, 76.
 Lister, Sir J., on amputation of ankle-joint, 87.
 — on excision of wrist, 127.
 Liston, Mr, on ligature of subclavian, 38-40.
 — on rhinoplastic operations, 180, 181.
 — on excision of upper jaw, 196.
 — on tracheotomy, 224.
 — on femoral hernia, 273.
 — on lithotomy, 303.
 Litholapaxy, Dr Bigelow on, 314.
 Lithotomy, 297.
 Lithotrity, 314.
 Little on club-foot, 343.
 Liver, operations on, 247.
 Lloyd on harelip, 192.
 Loreta's operation of gastrotomy, 241.
 Lorinzer on obturator hernia, 277.
 Lower extremity, amputations of, 71.
 Lupus, operative treatment of, 183.
 MACCORMAC on excision, 120, 126.
 — on rhinoplastic operations, 182.
 — on intubation of larynx, 226.
 MacEwen on intubation of larynx, 226.
 — on osteotomy, 314.
 — on radical cure of hernia, 284, 285.
 — on trephining of spine, 154, 155.
 M'Guire on ligature of aorta, 4.
 Macilwain on tracheotomy, 219.
 Mackenzie, Sir Morell, on thyrotomy, 228.
 Mackenzie, Dr R., on modification of Syme's amputation, 83.
 — on excision of joints, 112.
 Maclellan, Dr G., on amputation above the shoulder-joint, 69.
 Macnamara on ligature of femoral, 18.
 Makin on resection of intestine, 296.
 Malgaigne on Chopart's amputation, 79.
 — on harelip, 192.
 — on ligature of carotid, 32.
 Mamma, excision of, 232.
 Manec on ligature of axillary, 42.
 — on ligature of femoral, 23.
 Marsh on excision of hip-joint, 130.
 — on fissure of hard palate, 212.
 Maunder on excision of the elbow-joint, 124.
 Metacarpals, amputation of, 54.
 — excision of, 145.
 Metatarsals, amputation of, 72.
 Mickulicz's operation, 148.
 Miller on amputation of penis, 330.
 — on club-foot, 343.
 Milton on ligature of aorta, 4.
 Monteiro, Dr, on ligature of aorta, 4.
 Moreaus, the, on excision of joints, 111, 117, 122, 138.
 Morris on nephrectomy, 251.
 Morton, Dr, on radical cure of hernia, 279.
 Mules' operation, 177.
 Murray, Dr, on ligature of aorta, 4.
 Mussey on amputation above shoulder-joint, 70.
 NASAL POLYPI, removal of, 183.
 Needle operation for cataract, 166.
 Nelaton on fibrous polypi, 185.
 — on harelip, 189.
 Nephrectomy, 251.
 Nephro-lithotomy, 250.
 Nephrotomy, 250.
 Nephrorraphy, 252.
 Nerve-stretching, 346.
 Nerve suture, 350.
 Neurectomy, 347.
 Neurotomy, 347.

- Newman's statistics of nephrectomy, 251, 252.
 Nicaise on neurectomy, 351.
 Norris's statistics of ligatures, 22, 32.
 Nunneley on excision of tongue, 205.
- OBRE on obturator hernia, 277.
 O'Dwyer on intubation of larynx, 226.
 Oesophagotomy, 230.
 Ollier on excision of joints, 112, 130, 138.
 Orbit, operation on, 177.
 Os calcis, excision of, 146.
 Osteotomy, 344.
 Ovariectomy, 254.
- PAGET on excision of tongue, 205.
 Palate, fissures in soft, 209.
 — fissures in hard, 211.
 Pancoast, Professor, on amputation at knee, 93.
 — on excision of metatarsal, 150.
 — on neurectomy, 349.
 — on radical cure of hernia, 279.
 — on rhinoplastic operations, 182.
 Paracentesis of anterior chamber of eye, 164.
 — thoracis, 234.
 — abdominis, 238.
 Paré, Ambrose, on amputation at elbow-joint, 61.
 Park on excision of joints, 110, 112.
 Parker, R. W., on excision of hip, 134.
 — on tracheotomy, 217.
 Peixotto, Dr, on ligature of innominate, 29.
 Pelikan on excision of knee, 136.
 Penis, amputation of, 329.
 Percy on excision of joints, 111.
 Perineal section, operation of, 324.
 Phymosis, operation for, 327.
 Piles, removal of, 336.
 Pilz's statistics of ligatures, 32.
 Pirogoff's modification of Syme's amputation, 82, 84.
 Poland on ligature of popliteal, 24.
 Pollard, Bilton, on excision of hip, 135.
 Pollock on excision of lower jaw, 199.
 Polypi, nasal, removal of, 183.
 — anal, removal of, 336.
 Popliteal, ligature of, 24.
 Porro's operation, 264.
 Porta's statistics of ligature of femoral, 22.
 Porter, Professor, on ligature of innominate, 29, 30.
 — on ligature of common carotid, 30.
 — on ligature of femoral, 18.
 Post on ligature of external iliac, 11.
 Prewitt on internal carotid, 35.
 Prolapsus ani, 335.
 Pterygium, operation for, 162.
 Ptoxis, operation for, 157.
 Puncture of bladder, 326.
- Pupil, operations for artificial, 171.
 Pylorotomy, 242.
- QUAIN on anatomy of iliac, 4.
 — on anatomy of brachial, 46.
- RABÉ's statistics of ligature of femoral, 22.
 Radial, ligature of, 47.
 Ramsden on ligature of subclavian, 39.
 Rectum, excision of, 339.
 Regnoli on excision of tongue, 207.
 Rhinoplastic operations, 178.
 Ribs, excision of, 236.
 Ribes on fistula in ano, 334.
 Richardson on gastrotomy, 241.
 Richter on radical cure of hernia, 279.
 Ricord on amputation of penis, 330.
 Rigaud on amputation above the shoulder-joint, 70.
 Rivington's statistics of ligature of carotid, 33.
 Robson on cholelithotomy, 249.
 — on gall-bladder, 248.
 Rodgers, Dr, on ligature of subclavian, 38.
 Rose, Prof. W., on cleft palate, 208, 211.
 — on harelip, 192.
 — on excision of Gasserian ganglion, 347.
 Rothmund on radical cure of hernia, 281.
 Roux on ligature of subclavian, 40.
 — on ligature of axillary, 42.
 — on Chopart's amputation, 78, 79.
- SABATIER on excision of joints, 111.
 Saemisch's operation on cornea, 165.
 Salivary fistula, operation for, 203.
 Sanson on recto-vesical lithotomy, 313.
 Scalp, tumours of the, removal of, 155.
 Scapula, amputation of, 69.
 — excision of (Syme), 144.
 Schmucker on radical cure of hernia, 280.
 Schuh on radical cure of hernia, 279.
 Sclerotomy, 175.
 Sédillot's operation for ligature of carotid, 32.
 — on amputation of leg, 88.
 — excision of hip, 134.
 Senn on enterectomy, 246.
 — on gastrotomy, 242.
 — on intestinal anastomosis, 245.
 Senn's bone plates described, 245.
 Shoulder-joint, amputation above the, 63-69.
 — amputation at, statistics, 68.
 — excision of, 117.
 Signoroni on radical cure of hernia, 280.
 Sims, Dr M., on recto-vesical lithotomy, 313, 314.

- Skey on amputation of anterior portion of foot, 76.
 — on ligature of radial, 48.
 — on ligature of subclavian, 40.
 — on lithotomy, 303.
 Smith, Greig, on colotomy, 292, 294.
 — on hysterectomy, 262.
 — on liver operation, 248.
 — on nephrotomy, 250.
 — on ovariectomy, 258, 259.
 — on Porro's operation, 264.
 — on removal of uterine appendages, 261.
 — on splenectomy, 253.
 — on vaginal hysterectomy, 262.
 Smith, Henry, on piles, 338, 339.
 Smith, Dr Nathan, on amputation at knee-joint, 92.
 Smith's, Stephen, amputation at knee-joint, 93.
 — on ligature of radial, 48.
 Smith, Thomas, on staphyloraphy, 208, 211.
 Smyly on ligature of femoral, 18.
 Smyth on subclavian aneurism, 29.
 Snellen on ectropium, 157.
 Solis Cohen, Dr, on laryngectomy, 230.
 — on laryngotomy, 228.
 South on ligature of aorta, 4.
 — on tracheotomy, 226.
 Spanton on radical cure of hernia, 283.
 Spence, Professor, on amputations, 49, 62, 66, 102.
 — on ligature of anterior tibial, 26.
 — on excision of shoulder, elbow, knee, hip, and wrist joints, 120, 126, 130, 134, 139.
 — on tracheotomy, 219.
 Spine, trephining of, 155.
 Splenectomy, 253.
 Staffordshire knot described, 258.
 Stanley on excision of shoulder, 119.
 Staphyloma, operation for, 175.
 Staphyloraphy, 208.
 Steven, Professor, on ligature of internal iliac, 17.
 Stiles, Mr H. J., on excision of mamma, 233.
 Stokes's amputation, 95.
 — on ligature of aorta, 4.
 Strabismus, convergent, 162.
 — divergent, 163.
 Streathfield on entropium, 156.
 — on corelysis, 174.
 Stricture of urethra, operation for, 317.
 Stromeyer on excision of joints, 112.
 — on tenotomy, 341.
 Subclavian, ligature of right, 36.
 — ligature of left, 37.
 Subastragaloid amputation, 79.
 Suprapubic lithotomy, 311.
 Sym, W. G., on operations on eye, 156.
 Syme, Mr, on amputation at ankle-joint, 80.
 — on amputation of anterior portion of foot, 76.
 — on amputation through condyles of femur, 93, 94.
 — on amputation at hip-joint, 107.
 — on amputation above the shoulder-joint, 70.
 — on axillary aneurism, operation for, 43, 44.
 — on cheiloplastic operation, 187.
 — Chopart's amputation introduced by, 78.
 — on excision of elbow-joint, 113, 122, 124-126.
 — on excision of lower jaw, 199, 201.
 — on excision of joints, 112, 113, 125.
 — on excision of metacarpals, 145.
 — on excision of scapula, 144.
 — on excision of tongue, 204.
 — on Hey's operation, 76.
 — on ligature of femoral, 22.
 — on ligature of gluteal, 16.
 — on ligature of internal iliac, 17.
 — on ligature of subclavian, 39.
 — on modified circular amputation, 103.
 — on radical cure of hernia, 281.
 — on removal of polypi, 184.
 — on rhinoplastic operation, 178.
 — on stricture, 319, 322.
 — on wry neck, 342.
 Symington on sciatic nerve, 346.
 TABLE of circulation after ligature, 27, 48.
 Tait, Lawson, on cholecystotomy, 248.
 — on cholelithotripsy, 249.
 — on gall-bladder, 248.
 — on ligature of external iliac, 11, 13.
 — on Staffordshire knot, 258.
 — on removal of uterine appendages, 261.
 Taliacotian operation, 182.
 Tarso-metatarsal joint, amputation at, 74.
 Tarsus, amputation through the, 77.
 Teale on amputation, 49.
 — on amputation of fore-arm, 59.
 — on amputation of arm, 63.
 — on amputation of leg, 87, 89.
 — on amputation of thigh, 99.
 — on amputation of penis, 330.
 Teale, T. P., on cataract, 163.
 — on ligature of arteries, 2.
 Tenotomy, 341.
 Testicle, excision of, 332.
 Textor on amputation at elbow-joint, 62.
 Thigh, amputations of, 96-103, 109.
 Thompson, Sir H., on lithotripsy, 314, 317.
 — on stricture, 320, 322.
 Thomson, Mr, on ligature of innominate, 29.

- Thorax, operations on the, 232.
 Thornton on nephrectomy, 252.
 Thyrotomy, 228.
 Toes, amputations of, 71.
 Tongue, excision of, 204.
 Tonsils, excision of, 213.
 Tracheotomy, 216, 219.
 Trephining and trepanning, 152.
 Treves on enterectomy, 246.
 — on ligature of internal iliac, 7.
 — on perineal section, 325.
 — on umbilical hernia, 288.
 — on rhinoplastic operations, 182.
 Trichiasis, 156.
 Tripiet's amputation, 80.
 Trocar of Sir S. Wells described, 256.
 Tumours of scalp, removal of, 155.
 — of eyelids, removal of, 158.
 Tyrrell on treatment of brachial aneur-
 ism, 46.

 ULCER of the anus, 334.
 Ulnar, ligature of, 47.
 Upper extremity, amputation of, 50.
 Urethra, stricture of, 317.
 Uterine appendages, removal of, 261.

 VAGINAL hysterectomy, 262.
 Velpeau on ligature of external iliac,
 14.
 — on ligature of subclavian, 40.
 — on amputation at elbow-joint, 61,
 62.
 — on amputation at knee-joint, 92.
 — on radical cure of hernia, 279.
 Vermales on amputation of thigh, 104.
 Verneuil on Chopart's amputation, 79.
 Vertebral artery, ligature of, 41.
 Vessels of fore-arm, ligature of, 46.

 WAGNER on excision of scapula, 145.

 Wakley on stricture, 319.
 Warren on fissure of hard palate, 211.
 Watson, Dr P. H., on amputation of
 scapula, 69.
 — on excision of knee-joint, 138.
 — on excision of elbow-joint, 125.
 — on laryngectomy, 228.
 — on ligature of aorta, 4.
 Waxham's statistics of larynx intuba-
 tion, 227.
 Wells, Sir Spencer, on ovariectomy,
 254-261.
 — trocar, 256.
 — hernia, radical cure of, 281.
 Wheelhouse on perineal section, 324.
 — on excision of joints, 112.
 Whitehead, Mr W., on excision of
 tongue, 206.
 — on piles, 338.
 — on tracheotomy, 222.
 Williams, Mr Roger, on excision of
 mamma, 233.
 Williamson on excision of scapula, 145.
 Wölfler on pylorotomy, 243.
 Wood on femoral rupture, 287.
 — on radical cure of hernia, 281-283.
 — on tracheotomy, 226.
 — on umbilical rupture, 287.
 — statistics of ligature of carotid, 32.
 Wright on splenectomy, 253.
 — statistics of hip excision, 134.
 Wrist-joint, amputation at, 56.
 — excision of, 126-30.
 Wry neck, operation for, 341, 350.
 Wutzer on radical cure of hernia, 281.
 Wyeth, Dr, statistics of ligature of
 subclavian, 38, 40.

 ZEHENDER's statistics of ligature of
 carotid, 33.

PRINTED BY OLIVER AND BOYD, EDINBURGH.
