- (1) Differential movement of two stations situated one degree of latitude apart.

Every point on the earth's equator rotates during each hour through an arc of  $15^\circ \times 60' = 900$  miles in circumference whilst the pole itself has no movement at all. It is obvious that intermediate stations rotate through arcs of intermediate linear extent and, that as there are 90 degrees of latitude between the equator and the pole, every station on the earth's surface must travel on an average 10 miles per hour faster than those one degree further from the equator. *Supposing the earth to be a sphere*

The exact difference due to an interval of one degree, or 60 miles, at any latitude  $\angle$  is expressed by the formula  $900 \{ \cos \angle - \cos(\angle + 1) \}$ . It gives us 14.0 miles for lat:  $62^\circ$  & 10.4 miles for lat  $42^\circ$  which are the limiting parallels of my weather charts. It will be sufficiently exact for my purposes if I take the mean of these values or 12.2 miles per hour as constant throughout the whole of their area. In other words if ~~any two points~~ ~~any two points~~ CN be a meridian line, & Nn the differential movement of N compared with C in one hour, then

$$\frac{Nn}{CN} = \frac{12.2}{60} = \tan NCn = \tan 11^\circ 30'$$

on the supposition that CNn is ~~the~~ <sup>be</sup> treated as a plane triangle, accurately  $\tan NCn = \frac{\tan Nn}{\sin CN}$

- (2) Course of a particle of air within the area of the charts as affected by the differential movement above mentioned.

Suppose a particle of air  $\subseteq$  stationary above any place C to be abruptly propelled northwards through  $1^\circ$  to N & then be left to hover for an hour. The differential excess of C's velocity (over that of N) (which is shared in by  $\subseteq$ ) (will cause that particle to have travelled 12.2 miles to the eastward of N by the close of the hour, supposing its movement wholly unembarrassed. Its course will be along a great

Let us trace the course of a particle moving urged  
by an uniform force towards the Pole. Assume its  
velocity such that it travels  $\frac{d}{n}$  miles in the hour, the differential  
movement of the parallel it reaches at the close of the hour is  
[C.N. being a plane  $\Delta$ ]  $d \tan 11^\circ 30'$ . Divide  $\frac{d}{n}$  in  $n$  parts then the differential  
movement of two adjacent parts is  $\frac{d}{n^2}$  in one hour or  $\frac{d}{n^2}$  in the  
 $n^{\text{th}}$  part of an hour.

Suppose the particle  $\odot$  to be abruptly propelled through  $\frac{d}{n}$   
northwards and then allowed to hover for  $\frac{1}{n}$  of an hour its  
deflection will be  $\frac{d \tan 11^\circ 30'}{n^2}$ . Let the process be repeated another step  
then its additional deflection will be  $2 \frac{d}{n} \times \frac{1}{n}$ , or  $2 \frac{d^2}{n^2}$ , or its  
total deflection will have been  $\frac{d}{n^2} \{1+2\}$ . Proceeding in this  
way, at the end of the  $n^{\text{th}}$  interval it will have been  
 $\frac{d \tan 11^\circ 30'}{n^2} \{1+2+\dots+n\} = \frac{d \tan 11^\circ 30'}{n^2} \frac{n^2+n}{2} = \frac{d \tan 11^\circ 30'}{2}$  when  $n$  is infinite

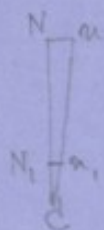

or the particle will have been deflected through exactly  
half the differential movement of the parallel it has reached  
due to the time during which it has been moving.

Its course will have been in a parabola to take  
 $y$  along the line  $d$  such that  $y:d::r:n$  or  $r^2 = \frac{y^2}{d}$   
then the deflection of C at  $y (=x) = \frac{d \tan 11^\circ 30'}{n^2} \cdot \frac{r^2}{2}$  ( $n$  being infinite)

$$\text{or } x = \frac{d \tan 11^\circ 30'}{n^2} \cdot \frac{n^2}{2d^2} y^2 = \frac{\tan 11^\circ 30'}{d} y^2$$

No account is here taken either of the <sup>retarding</sup> influence of  
friction or of the interference to free movement opposed by  
the surrounding air.

Whether we take  $d$  towards the north or towards the south  
the deflection is the same in amount & is always towards the right hand.

$$CN = a$$

$$CN_1 = \frac{a}{n}$$

A particle moving  $\frac{a}{n}$  units per hour  
will have a deflection  
=  $Nn$  in 1 hour  
=  $N_1 a_1$  in  $\frac{1}{n}$  of an hour

A particle moving ~~with~~  $\frac{a}{n}$  units per hour  
will have a deflection

$$N_1 n_1 = \frac{1}{n} N n \text{ in 1 hour}$$

$$\frac{1}{n} N_1 n_1 = \frac{1}{n^2} N n \text{ in } \frac{1}{n} \text{ of 1 hour}$$

circle, which for rough practical purposes & at moderate distance, may be considered coincident with a parallel of latitude.

On reversing the conditions of the problem, if  $\underline{c}$  be allowed to hover over  $\underline{C}$  <sup>fixed in space</sup> during the hour in question and then be instantaneously propelled one degree northwards, its course will lead it directly to  $\underline{N}$ . // The path followed

by a particle moving continuously forward and accomplishing 60 miles in the space of an hour, after any law of varying velocity we may please, must necessarily lie between these two extreme cases of a meridian line, on the one hand, and a line making an angle of  $11^{\circ} 30'$  with it, on the other.

If the onward movement be uniform in velocity,  $\underline{c}$  would reach the parallel of  $\underline{N}$  midway between it and  $\underline{n}$ , say at a point  $\underline{n}_1$ . Joining  $\underline{C}$  &  $\underline{n}_1$  by a straight line we should have  $\tan NCn_1 = \frac{6.1}{60} = \tan 5^{\circ} 48'$ .

We may further conclude that so long as the movement be uniform, no matter what the meridional distance  $\underline{x}$  travelled over in the hour may be the deflection per hour is always  $\propto \tan 5^{\circ} 48'$ , no account being made of retardation by friction, or of the interference of surrounding air.

Whether we take  $\underline{N}$  to the north or  $\underline{S}$  to the south the deflection is the same in extent and is always to the right hand.

(Continued at 2.a.)

Cyclones &  
Anticyclones

## (3) Rotatory winds

The gyration of cyclones has been frequently described but I will endeavour to trace the course of a particle of air under their influence with more precision than so far as I am aware has hitherto been effected. In the mean time I will explain what I have termed "Anti-cyclones", because they afford a more convenient illustration of rotatory storms.

a. Anticyclones. The state of the weather on the mornings of Dec 2<sup>nd</sup> 3<sup>rd</sup> 4<sup>th</sup> (See special maps) shows the continued divergence of currents from a central area <sup>of</sup> ~~of~~ calms, which is also characterised as ~~the~~ <sup>an</sup> area where the barometer attains ~~the~~ <sup>its</sup> greatest height. I presume this area to be a locus of dense descending currents just as the centre of a cyclone is a locus of light ascending currents. A further reason for this belief lies in the fact that a pure clear sky usually accompanies areas of dissipation indicating that a dry upper atmosphere has been brought down, in the same way that the rains & clouds of a cyclone prove that the damp surface atmosphere has been drawn up & its vapour condensed by the cold of a higher level.

Now suppose two currents of air, both proceeding from the same source, to travel respectively Northwards & Southwards. They must <sup>tend to</sup> both be deflected to the right hand & it is impossible but that the intermediate mass of still <sup>atmosphere</sup> ~~land~~ should yield in some degree to their pressure & be deflected also. If winds disperse on every side from a central area, the entire disc of outflow must accept to a calculable degree the

velocity due to its northern & southern portions, (which is 12.2 miles per hour with a radius of 60 miles or through an angle of  $11^{\circ} 4'$ .) is accounted for and that the <sup>other</sup> half remains wholly unsupplied. Therefore supposing the circle to move as a whole, it has only a velocity of one half of  $11^{\circ} 4'$  or  $5^{\circ} 32'$  per hour.

As every circle composing the disc moves with the same angular velocity, the disc must turn as a rigid whole. Abstraction is here made of the retardation due to friction which so far as it follows any law different from that of increase in direct proportion to increase of velocity, would cause the outer circles to move at a somewhat different rate to the inner ones.

Hence, leaving aside friction for the present, the course of every particle of air in an anticyclone <sup>within the area of my charts.</sup> is compounded of two separate portions, — the one its radial projection outwards which may follow <sup>any</sup> ~~any~~ law <sup>uniform or of</sup> of changing velocity, and the so long as all the particles radiated simultaneously share it alike, and the other of <sup>"direct"</sup> angular rotation round its point of departure of  $5^{\circ} 32'$  per hour.

By Spottiswoode's formula.

$$(\cos^2 \alpha \sin^2 \lambda + \sin^2 \alpha) \cos \omega t + \cos^2 \alpha \cos^2 \lambda = \cos D$$

$$\alpha = 0$$

$\lambda = 52^\circ$  which is that I have assumed as constant throughout my charts.

$$\omega t = 15^\circ$$

$$\sin^2 52^\circ \cos 15^\circ + \cos^2 52^\circ = \cos D$$

$$\log \sin 52^\circ = 9.896$$

$$\log \sin^2 52^\circ = 9.792$$

$$\log \cos 15^\circ = 9.985$$

$$\frac{9.777}{9.985} = \log .598$$

$$\log \cos 52^\circ = 9.789$$

$$\log^2 \cos 52^\circ = 9.578 = \log .379$$

$$\log .977 = 9.990 = \log \cos 12^\circ 10'$$

My results gave

11.30'

$$\frac{122}{600} = \tan \theta$$

p. 94

$$203333 = 11^{\circ} 30'$$

$n$ :

$$\begin{aligned} 1 \text{ mile} & \quad 1. \\ 2 & \quad \frac{1}{2} \\ n & \quad \frac{1}{n} \end{aligned}$$

$$\tan N C n = \frac{h-1}{h} = .101666 = \tan 5^{\circ} 45'$$

$$\begin{array}{r} h0 / 12.2 \\ \underline{203333} \\ 191986 \quad 11^{\circ} 4' \\ \underline{011347} \end{array}$$

$$\begin{array}{r} .0174 \\ \underline{.174} \\ .191 \\ \underline{12} \\ 203 \end{array}$$

compare the amount of force actually present with ~~that~~  $w^2$  in required  
 Let us examine the ~~amount of~~ <sup>required</sup> force which would be necessary  
 to effect an angular deflection of each point in the circumference of  
 to ~~compensate a rotation upon any one of the concentric circles~~ of which  
 the disc may be supposed to be formed equal to that which  
 influences its north & south points of the circle. <sup>(supposing that pressure is</sup>  
 where the deflecting influence  
 is wholly tangential.

# Rotatory winds

The gyration of cyclones has been often described but I shall endeavour to ~~illustrate~~ <sup>show</sup> the course of a particle of air under their influence. <sup>more definite than has yet been given</sup> in the mean time I wish to explain what I have termed anti-cyclones because they afford <sup>the</sup> most convenient illustration of rotatory winds. I have ~~drawn~~ <sup>seen</sup> the state of the ~~country~~ <sup>weather</sup> in the morning of Dec 2 3 & 4 which I have represented in detail, shows the divergence of currents from a central area, <sup>I call it</sup> which is <sup>also</sup> characterised by <sup>being</sup> ~~the~~ <sup>an</sup> area where the barometer ~~shows the greatest pressure~~ <sup>shows the greatest pressure</sup> I presume this <sup>area</sup> to be <sup>a</sup> ~~locus~~ <sup>locus</sup> of dense descending currents just as the centre of a cyclone is a <sup>locus</sup> ~~locus~~ of light ascending currents. A further reason for this belief lies in the fact that a pure clear sky <sup>usually</sup> accompanies these areas of dispersion, indicating that ~~the~~ <sup>the</sup> ~~presence of dry wind~~ <sup>dry</sup> atmosphere has been brought down, <sup>in the same way that</sup> ~~as~~ the rains and clouds of the cyclone show that the damp surface atmosphere has been drawn up & its vapour condensed by the cold of a higher level. Examination of the maps

Now suppose two currents of air both proceeding from the same source to travel respectively Northwards & Southwards - they must both be deflected to the right hand & it is impossible but that the intermediate mass of still air should yield to their pressure & be deflected also. In short if winds <sup>diverge</sup> ~~flow out~~ on every side from a central area the entire disc of outflow must accept to a <sup>calculable</sup> ~~considerable~~ degree the right handed deflection established in the northern & southern currents supposing them to have <sup>wholly</sup> ~~been~~ unembarrassed. If ~~we~~ <sup>let us</sup> ~~consider~~ <sup>examine</sup> the forces which would suffice to impart

Differential movement through space of 2 <sup>stations</sup> points on the Earth's surface  $1^\circ$  of latitude apart.

Having regard to the daily rotation of the earth we know that

In the course of each hour, a point on the earth's equator <sup>travels</sup> through an arc of  $15^\circ \times 60' = 900$  miles, in <sup>which</sup> whilst the pole itself has no movement at all, and intermediate <sup>stations and travel through arcs of</sup> points have intermediate <sup>linear extent</sup> distances.

As there are 90 degrees of latitude between the equator and the pole, it follows (on a rude average) that <sup>each</sup> point on the earth's surface travels 10 miles an hour <sup>farther</sup> than <sup>another</sup> point  $1^\circ$  lat. <sup>nearest to the nearest</sup> apart.

<sup>we can easily</sup> ~~at the equator or 10 miles an hour faster than one~~ <sup>calculate the difference in</sup> ~~at the same distance between it and the pole~~ <sup>between stations whose</sup> ~~at the pole.~~ <sup>latitude is a given number</sup> ~~by the formula~~

The northernmost <sup>parallel</sup> latitude in my weather charts, being

$62^\circ$  & the southernmost <sup>is</sup>  $42^\circ$  at which <sup>if we</sup> latitudes <sup>calculate</sup>

by the formula  $900(\cos 61^\circ - \cos 62^\circ) = 14.01$  miles

$900(\cos 41^\circ - \cos 42^\circ) = 10.41$  miles

<sup>we find the lat. in question to be  $42^\circ$  of the arc</sup> <sup>of a circumference of 12 miles through</sup>  $12.20$   
we see that, on a rough average throughout the whole chart, <sup>each</sup> point within it moves 12 miles an hour <sup>through space</sup> faster than ~~another~~ <sup>another</sup>  $1^\circ$  lat. to the North of it & 12 miles an hour slower than ~~another~~ <sup>another</sup>  $1^\circ$  lat. to the South of it. <sup>the difference</sup>

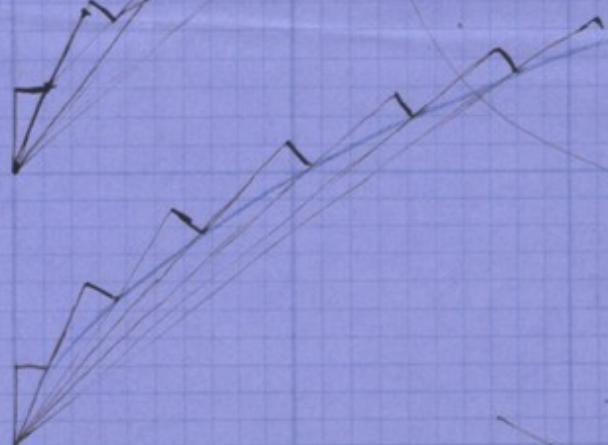

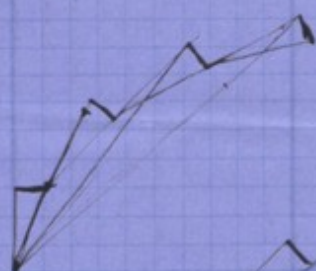

<sup>Correct</sup> Deflection of a particle of air, <sup>within the charts</sup> supposed to be unimpeded, on moving  $1^\circ$  in latitude. <sup>within the area of the charts.</sup>

~~If a~~ <sup>has</sup>

Let C be any station within the charts & N, S, two points <sup>on the same line</sup> ~~subsequently~~ <sup>respectively</sup>  $1^\circ$  lat. <sup>apart</sup> to the North & to the South of C.

If a particle of air <sup>be</sup> supposed to be moved <sup>instantaneously Northward</sup> from C <sup>to N</sup> <sup>in  $1^\circ$  that</sup> is to the point N & there <sup>be</sup> allowed to hover for an hour retaining <sup>the differential movement</sup> the rotatory <sup>velocity</sup> movement due to C, it follows that ~~it will~~ <sup>it will</sup> have caused it to have travelled 12 miles to the westward of C. or in other words the position of C will <sup>appear to be displaced</sup>  $12$  miles to the right hand side of the line CN.

Next let the conditions of the problem be <sup>be</sup> changed that C be supposed to hover for the hour above C & then be transported <sup>instantaneously</sup> northward <sup>to</sup>  $1^\circ$ . It is clear it would <sup>precisely</sup> arrive at N. <sup>without any</sup> <sup>deflection whatever</sup> ~~it would~~ <sup>be</sup> ~~the same is true~~ <sup>if he substitutes S for N,</sup> ~~for the right hand movement~~ <sup>if he substitutes S for N,</sup> Hence we conclude that as every possible form of continuous movement must lie somewhere between these two extreme <sup>positions of whatever</sup> ~~cases~~ <sup>that as a general rule</sup> if C moves north <sup>or south</sup>  $1^\circ$  in

Cyclones &  
Anticyclones

(infinite)

On these data we may readily protract the course of a particle of air in an anticyclone whenever we are able to determine the rate of propagation of the disturbance at the expiration of each hour (or other portion of time). By a particle of air, I mean one that has attained a certain distance, by a particle of air. Suppose it to move with uniform velocity through each of the belts. It will be deflected as shown in (2) through half the angle due to the amount of the differential movement, which is the distance of the particle from the centre of the disturbance. The deflection is then  $\frac{1}{2}$  of the angle  $\theta$  at the commencement of the hour, as the distance of the particle from the centre is  $\frac{1}{2}$  of the radius.

conclude that no account being taken of friction the <sup>possible</sup> ~~rapid~~ <sup>course</sup> of any particle of air in an anticyclone is compounded of two separate parts, the one its radial movement outwards <sup>which operates</sup> ~~which may~~ <sup>in each</sup> ~~following~~ <sup>any law</sup>, so long as ~~it~~ <sup>is common to</sup> all the particles <sup>radially simultaneously</sup> ~~phase it takes~~ <sup>a second</sup> of an angular rotation round its point of departure <sup>about</sup>  $\frac{1}{2}$  per hour.

<sup>we will take as our example</sup>  
On these data we will construct the movement of a particle of air under the conditions of divergence observed in the morning of Dec. 3. There <sup>is</sup> a central area of about  $1^{\circ}$  in radius where the winds are unobscured <sup>as we see in reference to previous pages</sup>, thence light airs <sup>say</sup>  $\frac{1}{2}$  to  $1$  mile an hour steal off <sup>continuously</sup> on all sides. <sup>It</sup> Calculation shows <sup>that</sup> this rate the ~~air~~ <sup>air</sup> that <sup>beginning at</sup> <sup>leaving</sup> the central area would have <sup>perfectly</sup> ~~been~~ <sup>transferred</sup> to a ring outside it <sup>which is</sup> bounded by a circle whose radius <sup>is</sup>  $100$  miles. Now ~~but~~ if we calculate the radii of a set of concentric circles such that the areas of the rings they enclose shall <sup>be equal to each other</sup> be identical with the area of the first ring we find them to form the following series.

(2)  
an hour its deflection owing to the rotation of the earth must lie between <sup>somehow</sup> 12 miles and zero & is always to the right hand.

To <sup>calculate</sup> <sup>throughout my interval</sup> the deflection when the movement is uniform we may suppose the  $1^\circ$  of latitude to be divided into  $n$  equal intervals <sup>so be generally passing in equal times by a given point, say Cape</sup> ~~so that each of them equals  $\frac{1}{n}$  of an hour~~. Suppose <sup>for  $\frac{1}{n}$  of an hour</sup> the motion to take place in ~~jerk~~ alternate jerks & hovering <sup>for  $\frac{1}{n}$  of an hour</sup> over each interval & ~~calculate~~ <sup>for time</sup> consider the result under each of the two extreme cases mentioned above. We must recollect that as each interval occupies  $\frac{1}{n}$  of an hour in length the hourly differential movement of the two points that limit it is ~~only~~  $\frac{1}{n} \cdot 12$  miles & that the same movement during  $\frac{1}{n}$  of an hour is only  $\frac{1}{n^2} \cdot 12$  miles.

~~We have~~ (1) Where the jerk precedes the hovering, the ultimate deflection is represented by the series

$$\frac{1}{n^2} \cdot 12 \{ 1 + 2 + 3 + \dots + n \} = 6 \cdot \frac{n^2 + n}{n^2} \text{ miles} = 6 + \frac{6}{n}$$

and (2) where the hovering precedes the jerk

$$\frac{1}{n^2} \cdot 12 \{ 0 + 1 + 2 + \dots + n-1 \} = 6 \cdot \frac{n^2 - n}{n^2} \text{ miles} = 6 - \frac{6}{n}$$

~~As  $n$  becomes the ultimate deflection, no longer lies between 0 and 12 miles, the motion becomes uniform & the deflection the same. When  $n$  is infinite, in which case the motion is uniform &  $n$  disappears in the face of  $n^2$  from both the above values, which both become  $\pm 6$  miles.~~

The ultimate deflection necessarily lies between these values and the greater  $n$  <sup>is taken</sup> becomes, the more nearly ~~the~~ <sup>will</sup> the motion approach ~~become~~ uniformity. When  $n$  is infinite  ~~$n$  disappears in the~~ <sup>the term</sup> presence of  $n^2$  & both the above values become identical & equal to 6 miles, which is <sup>the</sup> the deflection due to ~~an~~ <sup>uniform</sup> motion through  $1^\circ$  of latitude in one hour, in the latitudes embraced by the charts, & the angular deflection  $n/1$  to  $10$  is equivalent to about  $6^\circ$  which we may accept as another way of expressing the same result.

(4) leaving the  <sup>$N = 8$</sup>  ~~maximum~~ impulses to the agency of precisely the same cause, that produce a circuit in the case now first considered.

25 - mts 170  
21 - gentle  
20 - moderate  
in

$$a \sin \theta = d$$

$$D : a :: \sin \theta : 1$$

$$r \sin \theta = D$$

Let  $ABCD$  be a part of a rotating ring. Take ~~at~~ <sup>a small</sup>  $CD$  equal to  $AB$ .  
then when  $A$  moves to  $B$ ,  $C$  moves to  $D$  & the <sup>total component of its</sup> lateral movement of  $C$  is  $FD$ .

Now in order that the <sup>condition</sup> condition of uniform rotation be observed throughout the way of air FD should be equal to  $\frac{1}{2}b$ , which it is for

$$(1) \quad C \sin 90^\circ = F$$

$$a \quad ab:AK::CH:EO$$

$$AB \cap DA = DO \cap B$$

2) in  $\triangle ABE$   $\angle OAE = \angle ABE$

*Albion*

Hence we conclude that when air flows outwards on all sides from a central area <sup>of high barometric pressure</sup> we have necessarily a ~~symmetrical~~ regular rotation <sup>of the atmosphere</sup> round that area <sup>which</sup> more or less rapid at different radial distances according to <sup>the</sup> velocity of outflow.

Let us ~~make~~<sup>consider</sup> a graphic representation of ~~the~~<sup>the most</sup> typical case namely that where the air flows outwards with a uniform velocity from its point of departure and we will follow the conditions of the morning of Dec 3<sup>rd</sup> as <sup>velocity of outflow is</sup> regards the area where <sup>is taken</sup> we observe a central area of 60 miles in radius whence light airs proceed radially on all sides we will suppose them to have the ~~same~~ velocity usually ascribed to light airs, <sup>namely</sup> 15 miles an hour. Let us then draw two circles of 60 & 75 miles radius respectively.

the ring between which represents the space which the outflowing air from the central area will fill in the course of ~~one~~ hour. Further let us draw a system of concentric circles and find that the superficial area of each of them is equal to that of the first ring. A simple calculation shows the radius of the circles which enclose the various series of them to be six feet.

It follows that the air which at any moment may be contained in any one of these rings will have been transformed, wholly or in part, into the heat of the ring in the course of an hour, and that the air which has <sup>passed</sup> the margin of the circle at the beginning of an entire day will have equally arrived at the circle 24 at the close of it. Draw a line OA OB including an angle of  $60^\circ$  then the arc intercepted by each of these lines as they cut the several circles <sup>is</sup> ~~equal~~ <sup>the same</sup> ~~that~~ <sup>as</sup> ~~the~~ <sup>the</sup> ~~margin~~ <sup>margin</sup> of deflection rotation, with approx. rough accuracy, as we can attempt.

$$ab : AB :: EB : CB \quad ab = AB + \frac{EB}{CB} AB \times \cos \theta$$

$$EF = EC \cos \theta.$$

CB = deflection in a small interval of time.

$$PQ = Ph \cos \theta$$

$$Ph : x :: nc : mN$$

$$\text{also } PQ : CA :: mN : NC$$

$$CA \approx Nn :: CM \cos \theta : (CM - mN)$$

$$CA =$$

$$CA \approx r \cos \theta :: CB : r$$

$$CA = CB \cos \theta$$

$$PQ : CA :: mN : r$$

$$PQ = CB \cos \theta \cdot \frac{r-r'}{r}$$

$$b = \frac{dr}{dt}$$

$$b = \frac{r-r'}{r}$$

$$b = \frac{r-r'}{r}$$

$$b = \frac{r-r'}{r}$$

$$PQ = Ph \cos \theta$$

$$Ph = Nn$$

$$Nn : CB :: r-r' : r$$

$$Nn = CB \cdot \frac{r-r'}{r}$$

$$Ph = CB \cos \theta \cdot \frac{r-r'}{r}$$

Hence the velocity of any point P is half that due to MN, & is inversely as the distance from C, to point of draw circle

Circle which for rough practical purposes & at moderate distances may be supposed coincident with a parallel of latitude.

On reversing the conditions of the problem, if C be allowed to hover over C for the hour in question & then be instantaneously propelled one degree northwards its course will lead it directly to N.

The path followed by a particle moving continuously forward <sup>and accomplishing 60 miles in</sup> the space of an hour after any law of varying velocity we please to name, must necessarily lie between these two extreme cases of a meridian line on the one hand and a line making an angle of  $11^{\circ}30'$  with it on the other.

If the onward movement be uniform <sup>and at the rate of 60 miles per hour</sup> C would reach the parallel of N at a point <sup>60 miles, a not 12 from N & therefore</sup> such that joining C & N, by a straight line, the angle  $NCn_1$  <sup>is not far different from</sup>  $\frac{1}{2}(11^{\circ}30') = 5^{\circ}45'$ .  
 $\tan NCn_1 = \frac{60 \tan 5^{\circ}45'}{m}$  <sup>the movement</sup> represents the deflection in one hour, with sufficient exactness for the value of  $\frac{60}{m}$  <sup>the distance in miles, tangential path by r & the angle</sup>  $=$  not less than  $\frac{60}{m}$  <sup>is not far different from</sup>  $\frac{60}{m}$   $\approx 20$ , which are those with which we have to deal.

Whether we take N a point to the north & S a point to the S the deflection is the same & in both cases to the right hand.

If the onward movement be uniform & therefore at the rate of 60 miles per hour C would reach the parallel of N midway between it &  $n_1$ , or, joining N &  $n_1$  by a straight line,  $\tan NCn_1 = \frac{60}{60} = \tan 5^{\circ}48'$  & generally so long as the movement is uniform <sup>no matter what the meridional distance travelled over in the hour (= r)</sup> may be, the deflection is always  $r \cdot \tan 5^{\circ}48'$  no account being taken of

retardation by friction.

<sup>any point of the surface</sup> If we desired to find out the movement of an unimpeded particle of air propelled with a velocity varying according to any law we should determine the parallels of latitude at intervals  $h, h_1, h_2, \dots$  corresponding to the law of the first second or hour.

## Definitions.

42 Rutland Gate, S.W.  
May, 30 1881

It is as difficult to define well as it is important to do so. I certainly do not much like the definitions you enclosed (and which I return); and after many trials think it scarcely possible to succeed by treating the terms altogether dictionary fashion, but rather to incorporate them in a general explanation. This I have done as well as I can; please submit it to the members of the Council. I am very anxious to get it done quite well, before it is published.

(Sd) Francis Galton.

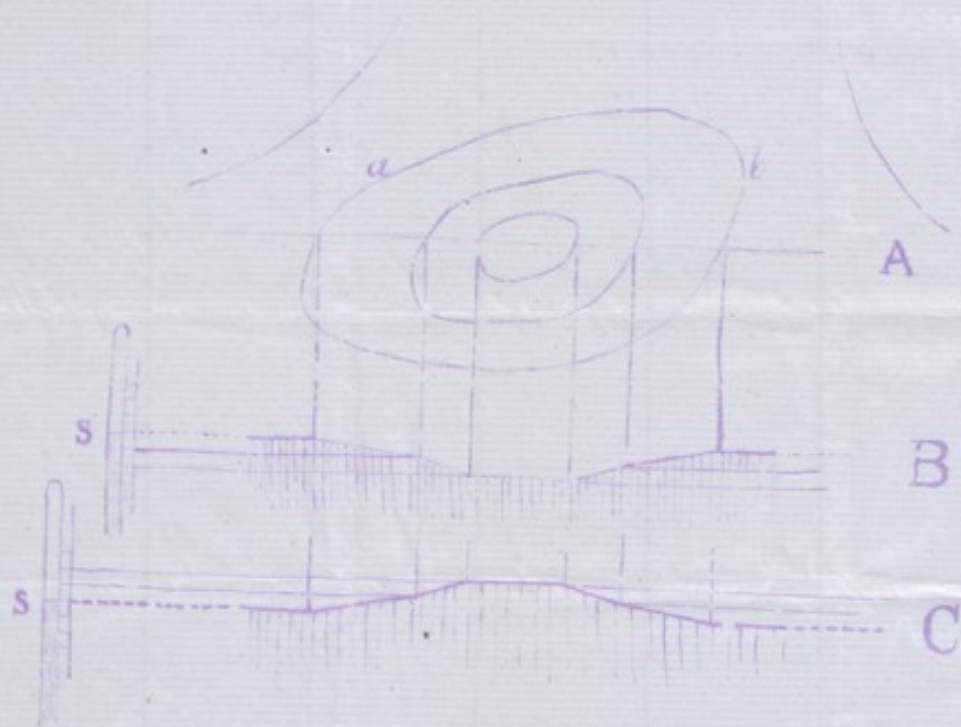

The variety in the distribution of isobaric lines is infinite, nevertheless there are two well defined forms which are rarely absent from any synchronous chart of a considerable portion of the globe. The changes in their shape, direction of movement and rate of progress can easily be traced day by day in successive synchronous charts, and the arrangement of all the other isobars is more or less closely dependent on them. They are therefore cardinal features in all descriptions of the distribution of barometric pressure.

They consist of a concentric series of closed isobars like those shown at A in the diagram, though often more irregularly disposed. In one of the two forms, the isobars decrease in value towards the centre, indicating a depression ~~section~~ in the adjacent barometric surface, as shown in the section at B. In the other form, they increase towards the centre, indicating an elevation, as shown at C. Both of the forms are bounded by the outermost closed isobaric line, a b, so that their "size" is defined as the area included within that boundary. Their "depth" or "height" as the case may be, is the difference between the value of their innermost and outermost isobars

isobars, usually drawn to the nearest tenth of an inch. Their "central area" is that which is enclosed by the innermost isobar, and their "gradient" at any point is the slope of their section through that point, it is measured radially in hundredths of an inch for 15 nautical miles.

The phrases used in speaking of the depressions are "areas of depression" or "areas of low barometer", or again they may be expressed in terms derived from the peculiarity of the winds with which they are invariably associated, as "cyclonic areas". In speaking of the elevations, the phrases used express precisely converse conditions, namely "areas of high pressure" and "anticyclones".

- A. Isobaric plan of an area either of low or of high pressure.  
 B. Vertical section of an area of low pressure.  
 C. . . . . high .  
 S. Barometric scales, divided into tenths of an inch.
