P R E F A C E.

THE aim which I have steadily kept before me throughout the following pages, when dealing with the causes, symptoms, and treatment of Diseases of the Ear, and the treatment of the Affections of the Nose and Pharynx which conduce to aural disease, has been, before all things, to be of service to the members of the Profession who feel themselves drawn to give special attention to a department the importance of which, I regret to say, is still only partially recognised.

It will be noted in the course of the work that where I have felt compelled to differ from justly respected authorities, I have fully set forth my reasons for so doing; and where I depart from traditional methods of treatment I have, by a sufficiency of detail, I trust, made my meaning and method clear.

I gladly avail myself of these few introductory lines to make my acknowledgments to Mr. RICHARD LAKE for the sections of Aural Polypi, and to Dr. FREDERIC HEWITT for valuable suggestions with respect to the administration of anæsthetics.

In sending forth my work I cherish the hope that it may be found materially to aid all earnest workers in the Profession.

T. MARK HOVELL.

105, HARLEY STREET, W.,

August, 1894.

CONTENTS.

CHAPTER I.

	PAGE
INTRODUCTION—GENERAL SKETCH OF THE ORGAN OF HEARING	1—3
Organ of Hearing in the Lower Animals, 2. The Sound-perceiving Apparatus; the Labyrinth and its Divisions, 2. The Sound-conducting Apparatus; the Tympanum and its Contents, the Membrana Tympani and External Meatus, 2.	
THE ANATOMY AND PHYSIOLOGY OF THE SOUND-CONDUCTING APPARATUS	4—23
Anatomy of External Ear, 4. Auricle and Meatus, 4. Description of Auricle: its Structure; the Integument covering it, 4. Muscles of Auricle, 5. Vessels and Nerves of Auricle, 5. Functions of Auricle, 6. Questions as to its Uses in the Reception and Transmission of Sounds, 7. Value of the Auricle as a Resonator, 8. Mr. Gardiner Brown's Views, 9. Function of Intrinsic and Extrinsic Muscles, 9. The Auditory Canal or External Meatus, 9. Cartilaginous and Osseous Parts, 10. Direction and Capacity, 11. Measurements, 12. Relations to Neighbouring Parts, 12. Portions of Temporal Bone corresponding with various Parts of the Ear, 13. Integument of the Meatus; Differences in various Parts, 14. The Ceruminous Glands, Schwalbe's view as to their Functions, 15. The Meatus in Infants, 16. Vessels and Nerves of Meatus, 18. Functions of Meatus, 18. The Ceruminous Secretion, 19. Development of Ear, 20.	

CHAPTER II.

	PAGE
THE SOUND-CONDUCTING APPARATUS (<i>continued</i>)—	
THE MIDDLE EAR OR TYMPANUM	24—62
Position, Contents, and Boundaries of Tympanum, 24. Membrana Tympani, its Size, Direction, Colour, and Structure, 25. External, Middle, and Internal Layers, 27. Shrapnell's Membrane, 29. Vessels and Nerves, 29. Inner Wall of Tympanum, 30. The Posterior Wall, 31. The Anterior Wall, 31. The Roof or Cranial Wall, 31. The Floor or Jugular Wall, 31. Dimensions of the Tympanum, 32. Functions of the Membrana Tympani, 32. The Ossicles, 33. Their Ligaments and Articulations, 35. Movements of the Ossicles, 35. Muscles of the Tympanum, the Tensor Tympani, and the Stapedius, 38. Lining Membrane of the Tympanum, 42. The Tympanum in the Fœtus, 44. Vessels and Nerves of the Tympanum, 45. The Eustachian Tube, its Osseous, Cartilaginous, and Membranous Portions, 47. Mucous Membrane, 49. The Pharyngeal Opening, 52. The Eustachian Tube in Children, 52. Muscles, Fasciæ, and Ligaments connected with the Tube, 53. Vessels and Nerves, 55. Functions of the Tympanum and Eustachian Tube, 55. The Mastoid Portion of the Temporal Bone; the Mastoid Cells, Description and Function, 57.	

CHAPTER III.

THE EXAMINATION OF PATIENTS SUFFERING FROM AURAL AFFECTIONS. GENERAL SYMPTOMS AND CAUSES . . .	63—69
Investigation of History of Case, 63. Points to be Ascertained, 64. Influence of Age, Occupation, and Surroundings, 64. Duration of Symptoms, 65. Injuries as a Cause, 65. Previous Diseases, 66. Hereditary Predisposition, 66. Pain as a Symptom, 67. Vertigo, 67. Subjective Auditory Sensations, 67.	

CHAPTER IV.

THE EXAMINATION OF THE EAR AND DETERMINATION OF THE HEARING-POWER	70—95
Examination of the Ear, 70. Sources of Light, 70. Mirrors, 73. Use of Specula, 75. Brunton's Auriscope, 75. Other Forms, 77. Methods of Using, 78. Points to be Noticed, 79. The Membrana Tympani, Normal Appearance, 79. Parts Seen Through it, 80. The Cone of Light, 80. Mobility of Membrane, 81. Use of Siegle's Speculum, 81. Division of the Membrane into Quadrants, 82. Determination of Hearing-Power, 82. Use of the Watch, 83. Formula for	

Registering Hearing-Power, 84. Bone-Conduction, 84. Politzer's Acoumeter, 84. Hughes' Sonometer, 86. Testing with High Notes, 87. Galton's Whistle, 87. Speech as a Test of Hearing, 88. Methods to be Adopted, 88. Whispered Speech, 89. The Tuning-Fork, 89. Number Requisite, 89. Tests for Bone-Conduction, 90. Use of the Watch, Tuning-Forks, etc., 90. Weber's Experiment, 90. Tuning-Forks with Clamps, 91. Rinne's Experiment, 93. Value of Tests, 93. Gruber's Modification, 94. Gellé's Method, 94.

CHAPTER V.

EXAMINATION OF THE NOSE, PHARYNX, AND EUSTACHIAN TUBES 96—132

Frequent Dependence of Diseases of Middle Ear upon Morbid Processes in Pharynx and Nares, 96. Importance of Examining these parts and Eustachian Tube, 97. Requisites for Anterior Rhinoscopy, 97. Parts Visible, 97. Examination of Mouth, Fauces, and Lower Part of Pharynx, 98. Parts Seen, 98. Posterior Rhinoscopy, 99. Parts brought into View, 102. Pharyngeal Openings of the Eustachian Tubes, 103. Digital Examination of the Naso-Pharynx, 104. Structures Distinguishable, 105. Examination of the Eustachian Tubes, 105. Tests of their Permeability, 105. Valsalva's Method, 105. Politzer's Method, 107. Description of Details, 108. Modifications suggested by Lucae and Gruber, 108. Results of Passage of Air into Tympanum, 110. Use of Manometer, 110. Use of Auscultation Tube, 111. Precautions in Employing Politzer's Method, 111. Occasional Unpleasant Symptoms, 111. Effect produced by Politzer's Method, 112. The Eustachian Catheter, Forms and Description of the Instrument, 112. Vulcanite and Silver Catheters, 114. Bag for Injecting Air, 115. Employment of the Auscultation Tube, 115. Introduction of the Eustachian Catheter, 116. Use of Air-Bag, 119. Other Methods of Introducing Catheter, 120. Plans recommended by Frank and Gruber, 120. Indications that the Catheter is in proper Position, 121. Obstacles to the Introduction of the Eustachian Catheter, 121. Methods of dealing with them, 121. Emphysema sometimes produced, 122. Sounds produced during Injection of Air, 124. Causes of Absence of Sounds, 124. Action of Stream of Compressed Air upon the Eustachian Tube and Tympanum, 125. Removal of Exudation, 126. Improvement of Hearing-Power, 126. Action in Cases of Perforation of the Membrane, 126. Comparative Value of the Various Methods of Inflating the Tympanum, 126. Passage of Bougies along the Eustachian Tube, 128.

CHAPTER VI.

	PAGE
METHODS OF TREATMENT	133—145

Syringing the Ear, 133. Method of Performing, 136. Symptoms occasionally caused, 137. Application of Heat and Cold to the Ear, 137. The Introduction of Medicated Solutions into the Meatus, 139. The Insufflation of Remedies in the Form of Powders, 140. The Air-Douche and Injections through the Eustachian Tube, 141. The Injection of Vapours and Gases through the Eustachian Tube, 144.

CHAPTER XVIII.

NEW FORMATIONS OF THE AURICLE AND EXTERNAL MEATUS .	200—215
---	---------

Angioma, 200. Fibroma, 202. Cysts, 202. Sarcoma, 203.
Epithelioma, 204. Lupus, 206. Osteomata, 207. Exos-
toses, 208. Symptoms and Treatment, 209. Case of Exos-
tosis Removed by Drill and Screw, 212.

CHAPTER XIX.

FOREIGN BODIES IN THE EAR	216—225
-------------------------------------	---------

Classification of Foreign Bodies: Vegetable, Animal, Mineral,
216. Symptoms caused by Insects in Meatus, 217. Treat-
ment, 218. Symptoms caused by Non-living Bodies, 219.
Reflex Symptoms, 219. Symptoms often Aggravated by
Attempts at Removal, 219. Diagnosis, 219. Prognosis,
219. Treatment, Various Methods and Precautions, 221.
Substances Liable to be Swollen by Moisture, 222. Various
Instruments for Extracting Foreign Bodies from Meatus,
223. Course to be Pursued when Extraction Impossible,
224. Partial Separation of Auricle, 225.

CHAPTER XX.

AFFECTIONS OF THE MEMBRANA TYMPANI	226—240
--	---------

Injuries of the Tympanic Membrane, 226. Indirect and Direct
Causes, 226. Symptoms, 227. Subjective Sensations, 227.
Alterations in Hearing-Power, 228. Objective Symptoms,

229. Rupture of the Membrane from Sudden Condensation of Air, 230. Mechanical Injuries, 231. Rupture of the Membrane by *Contre-Coup*, 232. Prognosis, 233. Treatment, 234. Inflammation of the Membrana Tympani or Myringitis, 234. Symptoms, 235. Abscesses in the Membrane, 236. Formation of Vesicles, 236. Diagnosis, 237. Prognosis, 237. Treatment, 237. Chronic Inflammation of the Membrana Tympani, 238. Causes, 238. Symptoms, 239. Course and Treatment, 239.

CHAPTER XXI.

DISEASES OF THE NOSE, PHARYNX, AND NASO-PHARYNX, CONNECTED WITH DISEASES OF THE MIDDLE EAR . . . 241—289

Influence of Diseases of Nose and Naso-Pharynx on Condition of Tympanum, 241. Acute Nasal Catarrh, 242. Causes and Symptoms, 243. Extension to Eustachian Tubes, 243. Objective Appearances, 243. Treatment, 243. Chronic Catarrh of the Naso-Pharynx, 244. Causes and Anatomical Appearances, 245. Condition of the Mucous Membrane, 245. The Secretions, 246. Symptoms caused by Swelling of the Mucous Membrane, 246. Nervous Disorders, 247. Course and Changes sometimes produced in Mucous Membrane, 247. Ulcerative Processes, 247. Connection between Chronic Naso-Pharyngeal Catarrh and Aural Diseases, 247. Treatment, 247. Local Applications, 248. Use of the Spray-Apparatus, 249. The Nasal Douche, 249. The Syringe, 251. Politzer's Method of applying Solutions to the Nares, 251. Inhalation, 252. Ointments, 252. Caustics in Solution, 253. Insufflation of Fine Powders, 253. Nasal Bougies, 255. The Galvano-Cautery, 256. Chemical Caustics, 256. Treatment of Ozæna, 257. Treatment of Enlargement of Posterior Extremity of Inferior Turbinate Body, 258. Treatment of Nasal Polypus, 259. Treatment of Enlarged Tonsils, 261. Granular Pharyngitis, 268. Morbid Growths in the Naso-Pharynx and their Treatment, 270. Removal of Tip of Uvula, 270. Measures for Restoring the Functions of the Muscles of the Tubes, 271. Adenoid Growths, 272. The Pharyngeal Tonsil, 272. Literature on the Subject of Adenoid Growths, 272. Their Anatomical Structure, 273. Etiology, 273. Symptoms, Subjective and Objective, 274. Disorders of Middle Ear resulting from these Growths, 275. Methods of Examination, 278. Digital Examination, 278. Inspection with the Mirror, 278. Diagnosis, 279. Treatment, 280. Method of Removing Adenoid Growths, 285.

CHAPTER XXII.

	PAGE
AFFECTIONS OF THE EUSTACHIAN TUBES	290—298

Extension of Morbid Processes through the Eustachian Tube, 290. Injuries to the Eustachian Tube, 291. Foreign Bodies, 291. Inflammation of the Eustachian Tube, 292. Anatomical Appearances, 292. Symptoms, 292. Examination of the Throat and Ear, 293. Treatment, 294. Constrictions of the Eustachian Tube, 294. Diagnosis, 295. Complete Atresia, 295. Undue Patency, 295. Ulceration of the Eustachian Tube, 296. Diphtheria, Small-pox, Tuberculosis, and Syphilis, 296. Treatment of Constriction, Abnormal Patency, and Ulceration, 297.

CHAPTER XXIII.

DISEASES OF THE TYMPANIC CAVITY—INTRODUCTION	299—302
--	---------

CHAPTER XXIV.

ACUTE CATARRH OF THE MIDDLE EAR	303—318
---	---------

Frequency and Causes of the Disease, 303. Affections of the Throat, 304. Part played by Micro-organisms, 305. Channels of Access, 306. Morbid Appearances, 306. Subjective Symptoms, 307. Impairment of Hearing, 308. Subjective Sensations, 308. Autophony, 308. Increased Temperature, 308. Objective Symptoms, 309. Appearance of the Meatus and Membrane, 309. Effects of the Air-Douche, 310. Auscultation and Sounds Heard, 311. Diagnosis, 311. Prognosis, 311. Treatment, 312. Attention to the Naso-Pharynx, 312. Relief of Pain, 313. The Air-Douche, 313. The Operation of Paracentesis, 314. Spontaneous Perforation and its Treatment, 317. Treatment of Adenoid Growths and of Enlarged Tonsils, when present, 318.

CHAPTER XXV.

CHRONIC CATARRH OF THE MIDDLE EAR	319—330
---	---------

Chronic Catarrh of the Tympanum, 319. Frequency and Forms, Catarrhal and Adhesive, 319. Causes, 320. Affections of the Eustachian Tube, 320. Anatomical Appearances, 320. Subjective Symptoms, 321. Deafness, Noises in the Ear, Giddiness, Autophony, Paracusis, etc., 322. Objective Appearances, 323. Condition of Membrana Tympani, 323. Use of the Catheter and Air-Douche, 324.

Effects on Appearances, 325. Perforation of the Membrane, 325. Course, 326. Diagnosis and Prognosis, 326. Treatment, 327. Attention to State of Naso-Pharynx, 327. The Air-Douche, Politzer's Method, the Catheter, 327. Chloride of Ammonium Vapour and Remedies in Fluid Form, 327. The Use of Siegle's Speculum, 328. Paracentesis and Plicotomy, 329. General Treatment of Chronic Middle-Ear Catarrh, 329.

CHAPTER XXVI.

CHRONIC ADHESIVE CATARRH OF THE MIDDLE EAR—OTITIS MEDIA CATARRHALIS SICCA—SCLEROSIS OF THE MIDDLE EAR 331—363

Nature of the Disease, 331. Origination and General Consequences, 332. Pathological Appearances, 332. Causes, 335. Symptoms, 335. Impairment of Hearing, 335. Subjective Sensations, 336. Hyperæsthesia Acustica, 336. Paracusis, 336. Objective Appearances, 337. The Membrana Tympani, 337. Contraction of Tensor Tympani Muscle, 338. Condition of the Naso-Pharynx and Eustachian Tubes, 339. Testing the Hearing-Power, 340. Course and Termination, 341. Diagnosis, 342. Prognosis, 345. Treatment, 346. Attention to Naso-Pharynx, 346. The Air-Douche, 346. Application of Remedies to the Tympanum, 347. Rarefaction of Air in the Meatus, 349. Politzer's Plan, 349. Lucae's Spring Pressure-Probe, 349. Hommel's Method, 350. Treatment of the Tinnitus, 350. The Eustachian Tubes, 351. General Hygienic Rules, 351. Operations proposed, 352. Removal of Tympanic Membrane and Ossicles, 353. Establishment of an Opening in the Membrane, 355. Division of the Posterior Fold of the Tympanic Membrane, 356. Division of the Anterior Ligament of the Malleus, 357. Multiple Incisions into the Tympanic Membrane, 358. Division of the Tendon of the Tensor Tympani Muscle, 359. Indications for Operation and Various Methods, 360. Results, 363.

CHAPTER XXVII.

ACUTE SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR. 364—383

Nature of the Disease, 364. Causes, 364. Micro-Organisms, 365. Frequency as affected by Age, Sex, Climate, etc., 366. Reasons for Frequency in Young Subjects, 367. Symptoms, 367. Subjective, as Pain, Impairment of Hearing, etc., 367. Objective, Changes in Tympanic Membrane, 369. Perforation, Signs of, and Methods of Discovering, 370. Character

of Secretion, 371. Course and Results, 372. Diagnosis, 375. Prognosis, 375. Treatment, 376. Antiphlogistics, 377. Paracentesis, 378. The Air-Douche, 379. Local Remedies, 380. Treatment of Cases of Spontaneous Perforation, 381. Mastoid Complications, 383.

CHAPTER XXVIII.

CHRONIC SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR . 384—417

Statistics showing Frequency of the Complaint, 384. Morbid Appearances in the Tympanic Cavity and Membrane, 385. Caries of the Ossicles, 387. Suppuration in the Upper Tympanic Spaces, 387. The Eustachian Tube, 387. Causes, 388. Influence of Age, Sex, etc., 389. Subjective Symptoms, 389. Impairment of Hearing, Tinnitus, Giddiness, 389. Pain as a Symptom, 390. Evidences of Nervous Disorders, 390. Objective Symptoms, 391. Discharges from the Ear, 391. Micro-Organisms, 392. Condition of the Membrana Tympani, 393. Perforations, their Size, Form, etc., 393. Condition of Tympanum, 395. Portions and Structures Visible through a Perforation, 395. Perforation of Shrapnell's Membrane, 396. Course and Results of Chronic Middle-Ear Suppuration, 398. Diagnosis of Perforations, 399. Prognosis, 401. Treatment, 403. Various Methods of Cleansing the Middle Ear, 403. The Syringe, Inflation, Enlargement of the Opening, 403. Aspiration, Condensation of Air, Dry Cleansing, 408. Use of Antiseptics, 409. Boric and Carbolic Acids, etc., 409. Caustics, Nitrate of Silver, 413. Astringents, 414. Gelatin Bougies, 415. Constitutional Remedies, 416. Methods of Improving the Hearing-Power, 416.

CHAPTER XXIX.

CHANGES IN THE MEMBRANA TYMPANI IN VARIOUS AFFECTIONS OF THE EAR 418—440

Cicatrization, 418. Persistent Perforation of the Tympanic Membrane, 421. Appearances and Consequences, 422. Artificial Substitutes, 424. Method of Determining Effect of Closing a Perforation, 424. Treatment of Perforations, 424. Attempts to produce Cicatrization, 425. Myringo-Plastic Operations, 425. Artificial Tympanic Membrane, 426. Appliances devised by Yearsley, Toynbee, Gruber, Hartmann, and others, 426. Rules to be Adopted, 429. *Modus Operandi* of such Appliances, 430. Indications for Employment of Artificial Membranes, 430. Calcareous

Deposits in the Membrana Tympani, 431. Appearances, 432. Symptoms and Treatment, 433. Thickening of the Tympanic Membrane, 433. Atrophic Processes in the Membrane, 434. Adhesions between the Membrane and the Wall of the Tympanum, 435.

CHAPTER XXX.

CONSEQUENCES AND SEQUELÆ OF CHRONIC MIDDLE-EAR SUP-
PURATION 441—446

Formation of Cholesteatomatous Masses in the Tympanic Cavities, 441. The Growth of Polypi, 441. Caries and Necrosis of the Temporal Bone, 441. Extension of Inflammation to the Mastoid Process and Cells, 441. Cholesteatoma of the Tympanum, Nature and Pathology, 442. Virchow's Views, 442. Theories advanced by Tröltsch, Habermann, and Politzer, 442. Symptoms and Consequences, 444. Diagnosis, 444. Prognosis, 445. Treatment, 445.

CHAPTER XXXI.

POLYPI OF THE EAR 447—463

Classification of Polypoid Growths, 447. Mucous Polypi or Granulation Tumours, 447. Fibrous Polypi, 448. Angio-Fibromata, 448. Myxomata, 450. Relative Frequency of Various Forms, 450. Etiology, 450. Chronic Middle-Ear Suppuration, 451. Sex and Age, 452. Seat of Origin, 452. Number of Polypi, 453. The Pedicle, 453. Size and General Conformation of Aural Polypi, 453. Symptoms, Subjective and Objective, 454. Consequences which may Result, 455. Development and Progress of the Growths, 455. Diagnosis, 455. Polypi of the Tympanum, with the Membrane Intact, 457. Treatment, 457. Operative and by Application of Remedies, 457. Removal by the Snare, 458. Politzer's Knife, 459. The Use of Scoops and Crushing Forceps, 460. The Galvano-Cautery, 460. Caustic and Astringent Applications, 461. Acids, 462. Alcohol, 462. Cases for which Adapted, 462. Acetate of Lead, 463.

CHAPTER XXXII.

CARIES AND NECROSIS OF THE TEMPORAL BONE 464—476

Causes, 464. Cases Due to Injuries, 464. Middle-Ear Suppuration, 464. Constitutional Disorders, 465. Parts most often Involved, 465. Varying Extent of the Disease, 465. Caries of the Ossicles, 465. Necrosis of Tympanic Walls, 466.

Subjective Symptoms, 467. Objective Symptoms, 467. Symptoms of Lesion of the Facial Nerve, 468. Paralysis, 468. Perversions of Taste, 469. Character of the Discharge, 469. Examination with a Probe, 470. Course, 470. Diagnosis and Prognosis, 471. Bezold's Statistics, 472. Occasional Multiplicity of Complications, 472. Treatment, 473. Special Measures for Dealing with Caries and Necrosis of the Ossicles, 474. Treatment of Necrosis of Temporal Bone, 476.

CHAPTER XXXIII.

AFFECTIONS OF THE MASTOID PROCESS 477—504

Alterations in Size of Cells, 477. Inflammation of the Mastoid Process, 478. Mastoid Periostitis, 478. Inflammation of the Mastoid Cells, 480. Causes of the Disease and Circumstances under which it Occurs, 480. Morbid Appearances, 481. Symptoms and Course, 483. Caries and Necrosis of the Mastoid Process, 484. Course and Consequences, 485. Prognosis, 486. Treatment, 486. Indications for Opening the Mastoid Process, 487. Various Methods of Operating, 491. Difficulties and Objects of the Operation, 500. Appearances Seen on Opening the Mastoid Process, 501. After-Treatment, 501. General Results and Prognosis of the Operation, 501. Statistics, 502. Cholesteatoma, 502. Effects on Hearing-Function, 502. Gravitation-Abscesses, 503. Significance of Attacks of Fever after Operation, 503.

CHAPTER XXXIV.

CRANIAL AND OTHER COMPLICATIONS OF MIDDLE-EAR SUPPURATION 505—522

Extension of Morbid Processes to Intra-Cranial Structures, 505. Cerebral Meningitis, 505. Two Forms, 505. Spots at which Perforation of the Bone is likely to Occur, 506. Course Taken by the Pus, 506. Symptoms, 507. Diagnosis, 508. Treatment, 508. Cerebral Abscess, Development and Symptoms, 509. Influence of Micro-Organisms, 511. Seats of Abscesses, 511. Stages of the Morbid Process, and Appearances presented by the Abscess, 512. Sinus Thrombosis as a Complication, 513. Diagnosis, 513. Terminations, 514. Trephining the Skull, 514. Abscess in the Cerebellum, 515. Phlebitis and Thrombosis of the Lateral Sinus and Jugular Vein, 515. Symptoms, 516. Course, 518. Diagnosis, 518. Treatment, 519. Ulceration of the Carotid Artery, 520. A TREATISE ON THE DISEASES OF THE EAR.

CHAPTER I.

INTRODUCTION—GENERAL SKETCH OF THE ORGAN OF HEARING.

Organ of Hearing in the Lower Animals — The Sound-perceiving Apparatus—The Labyrinth and its Divisions—The Sound-conducting Apparatus—The Tympanum and its Contents, the Membrana Tympani and External Meatus.

THE ANATOMY AND PHYSIOLOGY OF THE SOUND-CONDUCTING APPARATUS.

Anatomy of External Ear—Auricle and Meatus—Description of Auricle : its Structure ; the Integument Covering it—Muscles of Auricle—Vessels and Nerves of Auricle—Functions of Auricle—Questions as to its Uses in the Reception and Transmission of Sounds—Value of the Auricle as a Resonator—Mr. Gardiner Brown's Views—Function of Intrinsic and Extrinsic Muscles—The Auditory Canal or External Meatus—Cartilaginous and Osseous parts—Direction and Capacity—Measurements — Relations to Neighbouring Parts — Portions of Temporal Bone corresponding with various parts of the Ear—Integument of the Meatus ; Differences in various Parts — The Ceruminous Glands, Schwalbe's view as to their Functions—The Meatus in Infants—Vessels and Nerves of Meatus—Functions of Meatus—The Ceruminous Secretion—Development of Ear.

INTRODUCTION—GENERAL SKETCH OF THE ORGAN OF HEARING.

THE sense of hearing enables the mind to take cognizance of those oscillations of elastic bodies which cause the phenomena of sound. Such oscillations are transmitted to the ear through an elastic medium, and most frequently through the atmosphere ; but they may also be communicated by liquids, and with even

greater velocity by solid conductors possessing a high degree of elasticity, and directly connecting the source of the sound with the organ of hearing.

In its simplest condition, as in *medusæ*, the organ of hearing takes the form of minute capsules, containing a transparent jelly, and situated at the bases of the marginal tentacles, around the margin of the umbrella-like expansion. In *worms* and *molluscs*, the auditory organ is similarly represented by a closed membranous sac or vesicle, filled with fluid, in which one or more otoliths are found. The vesicle is lined with cells, which, in the higher groups, are connected at their bases with branches of the auditory nerve, and are furnished with bristles at their free extremities. These bristles are the terminal organs of the nerve; in some of the *annulosa* they have been seen to vibrate when sound was conducted into the water in which the creatures were placed. This vesicular membranous structure, with various modifications and additions, is found in all classes of animals, and constitutes the essential part of the organ of hearing, viz., the *sound-perceiving* apparatus. In the human subject it is represented by a more complex arrangement—the *membranous labyrinth*, contained in a small cavity excavated in the petrous portion of the temporal bone. This cavity, or osseous labyrinth, is incompletely divided into three parts, the *vestibule* (v), the *semi-circular canals* (H), and the *cochlea*, and similar terms are applied to the corresponding divisions of the membranous labyrinth, which are separated from their osseous case by the periosteum of the latter, and a clear fluid, termed the *perilymph*. On the outer side of the labyrinth is another cavity, the *tympanum* (P), in the anterior portion of which is the opening of the Eustachian tube (TE), communicating with the throat and providing for the access of air to the cavity. The tympanum is bounded externally by a membrane (T) resembling a drumhead, and connected with the internal wall by means of a chain of three small bones. The outer bone of the chain (K) is closely attached to the membrana tympani, while the inner one (s) is applied to an opening in the outer wall of the vestibule. The ossicles are articulated together by joints, admitting of certain movements under the action of small muscles, which thus alter the tension of the membrana tympani and the pressure of the lymph of the labyrinth. The ossicles serve to communicate vibrations from the former to the latter of these

structures. On the outer side of the tympanic membrane is a canal (AG), the *external meatus*, with an expanded portion for collecting vibrations and conducting them to the internal parts.

For purposes of description the organ of hearing is divided into three portions, termed respectively the *external*, *middle*, and *internal ear*, these being separated from each other in the manner above described. From a physiological point of view, the organ

FIG. 1.

SCHEME OF THE ORGAN OF HEARING.

AG, external auditory meatus; T, tympanic membrane; K, malleus with its head (*h*), short process (*kf*), and handle (*m*); *a*, incus with its short process (*x*) and long process—the latter is united to the stapes (*s*) by means of the Sylvian ossicle (*z*); P, middle ear; *o*, fenestra ovalis; *r*, fenestra rotunda; *x*, beginning of the lamina spiralis of the cochlea; *pt*, its scala tympani, and *et*, its scala vestibuli; V, vestibule; S, saccule; U, utricle; H, semi-circular canals; TE, Eustachian tube. The long arrow indicates the line of action of the tensor tympani; the short curved one that of the stapedius. (*Landois and Stirling.*)

may be regarded as consisting of a *sound-conducting* and a *sound-perceiving* apparatus; the former including the external and middle ear; and the latter, the structures of the internal ear, the auditory nerve, and the psycho-acoustic cerebral centre.

Before considering the diseases to which these various parts are subject, an account will be given of the anatomy and functions of the sound-conducting apparatus, and this will be followed by a description of the methods of examining the ear.

THE ANATOMY AND PHYSIOLOGY OF THE SOUND-
CONDUCTING APPARATUS.

Anatomy of the External Ear.—The external ear consists of two parts: the *pinna* or *auricle*, which projects from the side of the head; and the *auditory canal*, or *external meatus*, directed inwards, and extending to the *membrana tympani*, which constitutes the external boundary of the middle ear.

The **auricle** is free and expanded, resembling a shell, and forms a kind of funnel around the meatus. Its outer surface, which is directed somewhat forwards, presents several elevations and depressions, some of which are seen in reverse on the free portion of its inner surface. Bounding the greater part of its circumference is a prominent rim, the *helix*; and within this there is another curved prominence, the *antihelix*, which commences below in a projection termed the *antitragus*, and bifurcates above so as to enclose a space, the *triangular fossa*. Within the curve formed by the antihelix, and divided into two portions by the anterior extremity of the helix, is a large, deep, cup-shaped hollow, the *concha*, which opens into the auditory meatus. In front of the concha, and partially covering the meatus, is the eminence termed the *tragus*, while below the concha is a soft and pendulous portion, the *lobule*, or *lobe* of the ear.

The auricle consists mainly of a plate of yellow fibro-cartilage, covered with integument; it is attached by ligamentous fibres to the margin of the external auditory meatus of the temporal bone. A deep cleft, filled up by fibrous membrane, separates the principal portion of the cartilage from that of the tragus and antitragus. Other deep clefts exist between the antitragus and the posterior extremity of the helix, and between the commencement of the latter and the tube of the ear. The cartilage is wanting in the lobule, which is composed of fat and connective tissue. The integument covering the auricle presents a few differences on its two aspects. On its inner convex surface it is attached to the cartilage by connective tissue, containing many elastic fibres, and is freely movable, especially at the upper and lower extremities of the ear. On the outer surface, the skin is somewhat firmly attached to the cartilage; it is much thinner, and the epidermis is very delicate. On the convex surface many fat

cells are to be found in the connective tissue, and these are very abundant in the lobule; they are much more sparsely distributed on the outer surface. Fine hairs with sebaceous glands, and also sweat glands, are scattered over both aspects. The hairs are especially abundant and long about the tragus, the antitragus, and the intertragic notch. In male subjects and in old age they are often very prominent and stiff, and the sebaceous glands near the meatus are apt to become enlarged and filled with secretion.

Six small **muscles** pass between different parts of the auricle; four being situated on its outer, and two on its inner surface. Besides these, there are three muscles connecting the ear with the side of the head, and termed respectively the *superior*, *anterior*, and *posterior auricularis*, or the *attollens*, *attrahens*, and *retrahens auriculam*. Both sets of muscles are but feebly developed in the human subject; very few persons possess the power of moving the auricle and of altering the size of the angle at its attached portion. In many animals, on the other hand, the auricle moves freely under the influence of the will, and the power of estimating the direction whence sounds are propagated is thus considerably increased.

Vessels and Nerves of the Auricle.—The *arteries* are derived from the external carotid, a branch from which, the *posterior auricular*, is distributed mainly to the inner surface. The outer surface is supplied by the *anterior auricular* from the temporal, and these arteries freely anastomose with each other, sending branches through the cartilage and over its margin. The *occipital artery* also gives a branch to the back of the concha. The *veins* of the auricle join the temporal vein, and their blood thus passes into the external jugular. Some auricular veins open directly into the latter vein.

The auricle is supplied with *nerves* from several sources, viz., the *fifth pair*, the *facial*, the *pneumogastric*, the *cervical plexus*, and the *sympathetic*. The *auriculo-temporal* of the third division of the fifth supplies the outer surface of the ear; the *posterior auricular* of the facial, after receiving a twig from the auricular branch of the pneumogastric, is distributed to the inner surface, and gives filaments to the retrahent muscle. The *auricular* branch of the vagus is distributed to the integument of the back of the ear. The *great auricular* nerve is derived from the cervical plexus, and supplies the integument covering the mastoid process, the back

of the auricle, and the outer surface of the concha and lobule. The *occipital* nerve of this plexus also gives a branch to the back of the upper part of the ear and to the *attollens auriculam* muscle. The *vaso-motor* nerves of the auricle are derived from the upper cervical ganglion, and some nerves of this character appear to accompany the great auricular nerve. Section of the sympathetic in the neck of a rabbit is followed by dilatation of the blood-vessels of the ear and increase of temperature of the part, while opposite results are caused by irritating the peripheral end of the divided nerve. It would seem probable that vaso-dilator fibres are distributed to the auricle. They are said to be derived from the last branch of the cervical plexus, whence they pass into the first thoracic ganglion; irritation of these fibres has been found to cause dilatation of the blood-vessels of the ear. A hyperæmic condition of these vessels on one side is sometimes noticed in cases in which the sympathetic nerve in the thorax is compressed by enlarged glands.

Functions of the Auricle.—In addition to its acoustic functions, the auricle protects the external meatus, at least to some extent, from wind and dust, and it also helps to maintain an equable temperature and a proper degree of moisture within the canal. As a part of the organ of hearing, the auricle receives the sonorous vibrations and conducts them to its attached portion and to the meatus. It has also been considered to act as a sound-condenser, and as a resonator for high notes. It cannot be regarded as an absolutely essential part of the organ of hearing, inasmuch as when it is absent sonorous impressions are conveyed to the auditory nerve through the atmosphere, and little or no impairment of hearing-power is observed.

With regard to the *part played by the auricle* there are two questions to be considered. In the first place, it is necessary to determine the extent to which its vibrations are transmitted to the walls of the auditory meatus and the tympanum; and in the second place, the degree in which the auricle reflects the sound-waves which reach its surface, towards the column of air in the external meatus. In former times this reflection was regarded as the sole, or at all events, the principal function of the auricle; but at the present day, conduction of sound is considered to be its most important office.

Owing to its firmness and elasticity, the expanded auricle is well

adapted for the reception and transmission of sound-waves, some of which at the same time it reflects. Irrespective of its elevations and depressions, it forms a somewhat flattened plate, impulses against the surface of which are transmitted over it in every direction. These impulses are most freely conducted when the sonorous waves impinge perpendicularly upon the auricle, and the nearer this direction is approached the more extensive will the vibrations become. But the auricle is not a level surface, and the whole of it can never be acted upon in a perpendicular direction by sonorous undulations proceeding from a given point. The importance of the complicated elevations and depressions on its surface thus becomes manifest; for undulations impinging upon the auricle from any direction must fall advantageously, *i.e.*, perpendicularly or nearly so, upon some of them, and then be propagated without much loss of force. The most favourable position for the transmission of sound is when the ear is so situated that the plane of the largest portion of its surface is directed perpendicularly towards the source of the stimulus.

It is very difficult to estimate the amount of reflection which takes place from the auricle. Boerhave thought that this structure reflected all sound-waves impinging upon it, in such a manner that they were directed into the external meatus. Very careful experiments made with wax models of the ear have, however, shown that no matter at what angle the sound-waves impinge upon the auricle, only a very few of them can possibly be directed towards the meatus, and that there are but few points on the surface from which a sound-wave can take this direction. It would likewise appear that the double reflection from the concha to the tragus takes place to a very limited extent, and that the value of the auricle as a reflector of waves of sound is quite inconsiderable. A deep concha is said to be accompanied by increase of hearing-power, and some authors have supposed that the size of the angle which the auricle makes with the surface of the mastoid process influences the capacity for perceiving sounds; an angle of 40° is said to be the most favourable, while hearing power is considerably diminished when the angle is less than 15° . A general statement of this kind must, however, be incorrect, for there is no one angle which can be suitable for all sound-waves. The angle may, certainly, be of considerable importance with reference to sonorous vibrations arising *in front* of the head; we know by experience

that hearing-power for these sounds is increased by bending the auricles forward with the hands, and thus increasing the angles they form with the bone behind them. Persons whose hearing is defective constantly adopt this manœuvre, and also increase the recipient surface, by applying the palm of the hand to the back of the ear. The improvement in hearing is caused, not so much by increased reflexion of the sound-waves, as by the increase in the number of those waves, arising in front of the head, which can impinge perpendicularly upon the recipient surface, and thus cause more active vibrations. The same object is attained by the motion of the ears in the animals who are able to direct the orifices towards the source of the vibrations.

FIG. 2.

THE AURICLE, SHOWING ACOUSTIC POTENTIALS. (Gardiner Brown.)

In the act of listening, and whenever we wish to obtain a clear perception of some definite sound, we generally employ only one ear, and endeavour to place it under the most favourable conditions for hearing. We direct the axis of the auditory canal towards the sonorous vibrations, so that as large a portion as possible may enter directly into the canal, and at the same time the auricle, supposing that it forms a medium-sized angle with the head, is placed in a favourable position for the reception of the sound-waves, for many of its parts are perpendicular to them. The value of the auricle as a *resonator* was pointed out

a few years ago by the late Mr. Gardiner Brown.* Dr. Zaufal, of Prague, discovered that friction over the tragus produced the middle C in some perfect specimens of auricle, by reason of the vibrations excited in its cartilage. From some experiments made on the auricles of musical persons, Mr. Brown was led to believe, not only that Zaufal's statement was correct, "but also that in a well-formed auricle the whole free margin of the cartilage gives a beautifully graduated ascending scale of notes, forming a complete octave from the tragus in front to the posterior border of the helix behind (C, D, E, F, G, *a, b, c*)."

The antitragus yields a distinct and isolated note, the E, which serves to reinforce the E of the helix. The notes are produced by quickly passing the finger or the rubber-end of a pencil over the different segments between the radial lines indicated in the figure. It will be seen that the notes forming the bases of all music—namely, the first major triad, C, E, G—are produced by friction on the tragus, antitragus, and middle of the upper margin of the helix. The small muscles connected with the ear were believed by Mr. Brown to play a not unimportant part in connection with auditory perception. The *intrinsic* muscles "are serviceable chiefly in increasing the tension, and thus raising the pitch of the resonance of different parts of the cartilage, and regulating the size of its fossæ." The *extrinsic* muscles of the ear assist in the transmission to the tympanum of the vibrations falling upon the auricle, for they serve to render the attachment of the latter to the head more tense during the act of listening, and also keep the tubular part of the cartilage and its membranous connecting link well open, thus increasing the resonance of air in the external meatus. Dr. Burnett, of Philadelphia, so far agrees with Mr. Brown as to quote with approval Helmholtz's view that "the most probable function of the auricle is that of a resonator adapted to augment just those *high* notes or sounds most likely to be of interest and importance to man."

The auditory canal, or external meatus, passes inwards from the concha, and consists of two parts; one being cartilaginous and fibrous, and the other osseous. The former is a prolongation inwards of the cartilages of the concha and tragus. These form a channel open above and behind, and converted into a tube by

* "The Acoustic Potentials of the Human Auricle." Read before the Otological Section of the International Medical Congress, 1881.

fibrous membrane extending between the borders of the cartilage. The proportion of the canal made up of fibrous membrane increases from without inwards, while the cartilaginous portion decreases, and finally terminates in a small rounded extremity. Near its commencement it presents anteriorly two or three irregular trans-

The surface of the bone marked by lines; that of the cartilage by dots; the external meatus in darker shading; *a b*, external opening of the meatus, the tragus being regarded as a portion of the anterior wall; *b c*, external opening of the meatus, as ordinarily described; *a c + c d*, the cartilaginous portion; *d e*, the osseous portion of the external meatus. 1. The cartilage of the concha; 2, its border projecting forwards; 3, the cartilage of the tragus; 4, the parotid gland; 5, condyle of the lower jaw; 6, os tympanicum, anterior wall of the osseous meatus; 7, tympanic membrane; 8, tympanum; 9, internal carotid artery; 10, fibrous portion of the posterior wall of the meatus; 11, mastoid cells; 12, lateral sinus.

verse fissures (the fissures of Santorini), closed by a fibrous membrane which often contains a few muscular fibres. These gaps increase the mobility of the cartilage, and facilitate the straightening of the canal. The length of the external auditory meatus is variously estimated by different anatomists; the differ-

ences are mainly attributable to a want of agreement as to the external limits of the canal. Some authorities have included the tragus in their measurements of the walls of the meatus. As pointed out by Mr. Symington, "the only part of the outer end of the meatus which can naturally be distinguished from the concha of the pinna is its posterior wall, for this turns abruptly backwards, while the other walls pass outwards into the pinna without any distinct line of demarcation." Most anatomists now agree with Von Trötsch in taking as the external boundary of the meatus a sagittal plane passing through the outer end of its posterior wall. He gives 24mm. as its average length in the adult; the anterior wall being 27mm., lower 26, posterior 22, and upper 21. The cartilaginous portion is about 9mm. in length, its floor being decidedly longer than its superior and posterior walls. It is attached to the osseous portion by means of fibrillary connective tissue, containing many elastic fibres. The osseous portion has nearly double the length of the cartilaginous part; its measurements are thus given by Von Trötsch—anterior wall, 18; inferior, 16; posterior, 15; superior, 14 millimetres. At its inner end the osseous meatus is terminated by the *membrana tympani*, which is inserted into a narrow groove in the bone. This groove extends around the sides and floor of the opening, but is deficient in front and above; and to the notch thus formed, the grooveless segment of the tympanic ring, the *membrana flaccida*, or Shrapnell's membrane, is attached.

The general *direction* of the auditory canal is from without inwards and slightly forwards; but the cartilaginous portion in passing inwards is directed backwards and upwards, while the osseous portion turns downwards and forwards. The *capacity* of the meatus varies considerably in different individuals. The cartilaginous portion is sometimes so large as to admit the little finger; in other cases it is scarcely larger than a full-sized goose-quill. According to Dr. Burnett, the entire canal is often particularly wide and straight in the negro, so that the *membrana tympani* can be seen without the aid of the speculum. A similar condition is sometimes noticed among Europeans. The canal is oval in form; at the entrance the long diameter is perpendicular, but internally, and at the *membrana tympani*, the canal is widest from side to side. At the line of junction between the cartilaginous and bony portions, the canal is somewhat constricted,

and from this point its calibre increases towards both the tympanum and the entrance. At the latter spot it is again diminished. The average measurements in millimetres of the diameter of the canal are as follows:—At the entrance, 5–7; at the widest portion of the cartilaginous part, 9–11; at the junction of the portions, 7–9; and at the membrana tympani, 9–11. In some cases, the anterior wall of the osseous canal bulges inwards, so as to prevent the corresponding portion of the membrana tympani from being visible.

FIG. 4.

VERTICAL SECTION THROUGH THE EXTERNAL MEATUS. (*Schwalbe.*)

The surface of the bone marked by lines; that of the cartilage by dots. *ab*, the cartilaginous, and *bc*, the osseous meatus. 1, the cartilage of the tragus, bent down upon the upper wall of the meatus; 2 and 3, portions of the cartilage in the floor of the meatus; between them the incisura Santorini minor; 4, os tympanicum; at *b*, the wedge of connective tissue between the cartilaginous and osseous portions of the meatus; 5, the parotid gland; 6, internal carotid artery; 7, tympanic membrane; 8, the tympanum; 9, the malleus; 10, the squamous bone; 11, the concha.

The *relations* of the external auditory meatus to adjacent parts are of much practical importance. Its *anterior* wall is close to the condyle of the lower jaw-bone, two thirds of the posterior surface of which correspond to the osseous meatus, while the remaining third is in relation with the cartilaginous portion. As a result of its proximity, the movements of the lower jaw produce alterations in the calibre of the latter part of the meatus. If a finger be passed into the ear and the mouth opened, the meatus is

felt to increase in size, because the condyle of the jaw passes forwards; when the mouth is closed, the canal is lessened in size, because the condyle resumes its place in the glenoid fossa. External to the condyle, the upper end of the posterior border of the *parotid gland* reaches to the cartilaginous portion of the meatus. When suppuration takes place in the parotid, pus may find its way into the meatus, through one or other of the fissures already mentioned. In like manner, in cases of abscess or ulceration of the external meatus, purulent matter may pass through these fissures into the parotid gland. The *floor* of the external meatus is in relation through nearly its entire extent with the deep process of the parotid gland in the retromaxillary fossa. The *superior wall* of the meatus is represented internally by the attachment of the membrana tympani, and posteriorly it comes into relation with the mastoid cells. More externally, it is separated from the base of the skull by cellular air-spaces communicating with the mastoid cells, the distance between the two parts depending upon the degree in which these spaces and their walls are developed. The *posterior wall* of the meatus is separated by a very thin plate of bone from the mastoid cells, and is about 12mm. distant from the lateral sinus. In this wall is seen the tympano-mastoid fissure, and the mastoid cells are further connected with it by means of small canals containing vessels and strands of connective tissue.

Mention must also be made of other portions of the temporal bone which correspond with various parts of the ear. The *jugular fossa*, for half of its roof, forms the *floor* of the tympanic cavity, the anterior wall of which is a portion of the carotid canal; the *roof* of the tympanum is formed by a *thin plate* of bone on the upper surface of the *petrous portion*, external to the *jugum petrosum*, and near the angle of union with the squamous portion. The *superior border* of the petrous bone is grooved for the *superior petrosal sinus*, which begins at the back part of the cavernous sinus, and receives the blood from the ophthalmic vein, a relationship which may explain the occasional development of ocular and facial symptoms in thrombosis of the sinus from aural disease. The inferior petrosal sinus passes backwards along the inferior margin of the petrous bone, and ends in the lateral sinus, or in the internal jugular vein. The former receives the blood from the superior petrosal sinus.

On the posterior surface of the petrous portion is the narrow fissure for the *aquæductus vestibuli*. This is covered by a depressed scale of bone, and is situated three lines behind the internal auditory meatus. Through this aperture purulent secretion sometimes passes into the cranial cavity from the tympanum and vestibule. Another small aperture, for the *aquæductus cochleæ*, begins in a triangular wider depression in the posterior border directly below the internal auditory meatus. This canal passes upwards and outwards through the substance of the petrous bone to the *scala tympani*, and through it a communication takes place between the latter and the subarachnoid space. At the base of the skull, in the plate of bone between the jugular fossa and the carotid canal, is a small foramen through which the *nerve of Jacobson* (from the petrous ganglion of the glosso-pharyngeal) passes to the tympanum, and in the wall of the carotid canal is a small opening for the *tympanic branch* of the carotid plexus. The *auricular branch* of the *vagus* passes in a groove and foramen in the jugular fossa, and close to the canal for the tensor tympani muscle is a foramen for the *small superficial petrosal nerve*. The *large nerve* of that name, from Meckel's ganglion, through the Vidian nerve, passes in a groove on the anterior surface of the petrous portion to a foramen, the *hiatus Fallopii*, and is thus conducted to the aqueduct, where it joins the gangliform enlargement of the facial nerve.

The *integument* of the meatus is continuous with that of the auricle, but gradually becomes thinner and more delicate. It is firmly attached to the wall of the canal, and at the inner extremity it is stretched over the *membrana tympani*, of which it forms the external layer. It is easily detached from that structure after maceration in water, or when decomposition has occurred; the cuticular lining of the canal can then be drawn out in the form of a tube closed at one end.

The skin of the external meatus exhibits certain peculiarities in different parts. In the cartilaginous portion and on the roof of that part of the osseous meatus which is formed by the squamous bone, it resembles the ordinary integument. But in the remaining larger portion of the osseous meatus, it is very thin (not more than one-tenth of a millimetre in thickness), and closely blended with the periosteum, so as to form a shining fibrous membrane. Neither hairs nor glands are present; but near the *membrana tympani*

there are rows of vascular papillæ, parallel to the long axis of the meatus.

In the cartilaginous portion, and on the part of the osseous meatus formed by the squamous bone, the skin is supported by a thickish and firm layer of connective tissue, containing fat cells, but with papillæ only slightly marked. It contains many fine

FIG. 5.

SECTION THROUGH THE INTEGUMENT OF THE CARTILAGINOUS PORTION OF THE MEATUS. $\times 50$.

(Schwalbe.)

1, Epidermis; 2, 2, hairs; 3, 3, hair-follicles; 4, 4, sebaceous glands; 5, 5, pit-like depressions, into which the hair-follicles, with their sebaceous glands and the ceruminous glands, open; 6, other small pits divided by the incision; 7, excretory ducts of the ceruminous glands, with a bifurcation at *a*; 8, acini of the ceruminous glands.

soft hairs and sebaceous glands, which open into the follicles of the latter. The structures peculiar to this part are, however, the so-called *ceruminous glands*, which are found in great abundance at varying depths from the surface. These glands are a modification of the sweat glands, and are similar to those found in the eyelids. The duct of each gland opens into a pit-like depression, which

also contains a minute hair with its sebaceous glands. The walls of these glands consist of a layer of cubical epithelial cells, and an outer layer of longitudinal smooth muscular fibres; the cells are filled with many brownish-yellow granules. Schwalbe* states that he has not been able to discover any fat within the ducts or cells of these glands, and he therefore thinks that they do not secrete the fatty constituents of the cerumen of the ear. These, he considers, are formed by the sebaceous glands of the hair follicles, within which fatty masses are easily discoverable. The ceruminous glands are therefore wrongly named; they are really sweat glands modified in a peculiar manner, and in all probability contribute a fluid secretion, containing yellow or brownish granules of colouring matter, which is mixed with the fat yielded by the ordinary sebaceous glands. The fact that both kinds of glands open into the same cavity explains the mixture of the secretions. The number of these glands has been estimated at from one to two thousand. They decrease in size and number towards the membrana tympani. The mixed secretion is calculated to entangle particles of dust, and to prevent them from passing into the deeper part of the meatus. In some persons, the cerumen, if not carefully removed from time to time, forms hard masses, more or less blocking up the canal, and interfering with the conduction of sound and the vibrations of the membrana tympani.

The meatus in the new-born child differs in many respects from the same canal in adults. It forms a relatively narrow cleft, compressed from above downwards. "In the foetus the meatus is closed, its lower wall being in contact internally with the membrana tympani, and external to it with the superior wall. Towards the end of foetal life these become separated by an accumulation of epithelium, or vernix caseosa, in the meatus. This is first found at the inner end of the meatus, between the floor and the membrana tympani. . . . At birth, the walls of the meatus are either in contact, or the cavity is filled with vernix caseosa, so that a child is born with its ears practically closed."† Kussmaul states that the most discordant sounds made near a new-born child do not appear to disturb it.

According to Mr. Symington, the meatus in the new-born

* *Lehrbuch der Anatomie des Ohres*, S. 437.

† "The External Auditory Meatus in the Child." J. Symington, *Journal of Anatomy and Physiology*, vol. xix., page 28.

child is relatively longer than in the adult. In the former the floor measures 20mm., in the latter it is 26mm., or little more than one-fourth longer. After birth, the length of the meatus increases very slowly; the opening up of the canal would seem to be accompanied by some slight diminution in its length. "It is well known that the middle and internal ears are nearly as large at birth as in the adult, and the same would appear to be the case with the external ear, so far as the length of the meatus is concerned." The lumen of the meatus gradually, but very slowly, increases in size after birth; as compared with the length, it is relatively narrow in the infant.

A vertical section of the external auditory meatus of a fœtus in the ninth month shows that the tympanic membrane is placed on the inferior aspect of the cranium, and in a plane which is almost horizontal; attached to it externally, as a second portion of the superior wall is a part of the squamous bone, situated below the linea temporalis. This area (*superficies meatus*) is the sole representative of an osseous boundary of the canal in the fœtus and in the infant up to the end of the first year. In the new-born infant, the future osseous portion of the meatus is represented by fibrous tissue, into which ossification extends to form the greater portion of the osseous walls. This membrane, which might be called the fibrous or membranous tympanic plate (*Symington*) is thin at birth, but becomes thicker and firmer in a few months. According to Mr. Symington, the meatus, at birth, has an osseous roof and posterior wall; the anterior and inferior walls are fibrous. The innermost part of the osseous meatus is formed by the tympanic bone, the development of which commences by the rapid growth of the anterior and posterior tubercles on the tympanic ring of the new-born child. This ring is imperfect above; the gap, 1-2mm. broad, is closed by the curved lower border of the squamous portion, to which the extremities of the ring are united before birth. The ring itself gradually increases in depth, and forms an osseous tube, the tympanic bone, which becomes united behind with the petromastoid portion, and is separated in front from the squamous part by the Glaserian fissure. On the inner border of the tympanic ring is a furrow, the *sulcus tympaniticus*, to which the *membrana tympani* is attached. In the process of ossification of the external meatus, an aperture often remains in the lower and

anterior wall until the fifth year, and in some cases until adult life. After birth, the plane of the *membrana tympani* gradually becomes less and less horizontal. In the new-born child it makes an angle of 170° with the superior wall of the meatus; in the adult, the angle is about 140° .

Vessels and Nerves.—The largest artery supplying the meatus is derived from the *internal maxillary*. It passes through the anterior wall, and is distributed especially to the upper portion of the canal and also to the tympanum. Other twigs supplying the meatus are derived from the *posterior auricular* and *temporal arteries*. The *veins* take the same course as the arteries, and discharge their blood into the external jugular vein.

The *auricular branch* of the auriculo-temporal nerve of the fifth pair penetrates the anterior wall, and is distributed to the canal, which is also supplied by the auricular branches of the *facial* and *vagus* nerves. The branch from the latter comes from the jugular ganglion, and enters the posterior wall of the meatus. It sends one or more twigs to the *membrana tympani*.

Functions of the External Meatus.—The auditory canal conducts the sonorous vibrations to the tympanum, and also serves to protect the membrane from mechanical injury, and from sudden changes of temperature. When the external orifice is closed, sounds communicated through the atmosphere become much less distinctly audible, and it is therefore evident that the canal, by virtue of the air that it contains, conducts to the *membrana tympani* those vibrations which proceed directly from the sounding body, as well as those which are reflected into it by the auricle. But the canal is not a straight tube; it presents several curves, and its diameter varies in different parts, and therefore it is almost impossible that any vibration should impinge upon the *membrana tympani* without first striking the walls of the canal and undergoing reflection. The intensity of the vibrations is thus diminished; but the cartilaginous and osseous walls of the canal aid in the conduction of sound by transmitting the vibrations communicated to the auricle and the bones of the head.

When the meatus is closed, a remarkable change is produced in the perception of those sounds and noises which are conducted exclusively or mainly through the bones of the head to the internal ear. If one meatus be stopped-up with the finger, and a vibrating tuning-fork be placed between the teeth, the sound is heard more

distinctly on the stopped-up side than on the other; and if both orifices be closed, the sound is more distinct than when they are open. Similar differences are also observed when sounds are produced in the larynx; in both cases the increased intensity is due to the resonance of the air contained in the meatus. It has indeed been supposed that the difference is only imaginary; but its reality can be demonstrated by another experiment. If a vibrating tuning-fork be held against the upper incisor teeth until the sound is no longer heard, and the meatus be then closed, the perception of the sound returns. There must be a real increase in the intensity of the sound, causing the latter to become once more audible; though the manner in which such resonance is produced cannot be clearly demonstrated. It is possible that the vibrations of the *membrana tympani*, transmitted to the air in the external meatus, aid in increasing the loudness of the sound. When the canal is open, there is no obstacle to the escape of the sonorous vibrations, and their force is considerably diminished; when it is closed, they will communicate their vibrations partly to the walls of the canal, and partly to the object which closes it. Thus the vibrations would return to their starting-point, the *membrana tympani*, and swell the number of the impulses communicated thereto, and necessarily increase the effect produced upon the sound-perceiving apparatus. This explanation is based upon the supposition that sonorous vibrations, transmitted to the organ of hearing through the bones of the head, are communicated by the *membrana tympani* to the air in the external meatus. Politzer, in the last edition of his work, states that the increase in the sensation of sound noticed when the external meatus is closed is due to three causes, viz.: (1) increased resonance of the external meatus; (2) reflection to the *membrana tympani* and *ossicles* of the sonorous vibrations which are communicated by the cranial bones to the air in the external meatus; (3) alterations in the tension of the *membrana tympani* and *ossicles*.

The manner in which the experiments, as above described, are utilized in the diagnosis and prognosis of certain aural diseases will be discussed in the chapter on the Examination of Patients.

Under normal conditions the surface of the meatus is coated with cerumen or ear-wax, the mixed secretion of the so-called ceruminous and sebaceous glands. Whether this secretion subserves any acoustic purposes is a doubtful point. The fact

that when the secretion is absolutely wanting, hearing power is impaired, and tinnitus is sometimes complained of, has led to the supposition that the cerumen may prevent confused vibrations of the walls of the meatus and the production of that roaring sound which air causes when flowing into a shell.

Removal of the ceruminous secretion is aided by the movements of the jaw, and is often effected by various manual operations. The shape of the cartilaginous portion of the canal, in which the secretion is principally formed, tends to facilitate its extrusion. Dr. Burnett points out that as the wax increases in quantity, it must necessarily "slip into a broader, which is an outer, plane in the external auditory meatus, and thus at last it may be found at the mouth of the auditory canal." When in this position it is more freely exposed to the action of the atmosphere, and, becoming drier, is more easily detached. It is possible that the outward growth of the skin of the external meatus may help to force out the ceruminous secretion. The effects of its undue accumulation and retention will be described in a subsequent chapter.

Development of the Ear.—The most important part of the organ of hearing originates from the epiblast, a special involution of which forms the essential nervous apparatus and the epithelial lining of the membranous labyrinth. The mesoblastic tissue is the source whence the fibrous substance of the internal ear and the bony parts are developed.

The *auditory sac* first appears as a shallow depression in a thickened portion of the epiblast, in the region of the posterior brain-vesicle. The depression gradually deepens, and its aperture towards the surface rapidly narrows, the process resulting in the formation of a flask-shaped vesicle, which is situated opposite the dorsal end of the hyoidean arch. In a subsequent stage, the aperture becomes closed externally, and the neck or stalk of invagination persists as the *aquæductus vestibuli*.

The formation of the lateral and lower parts of the face, including the auricles and tympano-Eustachian passages, is closely connected with the development of the subcranial pairs of processes termed the *visceral arches*. Between each of these arches is placed on each side a cleft, which runs through the wall of the body from the external surface into the cavity of the pharynx, thus rendering the epiblast continuous with the hypoblast. The first

of these clefts, the *hyo-mandibular*, is the seat of the formation of the Eustachian passage, and cavity of the tympanum internally, while the meatus auditorius is developed externally round the dorsal part of the cleft by the outgrowth of the neighbouring parts of the two arches; the membrana tympani growing up between them. The external auricle is developed from the integument behind the meatus (Quain).

The cartilage of the first or *mandibular* visceral arch attains a considerable size, and remains visible in the human foetus up to the sixth or seventh month; its proximal portion is converted into the *malleus*. The second, or hyoid visceral arch, contains in its proximal portion the cartilaginous matrix of the *incus*, which becomes articulated with the head of the malleus, formed in the adjacent proximal part of the mandibular arch. The *stapes* is developed from cartilage belonging to the auditory capsule. During foetal life, the tympanic cavity is occupied by connective tissue in which the ossicles are imbedded; after respiration has been established, this tissue recedes before an expansion of the mucous membrane (Quain). The condition of the tympanum at birth will be subsequently referred to.

Two very different sets of processes take place in the development of the organ of hearing. The first set comprises those belonging to the formation of the tympano-Eustachian passages, and the accessory parts of the middle and external ear. The second includes those changes which are connected with the formation of the nervous structure or labyrinth of the internal ear. These latter changes occur more immediately in the primary epiblastic vesicle, and in the nervous elements derived from the medullary centre, the auditory capsule being developed from the mesoblastic wall.

The *tympano-Eustachian passage* is formed from a diverticulum of the pharynx, persisting as a blind recess (the Eustachian tube), and dilating distally into a chamber (the tympanic cavity) which partially surrounds the utriculus.

The *external auditory meatus* corresponds to the lower section of the epiblastic portion of the original hyo-mandibular cleft, and is formed principally, if not entirely, by the outward growth of the surrounding tissue in such a manner as to leave a deep tube. The *auricle* is gradually developed as a small flap in connection with the integument on the posterior margin of the first visceral

cleft. Congenital malformations of the external ear, with occlusion of the meatus and greater or less imperfection of the tympanic apparatus, are observed in connection with abnormal development of the deeper parts of the first and second visceral arches and intermediate cleft (Quain).

The *membrana tympani* and the *tympanic ring* are developed close to the external surface, and at an early period the membrane almost completely closes the dorsal portion of the hyo-mandibular cleft. The epithelium covering its outer surface is of epiblastic origin; internally the membrane is lined by pharyngeal hypoblast, while its fibrous and vascular parts are of mesoblastic origin.

The Labyrinth.—After the closure of the primary otic vesicle, as above described, various modifications occur in the shape of the cavity, indicating the formation of the various parts of the labyrinth. Its swollen portion is modified so as to form the utricle and the semi-circular canals, while a ventral diverticulum is developed into the cochlea and the sacculus hemisphericus. The narrow part becomes tubular, and remains in the substance of the petrous bone as the aqueduct of the vestibule.

The *two superior semi-circular canals* grow out from the lateral wall of the vesicle as two flattened processes; these are converted into tubes open at both ends, and subsequently become elongated and acquire an ampullary dilatation. The *horizontal semi-circular canal* is developed somewhat later in a similar manner.

The body of the primitive vesicle persists as the *vestibule* or *utricle*, but a smaller portion of the vesicle near the cochlear canal is cut off, and forms the *sacculle*. A constriction also takes place in the vesicle between the latter and the cochlear canal, and finally these two cavities communicate only by a narrow portion, the *canalis reuniens*. The separation of the sacculle from the utricle also leads to the division of the end of the recessus labyrinthi into two tubes, one of which communicates with each of these cavities.

The *cochlea* consists of a helicoid spiral tube developed as a simple process from the inferior end of the auditory vesicle. The tube is coiled upon itself from left to right, forming at last two and a half turns, and on the hollow side of the spiral a double ridge of thickened epithelium gradually appears; at a later stage this ridge is converted into the organ of Corti, and the structures connected with the lamina spiralis. The various stages in the

development of the cochlea in the higher forms are permanently retained in the adults of various lower animals.

The periosteum and the lymph-spaces around the labyrinth are formed of mesoblastic tissue. In the cochlea two longitudinal lymph spaces are formed, the dorsal of which (*scala vestibuli*) communicates with the vestibule, and at the apex of the cochlea is continuous with the ventral space (the *scala tympani*), which terminates blindly at the fenestra rotunda. The cavity (*scala media* or *canalis cochleæ*) lying between the two *scalæ* is the sensory portion of the cochlea, and is alone lined by epiblast. The *scalæ* and the bony labyrinth are protective structures (Haddon).

While the above-described changes are in progress, a deposit of cartilage takes place in the auditory capsule surrounding the vesicle, with ossification as a further stage.

The auditory nerve is developed from the hind brain, and grows through the mesoblast towards the otic vesicle. It pierces the auditory capsule in two main divisions, vestibular and cochlear, the latter of which is remarkable as having some ganglion cells in its growing extremity at a very early period of its development.

CHAPTER II.

THE SOUND-CONDUCTING APPARATUS (*continued*).

THE MIDDLE EAR OR TYMPANUM.

Position, Contents, and Boundaries of Tympanum—*Membrana Tympani*, its Size, Direction, Colour, and Structure—External, Middle, and Internal Layers—Shrapnell's Membrane—Vessels and Nerves—Inner Wall of Tympanum—The Posterior Wall—The Anterior Wall—The Roof or Cranial Wall—The Floor or Jugular Wall—Dimensions of the Tympanum—Functions of the *Membrana Tympani*—The Ossicles—Their Ligaments and Articulations—Movements of the Ossicles—Muscles of the Tympanum, the Tensor Tympani, and the Stapedius—Lining Membrane of the Tympanum—The Tympanum in the Fœtus—Vessels and Nerves of the Tympanum—The Eustachian Tube, its Osseous, Cartilaginous, and Membranous Portions—Mucous Membrane—The Pharyngeal Opening—The Eustachian Tube in Children—Muscles, Fasciæ, and Ligaments connected with the Tube—Vessels and Nerves—Functions of the Tympanum and Eustachian Tube—The Mastoid Portion of the Temporal Bone; the Mastoid Cells, Description and Function.

THE MIDDLE EAR OR TYMPANUM.

The Middle Ear, Tympanum or Tympanic Cavity, is a narrow irregular space, filled with air, in the substance of the temporal bone, and interposed between the external meatus and the labyrinth (Fig. 1, page 3). In front it communicates with the pharynx by the Eustachian tube; behind it opens into the mastoid cells, which are also filled with air; while extended across it is a chain of small movable bones, which place its outer boundary, the *membrana tympani*, in communication with the sound-perceiving apparatus. The bones are connected by ligaments and are moved by two minute muscles; and, in addition to these structures, the tympanum contains vessels and nerves, some of the latter being distributed to the contents of the cavity, while

others only pass through it. The tympanum is compressed from without inwards, its smallest measurement being in that direction. Its walls are not everywhere clearly defined, but it is possible to distinguish (1) an external or tympanic wall; (2) an internal or labyrinthine; (3) a posterior or mastoid; (4) an anterior or tubal; (5) a roof or cranial wall; and (6) a floor or jugular wall.

The *external* wall is formed by the membrana tympani and a small framework of bone. Above and in front, the osseous margin is interrupted by a small notch, across the mouth of which the membrane is extended. In form the membrana tympani is nearly oval, but it is wider above than below; its shape and size

FIG. 6.

v, Segment of tympanic membrane lying in front of handle of malleus; *h*, posterior segment of tympanic membrane; *u*, extremity of handle of malleus; *f*, anterior fold, and *f'*, posterior fold; *S*, Shrapnell's membrane; *k*, short process of malleus; *a*, long process of incus.

depend upon the form of the osseous framework in which it is set. In its greatest diameter, from above obliquely downwards, it measures nearly one centimetre, or two-fifths of an inch, while its largest transverse measurement is about eight millimetres. Its thickness is estimated at one-tenth of a millimetre. The plane of the membrane is by no means perpendicular to the axis of the meatus, but forms therewith an angle of about 75° , so that the external surface of the membrane looks obliquely downwards towards the floor of the meatus, and also somewhat forwards. To the inferior wall of the canal, the membrane is inclined at an angle of about 45° , while with the superior wall the angle of

inclination is about 140° . These measurements vary, however, in different subjects, on account of the variations in the relative lengths of the osseous walls of the meatus. The longer the anterior and inferior walls, as compared with the posterior and superior, the greater will be the obliquity of the membrane.

The *membrana tympani* is somewhat concave externally, and presents just below its centre a decided depression, the so-called *umbo*, corresponding with the lower end of the handle of the malleus which is inserted between its layers. Owing to the traction exerted by this bone, the membrane is drawn inwards and rendered tense. When looked at from the external meatus,

FIG. 7.

INTERNAL SURFACE OF THE LEFT MEMBRANA TYMPANI, ENLARGED. (Politzer.)

the membrane presents the appearance of a shallow funnel, the expanded portion of which bulges out somewhat in front and below. The more transparent the membrane, the less noticeable is the bulging, but in cases of opacity the funnel-shaped depression becomes very manifest. The handle of the malleus is directed from above and in front, downwards and backwards. So far as it extends, it divides the surface of the membrane into two portions, anterior and posterior, the former being the smaller of the two. At the anterior superior part of the membrane, near the

osseous margin, is a small projection, caused by the short process of the malleus, which is applied to its internal surface. Extending backwards and forwards, from this projection towards the circumference, are two folds, and within these and starting from the same point are two short *striae* or lines, which, with a tiny portion of the osseous margin, are the boundaries of Shrapnell's membrane, or the *membrana flaccida*.

The *colour* of the membrana tympani presents several normal variations, due for the most part to the ages of the individuals in whom it is examined. The colour also varies according to the source of the light employed, and the tint of the skin of the meatus. In children, the membrane presents a dull white tint, owing to the thickness of the epidermal layer; in adults, the colour is pearly gray, to which a slight tinge of violet and brownish yellow is sometimes superadded; in old age, it becomes whitish and more or less dull. In the anterior portion of the membrane is a bright triangular spot extending from the umbo downwards and forwards. The apex of this triangle is above and the base below, but the brightness does not extend quite so far as the circumference of the membrane. The peculiar brightness of this spot is probably due to the vertical direction of this portion of the membrane; the rays of light are reflected directly towards the eye of the observer. The appearance presented by the external surface of the membrane will be again referred to in the chapter on the Examination of the Ear.

The membrana tympani consists of three layers—an external, middle, and internal. The *external layer* is derived from the cuticular lining of the canal, and is made up of epidermic cells resting on connective tissue in which the tympanic vessels and nerves ramify. There are no papillæ in this cuticular layer, but behind the handle of the malleus a few glands have been detected. A relatively thick band of connective tissue passes from the upper wall of the meatus over the middle layer of the membrana tympani as far as the umbo, and parallel to the handle of the malleus.

The *middle layer* (lamina propria) of the membrane is strong and fibrous, and is attached through the medium of a still denser, almost ligamentous, portion to the bone, which presents a distinct rim for its reception, except at the upper part. This coat consists of fibrous lamellæ running in different directions; many bands of

fibres are seen to converge towards the centre, while others take a circular course. The former commence in the periosteum of the meatus and in the thickened portion at the circumference of the membrane, and pass towards its centre, where they are inserted into the handle of the malleus. More internally situated are the circular fibres, which are closely connected with the internal layer, and arise partly from the ligamentous ring and partly from the substance of the membrane. Some are inserted into the handle of the malleus, others into the circumference of the membrane; while another set blend with interlacing fibres. The circular fibres are most abundant near the circumference; towards the centre they become thinner and fewer. The handle of the malleus descends between the radiating and the circular fibres. In addition to the two layers just described, two other sets have been discovered, and named respectively *descending* and *arborescent* fibres. The former are external to the radiating fibres, and pass from the upper segment of the ligamentous ring towards the handle of the malleus. The arborescent or dendritic fibres are most abundant in the posterior part of the membrane; they arise near the periphery, and each divides into several branches which run irregularly and in different directions, passing over a greater or less extent of the membrane.

The *internal layer* of the membrana tympani is formed by the mucous membrane of the tympanic cavity, and consists of pavement epithelium and a thin layer of connective tissue. It is extremely delicate near the centre of the membrane; towards the periphery its surface is studded over with villous projections or papillæ. Further reference will be made to this layer in a subsequent paragraph.

The peripheral portion of the membrana tympani is considerably thickened and strengthened by the so-called *annulus tendinosus*, or ligamentous ring of connective tissue with closely arranged fibres and cartilage-cells. This ring serves to connect the membrane with the surrounding bone, and from it many of the fibres of the middle layer take their origin. It is deficient above, and is far more conspicuous on the internal than on the external surface of the membrana tympani.

Above the short process of the malleus there is a small segment of the membrane which differs considerably from the remainder in

being looser in texture and less resistant. It is bounded below by two striæ or lines, and above by the margin of a notch in the ring of bone. This so-called *membrana flaccida*, or Shrapnell's membrane, is composed of the outer and inner layers of the membrana tympani, the middle layer being altogether absent or represented by only a few fibres. The annulus tendinosus is also wanting. The *membrana flaccida* sometimes projects towards the tympanic cavity and sometimes bulges out towards the superior wall of the meatus. It is stated by some authorities that a small

FIG. 8.

AND OF THE MUCOUS MEMBRANE PROLONGED FROM THE CAVITY. $\times 350$.

(Schwalbe, after Brunner.)

- 1, Flattened epithelial cells of the mucous layer of the tympanic membrane; 2, ciliated epithelium of the mucous membrane of the ligamentous ring; 3, spot at which one form of epithelium passes into the other; 4, circular fibres of the ligamentous ring, divided transversely; 5, radiating fibres.

foramen, capable of admitting a bristle, exists in this membrane under normal conditions.

The membrana tympani is supplied with blood from the *vessels* of the external meatus, and of the tympanic cavity, and a complete capillary network exists in the fibrous layer. The deep auricular artery, a branch of the internal maxillary, gives off small twigs to the external surface, while those from the tympanic cavity are derived from a branch of the same artery, passing inwards through the Glaserian fissure, and also from a branch of the

stylo-mastoid artery. The veins of the outer layer pass into the external jugular; the remainder discharge their blood partly into the plexus surrounding the Eustachian tube, and partly into the lateral sinus. Lymphatic vessels ramify in all the three layers of the membrana tympani; on the internal surface free openings are said to exist in these vessels.

The *nerves* are derived mainly from two sources; a branch of

Twice the natural size. (Schwabe.)

a, b, c, d, f, The tympanum proper; *c, d, e*, recessus epitympanicus (aditus ad antrum); 1, the osseous tube; 2, semi-canal for the tensor tympani; 3, the processus cochleariformis; 4, the mastoid antrum; 5, the recessus epitympanicus, with the smooth convexity corresponding with the ampullae of the external and anterior semi-circular canals; 6, prominence caused by canal for facial nerve; 7, aperture in the facial canal; 8, course of the facial canal outside the tympanum, shown by a dotted line; 9, eminentia stapedii, with the opening for the stapedius muscle; 10, pelvis ovalis with the fenestra; 11, sinus tympani; 12, fossula rotunda; 13, the promontory; 14, opening into the tympanum of the lower portion of the canaliculus tympanicus; 15, opening into the tympanum of the upper portion of the same canal; between 14 and 15 the tympanic or Jacobson's groove for the nerve of the same name; 16, the superior or petrous opening of the canaliculus tympanicus; 17, the opening of the canal for the nervus petrosus profundus minor; 18, opening of the carotico-tympanic canal; 19, air-cells near the Eustachian tube.

the auriculo-temporal of the fifth supplies the external surface; the mucous coat contains filaments from the tympanic plexus, which is formed by Jacobson's nerve from the glosso-pharyngeal, branches from the fifth and the sympathetic nerve.

The *inner* or *labyrinthine* wall of the tympanum presents two orifices of communication with the internal ear. Near the upper part is the *fenestra ovalis*, an ovoid opening, about three millimetres

long, leading into the vestibule. Against this opening the base of the stapes is applied; while above it is a ridge, which more or less overhangs the fenestra and indicates the position of the aqueduct of Fallopius. This canal, which contains the facial nerve, begins in the upper part of the internal auditory meatus, passes between the cochlea and the vestibule, and on reaching the inner wall of the tympanum, turns backwards over the fenestra ovalis towards the pyramid in the posterior wall, whence it is directed downwards to the stylo-mastoid foramen. Below the fenestra ovalis is a rounded and prominent elevation named the *promontory* or *tuber cochleæ*, caused by the projection outwards of the first turn of the cochlea. This is marked by grooves or tiny canals which are occupied by filaments of the tympanic plexus. Its most prominent portion is distant about two millimetres from the umbo of the membrana tympani. Below and behind the promontory is the fenestra rotunda, situated in a slight depression, and closed by a thin membrane which separates the cavity from the scala tympani of the cochlea. The shape of the opening varies; it is sometimes circular and sometimes roughly triangular or even oval. In its longest diameter it measures about two and a-half millimetres.

The *posterior wall* of the tympanum presents at its upper part several openings (one of which is usually larger than the others), which lead into the mastoid cells. Situated at the lower and inner part is a small conical eminence called the *pyramid*, presenting at its summit a minute orifice, through which the tendon of the stapedius muscle passes.

The *anterior wall* of the tympanum presents above the canal for the tensor tympani muscle, and below this, separated by a curved plate of bone, the commencement of the Eustachian tube. A small portion of this boundary is formed by the posterior wall of the carotid canal. The *roof* or *cranial wall* is formed of a plate of bone near the angle of union of the petrous with the squamous portion. It varies much in thickness in different subjects. Sometimes only a very thin layer separates the tympanum from the middle fossa of the base of the skull; in other cases there are two compact layers with spongy substance interposed.

The *floor* or *jugular wall* is narrow and irregular, being in some cases convex and in others concave. These variations depend upon the size and form of the jugular fossa, which is under the floor of

the tympanum, and differences similar to those in the roof are sometimes noticed. Thus, in some cases, the two parts are separated only by a thin lamella of bone; in others, there are two layers with spongy tissue intervening.

The average dimensions of the tympanum as given by Tröltsch are as follows:—

Antero-posterior, from the ostium tympanicum of the					
	Eustachian tube to the mastoid cells...				13mm.
Vertical (greatest)	15mm.
Vertical at ostium tympanicum	5-8mm.
Transverse, least distance between membrana tympani					
	and promontory				2mm.
„	at the ostium tympanicum				3-4.5mm.

Functions of the Membrana Tympani.—The acoustic functions of this membrane are easily explained. In common with other tense membranes it is well adapted to receive sonorous vibrations from the atmosphere, and to communicate them to solid bodies with which it is connected. The undulations which pass into the meatus are transmitted to the chain of ossicles, and are thus conducted to another tense membrane, and thence to the perilymph of the labyrinth. There are two spots at which the membrana tympani is connected with solid bodies; at its margin it is attached to the osseous walls of the meatus, which are continuous with those of the labyrinth; and, secondly, a portion of its surface is in close union with the handle of the malleus. It is principally to this latter that the membrane communicates its vibrations, though some are doubtless transmitted to the internal ear by the bony walls of the cavity. This transmission is due to the elasticity of the osseous tissue, which is to be regarded as a secondary channel of conduction.

The vibrations of the membrana tympani are of a transverse character—that is to say, they take place in a direction perpendicular to its plane. In consequence of the manner in which the membrane is attached at its circumference, the central part or umbo will make the largest excursions, and the movements of the other portions of the surface will gradually diminish in extent toward the periphery, at which, owing to its firm attachment to the surrounding bone, the vibrations cease. Those movements of the membrane which are produced by the vibrations of the bones

of the skull must be longitudinal in character, and in the direction of the radiating fibres; but these have the same effect upon the membrane as the vibrations received from the air. The alternate shortening and lengthening of the radial fibres must produce movements of the umbo perpendicular to the plane of the membrane, or, in other words, transverse vibrations.

The vibrations of the membrana tympani are modified by alterations in its tension; the mechanism by which these changes are effected consists of the tympanic ossicles and their muscles and nerves.

The **ossicles** contained in the tympanum are three in number: the *malleus*, the *incus*, and the *stapes*. By means of the chain formed by these bones, the vibrations of the membrana tympani

FIG. 10.

THE AUDITORY OSSICLES (RIGHT).

(*Landois and Stirling*.)

are communicated to the perilymph of the labyrinth. The ossicles discharge another function—they provide points of attachment for the tympanic muscles, by the action of which alterations are produced in the tension of the membrane and in the pressure of the perilymph.

The *malleus* or hammer presents a large extremity above, termed the *head*, which articulates behind with the incus by means of an irregularly oval surface covered with cartilage. The head is bounded by a constriction or *neck*, from which the *manubrium* or *handle* passes downwards and slightly inwards between the inner and middle layers of the membrana tympani. The neck and the rounded head of the malleus, which are united to each other at an obtuse angle, extend upwards in the tympanum above the upper

border of the membrana tympani. The *handle* is about 5 mm. long, and is somewhat curved with the concavity in front; sometimes its lower extremity turns sharply forwards. It is firmly attached to the middle layer of the membrana tympani; its periosteal covering and a fibro-cartilaginous layer which surrounds the bone, affording points of attachment for the radiating and for some of the circular fibres.

The *long process* (*processus gracilis, processus Folianus*) passes from the neck forwards and outwards; in early life it extends to the Glaserian fissure, but in adults it is usually represented by a small process of bone connected with the fissure by means of ligamentous tissue. The *short process* is a slight conical projection from the neck; it projects upwards and outwards against the membrana tympani.

The *incus* (anvil) resembles a molar tooth in shape. It consists of a body and two processes: one short and horizontal, and the other longer and vertical in direction. On the anterior and upper part, the body of the bone presents two surfaces covered with cartilage, meeting each other at a right angle, and articulating with the head of the malleus. The short process is directed nearly horizontally backwards towards the posterior wall of the tympanum, with which it is connected by means of ligamentous fibres. The long process descends almost vertically behind the handle of the malleus to a level with the fenestra ovalis; it then bends inwards and somewhat forwards, and terminates in a *lenticular* process tipped with cartilage, which articulates with the head of the stapes. In early life this process constitutes a separate bone.

The *stapes* (stirrup) is articulated with the long process of the incus at an angle which looks upwards, outwards, and forwards. The bone closely resembles a stirrup, and consists of a head, neck, two crura, and a base. The *head* is directed outwards, and sometimes slightly forwards; the surface for articulation with the incus is depressed and covered with cartilage. Below the head is a slightly constricted part, the *neck*, more or less distinct in different specimens; from it the crura diverge. The posterior *crus* is longer and more decidedly curved than the anterior. Each crus is attached to the *base*, a plate of bone which is applied against the fenestra ovalis. The triangular space enclosed by the crura and base is sometimes occupied by a thin membrane. The

base is somewhat oval in shape. Its lower border is straight, or slightly concave; the upper margin is curved. The surface which looks towards the vestibule is covered with hyaline cartilage, and is somewhat convex; the outer surface is concave. In the natural state the crura of the stapes are close to the walls of the depression at the bottom of which the fenestra ovalis is situated.

The ossicles are articulated with each other, and are likewise attached at certain spots to the walls of the tympanum. The articular surfaces of the malleus and incus are covered with a thin layer of hyaline cartilage, and kept together by means of a capsular ligament. A fibro-cartilaginous plate, in the form of a meniscus, exists in the joint. The anterior ligament of the malleus is a band of fibrous tissue, which connects the remains of the long process with the Glaserian fissure. This ligament allows the process to rotate slightly inwards on its long axis; and when this rotation takes place, the head of the malleus is moved inwards and the handle outwards. The membrana tympani follows the movements of the handle, its tension being increased when the latter is drawn inwards, and diminished when the movement is in the opposite direction. The movements of the malleus are also regulated by another band of fibres, the posterior ligament, which passes from a crest on the neck of the bone forwards to the wall of the tympanum. These two ligaments form the common axis-band* of the malleus. There is also another band of fibres passing downwards and outwards from the roof of the tympanum to the head of the malleus. This band varies in length, and is altogether absent when the bony surfaces are in contact.

The articular surface of the malleus is elongated and oval in form, and shaped somewhat like a saddle; it is closely adapted to the articular surface of the incus. When the handle of the malleus is drawn inwards towards the tympanic cavity, the head of the bone moves in the opposite direction, and the lower projecting margin which bounds the articulating surface of the incus acts like the tooth of a cog-wheel in limiting the movement. The long process of the incus, which is parallel to the handle of the malleus, follows the inward movement of the latter; but when the handle moves outwards, as occurs when the tympanum is

* Helmholtz, *Pflüger's Archiv*, 1868, Bd. I. p. 1, and *The Mechanism of the Ossicles*, New Syd. Soc. Trans., p. 119.

distended, the long process of the incus does not move with it, inasmuch as the articulating surfaces are separated from each other. In other words, when the membrana tympani is pressed inwards, the malleus and incus move together, as though they were one bone; but the incus is unaffected when the malleus and the membrane move in the opposite direction, and hence it happens that the stapes is not liable to be detached either from the incus or from the fenestra ovalis.

The manner in which the two bones are connected determines the axis of their rotation. The articulating surface of the incus is fitted to the head of the malleus. The short process of the former bone is almost on the same level as the long process of the latter, and passes above the membrana tympani to be attached to the wall of the cavity. The long process of the incus is parallel to the handle of the malleus, but internal and posterior to it, and its

FIG. 11.

(From Wagner's *Lehrbuch der Physiologie*.)

lower extremity forms almost a right angle with the stapes. It is obvious that the movements of these bones must be somewhat complicated. When the malleus and incus move together, their common axis is not the ligament of the malleus, but a line drawn through the long process of the malleus, which is directed forwards, and the short process of the incus, directed backwards. It cuts the malleus just below the neck, and passes obliquely through the body of the incus. The rotation on this axis occurs in a plane which is vertical to that of the membrana tympani, and during rotation the handle of the malleus and the long process of the incus move together in one direction, either inwards or outwards, while the head of the malleus and the upper part of the body of the incus move in the opposite direction. The membrana tympani follows the movements of the handle of the malleus, the external depression becoming more marked when the latter is drawn

inwards, and diminishing with the opposite movement. The movement of the stapes must follow that of the long process of the incus; when the latter moves inwards, the base of the stapes presses against the fenestra ovalis, and is slightly withdrawn therefrom when the process moves in the opposite direction. Figure 11 illustrates these movements. It represents a vertical section of the membrana tympani with the ossicles seen from the front—(a) shows the position of the axis; the arrows indicate the direction of the movements of the various parts of the lever. The force is applied to the apex of the handle of the malleus; the short process of the incus attached to the wall of the tympanum constitutes the fulcrum; the apex of the incus is the point which acts upon the weight. Helmholtz has found that the entire length of this lever is about $9\frac{1}{2}$ mm.; the arm between the two extremities of the incus measures $6\frac{1}{3}$ mm., or about two-thirds of the whole. (Fig. 12, page 38.) Hence it follows that if the malleus and incus are firmly locked together by the cog-wheel arrangement, the excursion of the tip of the latter must be smaller than that of the corresponding part of the malleus; but the force of the pressure which it transmits to the stapes will be larger by one-half than the force which acts on the tip of the handle of the malleus.

The space through which the bony chain can move is extremely minute. According to Politzer, the greatest excursions take place at the tip of the malleus, and measure seven-tenths of a millimetre. Movement inwards is restrained by the tension of the membrana tympani, and rotation backwards by the anterior ligament of the malleus. But movement is still more powerfully checked by the pressure of the stapes against the margin of the fenestra ovalis, and by the elasticity of the membrane of the fenestra rotunda. If this latter membrane were non-existent, and its place were occupied by an osseous plate continuous with the wall of the tympanum, movement inwards of the base of the stapes would be impossible. When, however, the stapes is forced against the fenestra ovalis, the pressure communicated to the fluid of the labyrinth acts upon the membrane of the fenestra rotunda, causing it to yield as far as its elasticity will permit. Inward pressure of the base of the stapes is likewise resisted by the membrane covering the fenestra ovalis.

From the account thus given of the ossicles and their con-

nections and movements, the mode in which the vibrations of the membrana tympani are conveyed to the labyrinth will be easily understood. The transverse vibrations of the membrane cause the malleus and incus to oscillate around their common axis; the movements of the long process of the latter bone cause corresponding movements of the stapes against the fenestra ovalis. These vibrations set up wave-movements in the fluid of the labyrinth, the membrane of the fenestra rotunda yielding to the pressure thus applied.

Muscles of the Tympanum.—The tympanum contains two small

FIG. 12.

THE MALLEUS AND INCUS. (Helmholtz.)

The line *aba* touches from above downwards the apex of the short process of the incus, of the long process, and of the handle of the malleus; *h*, the head of the malleus; *i*, the body of the incus; *sp*, prominent border, bounding head of malleus; *pr.F*, remains of long process of malleus; *T.t*, attachment of tensor tympani muscle.

muscles, attached to the malleus and stapes respectively, and named the *tensor tympani* and the *stapedius*. The *former* consists of a tapering, fleshy portion, and a slender tendon. The fibres arise from the margin of the anterior opening of the carotid canal, from the cartilaginous end of the Eustachian tube and the adjoining portion of the sphenoid bone, and from the inner concave wall of the bony canal. They are often closely connected by means of tendinous or muscular slips with the origin of the tensor palati muscle. The fibres pass into the canal which is situated

above the osseous part of the Eustachian tube, and terminate in a rounded tendon, which bends over the processus cochleariformis nearly at a right angle, and then turns outwards to its insertion into the upper part of the handle of the malleus. The tendon forms a somewhat acute angle with the lower extremity of this portion of the bone, and with the anterior portion of its axis of rotation.

The *stapedius* muscle arises within the eminentia pyramidalis, and in the aquæductus Fallopii, where it lies in front of the facial nerve. At the apex of the pyramid, the fibres unite to form a thin tendon, which passes through an aperture in the bone, and runs forwards in the cavity of the tympanum to its insertion on the posterior border of the neck of the stapes.

When the tensor tympani contracts, the handle of the malleus and the membrana tympani are drawn inwards; the head of the malleus moves outwards, and is closely applied to the incus by means of the cog-wheel arrangement. The base of the stapes is pressed against the fenestra ovalis, and the normal tension of the membrana tympani is increased. When the muscle relaxes, the elastic force of the rotated axial ligament and of the membrana tympani restores the condition of equilibrium. The motor nerve for this muscle is derived from the otic ganglion, and is supplied by the third division of the fifth. Irritation of the peripheral portion of the latter nerve within the cranium has been observed to cause contraction of the tensor tympani muscle.

It would appear that the contraction of the tensor tympani during hearing is not continuous, but transient. When sound-waves first impinge on the membrana tympani and cause it to vibrate, a sudden contraction of the tensor occurs, but immediately passes off. Deep tones of less than 200 vibrations cause little if any contraction. As to the manner in which the necessary stimulus is communicated to the nerve supplying the muscle, it is probable that the auditory nerve is the channel through which reflex action is excited. The muscle, as a general rule, is not directly under the influence of the will, though in some cases the voluntary action of the muscles of mastication provokes an associated movement of the tensor tympani. Fick* stated that in his own case forcible contraction of those muscles caused a singing tone in the ear, and that a drop of mercury in a capillary tube,

* *Archiv f. Anat. u. Physiol.*, 1850, p. 526.

fixed air-tight into the external meatus, was rapidly drawn inwards towards the membrana tympani. Helmholtz and Politzer found that yawning was attended with increased tension of the membrana tympani, and enfeeblement of hearing for certain tones.

The tension of the membrana tympani modifies the perception of sounds in a very important manner. Increased tension lessens the receptive capacity for sonorous vibrations, and conduction to the nerve is thus weakened. A high degree of tension increases the resonance of the membrane for high tones; a low degree has the same effect with regard to deep tones. The function of the tensor tympani is therefore to diminish excessive vibrations, and to regulate the resonance of tones of varying heights. Müller's experiments have proved that a tense membrane on being struck communicates feebler vibrations to the air than one in a more relaxed condition, and it may be assumed that increased tension of the membrana tympani and its bulging inwards diminish the lever-like movement of the ossicles and the intensity of the undulations in the fluid of the labyrinth, and consequently the hearing-power. The latter result can easily be shown to occur by closing the mouth and nose and inspiring forcibly, in which case the air in the tympanum is diminished and the membrane bulges inwards; or by making a forced expiration when air is driven into the tympanum through the Eustachian tube and the membrane is bulged outwards. In both cases hearing-power is diminished. Politzer has, moreover, shown by direct experiments on the tympanum of a dog recently killed, that the contraction of the tensor tympani influences the conversion of the sonorous vibrations into those of the membrana tympani, and those movements of the incus and stapes upon which the intensity of the effect depends. These results are due firstly to the tension produced in the membrane, and secondly to the manner in which the base of the stapes is pressed against the fenestra ovalis.

The second function of the muscle is the alteration of the resonance of the membrana tympani. Wollaston discovered that impairment of hearing power, due to increased tension of the membrana tympani, was not uniform for all notes, but that low notes were less distinctly perceived, whereas high tones were either unchanged or intensified, as compared with their perception with a medium degree of tension of the membrane. It is well known that tense membranes are easily caused to vibrate, and

produce notes by sounds caused in their vicinity, corresponding with their own fundamental tones, or whose number of vibrations is some multiple of their own. Owing to the smallness and tension of the membrana tympani, its fundamental note is extremely high, so that it cannot vibrate in sympathy with the majority of the tones which act upon it. Vibrations are, however, produced by all tones from the highest to the lowest, and in both cases the amplitude of the vibrations is proportional to the intensity of the sound. Moreover, for clearness of sound-perception it is necessary that the membrane should cease to vibrate immediately the sonorous undulations have ceased to act upon it. Such after-vibrations are prevented by the attachment of the membrane to the chain of bones, which offer considerable resistance to its movements. The membrana tympani by itself would, like every other membrane, vibrate actively in sympathy with its own fundamental note or with the octave, but for all others, and especially for lower notes, it would exhibit less decided vibrations. Its capacity of responding to all notes and of diminishing their intensity in an almost equal degree in all cases, is due to its connection with the malleus. This diminution of the extent of the vibrations is no disadvantage; on the contrary, it appears to be a necessary condition for the perception of sounds. The sound-perceiving apparatus is so sensitive that only the feeblest waves are necessary to excite the auditory nerve, and if there were no check upon the vibrations of the membrane, the terminations of the nerve would be liable to suffer. The attachment of the malleus subserves another purpose—it prevents after-vibrations and the continuance of the sensation after the exciting cause has ceased to operate. The malleus acts, therefore, upon the membrane as a *damper*, and checks the movements after the last undulation has acted upon it. The resistance offered by the bone is increased by the weight of its head, by the elastic force of the ligament connecting the long process to the wall of the tympanic cavity, and by the comparatively unyielding character of the stapedio-vestibular articulation.

Various functions have been assigned to the stapedius muscle. It has been regarded by some as co-operating with the tensor tympani, and by others as its opponent. It has also been credited with the power of preventing excessive movements of the stapes in the fenestra ovalis. It cannot assist the tensor, for it contracts at

a right angle to the plane of rotation of the incus and malleus. When the muscle shortens, it must tend to draw the head of the stapes backwards, but inasmuch as the base cannot be moved in that direction, its anterior portion is displaced somewhat outwards, while the posterior part is pressed somewhat inwards, towards the fenestra ovalis. In some experiments on dogs, immediately after death, Politzer* found that when the stapedius muscle was caused to contract by irritating the facial nerve, pressure in the labyrinth was reduced, probably as a result of diminished tension of the membrana tympani. This experiment would prove that this muscle is the antagonist of the tensor, for contraction of the latter increases the labyrinthine pressure by increasing the tension of the membrana tympani. In some persons, when the eyelids are forcibly closed, the stapedius executes an associated movement. Mr. Toynbee regarded the stapedius as aiding the perception of faint sounds; when the muscle acts, the base of the stapes is withdrawn from the fenestra ovalis, and oscillates more freely in response to slight impressions. According to another view, the action of the muscle renders the stapes more firmly fixed, "as the fibrous mass (annular ligament), which surrounds the fenestra ovalis and keeps the stapes in its place, becomes more tense. The activity of the muscle, therefore, prevents too intense shocks, which may be communicated from the incus to the stapes, from being conveyed to the perilymph" (Landois). If this latter theory be correct, the small muscles of the tympanum may be considered as regulating the communication of sonorous undulations to the fluid of the labyrinth, preventing it from being too much affected by loud sounds, in a manner analogous to that in which the iris regulates the admission of light to the eye. The increased sensibility to sounds noticed in some cases of facial paralysis is attributed to loss of power of the stapedius muscle. Under such circumstances, the stapes is supposed to be less firmly attached to the fenestra ovalis, so that all impulses from the tympanum act more vigorously upon it, and excite more considerable vibrations in the perilymph.

Lining Membrane of the Tympanum.—The walls of the tympanum and the structures it contains are covered by a thin mucous membrane, continuous with that of the pharynx through the Eustachian tube, and prolonged backwards into the mastoid

* *Beiträge z. Anat. u. Physiol.* Leipzig, 1874, Heft 1, p. xxv.

cells. Several folds of the membrane traverse the cavity in various directions; one of these, termed the posterior fold, is a continuation of the posterior border of the external ligament of the malleus, and is in close relation with the chorda tympani. This nerve, on entering the tympanum, passes along the free border of the fold for about half its length; it then runs along its posterior surface to the side of the neck of the malleus, and is directed between the tendon of the tensor tympani and a prolongation of the anterior ligament of the malleus to the Glaserian fissure. Where the nerve leaves the free border of the fold, it has the long process of the incus on its inner side, and is attached to it by mucous membrane. Schwalbe states that the posterior part of the nerve is not free, but is usually invested by a special fold of mucous membrane. The anterior fold covers the anterior ligament of the malleus, and is firmer and shorter than the posterior fold. Other folds invest the tendon of the tensor tympani muscle, both processes of the incus, and the tendon of the stapedius. These folds, together with the tympanic membrane and the ossicles, form the boundaries of small *pouches*, the most important of which is situated between the posterior fold and the membrane. This communicates with another pouch termed Prussak's space, which is situated between the external ligament of the malleus and the short process of that bone. It is bounded externally by Shrapnell's membrane, and internally by the neck of the malleus. The importance of this pouch or space is due to the fact that isolated accumulations of secretions and of purulent matter are sometimes found in it.

The mucous membrane is closely connected with the periosteum, and appears as a thin transparent pellicle with a smooth, glistening surface. The periosteal layer is traversed by vessels and nerves, and is thickened for the reception of these structures. The character of the epithelium varies in different parts of the membrane. According to Kölliker, the surface of the ossicles, of the membrana tympani, and of the promontory is covered with tessellated epithelium; but the remaining portions by ciliated cylindrical cells. At the margin of the membrana tympani the latter cells are seen to become smaller, and gradually to lose their cilia. (See Fig. 8, page 29.) The connective tissue, which forms the basis of the membrane, shows a reticular structure in various parts, with meshes containing leucocytes. The periosteal

layer is made up of compact strands of connective tissue, running parallel to the osseous surface. Some of the fibrous bundles are raised above the general surface, and contain peculiar structures, formerly regarded as pathological products, but which Politzer has shown to be normal formations. These are generally oval, but sometimes pyriform bodies, having a fibrous structure, the fibres being arranged in layers parallel with the exterior outline. Each of these bodies is traversed from end to end by a fibrous stalk or band, attached at one extremity to the membranous surface below, and at the other to the osseous wall. These structures are purely connective-tissue formations, though they somewhat resemble the Pacinian bodies.

1, ciliated epithelium; 2, basal cells; 3, connective tissue of the mucous membrane.

Anatomists differ in opinion as to whether any glandular structures are contained in the mucous membrane of the tympanum. It was formerly held that these structures were absent, but Tröltsch has described racemose glands near the anterior pouch of the membrane, close to the entrance of the Eustachian tube. Other observers have noticed tubular glands lined with cylindrical epithelium and dilated at their extremities. Luschka and Sappey, on the other hand, state that no glands exist in the normal tympanum, and it may be regarded as certain that even if the contrary opinion be correct, the glands must be few in number and unimportant in character. The walls of the tympanum are moistened by a minute quantity of fluid, which may collect so as to become visible on the floor and in the pouches of the cavity.

The tympanum in the fœtus and in the new-born child presents certain peculiarities which require to be noticed. The cavity can scarcely be said to exist in the fœtus at the fourth or fifth month, for it is completely occupied by a reddish gelatinous material, which is in reality the thickened mucous membrane. According to Tröltsch, the enlargement of the membrane is observable in those portions which cover the labyrinthine wall, the floor and the ossicles, whereas the mucous layer of the membrana tympani is unaffected. This fœtal condition of the mucous membrane gradually becomes modified; the soft succulent structure loses its watery intercellular material, and is converted into fibrillary connective tissue. Opinions differ as to the time at which this change takes place, and as to its causes. Some authorities (as mentioned by Schwalbe) state that the change occurs and is completed during the eighth month, so that the tympanum is fully developed in the mature fœtus; others assert that the thickening of the mucous membrane remains till birth, and that its disappearance is the result of respiration. If this latter opinion be correct, the formation of a tympanic cavity is to be regarded as a proof of full and perfect respiration. Schwalbe, however, thinks that the reduction in the thickness of the membrane is the result of developmental processes, and is not dependent upon the access of air to the tympanum.

Vessels and Nerves of the Tympanum.—The arteries distributed to the tympanum are derived from the external and internal carotid. The ascending pharyngeal branch of the former gives off small twigs to the Eustachian tube and its muscles, and to the mucous membrane of the anterior and middle portions of the cavity. The stylo-mastoid artery, a branch of the posterior auricular, in its course through the aqueduct of Fallopius, gives off branches which pass through foramina in the posterior wall of the tympanum, and supply the mucous membrane, and that of the mastoid cells, and also the stapedius muscle. Branches of the middle meningeal artery, before it enters the cranium, are furnished to the Eustachian tube, and when the artery reaches that cavity it gives off a small twig, which enters the hiatus Fallopii and anastomoses with branches of the stylo-mastoid artery. A few twigs from the meningeal artery also pass through the roof of the tympanum. The temporal artery sends small branches through the Glaserian fissure; and lastly, the internal

carotid sends a few small twigs through minute orifices in the wall of the carotid canal. The venous blood passes into the middle meningeal vein, the deep auricular, and the veins of the pterygoid plexus. According to Prussak,* the capillaries of the tympanic mucous membrane are peculiar in several respects. The small arteries do not anastomose with each other, and the calibre of their branches, which are given off at acute angles, is very large in proportion to that of the trunk. As a result of this arrangement, the blood-pressure must be considerably diminished while the velocity of the current is increased, and both these alterations are unfavourable for the escape of exudation into the cavity. Some of the arteries appear to pass into veins without any intervening capillaries.

The lymphatics of the tympanum are most abundant in the deeper layers of the periosteum, and the vessels present many rounded dilatations. On the roof of the tympanum, the lymphatics communicate with infundibular or spherical spaces, traversed by a fine network and often filled with leucocytes, and thus resembling minute lymph-follicles.

The nerves distributed to the tympanum are derived from the fifth, seventh, and eighth cranial nerves, and from the sympathetic. The otic ganglion furnishes branches to the Eustachian tube and to the tensor tympani muscle, while the mucous membrane of the cavity is supplied by the tympanic branch (Jacobson's nerve) of the glosso-pharyngeal. This branch arises from the petrous ganglion, and passes to the tympanum through a canal, the opening of which is in the ridge of bone between the jugular fossa and the carotid foramen. On the inner wall of the tympanum the nerve forms a plexus with twigs from the sympathetic. One branch of the tympanic nerve, the small superficial petrosal, passes beneath the canal for the tensor tympani muscle, and thence to the exterior of the skull, through a small opening in the sphenoid bone, to end in the otic ganglion. The tympanic plexus is thus connected with the fifth nerve. Groups of ganglion-cells connected with the tympanic nerve have been discovered by Kölliker and Krause. The nerve to the stapedius muscle arises from the facial in the aqueduct of Fallopius, opposite the pyramid, and passes obliquely inwards. The sympathetic nerves are derived from the carotid plexus. They pass through the

* *Zur Physiologie und Anatomie des Blutstromes in der Trommelhöhle*, 1868.

posterior wall of the canal of that name, and join with the branches of the glosso-pharyngeal and fifth pair to form the tympanic plexus. The nerves contained in the deeper layer of the periosteum are for the most part medullated, but their branches which form a plexus in the more superficial layer give off non-medullated filaments. Ganglion cells are connected with the main branches, and are also found immediately beneath the epithelial cells.

Besides the nerves distributed to its structures, the tympanum also contains a portion of the chorda tympani nerve, which leaves the trunk of the facial while within the aqueduct of Fallopius, and crosses the cavity to join the lingual branch of the fifth, with which it passes to the tongue. It enters the posterior part of the tympanic cavity through a canal below the level of the pyramid, where it comes into contact with the posterior fold of the lining membrane (see page 43), and then passes forwards across the membrana tympani to the Glaserian fissure.

The Eustachian tube forms the channel of communication between the pharynx and the tympanum, and consists of two firmly connected portions, one being cartilaginous and the other osseous. The latter commences in the tympanum; the opening of the cartilaginous portion is in the lateral wall of the nasopharynx. From end to end the tube measures about 36 millimetres (1·4 inches), one-third of which belongs to the osseous portion. The direction of the tube is not uniform; the two portions being united at an obtuse angle. Looked at from above, the change of direction is scarcely visible; but it is always marked on the under side. The angle coincides with the narrowest part of the tube, and with the place of union of the cartilaginous and osseous portions. The calibre of the latter increases towards the tympanum; the passage through the cartilaginous part takes the form of a vertical slit, the height of which increases gradually towards the pharynx. The general direction of the Eustachian tube is from the tympanum behind and above, forwards, downwards, and towards the mesial line. Its axis forms an angle of 150° with that of the external meatus. The tube is usually said to present an outer and inner wall, a floor and a roof. The sides, however, almost meet below, and in the cartilaginous portion the upper boundary of the tube is the angle formed by the approximation of the walls.

The walls of the *osseous portion* of the tube at the tympanic end are continuous with those of the cavity, except below, where the orifice is marked by a sharp curve downwards to the anterior wall of the tympanum. The roof is formed by the floor and lateral wall, partly osseous and partly fibrous, of the canal for the tensor tympani muscle. On transverse section the osseous portion is triangular in form, with the base above and the apex below;

FIG. 14.

EUSTACHIAN TUBE AND TYMPANIC CAVITY, RIGHT EAR. (Poltzer.)

a, membrana tympani; *b*, head of the malleus; *c*, lower end of the handle of the malleus; *d*, body of the incus; *e*, short process of the incus; *f*, tensor tympani; *g*, ostium pharyngeum tubae; *h*, isthmus tubae; *i*, ostium tympanicum tubae.

towards the tympanum the lateral walls are separated below, and a floor may be said to exist, which is sometimes divided into two parts by a minute crest. The internal wall of the osseous tube is constituted by the neighbouring part of the carotid canal, and close to the tympanic orifice is the opening of the minute canal which transmits the small deep petrosal nerve. Minute perforations sometimes exist in the septum between the osseous

tube and the carotid canal. At the tympanic orifice the tube measures from above downwards about $4\frac{1}{2}$ mm., and $3\frac{1}{2}$ mm. from side to side; at the isthmus the width of the tube is about 1mm., while from above downwards the average measurement is 3mm.

The mucous membrane of the osseous portion of the tube is closely attached to the periosteum. The epithelium is of the columnar ciliated variety, and is destitute of glands. The membrane is thickest towards the floor of the tube, and contains a vascular network resembling cavernous tissue. Adenoid connective tissue is often found in the mucous membrane beneath the osseous lamella, separating the Eustachian tube from the canal for the tensor tympani muscle.

The cartilaginous portion of the Eustachian tube forms an incomplete wall, the deficiency being supplied by fibrous membrane. When a transverse section is made the cartilage is seen to be bent upon itself, so as to form an angle above, and to constitute about two-thirds of the tube. It is firmly attached by means of fibro-cartilaginous tissue to the indentations of the osseous portion. The cartilage is complete along the inner wall of the tube; its smaller portion forms the upper part of the outer wall. The inner wall increases in height from the isthmus to the pharyngeal opening, where it measures 12mm. At the latter spot the cartilage of the outer wall is much reduced in size, whereas at the isthmus the two portions are nearly equal. At the pharyngeal end the inner wall is much thickened, and its free vertical border, which projects into the side of the pharynx, is often slightly concave, and is prolonged for a short distance at a right angle, so as to assist in forming the floor. The cartilaginous portion, from the isthmus to the pharyngeal opening, measures 24mm., or nearly one inch.

The upper part, or roof of the cartilaginous portion, is firmly attached by means of fibrous tissue to the base of the skull. Commencing at the mouth of the osseous portion of the tube, a distinct furrow can be traced, running *inwards and forwards*, between the great ala of the sphenoid and the anterior surface of the extremity of the petrous bone. The fibrous tissue occupying the cleft is very closely connected with the roof and inner wall of the Eustachian tube. Further forwards, near the pterygoid process, the inner wall is free and comparatively movable, and projects into the pharynx. The outer wall, on the other hand, at its anterior part, is firmly connected with the bone, and its

extremity is attached to a process on the internal pterygoid plate. In its posterior two-thirds, this outer wall of the tube admits of considerable movement as a result of muscular contraction.

The continuity of this portion of the tube is often broken by clefts of various forms and sizes, and filled up with connective tissue and blood-vessels. Sometimes ridges of cartilage project into the canal, and small detached cartilaginous masses are not infrequent in the surrounding fibrous tissue.

Histologically, the cartilage of the Eustachian tube is of the elastic variety; fibres of the latter character are very abundant in the upper and posterior part. The capsules of the cells are distinctly hyaline; they are closely packed together with elastic fibres in the middle portions of the cartilage.

It remains now to describe the *membranous portion* of the tube, or that which completes the gap between the edges of the cartilage. This portion is lined by mucous membrane, continuous with that of the rest of the tube, and supported by a fascia closely connected with the perichondrium, and by the attachments of the tensor palati muscle. This membranous layer is mainly composed of connective tissue, the bundles of which are parallel to the axis of the tube, and the submucous tissue is strengthened by a comparatively thick layer of fat cells. The mucous membrane presents several longitudinal folds, and these are especially marked in the floor of the tube, towards the pharyngeal opening, the closure of which they appear to assist. Two other folds exist in the outer third of the cartilaginous portion; one on the internal and the other on the external wall. These form the floor of a triangle, the apex of which is in the hooked portion of the cartilage. Rüdinger,* who first described this arrangement, was of opinion that this portion of the canal remained permanently open, whereas the lower part, represented by a vertical slit, was always closed except during the act of swallowing. The upper division he termed the "safety-tube," while the lower constituted the "accessory cleft." The former provides a channel through which air in the tympanum can always pass into the naso-pharynx. Subsequently, Rüdinger was led to believe that in a state of rest the middle portion of the tube was always closed, but that the lower portion stood open, like a funnel, towards the pharynx. Moos states that the pharyngeal opening in a state of rest is

always closed by the folds which project upwards from its floor. Other authorities are of opinion that under ordinary circumstances the whole of the cartilaginous portion is closed. Whichever view be correct, it may be assumed that a capillary canal would be filled by the secretions of the tympanum. The greater part of the cartilaginous portion is in all probability closed, except when acted upon by the muscles about to be described.

The tube is lined by ciliated columnar epithelium with basal cells beneath, and goblet cells in varying proportions. The ciliary undulations are said to travel from the tympanum towards the pharynx, but various substances, such as hair, particles of soot, and snuff are stated to have found their way through the Eustachian tube to the tympanum. Beneath the epithelium is a loose connective tissue layer, with numerous cells, and still more externally the fibres are disposed in a somewhat circular direction. An important constituent of the mucous membrane of the tube is the so-called adenoid, or reticular connective tissue, containing numerous leucocytes, and presenting several modifications and stages of development, sometimes taking the form of a diffuse lymphoid infiltration, and sometimes constituting gland-like structures. Beyond the pharyngeal orifice, this reticular tissue surrounding minute depressions is continued into the pharyngeal tonsil. It is especially developed in children, but in adults it is abundant only in the pharyngeal third of the tube. The excretory ducts of mucous glands open into the bases of the pit-like depressions, as well as between them. These glands are copiously distributed throughout the tube, except at its upper portion.

The tissues in close contact with the cartilaginous part of the Eustachian tube are as follows: The tensor veli is applied to its lateral and anterior wall, being itself covered by a fascia and the internal pterygoid muscle. The levator veli extends along the floor of the tube, and the posterior and internal wall is at first covered by the origin of this muscle; but in front, it lies under the mucous membrane of the pharynx, and forms the anterior wall of Rosenmüller's fossa. In their further course in the pharyngeal wall, the muscles of the tube are thus placed: The salpingo-pharyngeus, and behind it, the ligament of that name, form the innermost layer beneath the mucous membrane. At the anterior border of the muscle, the levator veli takes a direction downwards and forwards, and at the mouth of the tube lies close under

the mucous membrane. Upon the outer side of these muscles are the constrictors, and still more forwards, the tensor veli muscle.

The pharyngeal opening of the Eustachian tube is situated in a depression in the lateral wall of the naso-pharynx. Its form varies, being oval, pear-shaped, elliptical, or triangular, with the larger extremity above, and directed somewhat forwards. In other cases it is a mere cleft or slit, while sometimes the opening is kidney-shaped. Its posterior boundary is formed by the pharyngeal end of the cartilage of the tube, the internal wall of which projects like a lip, and separates the opening from the fossa of Rosenmüller. Below, this projection is less marked, and is continuous with the salpingo-pharyngeal fold, and lower down with the posterior pillar of the fauces: it covers the salpingo-pharyngeus muscle. The upper border of the orifice is strengthened by a curved portion of the projecting ridge. In its longest diameter, the opening measures about 6mm., its anterior and upper extremity is about 6cm. from the anterior nasal spine, and 1cm. behind the posterior extremity of the inferior turbinate bone. The opening in adults is somewhat above the lower meatus of the nose, or 1cm. above the level of the hard palate.

During the acts of swallowing and speaking, the size and form of the orifice undergo certain changes; these have been observed in cases in which the upper jaw on one side and a portion of the nose had been removed. The opening undergoes no change in ordinary or forced breathing through the nose; slight movements are observable during inspirations of the latter character through the nose and mouth. A considerable change, however, is noticeable during speaking and swallowing. The swelling forming the posterior boundary moves backwards, and the salpingo-pharyngeal fold comes into view; in front of it, as a result of contraction of the levator palati, the floor of the orifice of the tube rises up and separates the walls from each other.

In children, as compared with adults, the Eustachian tube presents certain differences. It is decidedly shorter, but absolutely wider at the isthmus and at the tympanic orifice; the osseous part is longer in proportion to the cartilaginous, and the direction of the canal is almost horizontal. This conformation facilitates the removal of secretion when air is forced through the tube. Less than half the circumference of the tube is formed by cartilage; the pharyngeal orifice is a mere cleft, and the posterior

lip is decidedly less prominent. During foetal life, the opening of the tube is below the level of the hard palate; at birth, it reaches that level; in a child four years old, it is about 3mm. above it.

Several *muscles*, *fasciae*, and *ligaments* are connected with the cartilaginous and membranous part of the Eustachian tube, and are mainly concerned in rendering its orifice more or less patent. There are at least three muscles, of which the first in importance is the *tensor veli*, or, as it is sometimes called, the *dilator tubæ*. It arises from the root of the internal pterygoid plate of the sphenoid bone, from the external cartilaginous portion of the tube, and from the membranous portion. Its outer surface gradually becomes tendinous, and a portion of it is closely united with the aponeurosis of the internal pterygoid muscle in the pterygoid fossa. The muscle then turns round the hamular process, being here represented by a somewhat broad tendon, which passes into the aponeurosis of the palate, and is also attached in front to the posterior border of the hard palate.

When the *tensor veli* contracts it separates the hooked portion of the cartilage and the membranous part from the internal plate, and thus dilates the tube. Certain fibres which are attached to the lateral cartilage and to the notch at the base of the pterygoid plates are especially active in this direction. There is also a layer of fibrous tissue, connected on the one hand with the membranous portion of the tube, and on the other with the aponeurotic expansion of the tendon of the muscle, and this tissue is tightened when the muscle contracts and draws the membranous from the cartilaginous portion of the tube. The *tensor veli* is often closely connected with the *tensor tympani* muscle.

The act of swallowing invariably causes the Eustachian tube to open, but the latter result can be independently effected by some persons. The *tensor veli* muscle is supplied by the motor portion of the fifth nerve.

The *levator veli* arises from the under surface of the apex of the petrous bone, just anterior to the inferior opening of the carotid canal, from the commencement of the external plate of the cartilage of the tube, and from the contiguous portion of the floor as far as the posterior extremity of the internal plate. In their course forward the fibres of the muscle are applied to the lower aspect of the tube, being nearly parallel to its axis. Near the pharyngeal opening the muscle passes under the membranous

base of the tube downwards towards the soft palate, and divides into two portions. The smaller of these is continued forwards towards the posterior nares, and is inserted into the posterior nasal spine and the periosteum of the hard palate, while the larger portion passes downwards in the soft palate, and reaches the arch of the palate on the opposite side, the right and left muscles thus crossing each other. When this muscle contracts, its belly thickens, and forms a projecting cushion on the floor of the tube.

The principal function of this muscle is to elevate the soft palate, but by raising the floor of the tube at the pharyngeal opening, it so far diminishes the size of the aperture. This result is observed during deglutition, the act of speaking, and deep inspiration. The levator veli is not to be regarded as the antagonist of the tensor, for it comes into action during the first part of the act of deglutition, whereas the contraction of the tensor takes place at a later stage and causes the pharyngeal opening of the tube to enlarge. Moreover, the swelling caused by the contraction of the levator separates the walls of the tube to some extent, and alters the shape of the aperture, and this action lessens or altogether neutralizes the diminution caused by the swelling in the floor. It is therefore more correct to say that the action of the muscle is to modify the shape of the aperture, and to assist the effect of the contraction of the tensor veli by slightly separating the walls of the tube and by fixing the base.

The third muscle connected with the Eustachian tube is the *salpingo-pharyngeus*, or the *retractor tubæ*. This arises from the thickened pharyngeal end of the inner cartilaginous plate, and passes backwards to the muscles of the pharynx into the connective tissue between the latter and the mucous membrane. It is sometimes absent, and is seldom very conspicuous. When it contracts it draws the pharyngeal extremity of the inner cartilaginous plate in a direction backwards and downwards, and assists to open the mouth of the tube during the act of swallowing.

Several so-called *fasciæ* are described in connection with the Eustachian tube. (1) There is a layer of connective tissue between the tensor and levator veli muscles; it is attached to the membranous portion of the tube, and passes outwards and downwards. This *fascia salpingo-pharyngea* is attached to the hamular process, and to the lateral wall of the pharynx. Some fibres of the

tensor veli arise from this fascia, and when they contract they draw the membranous portion of the tube downwards and outwards. (2) Another fascia, which is connected with the internal pterygoid muscle, covers the lateral cartilage and the membranous tube, together with the tensor veli. When the internal pterygoid contracts, this fascia, the portion of the tube connected with it and the tensor veli are put upon the stretch, so that the first-named muscle forms part of the motor apparatus of the tube. (3) The *salpingo-pharyngeal* ligament arises from the posterior surface of the inner cartilaginous plate, and passes backwards to the constrictors of the pharynx. When the superior and middle constrictors act the internal cartilaginous plate is forcibly retracted, and this ligament, which often contains portions of cartilage, may therefore be described as the *retrahens tubæ*.

Vessels of the Eustachian Tube.—The tube is supplied by the ascending pharyngeal artery, a branch of the middle meningeal, and by small twigs direct from the latter artery and from the internal carotid before it enters the canal and while passing through it. The veins are numerous, and some of them have important relations. Those which form the internal pterygoid plexus pass along the external cartilaginous plate to the base of the skull, and some of them open into the cavernous sinus. These veins are freely connected with the plexus around the glenoid fossa and the anterior wall of the meatus, and open either into the facial or internal jugular vein. When this plexus is congested, the cartilaginous plates are brought nearer to each other, and the calibre of the tube is diminished.

The *nerves* of the Eustachian tube are supplied mainly by the fifth pair; the pterygoid branch is distributed to the tensor palati, and the pharyngeal opening of the tube receives twigs from the superior pharyngeal nerve. When the fifth nerve is irritated, the abductor tubæ contracts and the mouth of the tube is enlarged anteriorly. The levator veli is supplied by the pneumogastric. The osseous portion of the tube receives twigs from the tympanic plexus.

Functions of the Tympanum and the Eustachian Tube.—The membrana tympani and the chain of bones connected with it require space for their vibrations, and this is provided by the cavity of the tympanum. If the latter were not furnished with any channel of communication with the atmosphere, the air it

contains would be compressed by the inward movement of the membrane, the vibrations of which would meet with a corresponding resistance. As a second result, the membrane of the fenestra rotunda would be prevented from moving outwards when acted upon by the perilymph; but these consequences are prevented by the escape of air through the Eustachian tube. Moreover, if the cavity were tightly closed, its gaseous contents would be only such air as might escape from the blood-vessels, and this would be subject to frequent variations in composition and tension as compared with the air on the outer side of the membrane. These differences would modify the receptive capacity of the membrane for sonorous undulations and its power of conducting sound. The necessity for a tube connecting the tympanum with the outer air is thus easily demonstrated.

The Eustachian tube does not serve to conduct sonorous undulations from the pharynx to the tympanum, neither is it a channel for the passage of sounds produced in the throat. Under ordinary circumstances a man's own voice is not more distinctly heard than that of another person speaking close to him. When sounds are uttered with both nose and mouth closed and the orifices of the Eustachian tubes open, they are heard with exaggerated intensity, and they appear to originate within the tympanum itself, this difference being due to the fact that the tubes are open. Under ordinary conditions their walls are in apposition; the expiratory current and therefore the sonorous vibrations produced by the vocal cords do not pass into the tubes, for the air does not impinge upon the openings in a favourable direction, and can easily escape through the mouth and nares. The mechanism of the Eustachian tube presents no obstacle to the passage of air from the tympanum, but its valve-like closure obstructs the passage in the opposite direction, and the tube is opened either by muscular action, as in swallowing, or as a result of increased pressure of air, as in Valsalva's experiment. When the tube is open, the intensity of sounds produced in the larynx is due to the same cause as the alteration which is noticed when words are spoken through a tube into the ear. Besides this, when sound is conducted through the Eustachian tube, the vibrations of the membrana tympani are strengthened by resonance from the walls of the cavity. Some of the vibrations reflected from the internal surface of the membrane are thrown

back upon it from the sides of the tympanum, and thus strengthen the sound.

During swallowing the Eustachian tube opens and allows air to escape from the tympanum. At the beginning of the act, however, the movement upwards of the soft palate tends to close the opening. In the second stage of swallowing, the pharynx descends, the tensor palati contracts, and the orifice is rendered patent. Gellé, however, gives a somewhat different account of the phenomena which occur in the Eustachian tube during the act of swallowing. According to his* experiments, in that stage of the act during which the pharyngo-nasal cavity is shut off by the horizontal elevation and tension of the soft palate and the action of the superior constrictor, the walls of the tube are separated and the canal is opened. At that moment air is withdrawn from the tympanum, and the membrane becomes concave or moves inwards. Immediately afterwards air passes in the opposite direction, as a result of the elasticity of the membrane which comes into play when the action of the muscles of deglutition is suspended.

Besides that of admitting air to the tympanum, the Eustachian tube has another important function, viz., that of providing for the escape of secretions from that cavity. The movements of the cilia are directed towards the pharynx, but the opening of the tube is near the roof of the tympanum, and therefore unfavourably situated for the removal of secretion, when only moderate in quantity.

A description of the mastoid portion of the temporal bone and the mastoid cells will complete this portion of the subject.

The **Mastoid portion** of the temporal bone is situated behind the meatus; it contains cellular spaces which communicate with the tympanum, and are lined by mucous membrane prolonged from that cavity. Its external surface is convex and rough, and presents several foramina, one of which, much larger than the others, is situated close to the posterior border, and serves for the passage of a vein to the lateral sinus. Behind the aperture of the ear, the mastoid portion is prolonged downwards into a nipple-shaped projection—the *mastoid process*, on the inner side of which is a deep groove, the *digastric fossa*, which gives attachment to the posterior belly of the muscle of that name. On the inner boundary of this fossa is a slight groove for the occipital artery. In some

* *Suite d'Etudes d'Otologie, De l'Oreille*, p. 119, et seq.

specimens, another groove, running from before backwards, divides the mastoid process into two portions.

The outer surface of the mastoid process, and especially of its posterior part, is rough and perforated, and occasionally so incomplete as to allow the cellular structure of the bone to become visible. In extreme cases of this kind some of the air-cells open externally, and thus establish a communication between the tympanum and the subcutaneous tissues of the mastoid portion. Morbid contents of the mastoid cells might thus pass to the side of the neck and occiput, and Gruber* states that he has often seen emphysema of these parts result from injecting air into the tympanum. The internal surface of the mastoid process presents a deep sigmoid groove which lodges part of the lateral sinus: the mastoid foramen opens into this groove.

The mastoid cells communicate with the tympanum by means of one or more openings in the posterior wall of that cavity. At its upper part is a space which is termed the *recessus epitympanicus*, or *aditus ad antrum*, and contains the larger portion of the incus, and nearly half of the malleus. This space extends backwards into the mastoid *antrum*, the upper wall of which is directly continuous with the roof of the tympanum. The antrum measures from behind forwards about 12mm., and from above downwards about 8mm. Its floor may be said to begin at the spot where the short process of the incus is attached to the posterior wall, with which it forms almost a right angle, and it is continued downwards to the commencement of the mastoid process. It is considerably below the level of the opening by which the antrum communicates with the tympanum, and secretions are therefore liable to accumulate in this passage. The walls of the antrum present many openings, of various forms and sizes, communicating with the mastoid cells and with similar cells in the squamous portion of the bone. The mastoid cells may be divided into two sets; one extending horizontally backwards, and the other downwards into the mastoid process.

The *number, size, and contents* of the mastoid cells vary considerably in different specimens. Sometimes the cells contain air and occupy the whole of the mastoid process, and even extend backwards to the occipital suture, upwards and forwards to the root of the zygomatic process, and inwards for varying distances

along the petrous portion. They thus surround the superior and posterior wall of the osseous meatus and a large portion of the labyrinth, and are often found beneath the compact tissue of the wall of the jugular fossa, and of the posterior part of the carotid canal. In another class of cases the air-cells are confined to the base of the mastoid process, the remaining portion being either compact or occupied by reddish or yellowish diploetic tissue

containing much fatty matter. In 100 specimens examined by Dr. Zuckerkandl,* many variations were found in the proportion between diploetic and pneumatic mastoid cells. In 40 the cells were altogether pneumatic; in 22, completely diploetic as far as the antrum; in 29, the apex alone was diploetic; and, in 9 cases, the condition of the lower half was of that character, while the

* *Monatsschrift f. Ohrenheilkunde*, Bd. XIII. 1879.

cells of the upper half contained air. In rare cases, the mastoid process has a single cavity in its interior; but, as a general rule, there are many cellular spaces, either communicating with each other, or shut off by *septa* composed of the lining membrane. Many variations are found to exist in the form and size of the cells; those contained in the free portion of the mastoid process are usually the largest. (See Figures 16 and 18). The differences in the number, size, and position of the cells in different specimens are well illustrated in Figs. 15—19, copied from Gruber's work.

The relations of the mastoid cells and antrum to both surfaces of the bone are of much practical importance. On the dried bone, the upper part of the rim surrounding the meatus often presents a tubercle or spine (the *spina supra meatum*), with a small depression above, and these serve as guides to the mastoid antrum, being immediately superficial to it, and separated from it by compact and spongy osseous tissue about 6mm. in thickness. The outer layer of compact bone measures only 2mm., the remaining distance is occupied by spongy tissue, bounding minute pneumatic cells. A horizontal line directed backwards from the tubercle is always above the level of the floor of the antrum. The line of attachment of the auricle runs about 15mm. behind the tubercle, and an opening into the antrum from behind this line must take an oblique direction forwards and inwards. If made perpendicularly to the surface it will impinge upon the sigmoid groove, the bone being, on an average, $7\frac{1}{2}$ mm. thick at this part. This measurement, however, is subject to great variations; Schwalbe states that it has been found as low as 2mm., and as high as 15mm.

The thickness of the osseous lamella on the outer surface of the mastoid portion varies considerably. The upper part is generally thicker than the lower, and the apex is more compact than the part immediately above it. In some specimens the layer of bone is almost as thin as paper, and yields to very slight pressure. The openings often found on the surface are in part the remains of the squamo-mastoid fissure, and in part the results of absorption of the osseous tissue. In children, the permanence of the fissure may be a matter of importance, inasmuch as the connective tissue occupying the chink might allow inflammation to extend outwards from the pneumatic cells. In the adult bone, remains of the fissure are far less common. In the internal

osseous lamella covering these cells, there are two spots, where either apertures or cracks sometimes exist, or the crust is found to be extremely thin. One of these is situated in the layer of bone continued from the roof of the tympanum to that of the mastoid antrum. This layer is sometimes perforated by several minute apertures. Similar openings are occasionally seen in the thin osseous lamella which separates the lateral sinus from the posterior mastoid cells. Suppuration within the mastoid process may cause necrosis of this shell of bone, with phlebitis of the sinus as a further result.

The mastoid antrum and cells are lined by a very thin mucous membrane which is closely connected with the periosteum. Minute bands and threads of membrane stretch across and subdivide many of the pneumatic cells, so that the openings between the cells appear smaller than in the dried bone. In a few cases the openings between the mastoid cells and antrum have been found closed by mucous membrane. The epithelial layer consists of non-ciliated pavement cells.

Functions of the Mastoid Cells.—Little is known with regard to the physiological significance of the mastoid cells. According to some physiologists, the differences in the size and contents of these cells would seem to indicate that they do not subserve any very important purposes in connection with hearing. They may, however, be regarded as supplementing the capacity of the tympanum, which must not fall beyond a certain limit, if variations in pressure of a given amount are to produce corresponding vibrations of the membrana tympani. If the tympanum were reduced in size, slight excursions of the membrane would cause considerable expansive power of the contained air, and any further increase in the vibrations would be thereby checked. Moreover, for the reception of low notes, the tympanum must be of a certain depth and capacity, and hence the additional space furnished by the mastoid cells may be of considerable importance so far as these tones are concerned.*

* Burnett's *Treatise on the Ear*, p. 118.

CHAPTER III.

THE EXAMINATION OF PATIENTS SUFFERING FROM AURAL AFFECTIONS. GENERAL SYMPTOMS AND CAUSES.

Investigation of History of Case—Points to be Ascertained—Influence of Age, Occupation, and Surroundings—Duration of Symptoms—Injuries as a Cause—Previous Diseases—Hereditary Predisposition—Pain as a Symptom—Vertigo—Subjective Auditory Sensations.

IN order to arrive at a conclusion with regard to the nature and probable course of many affections of the ear, it is necessary to examine not only the organ itself, but the general condition of the patient, and to make inquiry into his previous history and any subjective symptoms of which he may complain. Morbid conditions of the ear may give rise to symptoms in other parts of the body, while diseases of other organs may be the real cause of symptoms manifesting themselves in the ear. Affections of the circulatory organs and of the nervous centres are often associated with subjective auditory sensations, in the absence of any discoverable changes in the ear itself.

In the investigation of the history of the case it is well to allow the patient to tell his own story, so far as it is possible for him to do so. In dealing with children, the information must, of course, be obtained from those in charge of them. Too many questions are apt to mislead a patient, and to cause him to describe symptoms not connected with his ailment. It is obviously desirable to conduct the examination in a regular manner, asking questions in a definite order, and carefully noting down the answers.

The following are the principal points on which information should be obtained from the patient:—

1. Age, occupation, habits, and place of residence.
2. The duration of the complaint, the circumstances under which it first appeared, and its course.
3. The general health of the patient, with especial reference to any diseases from which he may have suffered, *e.g.*, scarlatina, diphtheria, measles, whooping-cough, mumps, syphilis, throat affections, &c.
4. The occurrence of any aural affection among members of his family.
5. The nature of previous treatment (if any) of the aural affection.
6. The influence of external conditions, *e.g.*, changes of weather, &c., upon the deafness and other symptoms.
7. The presence or absence of pain, giddiness, and noises in the ears, the patient being invited to describe minutely any sensations of this kind.
8. Discharges from the ear at any time noticed; their duration, quantity, and character, and whether connected or not with pain or any other symptom.

The age of the patient determines to some extent the nature of the complaint, and is important in connection with the prognosis and treatment. Children are especially liable to suffer from inflammatory affections of the tympanum as a result of the extension of morbid processes from the naso-pharynx, and the frequent occurrence of measles and scarlatina among young subjects accounts for their greater liability to aural diseases. Between twenty and forty years of age, chronic catarrhal and suppurative affections of the middle ear are very frequent. In later life, these affections become less common, and chronic adhesive catarrh is the complaint most often met with. In old age the frequency of aural diseases is again increased; the tympanum is often the seat of chronic inflammatory processes, accompanied by thickening of the lining membrane and rigidity of the articulations of the ossicles. The auditory nerve, like other nerves of special sense, is apt to become less sensitive with advancing years. As a general rule, affections of the ear in old people are less amenable to treatment than similar diseases in young subjects.

Occupations, habits, and surroundings often play a decided part

in the causation of aural affections, and exercise considerable influence on their course. In one category may be grouped those occupations which involve constant exposure to the vicissitudes of the weather; and in another, those in which the auditory nerve is liable to be excited and irritated by loud and sudden noises. Thus catarrhal affections of the ear are somewhat frequent among gardeners, coachmen, and fishermen, while deafness caused by paralysis of the auditory nerve, and marked subjective auditory sensations, are often noticed among blacksmiths, chainmakers, coopers, and engine-drivers. With regard to *surroundings* and *habits*, it is well known that the development and course of many aural affections are much influenced by the patient's circumstances. Poor people living in cold damp localities are much more prone to suffer from catarrhal affections of the ear than those who are more favourably situated, and the progress of such complaints is apt to be affected in a corresponding manner. With regard to *diet* and *general mode of living*, it is certain that the immoderate use of alcohol tends to aggravate many diseases of the ear.

Duration of the Complaint.—The statements of the patient or his friends with regard to the duration of the complaint must be carefully sifted, inasmuch as the early stages of many diseases of the ear are unattended by pain or any marked disorder of function, and are therefore apt to be unnoticed. When the complaint is unilateral its origin is less likely to be observed, for the healthy ear may be equal to the ordinary requirements of the patient. Many people fail to notice any difference in their hearing power until marked impairment has occurred; it is only when they are unable to hear their friends' conversation, or when tinnitus becomes troublesome that their attention is directed to the state of the faculty in question. Morbid changes requiring months, or even years, for their development are not infrequently detected in patients who assert that their complaints are of quite recent origin.

Injuries.—If any injury to the ear be mentioned by the patient its nature should be carefully investigated. Blows on the side of the head have been known to cause rupture of the membrana tympani, and the complaint described as hæmatoma auris is often due to this cause. Severe injuries to the skull may involve the petrous portion of the temporal bone, and cause hæmorrhage into the middle or internal ear, beside rupture of the membrane. The

latter injury is sometimes due to concussion resulting from explosion of gunpowder, but instances of this kind are not so common as is generally supposed. In the cases that have been recorded there has probably been some antecedent affection of the tympanum or Eustachian tube, preventing the free circulation of air. Foreign bodies passed into the meatus may injure the membrane and set up inflammation of the tympanum. Affections of the meatus are not infrequently due to the patient's own efforts to cleanse the part or to relieve irritation, and not a few serious lesions have been caused by unskilful attempts to remove foreign bodies.

Previous Illnesses.—Direct questions should be put with regard to any previous diseases from which the patient may have suffered. Thus, it is often necessary to ask whether he has ever had scarlatina, measles, typhus, typhoid, small-pox, or syphilis, and whether he is liable to attacks of sore throat. (The connection between diseases of the throat and those of the ear will be fully discussed in a subsequent chapter.) It must also be remembered that aural affections are often connected with scrofula and tubercle, less frequently with rheumatism and gout, with inflammatory affections of the lungs, and with chronic disorders of the heart and kidneys. In another class of cases, the cause of the aural affection is to be found in some cerebral lesion, such as meningitis, tumours of the brain, &c.

Hereditary Predisposition to aural diseases is sometimes traceable, the affection, however, not being always the same in the parent and offspring. Thus in the case of a child suffering from purulent inflammation of the tympanum, it may be found on inquiry that the father is the subject of chronic adhesive catarrh. A tendency to catarrhal affections of the throat is often noticed among members of the same family. Of 500 cases of middle ear disease, investigated by Bezold,* the influence of heredity was traceable in 43 per cent., and in 28 per cent. among 381 patients suffering from diseases of the internal ear. Heredity plays a very important part in the causation of congenital deafness; this fact will be fully discussed in a subsequent chapter.

External Conditions.—It is desirable to ascertain whether the complaint is influenced by certain external conditions; such, for example, as changes of weather. Catarrh of the tympanum is

* *Munch. Med. Week.*, 1887, Nr. 28.

always made worse by exposure to cold and damp, and the patient should therefore be directed to avoid these injurious influences as far as possible. Exposure to cold is often assigned as the cause of the aural affection, and if the latter has really come on immediately after such exposure, the statement may prove to be correct. The entrance of cold water into the meatus, as in sea-bathing, is liable to cause inflammation not only of the external ear, but also of the tympanic membrane and tympanum.

The etiology of diseases of the labyrinth requires to be minutely discussed; its consideration will be deferred until the last section of this work is reached.

Pain as a Symptom.—When the patient complains of pain he should be questioned as to its character—whether it is continuous or periodic, and if the latter, at what time it comes on. Other points in connection with pain are its limitation to the ear, or its radiation to other parts, such as the side of the head, the throat, and the naso-pharynx. Pain is often absent in cases of chronic inflammation of the meatus and tympanum. It is nearly always severe in acute purulent inflammation of the tympanum, before the membrane has given way or been opened. Its intensity varies in different cases of the same disease, and is sometimes very slight, even where considerable destruction of tissue has taken place.

Vertigo.—The inquiry should further extend to other signs of nervous disorder: the occurrence of vertigo should be inquired into, and, if complained of, its characters should be ascertained, whether continuous or paroxysmal, whether excited by any special cause, and whether accompanied by vomiting.

The Condition of the Nervous Apparatus.—The condition of the auditory nerve and nerve-centres is the next subject for investigation, and two sets of symptoms, viz., *subjective sensations of hearing* and impaired perception of sounds, are connected with disorders of these parts.

Subjective Sensations.—The patient's own statements are, of course, the only guide with reference to subjective auditory sensations, and are not always to be depended upon. The nature, duration, and apparent place of origin are the main points to be investigated in connection with these phenomena. Many various expressions are used by patients to describe their sensations. Thus the sounds heard are said by different sufferers to resemble the

ticking of a clock, the ringing of a bell, the whistling of a steam-engine, the bubbling of water, the roar of the wind, the rattle of machinery, the humming of bees, &c. Musical sounds variously combined, the sounds of instruments and of voices, the cries of animals, the singing of birds, the buzzing of winged insects, and a vast number of other sounds are declared to be perceived in the absence of any objective cause. Patients are apt to exhaust their vocabulary in attempting to describe their sensations, and not infrequently assert that they are unable to compare them with any recognised sounds.

In some instances the sounds are continuous, the patients declaring that they are always conscious of them during their waking hours; in other persons the sensations are troublesome only at intervals. In the former class, the intensity of the sound is apt to vary from time to time. Sometimes various kinds of sounds are perceived simultaneously, and sometimes in succession. The intensity of the sound is often affected by the position of the head, being sometimes increased and sometimes diminished when the patient is lying down. In the former case the sensation may be so intense as to prevent sleep and to cause great distress. Inquiry should be made as to the time at which the sensation was first experienced, whether it preceded, accompanied, or followed any other complaint of the ear from which the patient may be suffering, and whether any alteration has taken place in the severity of the symptom as a result of treatment or otherwise.

The locality to which the sounds are referred is another point on which inquiry should be made. In most cases the sounds appear to originate in the ear; sometimes they are referred to the head generally, or to some particular portions of it—*e.g.*, the occiput, or vertex. In another class of patients, the sound appears to come from some point outside the head, its direction being always the same, or varying from time to time.

In all cases in which sensations apparently subjective are complained of, the surgeon should ascertain whether any objective cause is present. It sometimes happens that the noises can be heard by other persons; in such a case they depend upon pathological conditions in the interior of the ear, or in the Eustachian tube. Abnormal action of the muscles of the latter structure and of those of the ossicles may also cause some of these sounds. Further details with regard to subjective sensations and various

modifications of the function of hearing will be given in the chapters on affections of the auditory nerve.

Having thus obtained as clear an account of the symptoms as the patient is able to give, the condition of the external ear, tympanic membrane, and tympanum, and the amount of hearing power should next be investigated. The next chapter will be devoted to a consideration of the methods of examination.

CHAPTER IV.

THE EXAMINATION OF THE EAR AND DETERMINATION OF THE HEARING-POWER.

Examination of the Ear—Sources of Light—Mirrors—Use of Specula—Brunton's Auriscope—Other Forms—Methods of Using—Points to be Noticed—The Membrana Tympani, Normal Appearance—Parts Seen Through it—The Cone of Light—Mobility of Membrane—Use of Siegle's Speculum—Division of the Membrane into Quadrants—Determination of Hearing-Power—Use of the Watch—Formula for Registering Hearing-Power—Bone-Conduction—Politzer's Acoumeter—Hughes' Sonometer—Testing with High Notes—Galton's Whistle—The Tuning-Fork—Number Requisite—Speech as a Test of Hearing—Methods to be Adopted—Whispered Speech—Tests for Bone-Conduction—Use of the Watch, Tuning-Forks—Weber's Experiment—Tuning-Forks with Clamps—Rinne's Experiment—Value of Tests—Gruber's Modification—Gellé's Method.

A CAREFUL examination of the accessible parts of the ear is indispensable for the correct diagnosis and treatment of aural diseases; and the present chapter will contain a description of the manner in which such an examination is to be conducted in all its details.

Illumination of the Accessible Parts of the Ear.—

The first requisite is good light, and ordinary daylight reflected from white clouds is often sufficient; but in dull weather an artificial substitute is always necessary. For a fixed light either gas or the electric light is very suitable, and for occasional use a powerful mineral oil lamp answers the purpose well. For gas, the modifications of Mackenzie's Rack Movement Lamp (Figs. 20 and 21), which I introduced in 1878 will be found to be very convenient, and Messrs. Mayer & Meltzer have so arranged the bracket that it can be screwed into a wall as well as used in the standard form shown in the figure. The outer asbestos cylinder

shown in Fig. 21 should be fixed so that an interval of not less than three-quarters of an inch may exist between it and the metal chimney. The light emitted will be considerably increased if the interior of the chimney be kept whitened by painting it with oxide of zinc, made into a thin paste with water. For an electric light it is best to have the lamp fixed at the end of the third arm

FIG. 20.

FIG. 21.

THE AUTHOR'S MODIFICATION OF MACKENZIE'S RACK MOVEMENT GAS LAMP. The modifications consist of an asbestos outer cylinder over the concentrator, to prevent the heat causing discomfort to the patient, and a third joint to the arm of the bracket, to enable the direction of the light to be altered without the heated concentrator being handled.

of a similar rack-movement apparatus, and connected by flexible cords with the wires attached to the wall.

For the last fourteen years I have been using the portable mineral oil lamp, shown at Figs. 22 and 23. I had it made because I found that the portable lamps sold by instrument makers were practically useless, and did not give sufficient light to enable a

thorough examination of the throat, nose, and ear to be made. Fig. 23 shows the metal cap screwed on to the top of the reservoir ready for travelling. To prevent the oil from splashing out of the reservoir, I cover its surface entirely with segments of a wine cork, each about a quarter of an inch in thickness, and subdivided into pieces about the size of a pea. With the reservoir only three parts full, and the oil entirely covered with pieces of

FIG. 22.

FIG. 23.

THE AUTHOR'S PORTABLE LAMP.

cork of the size mentioned, the oil will not leave the reservoir unless the lamp is overturned. In this event the leather washer between the cap and the top of the reservoir will prevent the oil from escaping beyond the cap, if the latter has been properly screwed down. The asbestos shield on the left hand side of Fig. 22, as it is viewed from the front, protects the patient's face

from the light and heat of the lamp. A flannel bag lined with wadding enables the chimney to be carried with additional safety, and allows of its being handled when hot.

For examining the auricle, no instrument of any kind is required; the light should be allowed to fall directly upon it. For the examination of the meatus and of the membrana tympani it is necessary that the light should be reflected into the ear from a suitable mirror, and in order to gain a clear view of the membrane, and of the deeper portion of the meatus, it is generally necessary to employ some form of speculum. In the majority of cases, owing to the curved direction and small size of the meatus, the membrane is not visible unless a speculum be used.

For reflecting light into the meatus, a small concave mirror is required. It should have a diameter of about two and a half inches, and a focal distance of five or six inches. In the centre is

FIG. 24.

a small elliptical opening, through which the observer inspects the illuminated structures. When direct sunlight is used, a flat mirror is required, in order that the eye may not be dazzled by excessive light. The mirror may be attached either to a handle, or to a head-band by means of a ball and socket joint (Fig. 24); the latter contrivance enables the surgeon to use both hands in operating upon the ear.

Fig. 25 represents the late Mr. Gardiner Brown's hand mirror. It differs from the old-fashioned mirrors in having an elliptical opening instead of a circular one. The advantage of this is that when the mirror is held obliquely, the sight is not interfered with by the rays of light reflected from the edges of the opening, to nearly the same extent as is the case when the opening is circular. Although Mr. Gardiner Brown was the first to use an elliptical

opening for an aural mirror, he did not claim any novelty in the alteration of the shape of the aperture, as he was fully aware that the frontal mirror used for laryngeal examinations had been made in this way for several years. Whilst speaking of mirrors I may mention that all which are intended for aural or laryngeal use should have a perforation in the glass as well as in the metal back.

FIG. 25.

GARDINER BROWN'S REFLECTOR.

Some mirrors of Continental manufacture are still made with only a perforation in the metal back, the reflecting composition being scraped off the back of the glass to a corresponding extent to allow for vision. The objection to this mode of construction is obvious.

Having thrown a strong light into the meatus, the surgeon

FIG. 26.

CROCODILE-MOUTHED FORCEPS.

should take the auricle between his thumb and forefinger and draw it upwards, backwards, and a little outwards, so as to diminish the curvature of the cartilaginous portion of the tube. The tragus should at the same time be drawn forwards. If, as often happens, particles of cerumen and epidermis or purulent secretion obstruct the view, these should be removed by means of forceps (Fig. 26).

a fenestrated scoop (Fig. 27), a little cotton wool attached to a fine probe, or by the use of the syringe. A good light is indispensable whenever the forceps or scoop is used, and if the obstructing masses be in the deep portion of the meatus, syringing is generally necessary. The proper method of using the syringe will be subsequently described.

FIG. 27.

IMRAY'S SCOOP.

Ear Specula: Brunton's Auriscope.—For the examination of the membrana tympani the best form of speculum is that which is known as Brunton's.* It consists of a plated German-silver cylinder, to one end of which an ear speculum is fitted, while at the other there is an eyepiece containing a lens. Light is admitted into the instrument by means of a funnel-shaped tube which passes into its side at a right angle, and is

FIG. 28.

BRUNTON'S SPECULUM.

reflected through the end of the speculum by a perforated mirror placed across the cylinder at an angle of 45 degrees. Although the instrument is extremely simple in its construction, and easy to use, it has, nevertheless, been employed but little until recently. At this I am not surprised, as I have examined a number of instruments by different makers, and found that it was impossible

* See *Lancet*, vol. ii. 1865, p. 617.

to get a distinct view of the tympanic membrane, in consequence of the faulty construction of the speculum. The eyepiece usually fitted so tightly into the cylinder that it could only be moved with great difficulty, and the lens had not been made to focus at any particular distance from the end of the speculum. At my request Messrs. Mayer & Meltzer now make the instrument in the following manner:—A groove, B, is cut around the centre of the eyepiece, and when this groove is on a level with the end D of the cylinder, the lens C is focussed for normal vision, three-quarters of an inch beyond the end of the speculum. As the eyepiece is inserted into the cylinder for only half its length, the remaining half A, can be pushed in until the light is focussed on the membrane, or the half of the eyepiece in the cylinder can be pulled out to the necessary degree to obtain a distinct image for an eye that is not emmetropic. The tube at the side I have had made funnel-shaped, as shown in Fig. 28, instead of being a narrow cylinder expanding externally into a trumpet-shaped orifice. It is obvious that the present shaped opening admits more light than the one which was formerly in use. The inner surface of the cylinder and speculum end may be either dull black or polished; but the portion of the cylinder between the lens and the oblique perforated mirror should always be dull black. The speculum may be used with either daylight or artificial light; but except with sunlight, or on a very bright day, the latter gives the better illumination. I always use a rack movement lamp, and place the bullseye condenser against the funnel-shaped opening, in the side of the instrument; by means of the light thus introduced into the speculum a very distinct magnified view of the membrana tympani can be obtained. The lens which is now used has a magnifying power of three diameters at its focus. Whilst the examination is being made the patient should be seated with his face turned towards the light, and if a lamp be used, the burner should be on a level with his ear. With his left hand, the surgeon draws the auricle upwards and backwards, and then passes the speculum slowly, and with the utmost gentleness, into the meatus, keeping the tube of the instrument against the roof of the canal. If the inward movement of the speculum be impeded, or if pain be caused, the tube should be slightly withdrawn, and the wall of the meatus examined. It will, perhaps, be found that a smaller speculum is necessary. Three specula of different sizes are supplied with each

instrument, and for examining the membrana tympani it is well to use the largest speculum that can be introduced without difficulty.

The objection has been raised that Brunton's speculum is suitable only for purposes of diagnosis and not for manipulation or operation. But for diagnostic purposes it is surely no small advantage to obtain the best possible view of the object to be examined, and if lesions be detected requiring operations of any kind, an ordinary form of speculum can be employed. In such a case, however, the previous inspection of the parts through a magnifying lens is a decided gain. Brunton's speculum helps to make diagnosis more easy and more accurate; it is of course somewhat more expensive than a set of simple specula, but the difference

FIG. 29.

DALBY'S SPECULUM.

in price scarcely amounts to a drawback. Politzer* remarks that this (Brunton's) speculum is more troublesome to use than the ordinary form on account of the difficulty of concentrating the light upon the membrana tympani. Any difficulty of this kind is, however, soon mastered by a little practice in the use of the instrument. With regard to all specula, it must be remembered that their introduction sometimes causes a troublesome reflex cough, owing to irritation of the auricular branch of the pneumogastric nerve.

The more simple forms of Specula are too well known to require minute description. Different surgeons hold different opinions as to the most convenient shape, some preferring a

* *Lehrbuch der Ohrenheilkunde*, zweite Aufl., S. 57.

funnel-shaped tube, and others a somewhat conical form. Then, again, vulcanite specula have their advocates, while silver or plated instruments are preferred by some authorities. The kind of speculum which he has often used is apt to be regarded by the surgeon as the most convenient and the best adapted to its purpose. The speculum which I use for operative work is Dalby's, Fig. 29, and I have had it made $1\frac{3}{4}$ inches in diameter, which is rather wider than its original size. Metallic specula are less liable to be damaged; but the black internal surface of the vulcanite instrument serves to render the membrana tympani more distinct by contrast with the dark margin that surrounds it. By reflecting the light, metallic specula help to illuminate the membrane and meatus; sometimes the view is rendered indistinct by such reflection. Vulcanite instruments have the advantage of being lighter and warmer, and their introduction is therefore less unpleasant to patients.

Specula are usually made in four sizes adapted to the varying calibres of the meatus in different persons. When a metallic instrument is used, care should be taken that the edge of the tube introduced into the canal is rounded off and blunt, for if it be very thin and sharp, it is apt to scrape or cut the skin of the meatus, and cause bleeding and pain. The bivalve speculum, formerly much employed, has no advantages to recommend it. It is my habit to warm a metallic speculum before introducing it into the meatus.

Introduction of ordinary Speculum.—If the ordinary instrument be preferred, it should be employed in the following manner. When there is sufficient daylight, the patient should be seated near a window, with the ear about to be examined turned away from the light and directed slightly upwards. The surgeon should also be seated, so that he can look directly into the patient's ear. When a lamp is requisite, it should be placed a little behind the patient's head, and so arranged that the light may fall upon the mirror at an angle of 45° , and thence be reflected into the meatus. The auricle is then taken between the index and middle finger of the left hand, and drawn upwards, backwards, and outwards, and examined with the aid of the mirror. If the meatus be free from obstruction, the examiner takes the speculum between the thumb and first two fingers of the right hand and passes it gently and with a slight rotatory movement into the meatus, keeping the

instrument against the upper wall of the canal. The thumb of the left hand keeps the speculum in position, while the surgeon takes the mirror, brings it to within five or six inches of the patient's ear, and looks through the opening in the glass. By causing the right and left hands to work together, the one moving the mirror and the other the speculum, the membrana tympani is brought fully into view. It must be remembered that the size and curvature of the meatus vary in different individuals, and that it is sometimes impossible to gain a view of more than a portion of the membrana tympani. In some persons, the anterior wall projects considerably, and obstructs the view of the anterior and lower portion of the membrane. In such a case the smallest speculum should be employed and carefully moved in different directions.

Parts to be examined—the Auricle, Meatus, and Membrana Tympani.—The following are the points to be noticed in examining the external ear and the membrana tympani: the state of the auricle and the surrounding parts, especially of the mastoid region and of the tissues in front of the tragus and below the lobule. Next comes the external auditory canal, its calibre, direction, condition of its wall, presence or absence of cerumen, epithelial debris, and of foreign bodies. When the membrana tympani comes into view, its position, direction, colour, degree of transparency, form, size, curves, and the degree in which it reflects the light are the first points to be observed. The normal membrane has a polished and shining appearance, and a pearl-grey, or neutral grey colour, to which a slight brownish yellow tinge is sometimes superadded. The kind of light employed tends to modify the colour of the membrane; artificial light gives it a reddish yellow tint. In children, the membrane is often dull and somewhat opaque, owing to the thickness of the outer layer. But the latter may be very thin and delicate, in which case the membrane will be remarkably transparent, so that the promontory on the inner wall of the tympanum will be seen through it. In adults, the grey colour is most decided in the anterior portion, in front of the handle of the malleus, and less marked in the posterior portion. In old age the membrane often loses its lustre and assumes a dull, uniformly grey tint.

Near the upper part of the circumference of the membrane is a small prominence caused by the short process of the malleus,

which appears as a yellowish-white knob, projecting into the meatus. From this process, a yellowish-white streak or ridge, due to the attachment of the handle, runs downwards, backwards, and slightly inwards, and terminates in a rounded or flattened extremity in the lower half of the membrane. This extremity corresponds with the umbo of the membrane, and from it the so-called "cone of light" extends downwards and forwards almost to the periphery. At the umbo the membrane is decidedly opaque; according to Politzer, this appearance is due mainly to the deposit of small cartilaginous cells round the inferior extremity of the handle of the malleus. The yellowish-white knob, with the streak running downwards, the umbo, and the cone of light are the most prominent features connected with the *membrana tympani*; in some cases other structures contained within the tympanum come into view. Thus, the long process of the incus may appear through the membrane as a whitish streak, running behind the handle of the malleus; with increased concavity of the membrane, the *chorda tympani* may become visible, and sometimes the *fenestra rotunda* appears as a dark spot in the inferior and posterior portion. Extending from the short process of the malleus are two folds, one larger and more distinct, passing backwards, and the other forwards to the periphery. These folds form the lower boundary of the *membrana flaccida*.

The cone of light has been already referred to in the account of the anatomy of the tympanum. It requires a somewhat minute description, inasmuch as it is subject to many variations, under both normal and pathological conditions. This "cone" or bright spot is triangular in shape; the apex commencing below and in front of the umbo, while the base is close to the periphery. Over this triangular spot, the ordinary lustre of the membrane is seen to be exaggerated, the difference varying in degree according to the condition of the membrane, its inclination and curvature, and the permeability of the Eustachian tube. Sometimes the brightness is interrupted by an opaque streak, running either longitudinally or in the opposite direction; sometimes the brightness is confined to the more central portion, and is indiscernible elsewhere.

Politzer has shown that the cone of light is due to the inclination of the membrane to the axis of the meatus and to the concavity produced by the traction of the handle of the malleus.

When examined with the speculum and mirror, the anterior portion is opposite to the eye, and directly reflects the light thrown upon it. The portion in which the bright spot appears forms an angle of 45° with a vertical plane and of 10° with a horizontal one. When air is forced into the tympanum the cone is more clearly seen; on the other hand, the brightness diminishes when the membrane is drawn inwards. Hence a change in the appearance of the cone is a sign of the permeability of the Eustachian tube; but the latter condition may exist in the absence of any visible alteration.

Mobility of the Membrana Tympani; Siegle's Speculum.—It is often important to determine the mobility of the membrana tympani, and for this purpose Siegle's pneumatic speculum

FIG. 30.

SIEGLE'S PNEUMATIC SPECULUM.

is employed. This instrument (Fig. 30) has its wide extremity closed by means of a thin plate of glass, inserted at an angle of 45° . Near the glass plate a small nipple projects from the side, and over this an india-rubber tube, connected with a bag at its other extremity, is closely fitted. In order that the speculum should fit closely into the external meatus, a piece of india-rubber tubing is fastened around it. To examine the membrane, the speculum is passed into the meatus and held firmly with the left hand. Light is then thrown upon the membrana tympani by means of the concave mirror attached to the forehead, while the air in the meatus is alternately condensed and rarefied, by compressing and releasing the ball with the right hand. Care should be taken to pass the speculum into the osseous portion of

the meatus, for the walls of the cartilaginous part would be drawn inwards by the expansion of the ball, and would obstruct the view. Before introducing the instrument, the ball should be partially emptied of air. In order to obtain an enlarged view of the membrane, a lens may be substituted for the plate of glass closing the wide extremity, or may be inserted into the tube.

Under normal conditions, when air is injected by compressing the bag, the membrane is observed to move inwards, and the cone of light becomes smaller and less conspicuous. When the bag is allowed to expand, the membrane moves in the opposite direction, and the cone becomes brighter and more prominent. Siegle's method is especially valuable in cases in which the Eustachian tube is obstructed. It enables the surgeon to determine whether the membrane is adherent to the inner wall of the tympanum, and to estimate the degree of mobility of the handle of the malleus. As a result of adhesive inflammation of the tympanum, the articulation between the malleus and the incus is liable to become ankylosed, and the mobility of the membrane and of the chain of bones is thereby considerably impaired.

For the accurate description and record of changes observed, the *membrana tympani* may be conveniently divided into segments and quadrants. The following divisions are suggested by Urbantschitsch:—A line corresponding with the handle of the malleus is extended to the periphery, thus dividing the membrane into an anterior and posterior portion. Another line, at right angles to the first and dividing it into two equal parts, will mark off an upper and a lower segment. The membrane is thus divided into quadrants, two of which (upper and lower) are anterior and two posterior. The cone of light is in the anterior inferior quadrant; the vertical process of the incus is sometimes visible in the posterior superior quadrant.

DETERMINATION OF THE HEARING POWER.

In order to ascertain the amount of hearing-power, three tests are usually adopted, viz., (1) simple sounds, such as the tick of a watch, or those emitted by some specially constructed instrument; (2) ordinary conversation and certain modifications; and (3) the tuning-fork. These tests are admittedly imperfect; they do not measure the precise amount of functional disorder, but they are of

great practical value in many cases. Moreover, the statements of patients when these tests are employed are more to be depended upon and can be more easily checked than their description of sensations. In testing the sharpness of hearing for any special sound, *e.g.*, the ticking of a watch, it is necessary to use the same instrument again and again under precisely similar conditions before arriving at a positive conclusion.

The watch is the most convenient instrument for testing the hearing power, but it yields only two not very definite sounds. It is, however, easily handled, and the sounds themselves emitted by any one watch are of almost constant intensity; as a general rule, after winding-up the tick is somewhat louder than before. Different watches vary in the sounds they emit, and for testing purposes one having a sharp distinct sound should always be chosen. It should first be tested on an ear presumed to be normal, in order to ascertain the most distant point at which the sounds are audible. A stop-watch is particularly useful; it enables the surgeon to test the accuracy of the patient's statements.

The method of using the watch is as follows:—The patient is directed to shut his eyes, or to hold up a piece of paper or a fan to prevent the watch from being seen, and to close with the finger the meatus of the ear which is not being tested; the watch is then held at the extreme distance at which its sounds can be perceived by a person with good hearing-power, and gradually brought nearer to the patient, who is asked from time to time whether he hears the sound. When the reply is in the affirmative, in order to see whether the patient adheres to his first statement, the watch is moved again towards the ear from a distance, the position at which its tick was heard being marked by the forefinger of the hand not holding the watch, being held in that place. This procedure should be repeated several times, the patient's eyes being of course kept closed. It is unadvisable to begin the examination by placing the watch so close to the ear that its sound can be perceived; the auditory nerve once excited by a distinct sound is more readily affected by it for some little time afterwards. If, therefore, the examination be commenced with the watch held close to the ear, the patient is likely to be credited with more hearing-power than he really possesses.

The distance at which the watch is heard should be accurately

measured and noted down for future guidance. A useful formula for registering the hearing-power has been suggested by Dr. J. S. Prout,* Surgeon to the Brooklyn Eye and Ear Hospital. The hearing-power he records "as a fraction, the numerator of which is the distance at which the particular sound is heard, the denominator the distance at which it should be heard by an ear of good average hearing power." The denominator varies according to the watch or other instrument used, and is expressed in inches. Thus, supposing that a given watch can be heard by a normal ear at thirty-six inches distance, and by the ear of a patient under

FIG. 31.

POLITZER'S ACOUMETER.

examination at only six inches, his hearing-power would be expressed by the fraction $\frac{6}{36}$. If the patient hears the watch only when in *contact* with the ear, the formula $\frac{e}{36}$ may be employed, and if not at all $\frac{0}{36}$.

Poltzer's Hörmesser, or Acoumeter.—The fact has been already alluded to that different watches vary considerably in the pitch and intensity of their sounds, and to get rid of these imperfections Politzer† has invented an instrument termed a *hörmesser* or acoumeter. This instrument consists of a horizontal steel

* *Boston Med. and Surg. Journal*, Feb. 29, 1872.

† Politzer, *Lehrbuch der Ohrenheilkunde*, Aufl. II., S. 106.

cylinder (*c*) rather more than an inch long, and one-fifth of an inch thick, firmly connected by means of a screw with a perpendicular rod made of vulcanite (*h f*). Above the place where the cylinder is attached, a percussion hammer (*k e*) is fastened; this latter is movable upon its axis, and produces the sound by falling upon the steel cylinder. The intensity of the sound depends upon the height from which the percussion hammer falls; and in order that this height should be the same in all instruments, a small piece of vulcanite (*d*), furnished with a soft india-rubber plate, is attached to the posterior periphery of the rod as a check upon which the posterior short arm of the percussion hammer is pressed down with the middle finger. At the upper and lower extremity of the rod is a flat semi-circle (*b a*), adapted to receive the forefinger and thumb by which the instrument is held. Below the upper semi-circle is an india-rubber rod, 4cm. ($1\frac{3}{8}$ inch.) long, and terminating in a circular metal plate (*i*). This last contrivance is for testing the perception through the cranial bones, for which purpose the meatuses are closed, and the metal plate is brought into contact with the temple or the mastoid process. In the same manner, in cases in which the sound of the instrument is not heard at the shortest distance from the ear, the round metal plate is made to touch the orifice of the external meatus, in order to discover whether the sound is then perceived.

The sound produced when the hammer strikes the cylinder corresponds with the note c^2 (= 528 vibrations), and may be compared with the ticking of a loud watch. In using the acoumeter, attention must be paid to the position in which it is held, and the direction in which the sounds strike the ear. As a general rule, the sounds are heard more distinctly, and at a greater distance, when the instrument is held somewhat in front of the ear than when it is placed in a line with the meatus. When the hearing power is to be tested, the acoumeter is taken between the forefinger and thumb of the right hand, and the middle finger presses down the short arm of the lever, and thus raises the percussion hammer. Removal of the finger allows the hammer to fall upon the steel cylinder, and a sharp click is thus produced. The patient's eyes should be closed while the instrument is tried at gradually lessening distances until its sound is heard. Each ear must be separately tested, the opposite meatus being closed by the finger while the examination is going on.

Politzer states that the average normal hearing distance for his acoumeter is about sixteen yards, and that several advantages are connected with the use of the instrument. By reason of the greater intensity of its sound, the results obtained admit of a more definite comparison with the results of whispered speech than is the case when the watch is used; and therefore that when the hearing distance for the acoumeter is increased in any given case, a corresponding increase in the hearing distance for speech can be more surely inferred to exist. If the instruments are constructed exactly according to directions, a uniform sound is always produced. Moreover, the sounds can be made to follow each other rapidly or slowly, regularly or irregularly, as the surgeon chooses, and by making the patient count the clicks, his statements as to his hearing-power can be easily tested.

In estimating the results of examinations with the view to test the sharpness of hearing, it must be remembered that in this latter respect considerable differences are liable to exist in the same patient on different days, and also at different times of the same day. Hearing power is also influenced by the temperature and moisture of the air, and by various bodily and mental conditions. It is usually better when the weather is warm, dry and still, and when the patient's general health is good, than under opposite conditions.

Hughes' Sonometer is another instrument by means of which the hearing power can be tested, and variations while under treatment accurately estimated. It consists of two Leclanché cells, and an arrangement whereby the current can be rapidly interrupted. There is a rectangular bar, about 25cm. in length (10 inches), and divided into centimetres and millimetres, and along this slides a reel wound round with insulated copper wire. At each end of the bar is another reel also carrying wire, but firmly fixed, and these wires are connected with the Leclanché cells. The ends of the wire on the movable coil pass through the base of the instrument to terminals, and thence to a telephone which is applied to the patient's ear. When the movable coil is placed at zero, no sound is heard; but as it is slid along the bar towards the fixed coil on the left hand, the interruptions in the current produced by the microphone are heard in the telephone. When the instrument is used, the telephone is applied to the patient's ear and the coil placed at zero. It is then gradually slid

along the bar, until the patient states that he hears the sound. The distance from zero in millimetres is then noted, and the other ear is similarly tested. The value of this instrument consists in the facility with which variations in hearing-power can be detected, so far, at least, as its sound is concerned. But it must be remembered that an improvement demonstrated by this instrument does not necessarily imply any corresponding variation in hearing-power as regards speech.

Testing with High Notes, Galton's Whistle.—It is sometimes desirable to test the hearing power for very high notes. This varies considerably in different persons, and is generally much diminished in advanced life. Galton's whistle (Fig. 32) is a convenient instrument for measuring the upper limits of auditory perception. It consists of a brass tube, with a diameter of less than $\frac{1}{10}$ of an inch. The lower end is fitted with a plug, whereby the tube can be lengthened or shortened, and the pitch of the

FIG. 32.

GALTON'S WHISTLE.

note correspondingly changed. Galton's whistle has a compass of more than the three highest octaves, and its notes correspond to 6,461–84,000 simple vibrations in a second. It is very difficult to test unilateral impairment of hearing by its means, inasmuch as its sounds are heard by the normal ear even when the meatus is thoroughly closed.

With regard to the alterations in the hearing-powers for high and low notes, it may be stated in general terms that in affections of the middle ear the perception of high notes is less interfered with, while that of low notes is apt to be retained in disorders of the internal ear. There are, however, frequent exceptions to this rule. As pointed out by Politzer, very high notes are often distinctly perceived in cases of severe disorder of the labyrinth, while low notes may be distinctly heard when there is considerable interference with sound-conduction. Diminished perception of high notes is not a positive indication of disorder of the nervous

apparatus, for it often accompanies general impairment of hearing in cases of adhesive affections of the middle ear.

Speech is the most important test of hearing power. The human voice is capable of exhibiting great variations in pitch, intensity, and quality. Moreover, deaf persons most frequently seek advice because they are unable to hear what other people say, and the removal of this disability is the object of their desire. There is another advantage in the use of speech as a test. When the patient states that he can hear words uttered to him, the accuracy of his statement can easily be tested by causing him to repeat them.

In testing by means of speech, the patient should be placed at a distance of several yards from the examiner; his eyes should be closed, and the opposite ear should be carefully stopped with a moistened finger. It is very important that the patient should not see the lips of the speaker, inasmuch as deaf persons often attain great skill in the art of lip-reading. It is well to begin the examination by testing both ears together, even when the complaint is supposed to be unilateral. It must be borne in mind that great differences often exist between the hearing capacity for speech, and that for the watch and musical sounds. In one class of cases, the ticking of a watch can be heard only when the sound is produced close to the ear, whereas a whisper is audible at some yards' distance. In another class, the watch is heard at a distance, but speech only when the mouth is brought close to the auricle; and it sometimes happens, that when the impairment is bilateral, speech is heard best on one side and the ticking of a watch on the other. These varieties in the symptoms may be explained by supposing that the faculty of hearing various notes and sounds, and of distinguishing between them, is impaired or destroyed by morbid processes in various parts of the organ of hearing.

Words to be used in testing Hearing Power.—It is not a good plan to ask the patient questions, for he may hear some of the words and guess at the rest. The best mode to adopt is to pronounce single words, and to tell the patient to repeat them. The most suitable words to begin with are those which contain the soft vowels and the less pronounced consonants; and if these are not heard, others should be tried. Oscar Wolf has pointed out that the vowels possess the greatest volume of sound, for they are heard at the greatest distance, while that of consonants is

much less in degree. Wolf's investigations show the relative distances at which the vowels and consonants can be heard when loudly uttered. A (as in father) can be heard at 360 paces; O, at 350; E, at 330; U, at 280; S, at 175; R, at 90; F, at 67; T, at 63; B, at 18; and H aspirate, only at 12 paces. Owing to the great differences in the volume of sound possessed by the various letters, different words will be heard more or less clearly. As a general rule, whispered speech is the most suitable for testing the hearing; it is more likely to be uniform, and the difference between the sound of consonants and that of vowels is considerably reduced as compared with loud speech. It is not infrequently noticed that deaf people hear a moderately loud voice better than a *very* loud one; and this difference, according to Wolf, is due to the fact that in loud speech the sound of the vowels alone is intensified, while that of the consonants, which cannot be made much stronger, is quite drowned. The average hearing distance for whispered speech is about twenty-five yards.

When one ear is normal, it is difficult to gauge the amount of deafness, as even after the meatus is closed sound-waves are conducted through the bones to the healthy organ. In order to determine by which ear the sound is perceived, it is well to close, not only the one supposed to be normal, but the other which is being examined. If the sound be still perceived with the same amount of distinctness, it may be assumed that it has been heard by the normal ear; but if a difference be noticed, it is clear that the test has been applied to the affected organ.

The tuning-fork is also used as a test of the hearing power; but, as will shortly be described, this instrument constitutes the best appliance for testing the perception of sonorous undulations conducted to the ear through the cranial bones, and it is mainly employed for this purpose. When used as a *test for hearing*, the tuning-fork is caused to vibrate by striking it on the left hand or arm, or side of the knee; it is then held at varying distances from the ear. The tuning-fork generally used yields 256 double vibrations per second, and corresponds with the middle c. In testing the perceptive capacity for lower and higher notes, it is necessary to use tuning-forks of a corresponding pitch. For diagnostic purposes, Hartmann recommends six tuning-forks, corresponding with the notes c, c¹, c², c³, c⁴, and g⁴, respectively. The first of these yields 132, and the last 3168 vibrations per second. It is

desirable to ascertain, not only the distance at which the tuning-fork can be heard, but also the number of seconds during which its sound is perceived. Conta* has suggested that the handle of the fork should be connected with the patient's ear by means of an india-rubber tube, and Urbantschitsch† recommends, as a further improvement, that the tube should be T shaped. One branch is placed in the ear of the patient, and the other in that of the surgeon, who (supposing that his hearing be normal) is enabled to measure the defect by noting the time during which he hears the sound after it has ceased to be audible by the patient. If the tuning-fork be struck with great force, the duration of the vibrations will be somewhat increased; but the difference in this respect is never very great.

Bone Conduction of Sounds.—Having determined the perceptive capacity for sounds conducted by the atmosphere to the membrana tympani, and thence to the labyrinth, the degree in which sounds are transmitted through the cranial bones to the organ of hearing is the next subject for investigation. The instruments employed for testing this latter channel of conduction are the *tuning-fork*, the *watch*, and the *acoumeter*. When vibrating bodies are placed in contact with the bones of the cranium, the vibrations reach the labyrinth by two routes—viz., by direct conduction by the solid parts, and by transmission through the bones of the head to the membrana tympani and ossicles, and thence to the sentient structures of the internal ear. Conduction through the bones is, however, far less effective than conduction by the atmosphere to the external auditory meatus. If a vibrating tuning-fork be kept on the vertex until its sound is no longer heard, its tone again becomes audible when it is brought near the ear.

The tuning-fork is the most convenient and important instrument for testing the conduction of sound through the bones of the head. Weber's experiment is utilised for purposes of diagnosis. When a vibrating tuning-fork is placed on the vertex, or in contact with the middle incisors, and the meatus on one side is closed with the finger, the sound is perceived with exaggerated intensity by the occluded ear; if both openings are closed, there is an increase of sound in both ears. A similar exaggeration of

* *Arch. f. Ohr.*, Bd. I., S. 107.

† *Lehrbuch der Ohrenheilkunde*, S. 37.

intensity is found to exist in affections involving one ear, and interfering with the conduction of sound to the labyrinth. Such interference may be due to disorder situated either in the external or middle ear, and exaggerated intensity will be noticed in both cases, provided that the sentient apparatus be in a normal condition. If disease exist in the sound-conducting apparatus on both sides, but in unequal degrees, the exaggeration will in most cases be especially pronounced in the more seriously affected ear. On the other hand, in partial deafness due to affections of the auditory nerve, supposing that the sound-conducting apparatus be not implicated, a tuning-fork placed between the incisor teeth or on the vertex will be best heard by the non-affected ear.

In testing bone conduction, it is well to be provided with tuning-forks of various forms and sizes, and with corresponding differences in the intensity and pitch of the notes. Large tuning-forks, yielding middle and low notes, are the most useful; but it is also necessary to test the perception of high notes. Of those recommended by Hartmann, three are mentioned by Politzer as sufficient for all practical purposes. These yield the notes c (128 vibrations), c^2 (512), and c^4 (2,048) respectively. When a tuning-fork is caused to sound, over-tones are heard in addition to the fundamental note. High over-tones are discordant with each other, but are continuous and of equal intensity with the primary note. Hence it is that some confusion may arise in using the tuning-fork as a test for hearing if, as sometimes happens, the note be perceived by one ear and the over-tones by the other. To remove this source of error, Politzer recommends that each prong of the fork should be furnished with a movable brass clamp, capable of being tightly fixed by means of a screw. These clamps prevent, to a great extent, the addition of over-tones, and they have also another effect—viz., that of lowering the fundamental note. By moving the clamps the pitch of the note is changed; it becomes higher when they are moved gradually downwards, and lower when they are pushed upwards. The degree of difference in the pitch is also influenced by the weight of the clamps; the highest note is the fundamental sound of the tuning-fork, the lowest depends upon the weight of the clamps, as well as upon their position. Politzer* now recommends tuning-forks without clamps, but “having the prongs filed

* Translation of Third Edition, p. 132.

down near the place where they bend thinner than at their extremity. In these tuning-forks, when struck on some soft substance, there are no over-tones perceptible."

In using the tuning-fork for testing bone conduction, the instrument is struck against the hand or side of the knee, and the end of its handle is then applied to the vertex, or placed between the middle incisor teeth in the upper jaw. In a case of one-sided deafness, the discovery that the note is more distinctly heard on the affected side shows that the impairment is due to some impediment to the conduction of sound through the meatus. If the sound be more clearly heard by the normal ear, or on the least affected side in bilateral deafness, the diagnosis cannot be made with

FIG. 33.

GARDINER BROWN'S TUNING-FORK, FITTED WITH TUBE AND EARPiece,
AS USED BY THE AUTHOR.

an equal degree of certainty, for there may be either some affection of the middle ear, or some disorder of the labyrinth. If the functions of both auditory nerves are impaired, the tuning-fork on the vertex will be heard less distinctly in both ears, and in severe lesions will not be heard at all. When the perceptive capacity of the nerve on each side is the object to be determined, the tuning-fork should be applied to the temple or to the mastoid process, and the surgeon may estimate the patient's hearing-power by comparing it with his own, assuming that his auditory nerves are in a normal state. The usual plan is that the surgeon transfers the tuning-fork to his own mastoid process immediately the patient signifies that he fails to hear the sound. If it be still perceived by

the surgeon, it may be inferred that the auditory nerve of the patient is not in a normal condition. Some few seconds are, however, lost in transferring the instrument, and in order to obtain a more exact comparison, the author has for some years used a tuning-fork (Fig. 33) with a small projection attached to its stem, to which is fixed a piece of india-rubber tubing about two feet in length, having an ivory earpiece at its other end. By placing the ear-piece in his own ear, and the handle of the instrument to the mastoid process of the patient, the number of seconds during which vibrations can be heard after the patient has ceased to hear them, may be taken to indicate the degree of his bone conduction below the normal standard. An hyperæsthetic condition of the auditory nerve can also be detected by this means.

Application of Rinne's Test, Positive and Negative Results.—

Reference has been already made to another experiment devised by Rinne, in 1855, and utilised for purposes of diagnosis. He found that if a vibrating tuning-fork were held against the incisor teeth until its sound was no longer heard, it again became audible when the instrument was placed near the external meatus. Conduction through the latter is therefore more complete and effective than through the bones of the head. When in any given case the result is as above described—that is, when the tuning-fork is heard near the ear after it has ceased to be perceived through the bones—the test is said to be “positive.” When, however, the note is heard more distinctly and for a longer time through the cranial bones, the result is described as “negative” in character. This experiment offers a means of distinguishing between affections of the middle ear and disorders of the auditory nerve; but in order that a true inference may be drawn, it requires to be considered in connection with the degree of deafness as regards speech and with altered perceptive capacity for various notes.

According to Politzer, Rinne's test is of especial diagnostic value in cases of chronic middle-ear disorders, the nature of which cannot be clearly determined by other means. In such cases a “negative” result may be taken as indicative of some obstacle to sound-conduction, and the longer the tuning-fork can be heard through the bones as compared with aerial conduction the greater the probability that the diagnosis is correct. If the hearing-power be much impaired and Rinne's test give a “positive” result,

disorder of the nerve may be assumed to exist, but only when other symptoms and the history of the case point in the same direction. In employing this test, the vibrating tuning-fork should first be placed on the mastoid process, and subsequently in front of the ear; the difference in favour of aërial conduction should be noted in seconds. In the negative test the procedure is reversed, the fork is held in front of the ear till no longer audible, and then placed on the mastoid process.

Gruber's Modification.—Gruber* has suggested the following modification of Rinne's test. After the sound of a vibrating tuning-fork held in front of the meatus has ceased to be heard, the forefinger of the other hand is placed in the opening, and the handle of the fork brought into contact with it. The sound will again be perceived, and will continue for some little time. The explanation as given by Gruber is that by closure of the meatus a column of air is formed therein, and strengthens the sound, which again becomes audible. It is also possible that the altered conditions of tension and pressure in the middle and internal ear may contribute towards the result, and also that those sonorous vibrations which were previously lost by dispersion are more effectively conducted to the cranial bones and the sentient apparatus. The test is applied as above described, and the surgeon inquires whether the sound is again heard, and notes the duration of the sensation.

Gellé's Method.—Gellé† has recently proposed a method for distinguishing between labyrinthine and middle-ear affections. He places a vibrating tuning-fork in contact with the skull, and then condenses the air in the external meatus. Under normal conditions there is a decided diminution in the intensity of the sound; but if there be any obstacle to conduction—*e.g.*, ankylosis of the stapes—no alteration is perceived. On the other hand, if there be disease of the labyrinth and free movement of the stapes, the sound will be diminished with each condensation of the air, and the patient will complain of noises in the ears and especially of giddiness. The air is condensed by means of an india-rubber bag with an attached tube, the end of which is passed into the meatus. The tube is furnished with a manometer for regulating the pressure. Politzer states that Gellé's test is of little value in

* *Monatsschrift für Ohrenheilkunde*, XIX., S. 33.

† *Précis des Maladies de l'Oreille*, p. 338, *et seq.*

slight deafness, as in slight middle-ear affections and in those of the labyrinth the sound of the tuning-fork is lessened when air is condensed in the external meatus. Gellé's test very often agrees with the result of Rinne's experiments. Politzer admits, however, that the former test sometimes yields a positive result when other tuning-fork tests give no certain indications, and that this advantage is occasionally recognised in severe grades of deafness.

A watch having a somewhat weak tick is the most suitable for testing bone conduction; it may be applied either to the temple, to the malar bone, or to the mastoid process, the meatus on the side tested being closed with the finger. At first, the watch should be lightly, and afterwards firmly, pressed against the skull. If the result in one place prove to be negative, others should be tried before deciding that the auditory nerve cannot be thus affected. If the ticks be not heard, some impairment of perceptive power may be inferred to exist, and the acoumeter should then be used. A negative result indicates the existence of grave lesion of the sentient apparatus.

It must be remembered that, as age advances, vibrations produced by instruments in contact with the cranial bones are less distinctly heard; in persons over fifty years of age it not infrequently happens that while the tick of a watch held opposite the ear is clearly perceived, bone conduction is either defective or altogether absent. In such cases, the symptom has not the same significance as it possesses in younger subjects.

CHAPTER V.

EXAMINATION OF THE NOSE, PHARYNX, AND EUSTACHIAN TUBES.

Frequent Dependence of Diseases of Middle Ear upon Morbid Processes in Pharynx and Nares—Importance of Examining these parts and Eustachian Tube—Requisites for Anterior Rhinoscopy—Parts Visible—Examination of Mouth, Fauces, and Lower Part of Pharynx—Parts Seen—Posterior Rhinoscopy—Parts brought into View—Pharyngeal Openings of the Eustachian Tubes—Digital Examination of the Naso-Pharynx—Structures Distinguishable—Examination of the Eustachian Tubes—Tests of their Permeability—Valsalva's Method—Politzer's Method—Description of Details—Modifications suggested by Lucae and Gruber—Results of Passage of Air into Tympanum—Use of Manometer—Use of Auscultation Tube—Precautions in Employing Politzer's Method—Occasional Unpleasant Symptoms—Effect Produced by Politzer's Method—The Eustachian Catheter, Forms and Description of the Instrument—Vulcanite and Silver Catheters—Bag for Injecting Air—Employment of the Auscultation Tube—Introduction of the Eustachian Catheter—Modes of Overcoming Difficulties—Use of Air-Bag—Other Methods of Introducing Catheter—Plans Recommended by Frank and Gruber—Indications that the Catheter is in Proper Position—Injection of Air—Obstacles to the Introduction of the Eustachian Catheter—Methods of Dealing with them—Emphysema sometimes Produced—Sounds Produced during Injection of Air—Causes of Absence of Sounds—Action of Stream of Compressed Air upon the Eustachian Tube and Tympanum—Removal of Exudation—Improvement of Hearing-Power—Action in Cases of Perforation of the Membrane—Comparative Value of the Various Methods of Inflating the Tympanum—Passage of Bougies along the Eustachian Tube.

DISEASES of the middle ear are often due to extension of morbid processes from the pharynx and nares, and once set up are liable to be much influenced by the course of the original disorder. Inflammation of the naso-pharyngeal mucous membrane is a potent and common cause of acute and chronic catarrhs of the tympanum, and in treating cases of these disorders, remedies are

generally required for the condition of the throat and nose. The necessity for examining these parts is therefore obvious. The Eustachian tube discharges an important function in connection with the middle ear, and it likewise furnishes a channel through which remedies can be applied to that part. The condition of the tympanum is greatly influenced by that of the tube, and hence careful examination of the latter structure is indispensable for purposes of diagnosis.

Examination of the Nasal Passages.—The nasal passages admit of examination from the front (anterior rhinoscopy) and from the pharynx (posterior rhinoscopy). The requisites for anterior rhinoscopy are a good light, either natural or artificial, a concave reflector with head-band, and specula of various forms. A double-bladed speculum is the most convenient instrument (Figs. 34 and 35), and with its aid in favourable cases it is possible to inspect a

FIG. 34.

MUNCASTER'S NASAL SPECULUM.

FIG. 35.

THUDICHUM'S NASAL SPECULUM.

large portion of the nasal passages. The parts which can thus be brought into view are the septum and the anterior extremities of the inferior and middle turbinate bodies, the lower borders of which can be traced backwards for some distance. When the patient's head is inclined forwards, the floor of the nares and the inferior meatus are exposed, and by bending the head in the opposite direction, the middle turbinate bone and sometimes the roof of the nose can be seen. When the parts are much swollen, the space between the turbinate bones and the septum may be reduced to a mere chink, and in such cases it is necessary to press back the swollen tissue by means of a probe or small spatula. The application for a few minutes of a 5 per cent. solution of cocaine will cause the swelling to diminish.

The width of the nasal passages varies considerably in different

cases; under favourable circumstances, and with the aid of a suitable speculum, some portion of the naso-pharynx can be seen from the anterior nares. Zaufal's nose-specula consist of cylindrical silver tubes, $\frac{3}{25}$ — $\frac{7}{25}$ of an inch in diameter, and 4 to 5 inches in length, and having a funnel-shaped anterior extremity. Through these specula remedies may be applied to the posterior wall of the pharynx and the mouths of the Eustachian tubes, but they are very seldom required, and their introduction is apt to cause pain and some amount of hæmorrhage, and the area exposed to view is very limited.

The Posterior Nares.—The examination of the posterior nares is accomplished by means of a small laryngeal mirror (the same that is used for the larynx), and a mirror for reflecting the light into the throat. But before examining the naso-pharynx and posterior nares, it is well to notice the condition of the mouth and fauces and lower part of the pharynx.

The Pharynx.—The pharynx can be examined either by direct light, *i.e.*, by turning the patient's face towards a window, or by placing him with his back to the light and using a concave reflector. The latter is always necessary whenever artificial light is employed. The tongue is kept against the floor of the mouth by means of a depressor or the handle of a laryngeal mirror. In order to gain as complete a view as possible of the back of the pharynx, the patient should be directed to take a full inspiration or to pronounce the letter A (as "ah"). The parts that come into view are, the concave under-surface of the velum, the uvula, the anterior and posterior pillars of the fauces, with the tonsil between them, on each side, and a portion of the posterior wall of the pharynx. Various alterations, more or less intimately connected with the condition of the tympanum, are often found in one or other of these parts. Enlargement of the tonsils is very common in children; adenoid growths from the naso-pharynx sometimes come into view, while granular pharyngitis is often present in cases of catarrhal inflammation of the middle ear. Absence of disease in the lower part of the pharynx does not justify the conclusion that the naso-pharynx is also in a normal state. The state of the teeth should be carefully noticed; severe otalgia is sometimes due to dental caries. The condition of the tonsils is a point of special importance; if these organs are enlarged in an upward direction, they are apt to keep the soft

palate in a state of tension and to obstruct the action of the muscles connected with the Eustachian tube. In some patients it is difficult to depress the tongue sufficiently to allow the pharynx to be seen. Either retching is provoked immediately the spatula touches the surface, or the tongue bulges up against the hard palate. In some of these cases it will be found that the handle of the laryngeal mirror, used as a depressor, will meet with far less resistance, and will accomplish all that is necessary; but should this method fail, a view can generally be obtained by spraying the tongue and soft palate with a 2 to 5 per cent. solution of cocaine before an attempt is made to depress the tongue.

Posterior Rhinoscopy.—Posterior rhinoscopy is effected in the

FIG. 36.

FRAENKEL'S TONGUE-DEPRESSOR.

following manner. The patient is placed in the ordinary position for laryngoscopy, but his head should be somewhat higher than that of the surgeon, and inclined slightly forwards. He is then told to open his mouth as widely as possible, and continue to breathe naturally. A mirror of small size is passed below, and partly behind the soft palate, and as far back as possible into the pharynx. In some cases, a better view is obtained if the handle of the mirror is slightly curved to fit the floor of the mouth.

Some form of tongue-depressor is occasionally necessary, and the shape of that devised by Fraenkel (Fig. 36) is the most convenient; but in some patients the tongue can be kept out of

the way with the handle of the mirror. Although the shape of Fraenkel's tongue-depressor is convenient, I consider that the fenestration and transverse grooves are not only unnecessary, but are, moreover, liable to retain impurities. I use a tongue-depressor (Fig. 37) which has been made for me by Messrs. Mayer & Meltzer, of the same shape as Fraenkel's, but without the perforation and grooves. In passing the mirror backwards care must be taken to avoid touching the palate, base of tongue, or back of pharynx, otherwise the patient will scarcely be able to prevent retching. When it has reached the naso-pharynx, the mirror should be so held that its surface looks upwards and forwards. In some cases a better view can be obtained with a

FIG. 37.

TONGUE-DEPRESSOR USED BY AUTHOR.

Michael's mirror (Fig. 38), which is fitted with a movable reflecting surface, than with an ordinary laryngeal mirror. When the soft palate and posterior wall of the pharynx are separated by only a narrow space, it may be necessary to hold the former forward by means of a palate-hook. Some patients allow this to be done without the previous use of a local anæsthetic; but, in many cases, a satisfactory view cannot be obtained until a 2 to 5 per cent. solution of cocaine has been applied to the posterior surface of the soft palate by means of a brush fixed to a handle with a short rectangular curve, or a piece of absorbent cotton-wool fixed to a holder bent in a similar manner.

The palate tractors in most general use are Voltolini's (Fig. 39), and a simple loop of stout wire curved upwards at the end.

FIG. 38.

FIG. 41.

HOPMANN'S SELF-RETAINING PALATE TRACTOR.

I generally use the latter, as it is lighter than the former, and serves very well the purpose for which it is intended.

When the throat is irritable, the tonsils large, and the space narrow between the soft palate and posterior wall of the pharynx, it is sometimes difficult to obtain a good view of the naso-pharynx and posterior part of the nostrils.

In all cases the patient should be told to expire slowly through the nose whilst the examination is being made. In order to lessen the sensitiveness of the parts, a few minutes before the examination is made, a 2 to 5 per cent. solution of cocaine may be applied by means of a brush or spray producer to the velum, pharynx, and fauces.

Parts seen in Posterior Rhinoscopy.—The parts brought into view in posterior rhinoscopy are the elliptical choanæ, with the septum between them, the extremities of the turbinate bodies, the Eustachian orifice, and Rosenmüller's fossa on each side, the pharyngeal tonsil, and the upper surface of the palate. It is necessary to turn the mirror in various directions and to place it at different angles, in order to gain successive views of the various structures, only a portion of which are visible at the same time. In favourable cases (*i.e.*, when the palate is at some distance from the wall of the pharynx), by slight movements of the mirror, the vault of the naso-pharynx, the entire circumference of the posterior nares and the posterior border of the hard palate may be brought into view. Within the choanæ are seen the *turbinated bodies* on each side, the middle one being the largest and the most conspicuous; it is bluish-red, or greyish-blue in colour. Above it is the superior meatus, at the upper part of which the *superior turbinated body* can sometimes be made out. The portion visible is about as large as a pea, and has a yellowish tint. The middle meatus, below the middle turbinate, exhibits at its lower part the posterior extremity of the *inferior turbinated body*, which resembles in appearance an over-ripe plum. It is often only partially visible, its lower half being concealed by the palate; but sometimes it is enlarged to about the size of a raspberry, in which case its posterior extremity is in close proximity to the anterior lip of the Eustachian orifice. In some cases, the middle turbinate body impinges upon the septum and extends downwards almost to the floor of the nares, and touches the lower turbinate. The choanæ are about $2\frac{1}{2}$ inches high and $\frac{3}{8}$ inch across; they are separated from each other by a thin vertical median septal membrane, prolonged backwards from the posterior edge of the vomer.

Seen in the mirror, the septum appears as a sharply-defined ridge, of a pink colour and narrower in the middle than at either extremity. It must be remembered that the nasal septum not infrequently deviates to one side. In young subjects, the upper and back part of the pharynx, from side to side, presents a large mass of lymphoid tissue, constituting the *pharyngeal tonsil*. This structure is not distinctly circumscribed; it occupies the space behind and between the Eustachian tubes on each side, and extends to the roof of the cavity as far as the choanæ (Macalister). Its tissue resembles that of the faucial tonsils; in adult subjects, it is often unrecognizable. In the middle of the naso-pharyngeal vault, the mucous membrane sometimes presents an irregular, flask-like pit, the *bursa pharyngea*, "whose opening is usually narrow and directed downwards and forwards, its wider fundus pointing upwards towards the basi-cranial foramen. It is a pouch of mucous membrane which occupies the site of the continuation upwards of the pharyngeal tube, pinched off by the in-growth of the para-chordal cartilages, and thereby separated from the pituitary body above." According to some authorities, the existence of this structure is due to pathological changes in the pharyngeal tonsil.

The Pharyngeal Openings of the Eustachian Tubes and the adjacent parts can be seen on careful examination with an ordinary laryngeal mirror. The position of the parts seen is of course changed; the cartilaginous swelling which forms the posterior lip of the orifice appears in front in the mirror, while the anterior lip is seen behind it, or farther from the eye. The long diameter of the opening, when it can be seen in the mirror, is directed from above downwards and forwards. The depression, called Rosenmüller's fossa, which is situated behind the posterior lip, appears in front of it in the mirror, and is somewhat darker in colour than the swelling which it bounds. This fossa can be best seen when the patient's head is slightly turned to the opposite side. The opening itself is in the form of a rounded triangle; the mucous membrane is lighter in colour than that of the adjacent wall of the pharynx. The posterior lip of the opening is yellowish or yellowish-red in colour. The morbid changes in the pharyngeal orifice to be looked for in diseases of the middle ear are congestion and swelling of the lips and adjacent parts, profuse catarrhal secretion; the presence of adenoid growths, ulceration

and contractions, and in the posterior part of the nostrils a polypus or enlargement of the posterior extremity of a turbinated body. In children the roof of the pharynx is a frequent seat of adenoid growths, which, as will be shown in a subsequent chapter, are often associated with diseases of the ear.

Digital examination of the naso-pharynx enables the surgeon

$\frac{1}{2}$ nat. size.

FIG. 42.

THE AUTHOR'S FINGER-GUARD.

to ascertain the size and character of morbid growths existing in that cavity. It is performed by passing the forefinger behind the soft palate. If the right hand be used the surgeon stands on that side of the patient, but if the left, on the opposite side. The surgeon's finger should be protected to prevent it from being bitten by the patient, and for this purpose the author recommends a

FIG. 43.

THE AUTHOR'S FINGER-GUARD IN POSITION.

piece of india-rubber tubing, shown at Fig. 42, which has been drawn upside down in order to exhibit the piece removed from its right surface as the hand is held in Fig. 43. The guard should be about three inches in length and not less than one-eighth of an inch in thickness, with the lower half of the anterior half-inch cut away and a **V**-shaped piece also removed from the right side to

within half an inch of its anterior extremity, to allow the tubing to be pulled over the index finger until its front edge is behind the joint between the proximal and middle phalanges. By thus covering the first phalanx, the metacarpo-phalangeal joint and the head of the metacarpal bone, the parts usually bitten, are protected, whilst the two front joints of the finger are left free. The patient should be seated, and his head steadied by the surgeon's hand. Care must be taken not to press the uvula backwards, because it is difficult to get the finger behind the soft palate when it is closely applied to the posterior wall of the pharynx, and efforts at retching are very liable to be caused. The patient's head may be moved in various directions in order to facilitate the examination of the various parts, but this is usually unnecessary. If the finger cannot be easily passed into the naso-pharynx, its tip should be placed behind the lower part of the posterior pillar of the fauces on the side on which the surgeon is standing, and slipped upwards in the space between it and the posterior wall of the pharynx. By this means it will easily pass behind the soft palate. The structures which can be distinguished by the finger are the roof of the pharynx, the mouth of the Eustachian tube on each side, the projecting posterior lip and Rosenmüller's fossa behind it; the posterior border of the nasal septum, the boundaries of the posterior nares, the extremities of the middle and inferior turbinate bones, and the upper surface of the velum.

The utmost gentleness should always be used when examining this region.

EXAMINATION OF THE EUSTACHIAN TUBES.

The permeability of the Eustachian tubes is the condition upon which the discharge of their functions depends, and it may be tested in three ways—(1) Valsalva's method of inflating the middle ear; (2) Politzer's method; (3) the employment of catheters through which air is forced into the tubes.

(1.) **Valsalva's method** of forcing air into the tympanum is as follows:—The patient takes a deep inspiration, and then makes a forcible attempt at expiration through the nose with the mouth shut and the nostrils firmly compressed with the fingers. The air is thus forced upwards from the thorax, and being unable to escape through the mouth or nose, some of it passes through the

pharyngeal openings of the Eustachian tubes, and thence to the tympana. The patient is conscious of a sensation of pressure or fulness in these parts, which, if the tubes are healthy, subsides when saliva is swallowed, and the mouths of the tubes thus opened, but if the tubes are obstructed the feeling of fulness may remain for several minutes. It is best for the surgeon to compress the nostrils himself, because by suddenly relaxing the pressure, he can judge of the amount of expiratory force which is being used. Patients often appear to be blowing hard through the nostrils, when in reality they are either not doing so at all or else only to a slight degree, their energy being entirely or principally expended in merely distending their cheeks. If the membrana tympani be examined with a speculum as the air is thus forced into the cavity, it will be seen to bulge out slightly, especially at its posterior and superior segment. The cone of light is altered in size, and may entirely disappear. On using the auscultation tube two sounds are heard; one of these is due to friction of the air against the walls of the Eustachian tube, while the other, a short sound, is produced by the air striking against the membrana tympani. Care must be taken not to mistake the sound produced by the contraction of the pharyngeal muscles for that caused by the entrance of air into the tympanum.

When the mucous membrane of the tubes is much swollen, the expiratory pressure will be insufficient to force air into the tympanum. When the membrane is perforated, the method often succeeds, and may be employed to force secretions from the middle ear; the passage of air through the perforation causes a hissing sound. Permeability of the tubes may be inferred when positive results are obtained; if no air can be forced into the tympanum, some obstacle may be presumed to exist either in the tube or some other part of the middle ear.

In many cases Valsalva's method can be very easily accomplished, and with decided improvement in the hearing-power as a result. Too frequent repetition is, however, liable to cause congestion of the head with a similar condition of the tympanum, and a permanent alteration in the natural curves of the membrane, consequent upon its having become relaxed from being too often stretched by forcible expiration. Patients should therefore be instructed as to the number of times that the method is to be practised, whenever it is prescribed as a part of treatment.

I do not agree with Roosa,* where he says, whilst speaking of Valsalva's method of inflation, "and as a means of diagnosis it is, in most cases, vastly inferior to the use of the catheter or Politzer's method."

In my opinion, it affords a means of ascertaining the degree of obstruction to the entrance of air into the Eustachian tubes, which cannot be obtained either by the use of a catheter or Politzer's inflation, and, in some cases, renders unnecessary as a test the employment of either of these methods of injecting air.

When the Eustachian tubes are in a normal condition, or when their lining membrane is not much swollen, air can be forced through them by Valsalva's method; but when this cannot be done it is evident that they are obstructed to more than a slight degree. If the patient begins by expiring gently and gradually increases the force, the degree of pressure required to send air through the tubes can be ascertained, and at the same time by placing an auscultation tube in each ear and noticing whether both tubes open simultaneously, knowledge will be gained as to whether an equal amount of obstruction exists in both tubes, and if not, which is the more affected.

Neither a slight degree nor the comparative amount of obstruction can be estimated by means of a catheter or Politzer's inflation, unless one tube is blocked to a considerable extent, and, therefore, Valsalva's method of inflation possesses advantages which cannot be claimed for either of the other methods.

(2.) **Poltzer's Method** of forcing air through the Eustachian tubes, and of thus rendering them permeable, was suggested by some experiments he made as to the fluctuations in the air-pressure in the tympanum. During the act of swallowing, the naso-pharynx is closed below by the soft palate which comes into contact with the posterior wall; and if air be at the same time injected through one nostril and the other be tightly closed, the air in the nares and naso-pharynx will be more or less condensed, and forced through the Eustachian tubes into the middle ear on each side. The mouths of the tubes are opened by the act of swallowing, which thereby facilitates the passage of the air. The instrument recommended by Politzer† is a pyriform india-rubber bag, capable of holding ten to twelve ounces, and furnished with a slightly

* *Treatise on the Diseases of the Ear*, 6th Edition, p. 77.

† *Lehrbuch der Ohrenheilkunde*, S. 94.

curved tubular vulcanite nozzle. A short piece of elastic india-rubber tubing may be inserted between the nozzle and the bag, so as to prevent injury to the mucous membrane when the bag is compressed. Politzer now recommends the india-rubber bag he uses with the Eustachian catheter, but having a piece of hard india-rubber tubing, about $1\frac{1}{4}$ inches long, adapted to the nozzle.

The author of the method thus describes its details. The patient, seated in a chair, takes a mouthful of water, which he is to swallow when directed. The surgeon stands on his right side, and introduces the nozzle of the bag into one nostril, and then compresses the alæ of the nose closely around the instrument with the left thumb and forefinger. The patient is then told to swallow the water, and at the same moment the surgeon forcibly compresses the bag with his right hand. The air in the naso-pharynx is thus condensed and driven into both tympana; at the same time, the closure effected by the soft palate is forced open, and its vibrations cause a dull gurgling sound, which may generally, if not always, be regarded as an indication of the passage of air into the middle ear. The position of the surgeon should be quite to the side of the patient, because children and even adults do not always keep the mouth firmly closed, and consequently water may be forced out of it, and over the surgeon's coat, unless he stands out of the way. With adult patients water is often unnecessary, the act of swallowing being sufficient. Löwenberg has suggested that the surgeon should compress the bag at the moment the larynx is seen to rise. In employing the method in children's cases, the instruction with regard to swallowing may be dispensed with. In young subjects the capacity of the naso-pharynx is small, and the Eustachian tubes are short, and their mouths are easily rendered patent. During crying the soft palate comes into contact with the posterior wall of the pharynx, and thus facilitates the passage of air into the tubes.

Modifications of Politzer's Method.—Other modifications of the method of closing the naso-pharynx have been suggested by various surgeons. Lucae* suggests that instead of swallowing water, the patient should be instructed to pronounce the sound "ah," and thus to cause the soft palate to be applied to the posterior wall. Gruber† recommends that the patient should be

* *Virchow's Archiv*, 1875, Bd. 64.

† *Lehrbuch der Ohrenheilkunde*, S. 222.

directed to pronounce the syllable "huck," with emphasis on the last letter. The tongue is forced backwards, and its posterior part comes into contact with the soft palate. Gruber claims that when this syllable is pronounced with emphasis, the air in the naso-pharynx is more or less condensed, and that some passes into the Eustachian tubes. In employing this modification of Politzer's method, the surgeon compresses the bag as the patient utters the sound, with which he should be made quite familiar before the operation is begun.

Phonation presents several advantages as compared with swallowing; it is more easily accomplished, and takes up less time. The tubes are not artificially dilated, and less pressure is exercised upon the structures of the middle ear. The pressure can, however, be maintained for a longer period than is the case

FIG. 44.

THE AUTHOR'S 10-OZ. AIR-BAG FOR POLITZER'S INFLATION.

when a mouthful of water is swallowed. On the other hand, the original plan is sometimes successful when Gruber's fails, and it admits of a greater degree of pressure being exercised. In many cases the utterance of a syllable fails to close the pharynx, and the soft palate is forced downwards by the condensed air before any effect has been produced upon the Eustachian tubes. In addition to this, it must be remembered that the result of swallowing, so far as the tubes are concerned, is different from that of phonation; a degree of pressure which suffices to open the tubes in Politzer's method may fail to produce any effect when Gruber's plan is adopted. On the other hand, in some cases, owing to peculiar formation of the naso-pharynx, phonation proves to be the more successful plan.

In the case of children, Hinton used frequently to inflate the

tympana by blowing through a piece of india-rubber tubing, one end of which was inserted in his mouth and the other in one of the child's nostrils.

The instrument which I usually employ for Politzer's inflation (Fig. 44) has a capacity of ten ounces, and is fitted with either an india-rubber teat or Allen's pads. (Fig. 45.) The length of the tubing between the bag and its nozzle—about sixteen inches—enables the surgeon to move his arm freely whilst compressing the bag, and prevents the possibility of injury being caused by any movement of the surgeon's hand being communicated to the patient's nose. When Politzer's method of inflation is used, the patient should always be seated, because giddiness is liable to be produced by the sudden increase of pressure of air in the tympanum.

FIG. 45.

DR. PETER ALLEN'S AIR-PADS.

Results of Passage of Air into Tympanum: Use of Manometer.

—The passage of air into the tympanum generally gives rise to a decided sensation of fulness or pressure. The membrana tympani is bulged outwards, the change in this respect being more decided than that which results from Valsalva's method. The movement of the membrane can be positively tested by the insertion of an ear-manometer into the external meatus. This little instrument consists of a small glass tube, one portion of which is straight and the other U-shaped. The latter contains a drop or two of coloured fluid, and the straight piece is fitted into an india-rubber stopper, adapted to the size of the meatus. When this manometer is inserted hermetically within the canal, and Politzer's method practised, the fluid rises in the limb of the tube with each compression of the bag.

Use of the Auscultation Tube.—If the auscultation tube be used, a gurgling sound will, of course, be heard as the water is swallowed; but, besides this, the practised ear will distinguish the friction-sound of the air passing through the tube, and the short sound caused by the movement of the membrane. When perforation exists, a hissing noise may sometimes be heard with the unaided ear.

Precautions while Employing Politzer's Method.—When the parts are in a normal condition, the air will pass into both tympanic cavities with an equal degree of force; but the existence of an obstacle on one side will render the effect more marked in the pervious tube. Politzer recommends that in such cases, and likewise in those of unequal occlusion of both ears, the meatus on the normal or on the less affected side, as the case may be, should be stopped by the finger while the air is being injected. A similar precaution must be taken in cases of unilateral perforation of the membrane; the meatus must be firmly closed on that side, so as to prevent the air from escaping. Inclination of the head to one side facilitates the entrance of air into the opposite tube; thus, if it be wished to act especially upon the left tube, the head should be inclined towards the right shoulder.

The amount of force to be employed in injecting the air varies in different cases, and must be regulated by the degree of resistance that has to be overcome. Violent injections are likely to cause unpleasant sensations; rupture of the membrana tympani has ensued in some cases. By using two, three, or four fingers, the surgeon can easily vary the force with which he compresses the bag. It is well to employ slight pressure at first, and to increase it if required.

Occasional Unpleasant Effects of Politzer's Method.—It has been stated above that the injection of air, as in Politzer's method, sometimes causes unpleasant symptoms. Headache and giddiness are occasional results; attacks of faintness and a feeling of sinking are less common. Noises in the ears are more frequently produced, and this symptom may last for some time. If much force be used, air may pass into the œsophagus, and cause nausea and various uncomfortable sensations in the stomach. These will rapidly pass off if the patient takes a few deep inspirations. Rupture of the membrana tympani is a very rare accident; the injection of air through a catheter, as well as

by Valsalva's method, has also been known to produce it. In cases in which the accident has occurred, there has generally been some morbid condition of the membrane; such as atrophy or a cicatrix, or calcareous deposits. Under such circumstances, a slight rupture of the membrane is not likely to be attended with any untoward results; on the contrary, some improvement in hearing-power is generally experienced. When a morbid condition of the membrane is known to exist, rupture may be prevented by closing the meatus with the finger when the air is injected. Politzer states that a force of three to four atmospheres is required to rupture a normal tympanic membrane; the pressure employed when his method is practised rarely exceeds half an atmosphere.

General Results of Politzer's Method.—The effect produced by injecting air by Politzer's method varies with the nature of the lesion. When there is marked deafness as a consequence of swelling and accumulation of secretion in the tympanum and abnormal tension of the membrane, the improvement after the injection is often very considerable. But when structural changes have taken place, and the development of bands of connective tissue and adhesions interferes with the movements of the ossicles and membrane, and also when the nervous structures are the seat of the lesion, little, if any, improvement can be expected from the use of Politzer's method.

The indications for the employment of Politzer's method, and a comparison of its advantages as compared with those of Valsalva's plan, and of the use of the Eustachian catheter, will be given at the end of this chapter.

(3.) **The Eustachian Catheter: Forms and Description.**—The third method of injecting air into the Eustachian tube involves the use of a catheter which is passed through the inferior meatus of the nose into the pharyngeal opening. The Eustachian catheter is made either of silver or vulcanite, and should not exceed four and a half inches in length. It presents a curve near its thinner extremity, and its outer end is funnel-shaped, for the reception of the nozzle of an india-rubber air-bag. The curved portion or beak is about an inch in length, and forms an angle of about 135° with the straight portion. (Fig. 46.) In most cases, a small-sized catheter, No. 1 (English urethral catheter gauge),

conveys the air in sufficient volume into the middle ear, and when this is the case there is no advantage in using an instrument of a larger size, which is more likely to cause discomfort during its passage through the nostrils. For patients with nostrils of normal dimensions four sizes are sufficient, viz., a long and a short No. 1, and a long and a short No. 2. The difference in the length of the curve of the long and short instruments is $\frac{1}{16}$ of an inch. It is necessary, however, for exceptional cases, to have catheters with a longer curve than a long No. 1 and long No. 2, and of smaller

FIG. 46.

No. 2 CATHETER.

diameter than a No. 1. For the latter, size No. $\frac{1}{2}$ usually does very well. At the outer end of the catheter a ring is attached to that portion of the circumference which corresponds with the curve; the ring serves to indicate the position of the beak when the catheter is introduced. Special catheters should be kept for syphilitic cases, because the disease may be conveyed from one patient to another by means of these instruments. For some years past, I have used an instrument (Fig. 47) for these cases

FIG. 47.

CATHETER WITH COPPER COLLAR.

which has a collar of copper about three-eighths of an inch in width fitted to the funnel-shaped portion. This method of marking has the advantage of being cleanly and indestructible, and readily distinguishes the catheter from those used for ordinary cases. A catheter should be kept very clean, and disinfected after use, because catarrh as well as syphilis can be communicated by means of this instrument if proper precautions are neglected. The author now always uses silver catheters, because their diameter is less than a vulcanite catheter with the same bore, and they are as well

tolerated by patients as those made of the latter substance. Vulcanite catheters are cheaper than silver ones, and by some authors are considered more easy to pass when an obstruction exists, on account of their greater elasticity. This supposed advantage, however, the author has not experienced.

Vulcanite catheters possess one advantage as compared with silver instruments: they are not affected by remedies injected through them. They are, however, more difficult to cleanse, and this drawback is one of considerable importance in view of the possibility of the syphilitic virus and catarrh being conveyed by their means. After a vulcanite catheter has been used, it should be kept in a solution of perchloride of mercury (1-1000) for some hours, and then washed in warm water. Vulcanite catheters can be bent in any direction; to soften them, they should be dipped in hot water or held over a lamp, and when the requisite curve has been given, it can be rendered permanent by dipping the instrument in cold water. Metallic catheters are best disinfected by being boiled.

To Mr. G. F. Hodgson, of Brighton, the profession is indebted for the introduction of the shortened form of catheter now in general use in this country. About twenty years ago, finding the old-fashioned catheter, which was about seven inches in length, unnecessarily long, he had a piece cut out of one of his instruments and the ends joined with a collar of metal, so that the catheter was reduced to four and a half inches in length. The shortened instrument answered so well, that Mr. Hodgson had all new ones made to its length. When one of these catheters is in position, in most cases, not only is the funnel-shaped portion projecting from the nostril, but also about the eighth of an inch of the straight portion, clearly demonstrating that the reduced length of instrument is amply sufficient. The objection to the longer form of catheter is that it cannot be held properly in position (see Fig. 52, page 119), and, at the same time, the nozzle of the air-bag be securely kept in the funnel-shaped orifice whilst the injection of air is being made, unless the surgeon's fingers are unusually long.

Bags for Injecting Air.—For injecting air into the catheter, Politzer's india-rubber bag may be employed, but I prefer a bag (Fig. 48) fitted at one end with a valve (*a*), and at the other with a piece of tubing about fifteen inches in length, which has attached to its other end a vulcanite nozzle (*e*) made to fit accurately the

funnel-shaped end of the catheter. Immediately in front of the bag is a piece of leather (*c*), through which is passed a loop of silk (*d*) for suspending the bag to a button on the surgeon's coat, and it will be found best to attach it to one of the upper buttons, because when so suspended there is less probability of its dragging on the catheter than if it is fastened to one of the lower buttons. It is important that the bag should be suspended by its anterior part; because with this arrangement, if the bag be dropped, its weight falls upon the suspender and not upon the catheter, whereas if the bag is attached behind, any sudden movement will be communicated to the catheter. If Politzer's air-bag is employed, a piece of india-rubber tubing, several inches in length, should

FIG. 48.

INDIA-RUBBER BAG FOR INJECTING AIR THROUGH A CATHETER.

always be used to connect its nozzle with the catheter; this addition prevents pain being caused to the patient and possible injury to the mucous membrane by the movement of the bag being communicated to the catheter when the air is injected.

The Use of the Auscultation Tube, sometimes called Otoscope or Diagnostic Tube, enables the surgeon to ascertain whether the injected air passes along the Eustachian tube. This instrument (Fig. 49) consists of a piece of india-rubber tubing about thirty inches long, furnished at each end with an ear-piece made of a hollow piece of ivory or vulcanite, one to be introduced into the meatus of the patient and the other into that of the surgeon. Care must be taken that the auscultation

tube hangs freely, and is not compressed or bent at a sharp angle. The ear-pieces should be of such a size that they fit comfortably into the meatus, and it is well to have one made of ivory (*a*), and the other of vulcanite (*b*), to enable the surgeon to distinguish them, and keep one for his own use.

Introduction of the Eustachian Catheter.—For this procedure the patient should always be *seated*, with his head resting against the back of the chair, or a rest if one is provided, and the surgeon should always *stand* on the patient's right side. The chair (Fig. 50) is very convenient for this purpose: the head-rest (*e*) made by Messrs. Ash is easily adjusted to any position by the handle (*d*), and can be slipped either forwards or backwards

FIG. 49.

AUSCULTATION TUBE.

along the rod (*c*). Its height is regulated by the rod (*a*), which is secured by the handle (*b*).

The movable table (*f*) attached to the arm carries any instrument which may be required, and the clips fixed to it securely hold the stem of a glass, when fluid injections are required, and prevent the vessel being overturned. Before attempting to pass an Eustachian catheter, the auscultation tube should be placed in the patient's and the surgeon's ear, and the air-bag should be suspended from a button on the surgeon's coat. The tip of the nose should then be gently raised by the left thumb, whilst the hand is steadied by the fingers being rested on the patient's forehead. The catheter selected should be held very lightly in a vertical position by its

larger end, between the thumb and the first and second fingers of the right hand, with the beak uppermost, and directed towards the nostril into which it is about to be inserted. Care must be taken to keep the beak against the floor of the nose, otherwise it is apt to get into the middle meatus. To ensure this, the right

FIG. 50.

THE AUTHOR'S REVOLVING CHAIR.

hand should be raised as the catheter passes into the nostril, until finally the instrument is in a horizontal position. As soon as the beak is felt to touch the posterior wall of the naso-pharynx, it should be withdrawn half an inch, and turned outwards and slightly upwards, when it will be found to be in the orifice of the

Eustachian tube. The precise distance which the catheter must be withdrawn necessarily depends upon the antero-posterior dimensions of the naso-pharynx, but about half an inch is usually sufficient. The above and the following detailed methods for finding the orifice of the Eustachian tube are only of service to those who are unaccustomed to pass a catheter. After a little practice the beak of the instrument can be turned directly into the orifice of the Eustachian tube, without previous contact with the walls of the naso-pharynx. If the catheter is drawn backwards by muscular contraction, when the beak is turned outwards in the naso-pharynx, it is an indication that it is in the fossa of Rosenmüller. As soon as the beak of the catheter is in the Eustachian orifice, the third and fourth fingers of the left hand should be

FIG. 51.

CATHETER IN POSITION.

- 1, posterior ethmoid cells; 2, sphenoidal sinus; 3, anterior ethmoid cells; 4, frontal sinus;
5, entrance to maxillary sinus; 6, inferior meatus; 7, nasal duct; 8, Eustachian tube.

placed one on each side of the patient's nose, the palm of the hand being downwards and forwards (Fig. 52), and the outer end of the instrument grasped between the thumb and index finger. The nozzle of the air-bag should now be introduced into the funnel-shaped orifice, and the thumb and index finger of the left hand slipped forward to hold it in that position, the second finger supporting the catheter whilst this is being done. Air is then injected into the tympanum by compressing the air-bag.

The advantage of the method above described for holding the catheter in position, whilst air or fluid is being injected into the middle ear, is that the relative position of the surgeon's hand and the catheter with the patient's face remains unaltered if the patient moves his head; whereas, if the catheter is merely steadied by the

surgeon resting his fingers against the patient's nose or forehead, it is pressed into the tissues, and causes pain if the patient moves his head, because by so doing he alters the relative position of his face, and the surgeon's hand holding the catheter. When the beak of the catheter is thought to be in the orifice of the Eustachian tube, and the nozzle of the air-bag has been inserted into the funnel-shaped end, the bag should be compressed at first only gently, whilst the sound produced by the air is listened to by means of the auscultation tube, in order to ascertain whether the

FIG. 52.

SHOWING POSITION OF THE THIRD AND FOURTH FINGERS OF THE LEFT HAND WHILST A CATHETER IS BEING USED.

position of the catheter is correct. As soon as that is found to be the case, air may be more forcibly injected into the middle ear. If an india-rubber bag which is not provided with a valve for refilling it is used for injecting air, its nozzle must be withdrawn from the catheter before it is refilled by taking off the pressure. Unless this is done, secretion from the naso-pharynx will be drawn into the instrument as it expands, and may block up its opening. Compression of the bag should, therefore, be kept up until it is removed from the catheter. When distended with air, the bag is

replaced and again compressed, and these manipulations may be repeated four or five times, or more often if necessary. In the withdrawal of the catheter, the beak should be turned downwards and kept close to the floor of the nares. To prevent the tickling which the passage of the catheter is apt to produce, a 2 per cent. solution of cocaine may be injected into the nostrils. Finding that the metal cocaine spray producer in general use imparted a metallic taste to the solution, I requested Messrs. Mayer & Meltzer to make a fine spray producer in vulcanite, and after a little difficulty, they supplied me with the instrument shown at Fig. 53, which works very well. Messrs. Mayer & Meltzer have also made for me in vulcanite a spray producer with laryngeal bend for anæsthetising the larynx and lower part of pharynx.

FIG. 53.

VULCANITE COCAINE SPRAY PRODUCERS.

A brief reference may be made to other methods of introducing the Eustachian catheter. These are somewhat numerous, and it is only necessary to mention those which are likely to prove useful. Frank's method is convenient, inasmuch as the posterior border of the nasal septum is used as a guide in its performance. The catheter is introduced as before, with the point in contact with the floor of the nares. When the posterior pharyngeal wall is reached, the instrument is turned so that its extremity, as shown by the position of the ring, points towards the *opposite* side; it is then withdrawn until the beak is arrested by the nasal septum. The instrument is then steadied between the thumb and forefinger of the left hand, and turned upon its long axis through half a

circle, with the apex downwards. At the completion of this manipulation, the point of the catheter will be directed horizontally towards the pharyngeal opening of the Eustachian tube.

Gruber's Method.—In the method recommended by Gruber, the catheter is passed along the floor of the nares, as above described, until the posterior wall of the pharynx is reached. It is then withdrawn until it touches the posterior border of the hard palate. Care must be taken not to draw the catheter back into the nostril; to prevent it going too far, its outer end must be somewhat raised. The pharyngeal opening of the tube is about one-fifth of an inch behind the border of the hard palate; to find it, the catheter must be pushed slightly backwards, and then turned through a quarter or three-eighths of a circle on its long axis, with its apex directed outwards. The point will then impinge upon the pharyngeal opening, and will pass into it if the outer extremity be moved slightly downwards and towards the septum.

Indications that the Catheter is in Proper Position.—When the apex of the catheter is lodged in the opening of the Eustachian tube, a sense of resistance will be experienced when an attempt is made to turn it upwards. Its position will not be altered when the patient swallows, and if air be injected, the sound of its passing along the tube will be heard with the aid of the auscultation tube. If the beak of the catheter be lodged in Rosenmüller's fossa, there will be little, if any, resistance when it is turned upwards; if it be embraced by a fold of mucous membrane, the stem will move freely when the patient swallows or speaks.

Obstacles and Methods of Overcoming them.—Obstacles to the introduction of the Eustachian catheter are not infrequently met with; and when difficulty is experienced, the nose should be carefully examined with the aid of the concave mirror. Great sensitiveness of the mucous membrane, swelling of the parts, especially of the inferior turbinated body, deviations of the septum, cartilaginous and bony spurs, polypi and strictures from ulceration, may render the introduction of the catheter very difficult, or even impossible. As, therefore, the dimensions of the nostrils may vary very much, there is no rule for the position of the catheter during its passage. It often passes best if the beak is directed horizontally outwards beneath the inferior turbinated body, as soon as it is well within the nostril, and turned a little down again as it goes through the choana.

Sometimes the instrument can be passed by holding it lightly, and gently turning it from side to side whilst it is pushed backward; and occasionally complete rotation of the catheter will effect the desired end. If a large-sized catheter will not pass, a small-sized one should be tried, and at times an alteration in the curve of the beak will help to surmount the difficulty. A catheter should always be passed with the greatest gentleness, and in many instances it is best to allow it to find its own way. If the difficulty is caused by the swollen condition of the soft tissues, a 2 to 5 per cent. solution of cocaine will generally remove the obstruction.

When it has been found impossible to introduce the catheter through one side, an attempt may be made to reach the mouth of the tube from the opposite side. The catheter used for this purpose should have a long and strongly curved beak. It is passed into the nares in the manner already described, and when the posterior wall of the naso-pharynx is reached, it should be withdrawn half an inch, and the beak turned towards the ear which is to be catheterised.

In nervous and very sensitive people, attempts to pass the Eustachian catheter may be frustrated by attacks of retching or vomiting, and uncontrollable movements of swallowing. When these are very violent, it may be necessary to remove the catheter; they will sometimes subside if the patient takes deep inspirations through the nose. Convulsive attacks of coughing and continuous sneezing sometimes necessitate withdrawal of the catheter; but these difficulties can generally be removed by spraying into the nostrils a 2 to 5 per cent. solution of cocaine a few minutes before the instrument is introduced.

Emphysema sometimes Caused.—In a few cases the injection of air through the Eustachian catheter has caused emphysema beneath the mucous membrane, and extending to parts at a considerable distance from the throat. This accident may occur if the membrane be injured by the point of the catheter, and also in cases of ulceration. Under either of these circumstances, air may find its way into the sub-mucous tissue, and pass under the mucous membrane of the soft palate and pharynx to the orifice of the larynx, and to the subcutaneous connective tissue of the cheek and side of the neck. It has also been known to pass into the thorax between the ribs and the costal pleura. In two cases in

which a powerful air-pump was used to force air into the tube, the fatal result which ensued was probably due to emphysema of the glottis. If the catheter be carefully introduced, and the air-bag be employed, emphysema is very unlikely to occur; and should a small quantity of air pass into the sub-mucous tissue, it will become absorbed in the course of a few days.

The symptoms depend upon the amount and seat of the emphysema. On inspecting the mouth and throat, the mucous membrane of the soft palate and uvula is seen to be swollen and distended, so that these parts are considerably enlarged; the posterior wall of the pharynx is bulged out, and the lips of the orifice of the Eustachian tube are much larger than natural. The cheek on the affected side is puffed out, and the eyelids are swollen. The swelling may be so great as to be easily discernible; if slight, it may be detected on digital pressure. The subjective symptoms vary; a feeling of tickling and irritation in the pharynx is usually complained of, and if the larynx be involved in the œdema, difficulty of breathing will become very prominent. In the majority of the recorded cases, the emphysema subsided within a few days under the use of cold applications and gargles. Prominent emphysematous portions of mucous membrane may be incised with the point of a bistoury.

The accident above described ought never to occur, as it is caused by unnecessary, and therefore unjustifiable, force being used to introduce the catheter, and air being forced through it when the resistance shows that the catheter is not in its proper position. The sound conveyed by the auscultation tube should clearly demonstrate that the air is not passing into the tympanum.

The Risk of Conveying Syphilis by means of the Eustachian catheter must be carefully borne in mind. In treating a patient known to be suffering from syphilis one of the catheters with a copper collar (Fig. 47, page 113) kept for these cases should always be used, but if one is not at hand a catheter should be set aside solely for the use of the patient. In all cases the instrument should be disinfected by being placed in a 5 per cent. solution of carbolic acid, and afterwards boiled.

A vulcanite catheter should be washed after being taken out of the disinfecting solution, and burnt when its use is no longer required.

Sounds Produced during Injection of Air.—The injection of air into the Eustachian tube produces certain sounds which can be heard through the auscultation tube. With a normal condition of the parts the air entering the tympanum causes a blowing sound, which has been compared to that heard when rain falls upon the leaves of a tree. This sound is due to the friction of the air upon the walls of the tube and of the tympanic cavity, and upon the inner surface of the membrana tympani. Its character is influenced by alterations in the width of the tube and in the size of the catheter. With a narrow tube and also with small catheters the sound becomes shrill and high; under opposite conditions its pitch is changed. The condition of the membrana tympani considerably modifies the character of the sound; when the membrane is tense the sound is distinct and harsh, and may resemble that which is heard in cases of perforation, inasmuch as it appears to originate close to the ear of the listener. When the membrane is relaxed the sound is less distinct and soft.

Râles, or rattling sounds of various kinds, are often heard when the tympanum or Eustachian tube contains excess of secretion. Fine bubbling râles generally originate in the tympanum, whereas more distinct and interrupted sounds of this character are produced in the pharyngeal half of the tube. When the membrana tympani is perforated, the character of the sound is modified by the size of the opening, by the amount of secretion in the middle ear, and by the degree of permeability of the tube. A whistling or hissing sound is characteristic of a perforation, and when excess of secretion co-exists, bubbling râles will be superadded. These sounds will appear to originate close to the ear of the surgeon.

Sounds sometimes Absent.—It may happen that no sounds whatever are produced when air is injected. Supposing that the catheter has been properly introduced, this absence of sound may be due to impermeability of the tube from adhesion of its walls, to obstruction due to foreign bodies, or to the fact that the tympanic cavity is completely filled with secretion. In some cases the sound suddenly ceases, and then again becomes audible, and such alternation is repeated several times. This peculiarity may be caused by plugs of mucus occupying the tube and becoming detached from time to time, or by folds of mucous membrane acting as valves. It must not be forgotten that râles may be produced in Rosenmüller's fossa when the beak of the catheter is lodged

therein. The stream of air forms bubbles in the mucus of the fossa, and also throws into vibration the posterior lip of the tube. These sounds are heard as if produced at a distance from the ear. If the catheter be drawn forwards and its beak placed within the lips of the tube a marked difference will be perceived in the character of the sound, and will also be noticed by the patient.

Action of Compressed Air on Eustachian Tube and Middle Ear.—Before considering the relative advantages of the three methods by which air may be injected into the tympanum, it seems desirable to point out the manner in which compressed air acts upon the Eustachian tube and the structures contained in the middle ear.

When a current of air passes from the naso-pharynx into the tympanum certain effects are produced upon the Eustachian tube, the membrana tympani, and the structures covering the fenestra rotunda and the fenestra ovalis. The air distends the Eustachian tube and removes from it any excess of secretion, a portion of which is driven into the pharynx and the remainder into the tympanic cavity. The pressure of the air upon the walls of the tube tends to reduce any existing hyperæmia, and thus temporarily enlarges its calibre. The effect of the current upon the membrana tympani is very marked, and can easily be seen with the aid of the speculum and measured with the ear manometer. The injected air forces the membrane outwards, causing it to bulge into the external meatus. In this movement it carries with it the handle of the malleus, and this in turn, though to a lesser extent, draws the incus and stapes in an outward direction. If, as often happens, the membrane be too much curved inwards and tightly stretched, and the movements of the ossicles be much impeded, the forcible introduction of a current of air will restore the membrane to its normal position and re-establish its capacity for vibration. The marked improvement in hearing which often results from the employment of one of the methods already described is due to the increased mobility of the membrane and chain of ossicles.

There are other structures in the middle ear which can be acted upon by a current of air through the Eustachian tube. A common result of inflammatory processes is the formation of bands of connective tissue which considerably interfere with the movements of the membrane and ossicles, and these bands are stretched to

some extent by the force of the air. The tendon of the tensor tympani can be similarly affected. The two fenestræ are also acted upon, and undue rigidity caused by inflammatory deposit may be lessened or overcome. Abnormal tension in the labyrinth will be reduced by lessening the pressure of the stapes upon the fenestra ovalis.

Removal of exudation is another result of inflation of the tympanum. Such removal, however, can be effected only to a very limited extent when the tympanic membrane is intact; the exudation may be displaced and scattered, but the greater portion of it remains in the cavity. Its escape will be facilitated if, during the injection, the head is inclined forwards and to the opposite side. But even if little or no exudation escape, the inflation may effect considerable improvement in the hearing power by forcing the tympanic membrane outwards, and increasing the mobility of the ossicles, as above described. It will act beneficially in another manner, viz., by re-establishing the normal pressure of air in the tympanic cavity. As Politzer has pointed out, closure of the Eustachian tube in catarrhal and inflammatory affections of the middle ear causes rarefaction of the air in that cavity. As a result of the reduction of pressure, an exudation of fluid takes place from the blood-vessels and lymphatics, a condition which has been described as *hydrops ex vacuo*. The injection of air restores the normal pressure, reduces the hyperæmia of the mucous membrane, and thus promotes the absorption of the exudation.

When perforation exists, the effect of a current of air forced through the Eustachian tube is to propel any exudation into the external meatus, and thus to relieve the tube and the tympanic cavity. The membrane will be forced outwards, and will carry with it the chain of ossicles, so that the normal tension of the labyrinth will be to some extent restored. There is no risk of forcing secretion into the mastoid cells; experiments* have proved that when perforation of the membrane exists, morbid contents of the tympanum will be driven into the meatus by a current of air through the Eustachian tube.

Comparative Value of the Various Methods.—A discussion of their comparative value will complete this account of the various methods of inflating the middle ear.

(1) **Valsalva's method** has the advantage of simplicity and ease

* Michael, *Archiv für Ohrenheilkunde*, Bd. XI.

of execution; but where there is great resistance, the force of the current of air is likely to prove insufficient. As a means of diagnosis, a positive result implies that mechanical obstruction is either very slight or entirely absent; but if the result be negative, some obstacle may be inferred to exist. Also, when the tubes are unequally affected, it enables the relative amount of obstruction to be ascertained. It must always be borne in mind that inflation of the middle ear by this method, depending as it does upon forced expiratory efforts, produces hyperæmia of the cerebral vessels and venous congestion: it is, therefore, not unattended with danger when practised by persons the subjects of disordered conditions of the vessels in question. The mucous membrane of the tympanum likewise partakes in the hyperæmia, and too frequent repetition of the process is therefore likely to promote exudation.

When the membrane is perforated, Valsalva's method often proves very useful. Very little effort is required to force secretion from the tympanum into the external meatus. The patient should always be warned against too frequent repetition of the process, and if there be reason to suspect disease of the cerebral vessels, Valsalva's method should not be practised.

(2) **Politzer's method** of inflating the middle ear is of great value in all cases in which the use of the catheter is either impossible, or attended with great difficulties and drawbacks. Thus in children, among whom catarrhal affections of the middle ear are very common, catheterism is seldom possible, whereas Politzer's method is often quite feasible. Also in nervous adults and in cases of malformation of the nares, the latter plan is usually practicable. It is likewise preferable in cases of inflammatory swelling of the nasal or pharyngeal mucous membrane, a condition likely to be made worse by the use of the catheter. As compared with Valsalva's method, Politzer's plan has the advantage of forcing air into the tympanum at a lower pressure, which can, however, be raised at the will of the surgeon. In many cases the method can be practised by the patient himself, after a few instructions. Lastly, the sudden rush of air into the tympanum is sometimes more efficacious than the weaker current which passes through the Eustachian catheter.

(3) **The use of the catheter** is indicated in cases in which the disease is confined to one side, and whenever it is desirable to inject fluids into the middle ear. It is also useful when the

pharyngeal orifice of the Eustachian tube is much swollen, and resists the action of the current in Politzer's method. It may also be tried whenever the latter plan produces disagreeable results, such as distension of the stomach and giddiness. Lastly, auscultation can be better practised when the catheter is employed, because the force and amount of the air injected can be regulated, and the passage of air gives rise to a more distinct sound. Hence the catheter is especially suited for purposes of diagnosis.

From what I have been told by different medical men, it appears that there is a prevailing impression that the introduction of an Eustachian catheter is a difficult and very painful procedure, and, furthermore, that if attendance on an aural case is to be continued, and the patient's confidence retained, it is essential that a catheter should not be used. An old friend of mine, an exceptionally good practitioner, told me a short time ago that he had once tried to pass an Eustachian catheter, but had not since dared to make another attempt, for on the occasion the man on whom he was operating uttered a groan as the instrument was introduced, and then fell on the floor in a fainting condition. This was told me by my friend on my proposing to pass a catheter on himself; he having come to consult me for a slight defect of hearing. I may mention that now he not only passes a catheter dexterously on his patients, but also upon himself. Without doubt, Eustachian catheters are frequently passed in an improper manner. Patients on their first visit to me often are inclined to doubt the correctness of my assurance that it is a painless procedure, and object to this instrument being used because of their painful experience in connection with this operation.

The mistakes usually made are :—

1. Holding the catheter too firmly.
2. Using force during the introduction.
3. Using too large an instrument.

A catheter cannot be held too lightly, and should always be made to glide through the nostril, care being taken to keep it in the inferior meatus.

Passage of Bougies along the Eustachian Tube.—

Reference must be made to another method recommended by some authorities of testing the permeability of the Eustachian tube, and of relieving or curing constrictions, due either to swell-

ing of the mucous membrane or to growth of connective tissue in the sub-mucous layer. This plan consists in passing bougies along the tube with the aid of the catheter. As a matter of fact, however, the author never has recourse to this method of treatment; he doubts the efficacy of bougies thus used, and he is quite sure that they are capable of causing serious mischief. If the passage of a bougie be immediately followed by the restoration of some amount of patency to the tube, it is at least highly probable that the occlusion was due to a plug of inspissated mucus which would have been softened, and would have come away in a few days if a few drops of a weak alkaline solution had been injected through an Eustachian catheter. If the obstruction be due to swelling of the mucous membrane, it is difficult to suppose that any real benefit can result from the passage of a bougie, for the previous condition will be restored when the instrument is withdrawn. It is alleged that various medicaments can be conveniently applied with the aid of a bougie; but they can be used in solution with greater safety, and quite as efficiently, through the Eustachian catheter. The views of Drs. Roosa,* McBride,† and other aural surgeons, coincide with those of the author on this subject. The use of bougies, however, for purposes of diagnosis and treatment, is still advocated by several German authorities, and especially by Urbantschitsch.‡ A few American aurists regard bougies as indispensable in cases where obstruction of the Eustachian tube does not yield readily either to Politzer's method or to injections of air through the catheter. A brief description of the method of using the bougie will therefore be appended.

It must be remembered that the length of the Eustachian tube varies considerably in different cases ($1\frac{2}{3}$ – $1\frac{4}{5}$ inches); the seat of a constriction cannot therefore be exactly ascertained. The cartilaginous portion measures about 1 inch, and the osseous part rather less than half this length. The calibre at the isthmus is from $\frac{3}{30}$ to $\frac{4}{30}$ of an inch. According to Urbantschitsch,§ a constriction is indicated if the smallest bougie ($\frac{4}{30}$ of an inch) cannot be made to enter the osseous tube, or is passed with great difficulty. If the obstacle be at a distance of $\frac{1}{2}$ of an inch from

* *Treatise on Diseases of the Ear*, 7th Ed. p. 406.

† *Diseases of the Throat, Nose, and Ear*, p. 383.

‡ *Lehrbuch der Ohrenheilkunde*, 3 Aufl., S. 24.

§ *Archives of Otology*, vol. xii, p. 353.

the pharyngeal orifice, the stricture is in the cartilaginous portion; if at from $\frac{2}{5}$ — $1\frac{1}{5}$ inches, it is in the isthmus, or very close to it; if at from $1\frac{1}{5}$ — $1\frac{3}{5}$ inches, the obstacle is in the osseous portion. The possible existence of folds and angularities in the course of the tube must always be kept in mind. Urbantschitsch now recommends celluloid bougies as the most suitable; they are smooth and flexible, and are not affected by sublimate solution. Each extremity is rounded and slightly constricted below (*à boule*). These bougies are apt to become fragile after a time, and if minute transverse lines appear on the constricted portion the instrument should be discarded.

Preparation and Introduction of the Bougie.—A suitable catheter is selected (one having a long and decidedly curved beak is to be preferred), and the bougie is passed along it until the rounded head appears at the orifice. A small mark is then made on the bougie on a line with the funnel-shaped end of the catheter, and starting from this, a scale is constructed with marks at $\frac{2}{3}$ of an inch apart. The catheter is introduced in the usual way, and when it is in its proper position, as proved by auscultation, the bougie is passed along it until the first mark coincides with the outer extremity of the catheter. The bougie is then pushed onwards with a rotatory movement, only very slight force being used to overcome any obstacle that may be encountered. If the attempt prove unsuccessful, the bougie should be withdrawn and a thinner one tried. Constriction very rarely occurs on the tympanic side of the isthmus; it is therefore generally sufficient to pass the bougie just beyond the latter spot. In order to act upon the isthmus itself, the head of the bougie should be slightly withdrawn, and allowed to remain in position for a few seconds, or even for a few minutes.

The bougie should not be passed along the tube for more than $1\frac{2}{5}$ inches. If this limit be exceeded, the ossicles or tympanic membrane may be damaged, the bougie getting between the malleus and the incus, and impinging on the membrane. Perforation has been thus caused, and in other cases sudden deafness has resulted, probably from dislocation of the ossicles.

That the bougie has been properly introduced into the tube is shown (1) by the manner in which the catheter is retained in its position, and (2) by the absence of any alteration during swallowing, inasmuch as the action of the muscles of the tube and

pharynx produces little, if any effect, owing to the manner in which the bougie is held. When the latter has been withdrawn, it ought to appear slightly curved, somewhat in the form of the letter **S**, in correspondence with the course of the tube. If, on the other hand, the bougie be sharply curved upwards or downwards, it has probably failed to pass through the tube. The passage of the bougie gives rise to a sensation of pricking in the region of the larynx, and extending in the direction of the tympanum. As the head of the bougie passes through the isthmus, the sensation in the tympanum becomes more marked, and is often referred to the membrane. Pain extending downwards, and increased by the act of swallowing, indicates that the bougie is not passing properly along the tube. Passage of the instrument through the isthmus is generally accompanied by crepitation, which can be heard through the auscultation tube. Any symptoms caused by the introduction of the bougie usually pass off soon after its withdrawal. Urbantschitsch, from whose work the above account has been derived, states that in a few of his cases the use of the instrument has relieved the symptoms of migraine, and of trigeminal and occipital neuralgia.

According to the authority just quoted, the use of the bougie is indispensable in many cases of chronic catarrh of the tympanum; it often proves effectual after the catheter has failed to relieve. It is not to be limited to cases of stricture of the Eustachian tube, or to those in which there is evidence of a diminution of calibre, which cannot be dealt with in any other way. On the other hand, its use is indicated for the removal of swelling of the walls of the tube—an almost constant accompaniment of chronic tympanic catarrh. Urbantschitsch claims, in addition, that the passage of the bougie not only dilates the tube, but acts reflexly on the auditory centres through the sensory nerves. He denies Politzer's assertion that the effects of such reflex action rapidly pass off.

In the last edition* of his work on "Diseases of the Ear," Politzer states that the results of mechanical dilatation of strictures of the Eustachian tube are not, on the whole, very favourable. In cases [of constriction due to swelling, instead of the bougie, he sometimes uses a thin rubber capsule $\frac{4}{5}$ inch long, and $\frac{3}{10}$ wide, "which is fastened to the top of the catheter by a thread. After the insertion of the instrument into the tube, the capsule is

* Translation edited by Sir W. Dalby, p. 304.

inflated through repeated pressure of air into the catheter." The lateral pressure upon the vessels of the mucous membrane diminishes the amount of blood contained therein, and reduces the swelling.

For constrictions which do not yield to other methods of dilatation, and when an organic stricture is supposed to exist, Politzer considers that the introduction of a bougie into the Eustachian tube is advisable for the completion of the diagnosis, and as a method of treatment. He uses, as a general rule, bougies of silkworm gut, slightly club-shaped at the extremity. For severe constrictions he prefers the whalebone instruments recommended by Dr. Suarez di Mendoza. These are highly polished and rounded, and, in consequence of their greater resistance, pass more easily through the constricted portion. Each series contains eleven bougies, the ends of which vary in size up to 1mm. In order to provide for continuous dilatation of the Eustachian tube, Dr. di Mendoza has invented a catheter, which is divided into two parts lengthwise. "After the introduction of the bougie, one part of the catheter is first removed from the nose, then the bougie is lifted out by gentle lateral pressure of the now open second half, which is also removed. The projecting piece of the bougie is cut off close to the nostril, and remains twenty-four hours in the tube."

Politzer's opinion with regard to this method of treatment has been already stated. He admits that permanent improvement is very rare; that in many cases no dilatation is effected, and that aggravation of the local troubles is not unusual.

CHAPTER VI.

METHODS OF TREATMENT.

Syringing the Ear—Method of Performing—Symptoms occasionally Caused—Application of Heat and Cold to the Ear—The Introduction of Medicated Solutions into the Meatus—The Insufflation of Remedies in the Form of Powders—The Air-Douche and Injections through the Eustachian Tube—The Injection of Vapours and Gases through the Eustachian Tube.

IN order to avoid repetition in subsequent chapters, it seems desirable to give an account of those methods of treatment which are applicable to many diseases of the ear, and are therefore frequently employed. These methods include (1) Syringing the auditory canal; (2) The application of heat and cold to the ear and adjacent parts; (3) The introduction of medicated solutions into the meatus; (4) The insufflation of powders; (5) The air-douche and injections through the Eustachian tubes.

(1) **Syringing the Ear.**—The syringe is often used for the removal of foreign bodies and of accumulated ceruminous and purulent secretion. The meatus should be thoroughly examined before having recourse to the syringe, for much injury may be done if there be nothing to remove or if perforation of the membrane exist. Syringes in common use are made of glass, metal, and vulcanite. Glass and vulcanite syringes are fragile, and apt to get out of order; a syringe made of brass is, on the whole, the best (Fig. 54); it should hold from three to four ounces. The ordinary instrument is too well known to require minute description; the ring *e*, Fig. 54, at the end of the piston, should admit the thumb comfortably; the cap of the cylinder has rings, *d, d*, for the first and second fingers. The piston should be freely movable, while fitting closely into the cylinder. The nozzle, *a*, should be about an inch and a half long, and somewhat slender.

If thick or very bulbous at the extremity, it takes up too much room in the meatus, and prevents the ready escape of the fluid after injection.

I always use a syringe with a nozzle attached by a bayonet joint, *c*, and remove the nozzle before filling the syringe. For this arrangement the profession is indebted to the late Mr. Gardiner Brown. The advantages of this method are that the

FIG. 54.

SYRINGE, WITH NOZZLES FITTED WITH BAYONET JOINT.

syringe is filled far more quickly, on account of the greater size of the aperture in the neck, *g*, and thus the entrance of air into the syringe is almost, if not entirely, prevented, as the suction is materially diminished by the freedom with which the water enters. For some years past I have used a curved nozzle, *b*, Fig. 54, and find it in most cases more convenient than a straight one. It is best to direct the stream of water against the roof of

FIG. 55.

GARDINER BROWN'S EAR TROUGH.

the meatus; and by using a curved nozzle this can be done without the syringe coming into contact with the outer side of the trough. Care should be taken to keep the syringe as clean as possible. The fatty matter used to lubricate the piston may become decomposed owing to the development of fungi, and these latter, if injected into the ear, might set up disease. The piston should often be placed in carbolic solution, and lubricated with carbolised vaseline. For a patient's own use—for removing

purulent secretion—I recommend a small bottle-shaped india-rubber enema syringe, fitted with a bone nozzle.

To catch the fluid after injection, a bowl made of vulcanite, shaped to fit closely to the side of the neck below the ear, may be used; but I much prefer the ear-trough (Fig. 55), devised by the late Mr. Gardiner Brown,* or its modification (Fig. 57) made by Messrs. Mayer & Meltzer. The patient should be directed to hold the trough with the hand of the opposite side to the ear

FIG. 56.

EAR TROUGH IN USE.

which is being syringed, as shown in Fig. 56; by so doing the trough is kept more closely to the side of the head. The water used for injection should invariably be warm, the best temperature being between 100° and 105° Fahrenheit, as this allows for the slight loss of heat which occurs whilst the water is passing through and from the syringe, and leaves the water sufficiently warm to be comfortable to the patient.

* Gardiner Brown's ear trough may be obtained from G. F. Ellis, 64, Southville, Wandsworth Road, S.W.

Method of Using the Syringe.—Syringing the ear should be effected in the following manner:—The patient should be so placed that the light from a window falls directly upon the ear, and he should always be seated, because syringing the ear is liable to produce giddiness, and may even cause the patient, if standing, to fall. The patient should hold the bowl or trough in such a manner as to prevent the fluid from running down the neck and wetting the clothes. The syringe having been filled, it is well to turn the nozzle upwards and press upon the piston so as to force out any air which the cylinder may contain. With the left hand, the surgeon should then draw the auricle upwards, backwards, and outwards, so as to straighten the canal as much as possible. He should then place the nozzle of the syringe just within the meatus, and against its upper and posterior part, and

FIG. 57.

MAYER & MELTZER'S MODIFICATION OF GARDINER BROWN'S EAR TROUGH.

steady the syringe by resting its shoulder against the thumb of the hand which is holding the ear before pressing the piston home. By thus steadying the syringe, not only is greater power and accuracy obtained in directing the stream of water, but injury to the meatus is prevented should the patient suddenly move his head, because when thus held the head and syringe move together. It is well to direct the fluid against the wall of the canal, and not against the membrana tympani, and it is also advisable to begin with a very gentle current, and gradually to increase the force. In dealing with nervous patients, the water should be injected into the concha for a few seconds, as a preliminary procedure.

Symptoms occasionally Caused.—Syringing the ear, even when carefully performed, sometimes causes giddiness, nausea, and other unpleasant symptoms. These are mainly due to increased pressure upon the structures of the labyrinth, and are apt to be severe when perforations exist in the membrane, so that the fluid can act directly upon the fenestræ. If apertures likewise exist in the external wall of the labyrinth, the severity of the symptoms will be much increased. Besides giddiness and nausea, symptoms of meningitis have been known to supervene. Dr. Roosa* has reported a case in which severe syncope was caused by very gentle syringing of the ear. The patient, however, was liable to faint under the least excitement. Convulsive movements, and noises in the ears lasting for some time, have been noticed in a few cases. All these untoward symptoms are more likely to occur when cold water is employed. As a general rule, if proper care be taken, syringing is very well tolerated.

After syringing, the ear should be examined in order to see whether success has been achieved, and also to note the condition of the meatus. The canal should then be thoroughly dried and closed with a plug of cotton-wool. To ensure the removal of all fluid, the patient should bend his head to the side, and the meatus should be afterwards cleansed by pieces of absorbent cotton-wool introduced with aural forceps or the cotton holder. Other special details with regard to syringing will be found in subsequent chapters.

(2) **The Application of Heat and Cold to the Ear and Adjacent Parts.**—A douche of warm water to the meatus is of great service in cases of diffuse inflammation of that part, and in acute and chronic catarrh. A syphon arrangement, with a piece of rubber tubing and a jug of warm water, will answer all requirements; but the Fayette Taylor† aural douche, recommended by Roosa, is still more convenient. This apparatus consists of an ear-piece, with two holes bored through it, one lying above the other. Fitted into these holes are two tubes, one ascending and passing into the vessel containing the fluid, and the other passing downwards into a basin. At the smaller end of the ear-piece, the division between the holes is cut back about one-eighth of an inch, so that by placing the finger over

* *Archives of Otolaryngology*, vol. ix. p. 16.

† *Ibid.*, vol. viii. p. 355, and Roosa's *Diseases of the Ear*, p. 129.

this end, one continuous passage is formed from the top to the bottom. The upper extremity of the tube is funnel-shaped. The finger is placed over the small end of the ear-piece, and the tube is filled with water; the funnel-end is then dropped into the jug. The tubes, just as they enter the ear-piece, are next compressed, so as to arrest the flow, the finger is removed from the end, and the ear-piece is inserted into the auditory canal. Pressure is then withdrawn from the tubes, and the water immediately flows into and out of the meatus. Thus a current of water is caused to flow steadily over the walls of the canal, and the surface of the membrana tympani. In most cases the effect of the warm water is very grateful to the patient.

Warm poultices and hot fomentations are sometimes used in

FIG. 58.

LEITER'S APPARATUS FOR APPLYING COLD TO THE MASTOID PROCESS. (*Politzer.*)

the treatment of external otitis, whether diffused or circumscribed. They relieve pain and tension, but they are liable to cause relaxation, softening, and ulceration of the deep part of the canal, and of the membrana tympani. Moreover, their prolonged use stimulates the development of granulations, especially in cases of abscess of the meatus. A sponge dipped in hot water and wrung out, and frequently renewed, will answer the purpose of a poultice. Another simple method of applying warmth and moisture is to pour warm water into the affected ear and allow it to remain for a few minutes. This should be kept up for half an hour or longer, and repeated every three or four hours.

Cold may be applied to the ear in several ways, either to lessen the heat of inflamed parts or to cause contraction of the blood-vessels and lessen the supply of blood. For acute inflammation of the external or middle ear, cold may be applied by means of folds of linen previously dipped in water at a temperature of 45° Fah. and wrung out. A plug of cotton wool should first be introduced into the meatus. To produce a decided effect, the linen must be re-dipped in the water every few minutes. For cases of severe inflammation, recourse may be had to Leiter's coil (Fig. 58) or an ice-bag. To excite contraction of the carotid artery, Urbantschitsch* recommends Winternitz's india-rubber neck-bag, through which water is kept flowing. Pounded ice, wrapped in a handkerchief and applied to the front and sides of the neck, answers the same purpose. Cold thus applied for some minutes reduces the temperature of the external meatus.

(3) **The Introduction of Medicated Solutions into the Meatus.**—Liquid remedies may be introduced into the auditory canal either by pouring them directly from the receptacle in which they have been warmed, or by saturating a piece of cotton-wool and using the aural forceps. This latter method is sometimes employed in the treatment of diseases of the external meatus. Before introducing the liquid, the meatus should be properly cleansed, either by syringing or with cotton-wool, and if by the former method, the meatus must be carefully dried. The fluid should always be warmed before introduction, and this is best done by putting the requisite quantity into a small test-tube, and then placing the test-tube in water of the required temperature. The practice of warming drops in a spoon over a candle or lamp is liable to result in the ear being scalded, because the degree to which the drops have been heated cannot be estimated. If a test-tube is not at hand, a small phial may be used instead. If it be desired to affect only the tympanic cavity, five to ten drops will be sufficient; but to act on the meatus twenty drops or more will be required, according to its size.

The patient's head should be in such a position that the affected ear is directed upwards, and the auricle should be drawn upwards, backwards, and outwards. If the object be to act upon the middle ear, in cases of perforation of the membrane, the fluid may be forced inwards by making pressure on the tragus. The

* *Lehrbuch der Ohrenheilkunde*, Dritte Aufl., S. 48.

attempt, however, is not always successful, even when a large perforation exists. Gruber's* experiments show that, under the above circumstances, fluids instilled into the auditory meatus pass easily into the tympanum, provided that the structures of the external and middle ear are otherwise normal. Liquids thus introduced escape through the Eustachian tube without entering the mastoid cells, if the head of the patient be bent over as usual towards the opposite shoulder. When the Eustachian tube is completely occluded, and perforation exists in the membrane, a portion of the fluid can enter the tympanum, if there be sufficient space for its reception, and if, at the same time, the mastoid cells are accessible and contain air. Some of the fluid may pass into those cavities, the air being either displaced or compressed. If with an aperture existing in the membrane, the liquid introduced into the tympanic cavity does not escape through the Eustachian tube when the head is inclined towards the opposite shoulder, it may be inferred that obstruction exists either in the tympanum or in the tube itself.

When a perforation exists in the membrane, fluids may be driven into the tympanum, and through the Eustachian tube, by the plan suggested by Politzer. After pouring the liquid into the meatus, the nozzle connected with the tube of an air-bag is fitted closely into the aperture. On compressing the bag, the air and the fluid are forced into the tympanum and through the Eustachian tube, if the latter be permeable.

Solutions introduced into the meatus should be allowed to remain for several minutes, and then removed either by bending the head towards the affected side, or by introducing absorbent wool into the meatus. A plug of wool should be inserted after the parts have been thoroughly dried.

(4) **The Insufflation of Remedies in the Form of Powders.**—Drugs intended to be used by insufflation should be reduced to *very fine powder*, for otherwise they are liable to irritate the parts and form masses which may obstruct the canal. Thorough cleansing and drying are necessary before insufflation. The simplest instrument for this purpose consists of a glass tube or portion of a quill, to one end of which a piece of india-rubber tubing may be attached with advantage. The powder may be blown into the auditory canal, either by the mouth or with the aid

* *Zeitschrift für Praktische Heilkunde*, 1864.

of an india-rubber bag. Some years ago the author contrived the insufflator* shown at Fig. 59. It consists of a vulcanite tube four inches in length, having attached to one end a piece of india-rubber tubing about fifteen inches long fitted with a mouthpiece, *d*. There is an aperture, *a*, in the tube for introducing the powder, and a sliding ring, *b*, which covers the aperture as shown at *b'*. There is a valve between the aperture *a* and the india-rubber tubing to prevent powder being drawn by accident into the mouth. The length of tubing mentioned enables the instrument to be used either as an insufflator or as an auto-insufflator.

FIG. 59.

THE AUTHOR'S AURAL AUTO-INSUFFLATOR. (Half Size.)

(5) **The Air-Douche and Injections through the Eustachian Tube.**—The various methods of inflating the middle ear have already been described; they are frequently employed in the treatment of aural diseases. The principal purposes which they subserve are:—The ventilation of the tympanum, the restoration of the membrane and chain of bones to a normal position in cases in which these structures have been unduly pressed inwards, and the scattering and removal of secretion from the tympanum. The reasons for selecting any particular method will be given in the chapters dealing with those diseases to which these methods are applicable. It is sufficient to repeat the remark that when liquids or vapours are to be introduced through the Eustachian tube into the middle ear, the catheter is generally

* The insufflator may be obtained from Messrs. Mayer & Meltzer, 71, Great Portland Street, London.

indispensable. It must, however, be borne in mind that fluid should never be injected into the tympanum unless there is a perforation in the membrana tympani to allow of its escape.

When fluids are to be introduced into the tympanum, a small syringe is required in addition to the catheter and air-bag. The catheter, of moderate size, is introduced in the ordinary way, and passed well into the Eustachian tube. Air is then forced in so as to distend the tube, and to demonstrate that the instrument is in the right position. Eight or ten minims of the solution previously warmed are then injected into the catheter by the aid of the syringe; the air-bag is again used to force a stream of air through the catheter, and the fluid is thus driven in the form of a spray into the tympanic cavity. The quantity which reaches the tympanum depends on the condition of the walls of the cavity and of the Eustachian tube, and on the force with which the fluid is injected. It is also dependent upon the distance to which the catheter is passed. If the point of the instrument is not placed well against the orifice of the tube, the greater portion of the injected liquid will escape into the pharynx. The passage of fluid into the tympanic cavity can be recognised by auscultation; bubbling or crackling râles are heard, and appear to originate close to the ear of the listener.

Fluids may likewise be forced through the Eustachian tube without using the catheter, but there are various difficulties and dangers connected with all the methods that have been proposed. Without a catheter it is all but impossible to limit the injection to one tube, and to regulate the quantity of fluid which passes to the tympanic cavities. The consequences of an excess are apt to be very serious; violent inflammation of the middle ear has been thus caused, and in other cases the injection has produced intense pain, severe giddiness, and syncope.

Professor Gruber, however, recommends a plan whereby fluids can be conveyed into the Eustachian tubes without the use of the catheter. He points out that in cases in which the naso-pharynx is seriously affected, the introduction of the catheter is likely to cause much irritation, which aggravates the condition of the middle ear, and may thus counteract any benefit resulting from the injection. He uses a syringe capable of containing about three ounces, and with an olive-shaped nozzle sufficiently large to permit the nostril to be completely closed after its insertion.

Having filled the syringe, the surgeon raises the tip of the nose with his left thumb, and inserts the nozzle within one nostril, while closing the other with his left index finger. The syringe, held horizontally, is then emptied with the requisite amount of force. The soft palate is instinctively made tense, so as to shut off the naso-pharynx below, and the tongue is drawn back, so as to close the passage more firmly. The liquid which enters the post-nasal space flows round towards the opposite Eustachian orifice, and so into the other side of the nose. If the latter be closed, the liquid, under the pressure employed, passes through the Eustachian tube, when patent, towards the middle ear. Professor Gruber claims that this method is especially suitable for children, but the author is of opinion that it ought not to be employed unless the membrana tympani on each side is largely perforated.

The same authority asserts that liquids may be introduced into one Eustachian tube by the following process: The patient bends his head over towards the shoulder of the same side as the ear to be treated, and inclines his face somewhat downwards. From thirty to fifty drops of the fluid are then introduced into the lower nasal meatus of the affected side by means of a small syringe. As the latter is withdrawn, the surgeon closes the nostrils with his finger and thumb, and directs the patient to make a forcible expiration with the mouth closed, as in Valsalva's method. A portion of the injected fluid will pass into the mouth of the Eustachian tube on the lower side.

If there be a perforation in the tympanic membrane on each side, Gruber's method, and a somewhat similar plan recommended by Politzer, may be advantageously employed in some cases. If, however, there be a perforation only on one side, a catheter ought to be used, by the aid of which it is often possible to wash out the tympanum more thoroughly than can be accomplished by syringing the meatus. The catheter used for this purpose should be somewhat sharply curved, and introduced as far as possible into the tube. Air should be first injected in order to ascertain that the catheter is in the proper position; the nozzle of the syringe is then introduced into the mouth of the catheter, and the fluid is slowly injected. There is sometimes considerable resistance to the passage of the fluid, but with a little practice it may often be driven in a continuous stream from the external meatus. The

passage of the fluid is facilitated by causing the patient to make several swallowing movements.

The Injection of Vapours and Gases through the Eustachian Tube.—Steam is sometimes injected into the middle ear in cases of chronic adhesive inflammation. The apparatus required is as follows: A spirit lamp and a flask half-filled with water, and having in its cork or stopper two holes, for the reception of two glass tubes; a piece of flexible rubber tubing is attached to the outer end of each tube. It is well to make another small opening in the cork to provide for the escape of superfluous steam. An air-bag is connected with the free end of one of the rubber tubes; the end of the second tube terminates in a nozzle adapted to the Eustachian catheter, which should be made of vulcanite. The steam is driven into the catheter by compressing the bag somewhat quickly, and after each injection the nozzle should be removed from the catheter. Dr. Roosa* recommends the combined vapours of iodine and camphor. He adds two drachms of the latter to two ounces of tincture of iodine, in a wide-mouthed flask. Two tubes pass through the cork; one of these reaches nearly to the surface of the liquid, while its other extremity is attached to an air-bag. The other tube just passes through the cork; its other end is fitted with a nozzle adapted to the Eustachian catheter. The patient holds the apparatus in his hand, while the surgeon forces the vapour into the mouth of the catheter.

The vapour of chloride of ammonium has been used by some surgeons; it was introduced for this purpose by v. Tröltsch. The apparatus he devised consists of three flasks, connected with each other by glass tubes. The flasks contain respectively strong ammonia, hydrochloric acid, and acidulated water. When air is driven into the two first bottles, it conveys the vapours to the third, where the chloride of ammonium is generated. A tube leading from this bottle carries the vapour to the mouth of a catheter in the Eustachian tube. Various other apparatus for the generation of chloride of ammonium vapour may be obtained from instrument makers. When chloride of ammonium vapour is used care should be taken that it is thick and neutral, both of which conditions will be obtained if the acid and ammonia are properly mixed.

* *Treatise on Diseases of the Ear*, p. 401.

Air impregnated with the vapours of æther, chloroform, and turpentine, is sometimes injected into the middle ear. The method of procedure is very simple. A small quantity of the fluid is poured into a bottle and gently warmed. The nozzle of an air-bag which has been compressed is then placed in the neck of the bottle, and the bag is allowed to expand. The air thus charged with the vapour is then injected into the catheter in the ordinary way.

In using vapours of any kind in the manner above described, care must be taken that they are not too hot, and that they are not likely to irritate the throat or ear.

CHAPTER VII.

DISEASES OF THE EXTERNAL EAR.

MALFORMATIONS OF THE AURICLE AND EXTERNAL MEATUS.

CONGENITAL malformations and defects of various kinds not infrequently occur in the external ear. They may be described under the headings of absence, defective development, plurality, abnormal size and shape of the auricles and meatus, and abnormal positions.

Complete Absence of the Auricle is a very rare condition; on the other hand, malformations due to defective development are somewhat common and of very various degrees. They may be comparatively inconspicuous, and take the form of stunted development of some portion of the auricle; or the latter may be quite rudimentary, and represented only by a fold of integument and a fragment of cartilage. Between these extremes there are many intermediate forms. Examples of defective development of the helix and lobule are most common among insane persons. The defects may be either bilateral or confined to one side; but a rudimentary auricle on each side is rarely noticed.

Incomplete development of the external ear, when of a marked character, very seldom exists alone. It is generally associated with deficiency or absence of the tympanic ring, and therefore of the osseous portion of the meatus, and with imperfect development of the tympanum and ossicles. In some cases there is no trace of a meatus; in others there is only a short and blind passage. Serious abnormalities of the external ear are likewise apt to be connected with defective development of the lower and upper jaw, and of the sphenoid and palate bones. Hare lip and cleft palate are not uncommon in such cases, and unilateral malformations are

often associated with defective symmetry of the two sides of the skull.

Supernumerary Auricles and multiplicity of various portions are not uncommon. Wilde cites the case of "a child with four ears, two naturally placed and two lower down on the neck; there were in this instance two petrous portions in each temporal bone." A similar case is reported by Mr. Birkett.* A young girl, in addition to irregularities in her ears, had on each side, over the middle of the sterno-mastoid muscle, a large growth resembling the lobule of the ear, and containing fibro-cartilage and a small artery. According to Sir J. Paget, supernumerary auricles are found only over the lines of former branchial fissures, and may be considered as cutaneous opercular growths, homologous, though

FIG. 60.

MALFORMATION OF THE AURICLE. (*Gruber.*)

abnormally with the natural auricles, which guard the first cleft. Supernumerary portions, termed auricular appendices, are most often found near the tragus and lobule. This latter part sometimes presents a perpendicular cleft, extending from its apex. Absence of a definite anterior border to the lobule is often noticeable.

Abnormal Size and Shape of the Auricles.—In one class of cases one or both auricles are excessively large; in another, an opposite condition is noticed. Symmetrical enlargement of the whole auricle is comparatively rare; but increased size of various portions is not uncommon, and may be artificially

* *Trans. of Path. Soc.*, 1858, vol. ix. p. 448.

induced. Thus, hypertrophy of the lobule, often seen in women in Eastern countries, is the result of wearing heavy earrings. A very small auricle is sometimes met with, either having all its parts perfect, or more or less defective. Sometimes the ear resembles that of an animal.

Anomalies of position.—Mention has been already made of those cases in which the auricle is attached to the neck, side of the face, &c. In another class of cases, the auricle is normally attached to the head, but the expanded part, instead of lying more or less close to the head, stands out almost at a right angle. In an opposite class, the auricle is adherent to the side of the head.

Malformations of the External Meatus are often accompanied by similar conditions of the auricle and tympanum. The passage may be entirely absent, or represented only by a blind cleft or fissure, or by several minute canals. In another class of cases there are two distinct auditory passages, either communicating with each other or remaining separate. In one recorded instance, the supernumerary passage was behind the auricle, and extended to the tympanic membrane. Diminished calibre of the meatus is frequent among deaf and dumb children. A similar condition of the cartilaginous meatus sometimes occurs in old age, and is due to relaxation of the part, and especially of those fibres by which the membranous portion is attached to the squamous bone. Projections in the wall of the meatus likewise diminish its calibre, and the same result is produced by chronic inflammatory conditions leading to thickening of the walls, by cicatricial contraction, and various morbid growths. Acquired atresia may be due to chronic eczema of the meatus, as in a case recorded by Professor Moos.*

Dr. Eugen Joel† has collected eleven carefully recorded cases of congenital closure of the meatus. In almost every instance the osseous portion of the auditory canal was represented by a mass of compact or cancellous tissue; occasionally a small defect in the bone could be observed, and in some specimens a narrow fissure led into the tympanum. In most cases the rudimentary auricle exhibited traces of an auditory aperture in the shape of a shallow depression; but in some instances no such trace of a meatus could

* *Archives of Otolaryngology*, vol. xiii, p. 237.

† *Ibid.*, vol. xviii, p. 317.

be discovered. The cartilaginous portion of the auditory canal was occasionally present, and formed a pouch, closed at the tympanic end. The tympanic bone and the membrana tympani were invariably absent; the tympanum was either much narrowed or replaced by osseous tissue; the ossicles were either entirely missing or imperfectly developed, whereas the labyrinth was rarely affected.

Closure of the meatus by membranous formations is sometimes congenital,* and either the commencement of the canal or the passage itself may be thus affected. Urbantschitsch points out that the tissue blocking up the meatus consists of epithelium alone, and does not contain any of the deeper structures of the cutis. In some animals—*e.g.*, dogs, cats, rabbits, and mice—such occlusion of the meatus at birth is a normal condition; the epithelial tissue subsequently undergoes retrogressive metamorphosis.

Prognosis.—In cases of severe congenital malformation of the auricle, no definite forecast can be made as to the hearing-power of the child. Regard must always be paid to the probability of a similar condition of the tympanum and labyrinth. When the child is more than six months old, and fails to start when loud sounds are produced near to it or to turn its eyes in their direction, the conclusion is inevitable that hearing-power is absent. If the malformation be unilateral, the unaffected ear should of course be closed during the experiments.

Treatment.—In cases of absence of the meatus, attempts have been made to form a canal leading from the defective auricle to the tympanum. The results are almost always unsatisfactory, inasmuch as the middle ear is rarely normal, and the position of the auricle may be no guide to that of the deeper structures. It might, however, be justifiable, in cases of bilateral atresia of the meatus, to make an exploratory incision towards the membrana tympani, and to endeavour to create a canal by means of sponge tents. No operation is practicable in cases in which an osseous mass occupies the place of the auditory meatus. When the malformation is unilateral, it is inadvisable to interfere with it, except, perhaps, in cases of adults in whom Weber's experiment (page 90) yields fair evidence of a normal condition of the deep structures on the affected side. If the obstruction be membranous in

* See a case recorded by Dr. Knapp, *Archives of Otology*, vol. xi. p. 19.

character, it may, of course, be divided with some prospect of success. Occlusion due to this cause sometimes results from chronic catarrh of the middle ear, with implication of the meatus.*

When the auricle is very small and much deformed, the patient's appearance will be improved by its removal and the application of an artificial substitute. Redundant portions of the auricle may likewise be removed with the knife or scissors; and when the whole auricle is abnormally large, improvement may sometimes be effected by the judicious curtailment of various portions.

The surgeon is sometimes called upon to rectify the deformity of a projecting auricle. Bandages and pads may be tried, but much time and patience would be required for any improvement, and they seldom prove efficacious. In marked cases, when the patients are very anxious to have something done, improvement may be effected by removing a piece of integument from the angle behind the ear. A curved incision, with the concavity looking inwards, is made on the auricle, and another of a similar character over the root of the mastoid process. The elliptical portion of skin is then removed by careful dissection. The integument is separated from its attachments for a little distance along the margin of the wound, and the edges are carefully brought together by suture; a bandage is applied so as to keep the ear close to the head until union has taken place. This operation generally yields satisfactory results.

A more extensive operation, suitable for marked instances of this deformity, has been suggested and performed by Dr. Ely,† of New York. Its details in one case were as follows:—An incision was made through the skin along the entire length of the furrow at the back of the ear, and, commencing at its upper extremity, a second incision was carried over the posterior surface of the auricle, in a curved direction, down to the lower end of the first cut. The skin and subcutaneous tissues were then dissected off. Two incisions, nearly parallel to the former ones, were next carried through the cartilage, and an elliptical piece of the latter, measuring $1\frac{1}{8}$ by $\frac{1}{3}$ inch, was removed. The pieces of excised skin were considerably larger. The edges were then united by ten sutures—seven including the skin alone, and three passing through

* *Archives of Otolaryngology*, vol. xv. p. 75.

† Roosa, *Diseases of the Ear*, 7th Ed., p. 99.

the cartilage likewise. "Owing to the natural folds of the latter structure, it was impossible to secure perfect coaptation of the anterior surface of the auricle, and a small space was here left to heal by granulation. The dressing consisted of absorbent cotton and a bandage. Healing ensued with very little pain or swelling; the posterior incision united by the first intention, and the anterior wound by granulation." In operating upon the second ear, Dr. Ely transfixed it with a scalpel, and excised a piece of cartilage of the desired shape and size, together with its overlying skin. Additional skin was then removed from the posterior surface, and the result was as satisfactory as in the first ear. The posterior cicatrices were hidden by their position, and those on the anterior surface were scarcely noticeable.

Congenital Aural Fistulæ.—The last class of malformations requiring notice includes the so-called "congenital fistulæ of the auricle." These are small canals, the openings of which are usually found near the tragus and on the anterior portion of the helix. They are only a few millimetres deep, and often contain a whitish fluid; small cysts are apt to result from occlusion of the orifices. They are sometimes noticed in several members of the same family, and are occasionally traceable through several generations. As stated by Professor Gruber, they have no anatomical relationship to the canals or cavities of the ear, but are the remains of the first branchial cleft, and are therefore wrongly named "aural fistulæ." They sometimes come under the notice of the surgeon when their walls become inflamed, as a result of the entrance of foreign bodies, and when they are converted into cysts. Sir James Paget* has recorded several instances of branchial fistulæ in the external ears occurring in the family of a gentleman, perfectly well formed in other respects, but having a branchial fistula on the right side of the neck. "His father and a sister, as well as four of his own children, had similar malformations; the fistula in two of the latter being on the left side, and in the other two symmetrically disposed on each side of the neck. But in addition to these cervical fistulæ, the gentleman himself, his sister, and five of his children, each presents fistulæ in the helix of one or both ears." These corresponded with the description given above; they were less soft and flexible than the

* In a paper read before the Med.-Chir. Society, Nov. 27, 1877. See *Lancet*, Dec. 1, 1877.

cervical fistulæ, producing no secretion, and causing no annoyance. Sir J. Paget regarded these aural fistulæ as probably due to the incomplete closure of the upper, or post-oral fissure. The membrane lining the branchial fistulæ is apt to show signs of irritability when touched with a fine probe. Convulsive attacks of coughing may be thus induced.*

CHAPTER VIII.

DISORDERS OF THE SECRETION IN THE AUDITORY MEATUS—
ACCUMULATION OF CERUMEN.

UNDER normal conditions, the secretion of the ceruminous glands is sufficient only to lubricate the surface of the cartilaginous portion of the meatus, but increase of the secretion is not infrequent, and is due to a variety of causes. The fluid yielded by the glands is normally of a light-yellow colour, and becomes converted into thin dry scales. When the secretion is in excess, these scales form soft masses, which eventually become hard and brittle, and more or less occlude the meatus. Their colour changes from light yellow to dark brown or black, and in the course of time they form ragged plugs, sometimes displaying bright facets on their surface, owing to the presence of cholestearine. Besides the secretion from the ceruminous glands, these plugs contain epidermic scales and hairs, and in diabetic cases sugar can sometimes be detected.

Causes.—Ceruminous plugs are due either to abnormally increased activity of the glands, or to obstacles to the escape of their secretion. They are far more common in males than in females. Increased glandular activity is sometimes noticed in individuals whose skin evinces a similar condition. Increase and hardening of cerumen may occur alone, or may be symptomatic of inflammation of the external and middle ear, and I am inclined to attribute the formation of such plugs almost invariably to this cause. The diseases and conditions in which the accumulation may occur are (1) chronic suppuration of the tympanum; (2) chronic non-suppurative inflammation of the tympanum; (3) diffuse inflammation of the auditory canal; (4) foreign bodies; (5) parasitic inflammation. Hardening of the cerumen also

occurs in disease of the internal ear, and in these cases removal of the wax may slightly or even considerably improve the hearing (Roosa). To these may be added eczema of the meatus and improper methods of cleansing the canal, *e.g.*, with a pointed piece of towel, by which the secretion is pushed more deeply into the ear. Politzer observes that ceruminous accumulation is much more often found in those who cleanse the meatus than in those who neglect it. Under normal conditions, the motions of the jaw tend to remove dry scales of cerumen. With regard to obstacles to the escape of the secretion, it is evident that constrictions of the meatus and exostoses of the canal are likely to act in this manner; and foreign bodies may be included in the same category.

Symptoms.—Inspissated cerumen may remain in the meatus for considerable periods without causing any subjective symptoms, provided only that a passage be left for the transmission of sonorous impressions to the tympanum. It is to the position rather than to the quantity of the accumulated cerumen that the symptoms are likely to be due. These consist in more or less marked deafness, a sensation of fulness in the ear, tinnitus and giddiness, the two latter being the result of pressure upon the membrana tympani. As a general rule, plugs of cerumen do not materially affect the hearing until they occlude the meatus. Deafness may occur quite suddenly, owing to displacement of the hardened material, or to its becoming swollen, in consequence of the entrance of water into the ear. If the walls of the meatus be irritated by the mass, the irritation may be conveyed to the auditory nerve by the branches of the fifth pair, and various abnormal sounds may be heard. Pain in the ear is less frequently experienced, but it may be very severe, and extend to other parts of the head and to the neck. Motor disorders have been occasionally observed, *e.g.*, blepharo-spasm, and facial paralysis, the symptoms disappearing after removal of the plug. Great depression of spirits, almost amounting to melancholia, was observed in a case reported by Dr. Roosa; speedy relief was obtained after the wax had been removed. Cough is sometimes complained of, the irritation being conveyed either directly by the auricular branch of the vagus, or by the auriculo-temporal of the fifth to the latter nerve, the deep origin of which is close to that of the sensory root of the fifth nerve. The medulla oblongata is accus-

tomed to receive impressions through the vagus from the larynx, and hence the irritation occurring in the ear is referred to that organ. In a case recorded by Mr. Percy Jakins,* the cough, which had existed for four years, was accompanied by gradually increasing weakness, night-sweats, and occasional delirium. The patient was supposed to be consumptive; but all the symptoms rapidly disappeared after removal of cerumen from both ears.

On examining the ear, the cerumen may be found to cover several spots, or to occupy the canal in the form of scales or crusts or rounded masses, but it is often seen as a dark brown or black plug, extending from the orifice of the meatus down to the membrana tympani. Occasionally a plug of this character is covered by a layer of epidermic scales, which envelope it like a sac. In children, the wax is generally yellowish, and deposited in layers. After the removal of the accumulation by the aid of the syringe, the surface of the meatus and the membrane are often seen to be reddened and injected, but these appearances are due in great measure to the irritation of the syringing. In some cases the accumulated masses set up inflammation, and even ulceration, in the meatus. Other changes sometimes seen are the result of pressure; thus the membrana tympani may be pushed inwards, and in a condition of atrophy, while sometimes openings form. In other cases the effects of pressure are seen in the walls of the canal, which are atrophied and partially destroyed, so that the meatus is dilated, and the cerumen may pass into the tympanum, and likewise into the mastoid cells. It is possible that, in these cases, the accumulation of cerumen was the result of chronic suppuration, which was also the real cause of the damage to the meatus.

The Diagnosis of ceruminal accumulation is, for the most part, easily made; the speculum may be required, but examination with the naked eye is often sufficient. The meatus is seen to be occupied by a yellow or brownish mass, the consistence of which varies greatly. Foreign bodies in the ear, and especially plugs of cotton wool, inspissated discharges, and epithelial masses may be mistaken for accumulations of cerumen. In all obscure cases of cerebral disorder, the ear should be very carefully examined. A case is recorded by v. Tröltsch† of a patient who,

* *Practitioner*, 1887, vol. i. p. 423.

† *Lehrbuch der Ohrenheilkunde*, 1881, S. 95.

after a fall, suddenly became giddy and deaf, and was treated by various remedies, including the application of a seton. It was found on careful examination that a plug of cerumen was the cause of the symptoms.

The Prognosis in cases of inspissated cerumen may be somewhat uncertain, inasmuch as the condition is not infrequently associated with other affections of the ear. If the deafness has come on rapidly, and improvement spontaneously occurs from time to time, a plug of cerumen is likely to be present. If the sounding fork, placed on the head, be indistinctly heard on the occluded side, some affection of the internal ear may be suspected. It was pointed out by Toynbee that ceruminal accumulation often exists in cases of adhesive processes in the middle ear, and of affections of the labyrinth. Intermittent loss of bone-conduction has been noticed in some cases of plugging of the meatus by cerumen; it passes off after the wax has been removed. It must be remembered that recurrence of accumulation is not uncommon, even in persons of cleanly habits.

Treatment.—The removal of ceruminal accumulation is best effected by syringing the ear with warm water (temperature 100° to 105° Fahrenheit). If the plug be dry and hard it is better, before using the syringe, to soften it by filling the meatus with warm water. The water should be allowed to remain for several minutes, and it must be remembered that the immediate effect will probably be an increase of deafness and tinnitus, this being due to the swelling of the plug. If the mass does not come away readily on the syringe being used, after water has been allowed to remain in the meatus for a few minutes, it may be gently moved by means of a chromic acid carrier or a probe. This should never be done without a strong light being thrown at the time through a speculum upon the plug, for fear of injury to the neighbouring structures. If this procedure causes pain, and but little wax is removed when the ear is again syringed, it is best to wait until the mass has been softened by other means before a further attempt is made to get it away.

For softening cerumen the following formula is suitable:—

R. Sodii Bicarb.	gr. x.
Glycerini	ʒij.
Aq. Destill.	ʒij. Misce.

A few drops to be warmed, and placed in the ear several times a

day, until the mass has become thoroughly softened. The ear should be carefully examined during the syringing process, lest the latter should be continued after all the cerumen has come away. After complete removal of the plug, the hearing is in most cases improved, and the subjective symptoms disappear, but normal hearing is not generally obtained, because the accumulation of cerumen is usually secondary to some other affection. The meatus should be carefully dried with absorbent wool, and a small plug of cotton wool should be introduced, and renewed from time to time for several days, if the weather be cold or damp. The cutis and the membrana tympani are apt to be very sensitive after a plug has been removed. Accumulations of cerumen are very liable to recur, and it is well to have the ear syringed from time to time, and to make use of the soda and glycerine drops. To prevent relapses, Dr. Knapp* recommends the occasional use of lukewarm soap-water. This is kept in the ear for about fifteen minutes, and then stirred with a camel-hair brush as deep in the canal as the patient can reach; then the ear is syringed with warm water, wiped dry, and for a short time protected with a little absorbent cotton wool. Any co-existing affection of the ear should, of course, be attended to.

An opposite condition, namely, **Deficiency of Cerumen**, far less frequently occurs, but it sometimes happens without any apparent cause, and sometimes associated with disorders of the middle ear, as a result of some affection of the trophic nerves. Marked dryness of the meatus is often an early symptom of adhesive inflammation of the middle ear. Inflammatory processes in the meatus also check the secretion of cerumen, and the same result is sometimes due to senile atrophy of the glands. Frequently washing the meatus is said to diminish the secretion. The symptoms of this condition are a feeling of dryness and irritation in the meatus, which on examination is seen to be pale and dull. There is no necessary impairment of hearing, and when this symptom is present, being due to disorder of the middle ear, the reappearance of cerumen is by no means a certain indication of improvement.

Treatment.—In order to relieve the irritation a little vaseline or glycerine may be applied to the meatus, and if these fail, white precipitate ointment may be tried.

* *Archives of Otology*, vol. xi. p. 204.

CHAPTER IX.

INJURIES OF THE AURICLE—BURNS AND SCALDS—
FROSTBITES.

Injuries to the Auricle—*e.g.*, contusions, incised and lacerated wounds, either confined to this part or associated with injuries of adjacent structures—are of common occurrence. The symptoms and their severity depend upon the nature and degree of the force to which they are due. Portions of the auricle are sometimes completely separated, and union often results if the parts are brought into apposition and sutures are carefully applied. Such a favourable termination has been observed even when several hours have elapsed since the injury. Piercing the ears (for the reception of ear-rings) is usually a harmless operation; but in rare cases, when a prolongation of the cartilage extends into the lobule, severe inflammation has been observed. In other cases, again, heavy ear-rings have been known to cut through the lobule. The condition known as othæmatoma, which is often of traumatic origin, will be described in a succeeding chapter.

Wounds of the auricle are to be treated according to the ordinary rules of surgery; antiseptic measures are easily carried out and good results are generally attainable. When adjacent structures are also implicated, both treatment and prognosis must be correspondingly modified.

Injuries to the External Meatus may be caused either by direct or indirect violence; and in both cases the neighbouring parts, viz., the auricle, the membrana tympani, and the petrous part of the temporal bone are liable to be implicated. Fracture of the anterior wall may be caused by a blow on the lower jaw.

Direct injury to the meatus is often caused by foreign bodies, inserted either by accident or intentionally. These and their

effects will be described in a succeeding chapter. The meatus is often involved in cases of injury to the auricle. Incised wounds, limited to the cartilaginous portion, are seldom, if ever, serious, though the parotid gland may be implicated; but when the osseous part is injured, long-continued suppuration, followed by contraction, is likely to result. Wounds of the posterior wall may extend into the mastoid cells, and there is always the risk that the injury to the deep part of the meatus may involve the tympanic membrane. Inflammatory processes after wounds may extend to the middle ear through the petro-tympanic fissure, as well as through the intervention of connective tissue and vessels.

The Diagnosis in these cases is for the most part easy, unless the meatus be very much swollen. Cold compresses should be applied, and the wounds may be subsequently dressed with boric acid ointment or other antiseptic. The risk of contraction should always be borne in mind. When necessary, laminaria or sponge tents may be introduced into the meatus.

Fracture of the Walls of the Meatus generally results from indirect violence—*e.g.*, a blow upon the lower jaw. In old persons this latter injury may easily cause a fracture of the glenoid fossa, and a blow on the chin may produce this result on both sides. In one case, the condyle of the lower jaw was driven into the meatus.* The upper wall of the canal is liable to be involved in cases of fracture of the base of the skull.

The symptoms of these injuries are not always very definite. Pain is, of course, complained of; crepitation can sometimes be detected, and there is usually more or less deformity. Hæmorrhage is likely to be profuse when the upper and posterior walls are involved; if the skin be not torn the blood will accumulate under it. Escape of cerebro-spinal fluid does not necessarily indicate fracture of the meatus, for it occurs likewise in severe injuries of the labyrinth. In fractures involving the glenoid fossa, movement of the jaw will be painful and difficult.

Fractures involving the anterior and inferior walls of the meatus generally admit of a favourable prognosis. On the other hand, the prospect is bad when the superior wall is fractured, and especially when there is reason to suspect that the base of the skull is likewise injured.

Burns and Scalds.—The auricle is not often the seat of

* Gellé, *Précis des Maladies de l'Oreille*, p. 69.

burns, unless the neighbouring parts are also involved. Scalds sometimes occur in persons, such as waiters and others, who are in the habit of carrying on their heads vessels containing hot fluids. The part is occasionally injured by mineral acids being thrown upon it, and extensive sloughs and ulceration are thereby caused. When the orifice of the meatus is involved, contraction is liable to ensue as a result of cicatrisation.

The treatment of burns of the auricle is the same as that of similar injuries elsewhere. Vesicles should be carefully pricked, so as to evacuate their contents and preserve the epidermis as a covering, and vaseline or boric acid ointment may then be applied. Either the liniment of lime or carron oil is a suitable dressing for more severe cases. When the inner surface of the auricle and the adjoining portion of the head are the seat of the burns, great care is necessary to prevent adhesion during cicatrisation. The parts must be kept separated by layers of cotton-wool or lint. Especial care is necessary in treating cases due to the effects of mineral acids. The extensive sloughing is apt to cause great destruction and considerable deformity, and when the meatus is involved, the aperture is likely to be more or less occluded. This result should be prevented as far as possible by keeping pledgets of lint and afterwards sponge tents in the opening.

Frost-bite.—Owing to its exposed position the auricle is especially prone to exhibit the effects of severe cold. These are seen in various forms and stages; as a result of prolonged exposure to low temperatures, the auricle, like the nose, may become completely frozen, with necrosis and gangrene of portions of skin and cartilage as speedy consequences. In far more common cases, often seen in this country, circumscribed portions of the ear become red and swollen, the skin gives way and cracks, blood is discharged and crusts form. The most common sufferers from these so-called chilblains are young persons of both sexes, of delicate constitutions, and the effects of the cold are apt to manifest themselves every winter. It is not, however, necessary for the production of chilblains that the temperature should be below the freezing point.

The symptoms of chilblains are too well known to require description. When the ear is affected severe pain is complained of, associated with itching and a sensation of heat, which latter is apt to be very troublesome when the patient goes into a warm room.

The treatment of frost-bite affecting the ear may be summed up in a few words. In recent cases soon after exposure the part should be rubbed with cold water or snow, and friction continued until circulation is restored. For the after-effects, circumscribed swellings may be painted over with a mixture of the tinctures of iodine and opium, or with collodion and iodol. Cracks and ulcers are best treated with boric acid ointment, and when they are very irritable, a solution of nitrate of silver may be applied with advantage.

CHAPTER X.

OTHEMATOMATA, OR VASCULAR TUMOURS OF THE
AURICLE.

THIS term is used to designate tumours of various sizes formed in the auricle, and sometimes in the external meatus, as a result of the subcutaneous escape of blood from the vessels. Two forms are described, viz., traumatic and spontaneous, the former being often associated with other injuries of the auricle, such as rupture of the cartilage; the latter occurring without apparent cause. In rare cases, spontaneous effusion of blood beneath the nasal mucous membrane has been observed in association with spontaneous othæmatomata, and in some instances of the latter character, occurring in lunatics, hæmatoma of the dura mater has been discovered after death. Some authorities do not believe that othæmatoma can be developed in the absence of previous injury.*

It was formerly supposed that spontaneous effusion of blood into the tissues of the auricle occurred only among insane patients; but this is by no means the case, though the condition is much more commonly found in these subjects, and more often in men than in women. Dr. Hun† reports twenty-four instances, of which twenty-three occurred in males; and it would seem that hæmatoma auris in the subjects of brain-disease is a highly unfavourable symptom, and points to an incurable lesion.

It appears, from Dr. Hun's statements, that the idiopathic and traumatic forms of the condition differ considerably from each other. He records a case in which an insane patient, the subject of hæmatoma of one auricle, received on the other a blow from a

* *Archives of Otology*, vol. xiii. p. 303.

† *American Journal of Insanity*, July, 1870.

broom-handle, which caused swelling and ecchymosis, but not hæmatoma. He attributes the spontaneous occurrence of the condition to a twofold cause, viz., cerebral congestion, and centripetal irritation of the system by the emotions. The majority of his patients were the subjects of general paralysis and melancholia, and in these conditions there is a tendency to repeated congestions of the head with consequent dilatation of vessels. Other writers allude to morbid changes in the part as favouring the occurrence of othæmatoma; the most important of these are, softening and degeneration of the cartilage, and atheromatous disease of the vessels, which causes them to become very friable. Some authors associate fissures of the cartilage with softening, and state that these conditions are not infrequent in emaciated and cachectic individuals suffering from mental affections. The cartilage, in such cases, breaks up into several layers, inclosing irregular cavities containing mucoid fluid and connective tissue. It is obvious that changes of this kind in the cartilaginous tissue predispose to rupture of blood-vessels, and the formation of vascular tumours, and that in consequence of the fragility of the tissue, the effused blood may rapidly force its way through the separate cartilaginous layers.

In connection with the influence of nervous disturbance upon the formation of these tumours, some of Dr. Brown-Séquard's experiments have an important bearing. He found that in guinea-pigs, sections of a restiform body near the calamus scriptorius will produce hæmorrhage under the skin of the ear, to be followed afterwards by gangrene, and that these appearances are most marked on the injured side, and less prominent on the other one. He has also found that section of the sciatic nerve will produce the same results, by reflex action on the medulla, and he is led to believe that disease of the base of the brain, not always causing insanity, is the origin of hæmatoma auris. It would seem that this condition of the ear is not confined to the human subject. Several instances of othæmatoma, occurring (without obvious cause) in cats,* have lately been placed on record. In one instance, after the swelling subsided, the ear began to shrink, and ultimately formed a puckered irregular mass close to the side of the head.

Symptoms. — The appearance of a spontaneous hæmatoma

* *British Medical Journal*, 1889, vol. i. pp. 187, 648.

auris is usually preceded by redness and swelling of the ear and side of the face; but sometimes no premonitory symptom is observable. As a general rule, the tumour shows itself on the external surface of the auricle, and generally in the upper half (Fig. 61), as a roundish, smooth, bluish-red mass, varying in size, tense, and more or less elastic. Similar tumours have occasionally been observed on the posterior surface of the auricle. In some cases the skin is comparatively normal in colour. The ridges of the auricle are obliterated, unless the blood is extravasated into the substance of the cartilage. In the majority of

FIG. 61.

cases, the swelling is developed within a few hours, and remains for some time without change. There may be no subjective symptoms, or the patient may complain of some amount of pain, with a feeling of tension, heat, and tingling. The tumour either bursts spontaneously, or gradually subsides, and undergoes certain changes to be presently noticed.

In traumatic cases, the left ear is more often affected than the right, and the appearances vary with the cause and severity of the injury. As a general rule, the tumour is rapidly developed, inasmuch as it is due to extravasation of blood from vessels

ruptured by violence. Fränkel's* experiments, however, show that twenty-four hours or more may elapse before the swelling appears. The site of the extravasation is either between the skin and the perichondrium, or, more rarely, between the latter and the cartilage.

In both classes of cases, the effused blood becomes partially or completely absorbed as time goes on, but more or less deformity is apt to remain, owing to the changes in the cartilage. In traumatic cases, when the cartilage has been broken and the fragments displaced, the deformity may be very considerable. An auricle, thus deformed, is a distinguishing mark of some old statues of Hercules and Pollux. At the present day, instances of "shrunk ears" in lunatic asylums are far less common than in former times, when there was less supervision over the patients and their attendants. On the other hand, cases are becoming somewhat common among football players. As rare consequences of othæmatoma, little masses of bony tissue become developed in the auricle; chalky deposits are more common. Suppuration is an occasional result, and in one case of traumatic othæmatoma, recorded by Gruber, ulceration and septicæmia ensued.

Treatment. — In spontaneous cases the treatment is very simple. If the tumour be small and not very tense it may be left to subside by itself. Under opposite conditions the fluid should be drawn off with a trocar or evacuated by means of a small incision, and pressure afterwards applied to prevent refilling. In traumatic cases, the relief of pain and the prevention of disfigurement are the objects to be aimed at. The tumour, if tense, should be evacuated, and cold applications used. If coagulation has taken place, it will be necessary to incise the swelling and to remove the clot; cold applications and pressure will constitute the remainder of the treatment, and when all active symptoms have subsided, careful massage will probably aid in restoring the normal condition. If this prove unavailing, pressure should be persevered with, and tincture of iodine should be applied from time to time.

* *Archives of Otology*, vol. xiii. p. 303.

CHAPTER XI.

PERICHONDritis OF THE AURICLE.

INFLAMMATION of the fibrous membrane covering the cartilage of the auricle gives rise to symptoms more or less resembling those of othæmatoma. The upper part of the auricle is the portion mainly affected, whereas the lobule generally escapes. The prominent symptom is the formation of one or more roundish swellings, which are more or less hot and painful. Considerable deformity is apt to remain after their subsidence.

Symptoms and Progress.—In some cases the inflammation supervenes without any obvious cause, and is confined to the perichondrium and cartilage of the auricle. In others, the inflammatory process extends from the meatus, which may be the seat of furuncle. In the former case, sharp, shooting, and continuous pain may be the first symptom, and may continue for several days in the absence of any visible change. Redness and swelling then commence in a circumscribed spot, and gradually become more marked. Fluctuation is soon manifest, and the swelling continues to increase until it involves more or less of the concavity of the auricle and encroaches on the meatus. The surface of the tumour is pale red in colour and uneven, but the natural elevations and depressions are obliterated. In the course of time, unless incisions are made, the skin gives way at one or more points, and a quantity of viscid serous fluid escapes. The discharge subsequently becomes purulent, and fistulous openings are likely to remain. The subsequent course is apt to be very tedious; several months may elapse before recovery takes place. In one recorded case,* the swelling involved various portions of the auricle in succession, and caused so much deformity that no part

* *Archives of Otology*, vol. xix. p. 8.

could be recognised. Tuberosities took the places of the fossæ, and the auricle appeared like a lump of flesh. The amount of resulting deformity varies with the degree of the inflammation. In rare cases, portions of the cartilage become necrosed and detached; in others, considerable contraction of the meatus is super-added to the deformity. Ossification of the cartilage is an occasional result.* The posterior surface of the auricle is sometimes involved, and when this is the case large abscesses may be formed.

Treatment.—In the early stage, cold applications may be tried with the view of checking the inflammatory process. When fluctuation is perceptible, it is best to make a free incision through the tumour, and to scrape away the contents with a sharp spoon.† Any sinuses that may have formed should be carefully slit up, and granulation tissue should be scraped away. Provision must be made for thorough drainage, and iodoform or alembroth gauze, covered with cotton wool and a bandage, forms a good subsequent dressing. In later stages, when much deformity has resulted, improvement may sometimes be effected by removing hardened and prominent pieces of cartilage, and readjusting isolated portions. In a case thus treated by Dr. Knapp, the deformity was greatly diminished. The anatomical examination of the portions removed showed that they contained well-developed true osseous substance.

CHAPTER XII.

HERPES OF THE AURICLE—ECZEMA OF THE AURICLE.

THE auricle is occasionally the seat of herpetic eruptions, which may show themselves on this part alone, or on the face and neck at the same time.

Causes.—Inflammatory processes in the deeper structures of the ear are sometimes attended by herpetic eruptions on the auricle. In the absence of any such causes, the complaint is usually attributed to disordered digestion or to chills; it is commonly seen in adults, but children are not exempt from it.

Symptoms. — The appearance of the vesicles is generally preceded by more or less fever, and local pain of a severe stinging or burning character, the latter symptom being especially troublesome when the eruption extends into the meatus. The pain may exist for several days before any local signs appear. The distribution of the vesicles is sometimes connected with that of the nerves supplying the part, and the complaint may then be regarded as a symptom of neuritis. The nerves especially implicated are the branches of the great auricular from the cervical plexus, and those of the auriculo-temporal branch of the fifth. When this latter nerve is affected, the eruption, as is generally the case, appears on the external surface of the auricle and the anterior margin of the meatus; the branches of the great auricular are distributed to the internal surface and to the meatus.

The appearances are those of herpes elsewhere. Small red patches are first noticed, and these become studded over with papules, which are speedily converted into vesicles, closely set and sometimes confluent, so as to form bullæ. The meatus may thus be completely occluded, and sometimes the membrana tympani is likewise the seat of eruption. The contents of the vesicles are at

first limpid and pale, but subsequently become opaque and yellow. After a few days either the vesicles dry up and form scabs, which fall off, leaving a reddened surface, or little ulcers result. When the meatus is affected, there may be profuse discharge from such breaches of surface. In some patients there is more or less deafness and tinnitus during the course of the complaint, which is occasionally prolonged by the appearance of successive crops of the eruption.

Treatment. — In the early stages, the general health of the patient is likely to require attention; purgatives and tonics are generally indicated. Severe pain may be relieved by cold applications, or by painting the part over with a mixture of extract of belladonna and glycerine. When vesicles have formed, they should be protected from injury; powdered starch may be dusted over them, and cotton wool subsequently applied. When supuration has occurred, the pustules may be opened with advantage; but care should be taken to preserve the epidermis. Any ulcers that may form should be dressed with boric acid ointment or powdered iodoform; and when the meatus is the seat of the complaint, and there is more or less discharge, powdered boric acid should be used by means of an insufflator.

Eczema of the Auricle and Meatus.—This is a somewhat common affection, and, owing to the anatomical structure of the parts, the complaint is in some respects different from eczema in other portions of the body. It is, moreover, liable to produce more or less impairment of hearing. It occurs in two forms, acute and chronic. Children and young girls are most often affected.

Causes.—An eruption of eczema on the auricle is frequently associated with disorders of menstruation, and occasionally with the climacteric period; in some cases, there are evidences of scrofula, or rickets, or of general malnutrition. The exciting cause is often obscure; but the influence of local irritation is sometimes traceable. Thus exposure to the sun's rays, warm fomentations, and frictions with various stimulating ointments or liniments, are liable to produce an eruption. A somewhat more common cause is the irritation produced by the discharges in cases of otorrhœa, and the scratching practised to relieve the uncomfortable sensations. The eruption is most liable to occur, and to prove very obstinate, when the otorrhœa is associated with caries of the tympanic walls; it is, in all probability, due to the

organisms contained in the discharges. The spread of the eczema may be explained in a similar manner. Dr. Rohrer, of Zurich, inoculated rabbits' ears with cultivations of diplococci obtained from the serum of the vesicles of eczema, and produced a similar eruption. The conversion of the vesicles into pustules is associated with the development of staphylococci. Gruber states that eczema of the ear is sometimes due to irritating matters (dyes, &c.) contained in scarves used to cover the part. Politzer alludes to cases in which circumscribed eczema, on the upper part of the crest of the helix, and occurring symmetrically in both ears, was apparently caused by sleeping on hard horsehair pillows. Eczema sometimes occurs in an epidemic form among school children, and is possibly due to contagion.

Symptoms.—Acute eczema of the ear gives rise to sensations of tension, itching, and burning in the part, and in children the eruption is commonly attended with fever and restlessness. Complete or partial occlusion of the meatus by the eruption will diminish the hearing-power, and cause tinnitus and other abnormal sensations. The eruption may occur on both surfaces of the auricle; it is most often seen in the fossæ of the upper half of the outer surface, in the neighbourhood of the lobule, and in the angle between the ear and the head. Both ears are generally affected.

The appearances resemble those of eczema on other parts of the body. There is redness and swelling of the skin, followed by the formation of closely-set vesicles, which are apt to burst and leave raw surfaces. These latter become covered with crusts, beneath which a viscid or purulent fluid is secreted. In time the crusts fall off, leaving either a dry surface or small fissures and ulcers, covered with purulent secretion. In slight cases, the process sooner comes to an end; the vesicles dry up, and desquamation takes place.

When the meatus is the seat of the eruption, the epidermis soon becomes detached, the cutis is more or less infiltrated and swollen, and a discharge of turbid serous fluid is a common symptom. The appearances then resemble those of diffuse inflammation of the meatus; but the eruption on the auricle will serve to indicate the real nature of the case.

Acute eczema generally subsides under proper treatment; but the duration of the complaint varies from a few days to several weeks, and the eruption is very prone to recur and to break out

on fresh portions of the auricle. After repeated attacks, the condition is apt to pass into a chronic stage, accompanied by thickening of the part and other changes. The subcutaneous connective tissue becomes much hypertrophied, and the auricle is enlarged and rigid, while the meatus is lessened in calibre, owing to the thickening of its walls. The surface is covered with crusts or scales, or both forms may be combined. In the scaly form, the auricle is enlarged and reddened, and is the seat of continuous desquamation. In mild cases, the eruption is confined to portions of the auricle; but in severe forms, it extends over the entire ear, and to the face, scalp, and neck, as well as into the meatus. Fissures are very liable to form in the normal grooves and depressions, and especially behind the ear. The itching is generally very troublesome, and patients not infrequently injure the part in their efforts to relieve the uncomfortable sensation. Noises in the ear, arising from the same causes as in the acute form, are often complained of, and hearing may also be impaired as a result of congestion of the Eustachian tube and tympanum.

Chronic eczema of the auricle is often very obstinate. Proper treatment will generally cause improvement or recovery; but relapses are very prone to occur.

There is no strict line of demarcation to be drawn between the acute and chronic forms; the former often run into the latter, and cases sometimes occur which are best described as subacute. Thus, in young children of a scrofulous habit, we often see crusty and impetiginous eczema involving the posterior surface of the auricle, and the hollow of the concha, and forming part of a widely-spread eruption affecting the head and face. These forms of eczema are distinguished by the copious production of scabs and crusts, attached to a much-reddened and inflamed base. The intense itching causes children to scratch the part freely, and ugly bleeding sores are thus produced. Febrile symptoms are often marked, and the absorption of the purulent secretions causes swelling and sometimes abscess in the adjacent glands.

The **Diagnosis** of eczema of the ear is for the most part easy. Rare cases of seborrhœa resemble the scaly form, but differ in not presenting any redness and infiltration.

The **Prognosis** varies with the nature of the case. The most obstinate forms are those which are associated with constitutional conditions.

Treatment.—In dealing with a case of eczema, the general condition of the patient almost invariably requires attention. If there be evidences of anæmia, good food, and some preparation of iron are, of course, indicated, and arsenic is generally advantageous in these cases. In scrofulous subjects, good diet, cod-liver oil, and the syrup of the iodide of iron will aid the action of local remedies. For dyspeptic and gouty subjects alkaline purgatives are generally suitable, and the diet and mode of living should be properly regulated. In most cases of chronic eczema, and especially when relapses are frequent, a course of arsenic will prove beneficial.

The *local* treatment of eczema affecting the ear varies with the stage of the complaint. In acute eczema the auricle should be carefully protected from irritation; it should be neither washed nor syringed, but kept well anointed with vinolia, or failing that, with vaseline or other emollient ointment. If there be much inflammation, the solution of liquor plumbi subacetatis applied on lint may replace the ointment; and for the relief of pain the part may be painted over with a 2 to 5 per cent. solution of cocaine. Another remedy for this stage of the affection is ichthyol dissolved in alcohol (1 part to 50), or made into an ointment with vaseline (1 to 10).

When the stage of crust-formation has been reached, the scabs must be removed in order to allow remedies to act on the affected part. They should be first softened by the application of glycerine or almond oil, and then gently detached. After their removal, and without irritating the skin any further, the auricle should be painted over with some medicated ointment, and pieces of linen or lint smeared over with the same ointment are then to be carefully applied and kept in close contact with the affected part. A large number of preparations are useful for the purpose, and may, if necessary, be tried in succession until a good result is obtained. The ointments of zinc and of boric acid are frequently used; the Germans recommend Hebra's diachylon ointment, composed of equal parts of diachylon plaster and olive oil. Whichever ointment be selected, the lint bearing it should be closely fitted to the depressions on the auricle, and a small plug must be introduced into the meatus. The dressings should be changed at least twice every twenty-four hours, and water must not be used for cleansing the part, but this should be effected by

means of cotton wool and a little olive oil. Salicylic acid is another remedy which yields good results in these cases of eczema, both in the impetiginous and scaly forms, and when the part is covered with crusts. One part of the acid is mixed with ten parts of soap plaster; the mixture is spread somewhat thickly on linen, which is to be carefully applied to the irregular surface of the auricle. If, in spite of this treatment, crusts continue to form, the part should be painted over twice a day with balsam of Peru, which tends to check their development.

In favourable cases the crust-formation ceases, the discharge lessens, and the auricle assumes a more healthy appearance. In this stage it should be carefully protected from irritation of all kinds; washing is to be prohibited, and cleansing must be done with cotton wool, after which vaseline or boric acid ointment is to be applied.

In the scaly form of eczema, the treatment depends upon the degree of the affection and the amount of infiltration into the subcutaneous tissue. For slight cases, the white precipitate ointment is a good application, and if this fail recourse may be had to boric acid ointment, or to a solution of boric acid in alcohol—1 to 20. Dr. Knapp* recommends an ointment of the yellow oxide of mercury (1 to 2 per cent.) and vaseline, and that the parts should be covered with absorbent cotton as a protection from wind and cold. In more severe forms, with thickening of the epidermis and infiltration of the cuticle and subcutaneous tissues, more active remedies will be required. The part may be covered with salicylic soap plaster, which will tend to soften the indurated parts, and will remove the thickened epidermis. Salicylic acid may likewise be applied as a pigment, two drachms in powder being mixed with one drachm of carbolic acid and ten of glycerine.

Preparations of various kinds of tar are often useful in eczema. The Oleum Cadinum (*Huile de Cade*) and the Oleum Rusci Pyroligneum are generally used. In severe cases, one of these is applied on a stiff brush several times daily, and the part is then dusted over with powdered starch. When the skin becomes softer and paler, the same remedies may be applied as ointments, diluted with vaseline in various proportions. Zinc ointment and an ointment composed of ichthyol one part to ten parts of lano-

* *Archives of Otology*, vol. xi. p. 201.

line are sometimes efficacious. The oleate of zinc, combined with equal parts of vaseline, is said to be preferable to ordinary zinc ointment, inasmuch as it does not coat the surface with a crust of débris, which checks healing, and irritates the part on removal. If these remedies fail, carbolic acid ointment may be tried (1 to 20 of vaseline, with a little glycerine), or a solution may be used composed as follows: acid carbolic, 10 parts; alcohol and glycerine, of each 50 parts, and 250 parts of water.

When the external meatus is the seat of an eczematous eruption, it must be kept free from accumulation of débris, but adherent epithelial crusts must not be forcibly removed by syringing, which would act as an irritant. Gruber recommends that such crusts should first be softened by applying a solution of carbonate of potash in glycerine (1 to 150); the ear may then be carefully syringed. The same author recommends sulphate of zinc for mild cases, without pain; it may be dissolved in glycerine—5 grains to the ounce—and of this, 10 or 15 drops warmed are placed in the ear twice or three times a day. In obstinate cases a solution of nitrate of silver—8 grains to the ounce—should be painted over the surface, and this may be repeated from time to time after the blackened epithelial scales fall off. When much swelling exists, and the canal of the meatus is considerably obstructed, a small pledget of lint smeared over with one or other of the above-mentioned ointments should be placed in it, so as to exert some pressure upon its walls. In more marked cases, it may be necessary to use tents of sponge or of laminaria in order to restore the normal calibre of the part.

In most cases of eczema it is necessary to try several remedies before a good result is obtained, and the list of those at the command of the practitioner is somewhat lengthy. After the eruption has disappeared, and the parts have assumed their normal condition, it is desirable to guard against relapses by persevering with some mild form of treatment. The white precipitate ointment is one of the best remedies available for this purpose.

CHAPTER XIII.

CIRCUMSCRIBED OR FURUNCULAR INFLAMMATION OF THE
EXTERNAL MEATUS.

IN this complaint the inflammation is limited to one or more spots, and leads to the formation of abscesses or boils. Cases of this kind are somewhat common, their frequency being due to the number of glandular structures contained in the meatus, the cartilaginous portion of which is most often affected. The disorder is more common in adults than in children, and is usually limited to one ear, the left being more often affected than the right. Recurrences, especially during the spring and autumn, are noticed in a large proportion of cases; epidemics of the complaint have been observed in Paris and in Vienna.

Causes.—The complaint sometimes occurs in persons apparently healthy; but in the majority of cases there is likewise some disorder of the general health. Sometimes there are indications of plethora, but signs of impaired nutrition, scrofula, and anæmia are much more common. Furuncular eruptions in other parts not infrequently coexist; in some cases an eruption of eczema in the meatus has preceded the inflammation. Exposure to cold, mechanical irritation, and the application of remedies to the meatus are occasionally followed by the development of furuncles. Chronic suppuration of the middle ear is another, and a more common cause, the irritation being probably due to the micro-organisms contained in the discharges. Some authorities are of opinion that in cases in which no other affection is present, furuncular inflammation of the meatus is almost always due to pyogenic bacteria. Löwenberg* was the first to demonstrate the presence of such organisms in the pus from aural furuncles, and

* *Archives of Otology*, vol. xi. p. 273.

his observations have been confirmed by subsequent investigators. According to his view, when a furuncle has once been formed by an accidental accumulation of specific micrococci in a gland-follicle, a relapse and extension are brought about by propagation of the microbes on the surface to other follicles, thus producing new furuncles by auto-contagion. Only the worst cases of furuncles must be explained by the circulation of micrococci in the blood. Kirchner states that he has often discovered the staphylococcus pyogenes aureus in the pus of these furuncles, and has produced abscesses in animals by inoculating them with the cultivated products. Other experiments prove that infection may take place when the skin is perfectly sound, provided that the fluid containing the micro-organisms be applied to it with the aid of friction. Microscopic investigation then shows that the organisms have passed into the hair-follicles. It is, however, difficult to account for those cases in which the application of such remedies as chloroform, æther, and solutions of carbolic acid to the meatus is followed by furuncular inflammation. Cases in which the disorder is probably due to direct contact with decomposing materials are seen among butchers and horse-slaughterers, and persons employed in dressing hides. In diabetic patients, the meatus is occasionally the seat of furuncles, and this part may be affected when boils follow the administration of bromide of potassium. Löwenberg explains the relation of diabetes to furuncles by stating that sugar is conducive to the formation of micrococci.

Symptoms.—The anterior and the inferior walls of the meatus and the inner surface of the tragus are the parts most often affected. There is at first more or less diffused redness and swelling, which soon become more marked and defined, so that the meatus is to some extent obstructed. In some cases, two or more such swellings exist at the same time. The abscess pursues the ordinary course; after a few days the swelling becomes softer, and evidences of suppuration are apparent. If left to itself, the abscess breaks and fragments of necrosed connective tissue escape with the pus and blood. Healing is sometimes retarded by the formation of ulcers or granulations; but usually the abscess closes in the ordinary way. The inflammation is apt to spread to the adjacent parts; the parotid and neighbouring lymphatic glands sometimes become swollen and painful, and the

tissues covering the mastoid process may be similarly affected, especially when the abscess is situated on the posterior wall of the meatus. More or less œdema of the side of the face and neck is sometimes present. Should the inflammation spread to the tissues connecting the auricle with the skull, the former will project from the side of the head.

The **Subjective Symptoms** are such as might be expected from the nature and seat of the complaint. Pain is always more or less severe, and is apt to be accompanied by febrile symptoms, especially if the deeper parts of the meatus be involved. The pain increases with the progress of the inflammation, and often extends for some distance around the ear. It is aggravated by movements of the jaw, as in speaking and eating, and by touching the auricle; it is always worse at night. In children, high fever may be accompanied by vomiting and delirium, so that the symptoms resemble those of meningitis.

Escape of the contents of the abscess is followed by marked relief of all the symptoms, and, unless other swellings form, the pain rapidly subsides, and is succeeded by a feeling of fulness and itching, which soon passes off. For some days, however, movement of the jaw may be more or less painful.

While the abscess is forming, deafness is generally present, though the patient may not be aware of any difference, unless the meatus be completely occluded. When the deep part of the canal is affected, the deafness may be due to implication of the membrana tympani. Noises in the ears, and sensations of pressure and fulness, are often complained of. These symptoms are due to hyperæmia and increase of pressure in the labyrinth, and they subside after the abscess has burst or been opened. When the inflammation involves the more external portion of the canal, the subjective symptoms may be very slight or altogether absent.

In exceptional cases the abscess, instead of healing up, continues to discharge for some time. According to Prof. Gruber, this peculiarity is due mainly to the position of the abscess. Prolonged suppuration is more liable to occur in certain parts of the auditory canal than in others, and increased vascularity would seem to account for the difference. Thus when the upper wall is affected, the processes are peculiarly severe and obstinate. In this part the vessels are larger and more abundant than elsewhere, and

the tympanico-squamous fissures likewise favour the spread of inflammation. The general health of the patient may considerably influence the healing process. In cachectic subjects, the abscess not infrequently continues to discharge a thin serous fluid, which is found to be connected with the development of granulations or polypoid growths. In such cases, several abscesses are apt to form in succession, causing much pain and distress to the patient.

As a general rule the consequences of furuncular inflammation of the meatus are confined to the canal itself, but the mischief sometimes spreads to the surrounding bones and to the contents of the cranium. Extension to the parotid may easily take place through the clefts in the cartilage, and if, as sometimes happens, fissures exist in the upper and posterior walls, the inflammation might spread to the base of the brain and to the mastoid cells.

Diagnosis.—There is seldom any difficulty in distinguishing an acute abscess from other affections of the meatus; it is only in exceptional cases that any mistake is possible. Of the tumours with which abscess may be confounded, only one, viz., exostosis, originates in the meatus, while others starting from other parts sometimes protrude into the canal. In exostosis, the tumour is hard and resistant, but slightly tender on being touched, does not present signs of inflammation, and its appearance never rapidly changes.

With regard to tumours projecting into the meatus, polypi occasionally more or less resemble abscesses, inasmuch as they sometimes form tense, smooth, and shining tumours. Their mode of growth is, however, very different, being painless and comparatively slow; a probe can be passed round a polypus and between it and the wall of the meatus, and, if the swelling be pricked, it will discharge only a little blood and will not diminish in size. If the polypus contains cysts, these, of course, will collapse when pricked, but the discharge will be thin and watery.

Purulent collections finding their way into the meatus from other parts far more closely resemble abscess of the meatus itself. Thus, abscess of the parotid gland may extend through the clefts in the cartilage, or through the line of union between this and the bone, and appear as a swelling in the walls of the meatus. The nature of the case will, however, appear from its history and

symptoms; in parotid abscess, there will be marked swelling in front of the ear, and the tumour in the meatus will increase in size when pressure is made on that part. The quantity of pus discharged will be greater than in abscess of the meatus, and pressure on the parotid region will increase the flow. Pus may likewise find its way through the posterior wall, and in this case, from the mastoid cells; but there will be no difficulty in distinguishing such cases. The pain, redness, and swelling over the mastoid process, the symptoms of suppuration within the tympanum, and the history and progress of the case will indicate the source of the mischief.

Prognosis.—Furuncular inflammation is rarely a serious complaint, and generally ends in recovery. Relapses are, however, very common, and in debilitated persons the pain and discharge will tend still further to reduce the strength. If the inflammation extend to adjacent parts, and especially to the mastoid cells or the dura mater, the prognosis will become grave.

Treatment.—If the case be seen in the early stage, an attempt may be made to cut short the inflammation; it is, however, rarely successful. Cold may be applied to the parts by means of Leiter's apparatus, and in plethoric subjects purgatives and low diet are generally advantageous. Two or three leeches may be tried, applied in front of the ear, or over the mastoid process, but their application, though it may lessen the pain, rarely checks the progress of the inflammation. Some authorities recommend that nitrate of silver, either in the solid form or in a strong solution, should be applied to the surface of the meatus. Scarification of the reddened and swollen portion is another plan which sometimes avails to cut short the inflammation; but it is better to make a single free incision into the tumour. This will relieve tension, and the pus, if not reached by the incision, will more readily make its way into the opening. There is yet another plan having the same object, and recommended by Dr. Gruber.* This consists in the introduction into the ear of conical plugs of gelatine, containing about the sixth of a grain of extract of opium, or half the quantity of hydrochlorate of morphine. These preparations are used as follows: the external meatus is carefully cleansed with a warm 4 per cent. solution of carbolic acid, the "aural ovoid" is then introduced into the ear with a pair of forceps, and retained

* *Lehrbuch der Ohrenheilkunde*. II. Aufl. S. 292.

in position with a little cotton wool. The gelatine rapidly dissolves and acts as an antiphlogistic, while the morphine relieves the pain. The application is to be renewed, according to the symptoms, from once to three or even four times a day, and when improvement has taken place, half the quantity may prove sufficient. Dr. Gruber states that since he has made use of these preparations, he has witnessed excellent results, and has rarely had recourse to scarification, a method which he formerly recommended.*

When pus has obviously formed, a free incision is the proper treatment, and bleeding should be encouraged by pouring warm water into the ear. A knife, resembling that used for tenotomy, is the best instrument for making the incision, which should extend down to the bone or cartilage. After the operation the wound should be painted over with carbolised glycerine or solution of boric acid, and then it is well to insert a small pledget of moistened lint, but not so thick as to cause pain. As a general rule the suppuration soon ceases, the swelling passes off, and the wound heals in a few days. The boric acid solution may be applied several times daily until cicatrisation is complete.

If the case be considered as not quite ready for incision, attempts should be made to hasten the suppuration, and at the same time to relieve the pain. When the abscess is situated in the deeper part of the meatus, both indications may be fulfilled by instilling from time to time warm decoction of poppies, to which a little laudanum has been added. The fluid should be dropped into the ear every half-hour, and allowed to remain for several minutes, when the meatus should be plugged with cotton wool. For abscesses involving the cartilaginous portion, plugs of cotton wool, saturated with a warm solution of the acetates of lead and of morphine, are the best applications. The exposure of the ear to steam and the use of warm poultices to the auricle are to be deprecated; the latter is apt to cause inflammation of the parotid gland and periostitis of the mastoid process. For the relief of violent pain, recourse may be had to a morphine ointment, 1 to 50 of vaseline, and the same remedy may be given internally or injected subcutaneously. Politzer recommends the

* These "aural ovoids" can now be obtained from Messrs. Bullock & Co., of Hanover-street, Regent-street. (See note on page 242 of the translation of Dr. Gruber's work.)

introduction into the meatus of a longish piece of lard covered with morphine and boric acid ointment (boric acid, gr. 15; vaseline, gr. 300; morph. acet., gr. 3). The same author points out that antiseptic treatment is of great value in dealing with furunculosis of the external meatus. Repeated eruptions are not uncommon, and are doubtless due to bacteria. The best remedies are carbolic acid mixed with glycerine (1 part to 30) applied with a brush, and boric acid in powder or in an alcoholic solution; these remedies may be used both before and after the abscess has burst or been opened. Löwenberg recommends boric acid in aqueous or alcoholic solutions, both before and after the escape of pus. It is well indeed to persevere with the antiseptic treatment after incision and until the wound is healed: the subsequent development of furuncles is thus checked. In obstinate cases, with frequent relapses, a solution of perchloride of mercury in alcohol (1 to 1,000) may be dropped into the ear thrice a day, and a warm solution of calcium sulphide (1 per cent.) has likewise been recommended. Even should there be no second abscess, an irritable state of the meatus often continues for some time. For this condition, white precipitate ointment is a very good application. Granulations and polypoid excrescences are best treated by the careful removal of secretion and touching them with a solution of chromic acid, and afterwards insufflating powdered boric acid into the meatus several times a day. In obstinate cases the instillation of alcohol is often beneficial. As in most cases of furuncular inflammation of the meatus, the general health is impaired, tonics and other suitable constitutional remedies must not be omitted.

CHAPTER XIV.

DIFFUSE INFLAMMATION OF THE EXTERNAL AUDITORY
MEATUS.

THIS affection occurs in two main forms: in the first, the inflammation involves only the superficial layers of the cutis, with desquamation as a result. In the second form, the various layers of the soft parts lining the meatus are uniformly affected, the inflammation being of the phlegmonous character, and presenting the ordinary symptoms. The process extends over more or less of the meatus, and generally involves the membrana tympani and the tympanum itself.

Causes.—Diffuse inflammation of the meatus is somewhat more common in children than in adults; it seldom occurs as an idiopathic affection. It most often follows upon inflammatory diseases of the middle ear attended with perforation of the membrane; and it is sometimes witnessed (as a result of extension from the surface) in the course of scarlet fever, measles, and small-pox. Severe eczema of the meatus, especially if the part be irritated, may lead to diffuse inflammation. The presence of foreign bodies, accumulations of cerumen and chemical irritants, are less frequent causes. A peculiar form of the complaint is due to the presence of fungi. When associated with purulent inflammation of the middle ear, it is probably due to the micro-organisms contained in the discharges. An attack of diffuse inflammation sometimes results from the entrance of cold water during bathing. Syphilis is an occasional cause, and an abscess is sometimes the starting-point of diffused inflammation, which may extend over the entire meatus. Cases due to diphtheria will be described in a subsequent chapter.

Symptoms.—These are more severe than in the circumscribed form. In acute cases the patients complain of severe pain, deafness and noises in the ears, and more or less fever generally accompanies these symptoms. If the inflammation be of a superficial character, on examining the ear the meatus will be found to be reddened and somewhat swollen, and its surface covered with scales of desquamated epidermis. In the phlegmonous form, the osseous portion of the canal is most often affected, and the redness and swelling are very marked. The membrana tympani is likewise implicated, and, if the parts will permit the introduction of a speculum, it is seen to be dull and hyperæmic, especially at the periphery and along the handle of the malleus. Its boundary is also indistinct, in consequence of the swelling of the wall of the meatus. Abscess may form in the membrane, and cause perforation and inflammation in the tympanum. As the case proceeds, the appearances vary according as the deeper or the more superficial parts are involved. When the latter are mainly affected, in the course of a few days more or less secretion escapes from the meatus, the fluid being at first serous and tinged with blood, and afterwards purulent. Its odour, which is generally very marked and disagreeable, is due to the presence of saprophytic bacilli. When the deeper parts are affected, there is a diffused swelling, more or less hard and red, not always uniform, but usually more prominent in some parts than in others.

When the inflammation has commenced in the osseous portion of the meatus, it generally extends to the periosteum and to the connective tissue of the cartilaginous part. The integument over the mastoid process and the parotid and neighbouring lymphatic glands is apt to become swollen and painful. The subsequent course of the complaint depends mainly on the causes to which the inflammation was due. External otitis, set up by foreign bodies or other irritants, generally subsides under proper treatment; but, in other cases, improvements are wont to alternate with relapses, and many weeks may pass before the inflammation really comes to an end. The constitutional condition of the patient has a marked influence on the course of the inflammation. In scrofulous and debilitated subjects, the swelling is apt to be less marked, the walls of the meatus are relaxed and studded over with granulations, covered with a thin secretion, having an unpleasant odour, and sometimes mixed with blood.

The condition is likely to prove obstinate, and fails to subside until proper attention is paid to the general condition.

There is a rare form of the disease which is characterised by the appearance of hæmorrhagic vesicles on the walls of the osseous portion of the canal (*otitis externa hæmorrhagica*). According to Dr. Gorham Bacon,* this form occurs usually without any known cause, in young persons, and commences with moderate pain, tinnitus, and slight deafness. On examination, the vesicles appear as dark blue elongated swellings in the osseous meatus, generally on the inferior, more rarely on its posterior wall; they often extend inwards to the *membrana tympani* and outwards to the cartilaginous meatus, and block up the canal to a greater or less extent. The condition is that of superficial inflammation of the cutis, the epidermis being raised by the hæmorrhagic exudation. The swelling is soft and yielding, and is easily punctured; the fluid that escapes is more or less tinged with blood. When left to itself, either the vesicle gives way, or its contents become absorbed, the process being completed in from eight to fourteen days. Males are more often affected than females, and the left meatus is more frequently involved than the right. The pain is seldom severe. Dr. Swain† has recorded five cases of this character, more or less closely associated with attacks of influenza.

The most frequent result of diffuse external otitis is a return to the normal condition, but for some time before this is established, there may be increased formation and detachment of epidermis, or increased secretion of cerumen. Inasmuch as the *membrana tympani* is often implicated, perforation is not uncommon. Sometimes the complaint passes from the acute to the chronic form; the pain and fever subside, while the discharge continues in increased quantity, and such consequences as hypertrophy of the cutis, granulations, and bony growths in the meatus, more or less occluding the canal, may become developed in the course of time. Syphilitic and diphtheritic inflammation may result in extensive destruction of the soft parts and of the osseous walls, with consequences dangerous to life; in less severe cases, adhesions and contractions of the canal are sometimes thus caused.

* *Archives of Otology*, vol. xix. p. 1.

† *Ibid.*, vol. xx. p. 197.

The **Prognosis** of diffuse external otitis is for the most part favourable, and especially if the complaint be confined to the soft parts of the canal. If, however, the bone be implicated, or if the mischief spread to the membrana tympani and tympanum, the consequences may be very serious, though they may not be exhibited until long after the disease in the meatus has quite subsided. The inflammation has been known to extend through the superior and posterior wall of the osseous meatus to the mastoid cells, and also to the lateral sinus. It may likewise extend upwards to the base of the skull, and produce lesions in the membranes and in the brain itself. The inflammation may extend in yet another direction, viz., forwards to the articulation of the lower jaw, and to the parotid gland. In the former instance, its course is favoured by the existence of a fissure in the osseous wall; and in the latter, by a similar condition in the cartilage. With regard to the condition of the tympanum, it may be impossible to foretell with accuracy the result of perforations or of extensive infiltration in the membrane; though if the perforation be small, and there be no serious constitutional dyscrasia, it may be expected to heal in a few weeks. The same may be said of thickening and infiltration; this condition may subside without impairment of hearing, but in severe cases, and especially if periostitis and other complications be present, the change for the worse is likely to be permanent. In scrofulous, much debilitated children, the prognosis is very unfavourable; destruction of the membrane and permanent loss of hearing are likely to result.

Treatment.—The indications are much the same as in the circumscribed form; the causes of the complaint must be sought for and removed when possible. If the patient be seen at the commencement, when hyperæmia is very marked, the best plan is to scarify the swelling freely; tension and pain will be thereby much relieved, and the progress of the inflammation may possibly be cut short. When desquamation and a moist condition of the surface are the prominent symptoms, the insufflation of calomel or finely powdered iodoform will prove efficacious. When the surface becomes dry, an ointment containing 5 per cent. of naphthol forms a good application. If the process has gone on to suppuration, a free incision is urgently indicated, and delay may be attended with very serious local and general results. All

stimulating applications must, of course, be avoided in the early stages; warmth may be applied by means of Leiter's apparatus filled with warm water. In the chronic stage attended with free discharge constitutional treatment is always required. The insufflation of finely powdered boric acid is the best local measure, and if this fail, a few drops of warm rectified spirit may be poured into the meatus. A strong solution of nitrate of silver (20 to 30 grains or more to ℥i.) is another remedy. For the relief of pain, the surface may be painted over with a solution of atropine, using ℥iij. of a 1 per cent. solution.

CHAPTER XV.

CROUPOUS AND DIPHThERITIC INFLAMMATION OF THE
EXTERNAL AUDITORY MEATUS.

Croupous Inflammation of the External Ear is very rarely seen, though Wilde alludes to its occurrence, and several cases are reported by German authorities. The osseous portion of the canal is the seat of the deposit, which takes the form of greyish-white false membrane, easily removable by means of a probe. The attempt, however, causes severe pain, and more or less hæmorrhage. The membrana tympani is similarly covered, and the formation is repeated from time to time until the whole mass comes away, and the process terminates. The development of the deposit is attended with pain and slight fever, and in one case was associated with a similar exudation on the tonsils. In other instances, the deposit appeared in the course of middle ear inflammation and circumscribed external otitis. The prognosis is favourable; the complaint comes to an end spontaneously in a few days, and may be cut short by the insufflation of boric acid.

Diphtheritic Inflammation of the Meatus is attended with marked febrile symptoms and pain of a very violent character. The affected spots are covered with patches of white exudation, which remain for some time firmly adherent, and whose detachment reveals deep ulcers and fissures. A purulent or bloody discharge escapes from the ear, the parts are considerably swollen, and the surrounding structures are in a similar condition. The exudation may be found both on the auricle and in the meatus, or it may be confined to one of these parts; in some cases a similar exudation is found in the throat, nose, and mouth.

Diphtheritic exudation is said not to occur when the cutis is sound, and in most of the cases which have been observed the deposit has been of a secondary character, affecting ears already the seat of ordinary inflammation. The patients are generally scrofulous and debilitated subjects, whose ear affection has been neglected. In one case the diphtheritic deposit made its appearance after the patient had held her ear over a vessel of hot water, probably impure, for the relief of external otitis. In the course of a few days violent pain, accompanied by fever, was experienced, and when the ear was examined, a white diphtheritic deposit, firmly adherent and bleeding when touched, was detected in the meatus.

The course of the disease varies. Sometimes the exudation is speedily detached; sometimes it remains adherent for many days, and when separation takes place a fresh deposit ensues. After detachment, ulcers may remain for a considerable period, and cause much trouble. In very severe cases gangrene of the soft parts may result from diphtheritis of the meatus. The complication has been observed in institutions in which a case of gangrene had occurred; the patients are usually scrofulous and ill-nourished children. It has also been noticed in an epidemic form. The progress of the local affection is very rapid; the inflammation may be confined to small spots, but it speedily leads to gangrene. More or less extensive sloughs form, extending through the soft parts to the bones, which may also perish, and the destruction has been known to spread to the cheek, forehead, and neck.

The **Diagnosis** of diphtheritis of the external ear depends upon the discovery of the firmly-adherent membrane, attempts to remove which cause much pain and hæmorrhage. The nature of the exudation is placed beyond doubt if the nose or pharynx be the seat of a similar deposit, or if an epidemic of the complaint be raging in the neighbourhood.

The **Prognosis** varies with the general state of the patient; it is favourable if the health be otherwise good, and if the complaint be seen in an early stage. It is unfavourable under opposite conditions, and also if there be similar deposits in the pharynx or nose. In cases in which the throat is affected, the mischief is apt to spread along the Eustachian tube to the middle ear. Such extension is sometimes witnessed in cases of scarlatina, though in

that complaint middle ear suppuration more often occurs without a diphtheritic process. When this latter is present, it almost always causes serious changes, not only in the membrana tympani and the ligaments of the ossicles, but in the walls of the cavity. Impairment of hearing is almost certain to occur, even without caries of the labyrinth; it is said to be due to secondary inflammation with small-celled infiltration of the membranous labyrinth.

Treatment.—Antiseptic remedies are to be relied upon for the treatment of diphtheritis of the external ear. When the affection is of a primary character, Politzer recommends that the meatus should be filled from time to time with lime-water, in order to promote detachment and separation of the diphtheritic membrane. The fluid, first warmed, should be allowed to remain in the ear for about twenty minutes. The meatus is then to be syringed out with a weak solution of boric acid, after which the same drug, finely powdered, or iodoform should be blown into the ear. The local application several times daily of solution of the perchloride of iron (1 to 10 glycerine) is also recommended. If relapses occur, the affected parts should be brushed over with carbolised glycerine (1 to 15) or carbolised spirit (1 to 20), and several times a day the meatus should be filled with an alcoholic solution of boric acid (1 to 20), or with a similar solution of salicylic acid (1 to 100), or of perchloride of mercury (1 to 1,000). No attempt should be made to remove the false membrane by mechanical means.

CHAPTER XVI.

PARASITIC INFLAMMATION OF THE EXTERNAL MEATUS.

SYMPTOMS of inflammation in the external meatus are occasionally due to the growth and accumulation of certain fungi, of which the *aspergillus niger*, *flavescens* and *fumigatus*, and the *trichothecium roseum* are the most common. It is only during the last thirty years that these parasites have been carefully studied; at first

FIG. 62.

ASPERGILLUS NIGER: HEADS WITH CONIDIA. $\times 600$. (Siebenmann.)

their effects were supposed to be limited to the membrana tympani, but it is now fully recognised that external otitis may be due to their presence. It is, however, true that in their advanced stages of development they are most commonly found on the membrane, and in the adjoining portion of the meatus,

where they set up superficial inflammation. The fungi are generally mixed with masses of epidermis, cerumen, hairs, and inspissated secretions, the colour of which they modify in various ways. Sometimes they appear in tiny patches, of a black, brown, yellow, greenish, or even reddish tinge. In a case recorded by Dr. Knapp, a cotton pellet, which, moistened with glycerine lotion, had lain for some time at the bottom of the canal, and served as an artificial drum-head, was found covered and pervaded with *aspergillus niger*.

The **Microscopical Appearances** differ according to the kind of the parasite and the stage of its development. In the fully-formed *aspergillus niger*, there is a greyish-white base or mycelium, from which small tubes sprout upwards. These have a double contour, and are sometimes divided transversely; at their unattached ends they present enlargements, or recept-

FIG. 63.

ASPERGILLUS NIGER: FOUR SPROUTING STERIGMATA. $\times 250$. (Siebenmann.)

acles, consisting of penicillate cells, to which lines of spores are attached. The colour of these spores varies according to the kind of fungus; some are yellowish or reddish; others, black.

Experiments have shown that the presence of these spores is not, *per se*, sufficient to cause inflammation in the healthy ear, but other conditions, either of an individual or local character, appear to be at the same time necessary. Anything which tends to loosen or detach the epidermis assists the action of the fungi upon the cutis: thus, Politzer* has recorded a case in which the meatus was filled with aspergilli, but showed no sign of inflammation. He slightly incised the cutis, and after a few days inflammatory infiltration became developed, and required fourteen days for its subsidence. In another case the inflammation was excited by a scratch caused by a speculum.

* *Loc. cit.*, Erste Aufl. S. 690.

The cerumen of the ear is said to be an unfavourable medium for the growth of these fungi, and their development is quickly checked by decomposed pus on account of the ammonia which it contains.* Fresh pus has no such effect upon aspergilli,

FIG. 64.

ASPERGILLUS FUMIGATUS: HYPHÆ AND ORGANS OF FRUCTIFICATION.
CULTURE IN GELATINE. $\times 60$. (Siebenmann.)

FIG. 65.

which have been found in the discharge in a case of suppuration of the middle ear. The growth of the fungus is favoured by anything which tends to render the discharge more serous in character, and to prevent decomposition. Hence solutions of tannin and zinc stimulate the development of the aspergillus.

* F. Siebenmann, *Archives of Otology*, vol. xii. p. 207.

The spores find a favourable resting-place in the meatus, inasmuch as they are kept at a suitable temperature, and are protected from external and mechanical agencies. Fatty substances (the cerumen being an exception) would appear to favour their growth, and they are said to be most often

FIG. 66.

ASPERGILLUS FUMIGATUS: SPHERICAL HEADS WITHOUT CONIDIA. $\times 300$. (Siebenmann.)

FIG. 67.

ASPERGILLUS FUMIGATUS: MYCELIUM. $\times 600$. (Siebenmann.)

met with in persons dwelling in damp rooms. Politzer observed a case in a young man employed in the manufacture of yeast. Children are rarely affected; the majority of the patients are middle-aged, and are found to have suffered at some time or other from chronic catarrh of the tympanum, or from some inflammatory affection of the meatus, for the relief of which oil of some kind has been applied. It would also

appear that the mycelia are able to penetrate into the tissues of the membrana tympani.

Symptoms.—Fungi may be present in the meatus without causing any subjective symptoms, and in order for them to set up irritation some loosening or detachment of the epidermis appears to be necessary. Their presence then produces a sensation of fulness, itching, or even pain, noises in the ears, and some amount of deafness. The pain is said to be of a dull, heavy character. The tinnitus and deafness are due in part to pressure on the membrana tympani, and partly to irritation of the more internal portions of the ear. The presence of the fungi usually gives rise to more or less thin serous discharge.

On examining the meatus the fungus-masses are found to occupy the inner third, and to overlie the membrana tympani in the form of a yellowish or whitish layer, from which minute stalks with rounded heads may occasionally be seen to rise. These hair-like projections give a velvety appearance to the mass, and the colour of the surface depends upon the kind of fungus. Sometimes the growths appear in patches over the membrane, and sometimes they are confined to the meatus. The former is the most usual seat of the fully-developed fungi; after their removal, which, in the early stage, is a matter of some difficulty, the spots to which they were attached present a reddened appearance, and are devoid of epidermis. If the redness prove permanent, a re-development of the parasite may be anticipated.

The course of the complaint may be either acute or chronic; if left to itself the parasitic mass becomes fully developed in from one to two weeks. It may then become either partly or entirely detached, but relapses are very apt to take place in the absence of treatment, so that the disorder becomes chronic. Perforation of the tympanum may result from the inflammation. Syringing the ear always relieves the pain and other symptoms; but unless proper treatment be superadded, the improvement is only temporary.

Diagnosis.—This can never be difficult if the ear be carefully examined with a speculum. Dark-brown masses of epithelium, dust of various kinds, and especially coal-dust, may line the meatus, and somewhat resemble a fungus-growth. In one case, tiny fragments of leather derived from a syringe were mistaken for parasites, but in all such cases the microscope will detect their

true nature. The addition of a little liquor potassæ with glycerine clears up epithelial fragments, and brings the fungi more clearly into view.

Prognosis.—The prognosis is always favourable, inasmuch as the parasites are easily destroyed by remedies. A tendency to relapse is, however, noticeable, especially in persons living in damp localities. Perforation of the membrana tympani may also occur, and the parasites may enter the tympanic cavity and multiply there. Under such circumstances, the complaint may prove very obstinate, on account of the difficulty of applying remedies to the various portions of the tympanum.

Treatment.—This is of a satisfactory character, and the remedy mainly to be relied upon is strong alcohol. The parasitic masses should be removed as far as possible by syringing the ear, or with the forceps, while the ear is well illuminated, and the meatus should then be filled with warm alcohol, which should be allowed to remain for about a quarter of an hour. This treatment should be repeated two or three times a day until the parasite is quite got rid of, and to prevent recurrences the alcohol should be used weekly for several months. If it cause pain it should be diluted with a little water. In very obstinate cases, Politzer recommends a solution of perchloride of mercury in alcohol (1 to 500). This treatment very rarely fails, but should it do so, other remedies may be tried. Thus, calomel or boric acid finely powdered may be used with an insufflator; or a strong solution of the permanganate of potassium may be poured into the ear. A ten per cent. solution of nitrate of silver similarly used has proved efficacious. Siebenmann recommends an alcoholic solution of salicylic acid (4 per cent.).

Prophylaxis.—The same authority states that by way of prophylaxis the following rules should be observed:—

All unnecessary applications of fats to the ear, as well as aqueous instillations or injections, should be avoided.

Loss of epidermis and cerumen should be prevented as far as possible.

All secretory processes of the external and middle ear should be carefully treated, dry remedies being the most suitable.

Alcohol kills the fungi and lessens secretion.

All instruments used in removing fungus-membranes should be very carefully disinfected.

CHAPTER XVII.

SYPHILITIC AFFECTIONS OF THE EXTERNAL EAR.

Primary Syphilitic Sores of the auricle and meatus are of very rare occurrence, and only a few cases have been recorded. Professor Lang,* of Innsbruck, mentions two instances; in one of these there were two sores, one on the cheek and the other on the lobule. The patient, a man aged fifty-six, had been infected by using a towel belonging to a son who was suffering from the disease. In another case,† the sore was situated on the tragus and the anterior wall of the meatus, and the infection had been communicated from the lips of a prostitute. Politzer cites two cases, mentioned by other writers.

In the cases above mentioned, the sores presented the usual appearances; the parts behind the ear, the side of the neck, the parotid, and the submaxillary regions were all more or less swollen.

Secondary Syphilitic Manifestations are not infrequently seen on the auricle and external meatus; they take the form of maculæ, papules, condylomata, pustules, or their consequences, such as desquamation, ulcers, and cicatrices. Similar eruptions are always present at the same time on different parts of the body, and especially on the forehead and face. Gummatous growths are rare in the auricle, but they have been known to spread over the entire part, and to cause extensive ulceration and destruction of tissue.‡ The meatus is the occasional seat of

* *Vorlesungen über Pathologie und Therapie der Syphilis*, S. 430.

† This case is recorded by Dr. Zucker, of Berlin, *Archives of Otology*, vol. xiii, p. 245.

‡ See a case reported by Mr. Field, *Brit. Med. Journ.*, October 6, 1877.

condylomata and ulcers, the former being usually associated with similar manifestations in other parts. Confluent condylomata have been noticed on both sides. These growths occur in an early stage of the disorder, and most frequently appear at the bottom of the meatus. The majority of cases occur in women already the subjects of otorrhœa. Red or brownish patches are first seen, becoming gradually raised by infiltration and developing into condylomata with a more or less uneven surface. These growths may completely occlude the meatus, and be mistaken for polypi. Superficial disintegration results in the formation of ulcers, which after a time cicatrise, sometimes causing contractions in the meatus. The glands in the neighbourhood of the ear are more or less swollen. In a case recorded by Dr. Würdemann,* of Milwaukee, fifteen years were said to have elapsed between the primary disease and the appearance of condylomata in the meatus.

At first the condylomata may give rise to no marked subjective symptoms; but, during the stage of ulceration, there is generally more or less violent pain in the ear, increased by movements of the lower jaw. Tinnitus aurium and deafness are generally present, being due either to obstruction in the meatus or to extension of the disease to the tympanum; perforation of the membrane has been occasionally noticed. Professor Lang describes a case of papulous infiltration of the membrane, in a woman aged twenty, recently affected. A papular growth as large as a hempseed was found to occupy a portion of the membrane, corresponding with the short process of the malleus; the anterior superior quadrant was of a deep-red colour; the remainder of the membrane was uniformly dull. On the left side the membrane was also cloudy and marked by vascular injection behind the short process. Hearing was much impaired on the right side, but all the symptoms improved under treatment.

The **Diagnosis** of condylomata of the auricle and meatus is for the most part easily made, inasmuch as other signs of the disease are sure to be present in various parts of the body. The genitals, groins, throat, and neck, should, of course, be carefully examined. The **Prognosis** is favourable if proper treatment be employed.

Gummatous Growths very rarely affect the external ear; when present they may take the form of diffuse infiltration or

* *Archives of Otology*, vol. xxi. p. 303.

of tubercles, about the size of a pea or larger. This form of disease of the auricle is one of the later manifestations of syphilis. In a case described by Dr. Burnett,* the growth appeared as a circumscribed infiltrated lump on the posterior surface of the auricle, and gradually increased until, in a month or six weeks, it had diffused itself throughout the greater part of the auricle, and somewhat over the mastoid portion. The infiltration gave rise to thickening and considerable deformity, and after several weeks softening and ulceration took place. The destruction of tissue proceeded at a rate varying with the general condition of the patient; there was no pain, but a very offensive odour, and a copious yellow discharge. A few similar cases have been recorded by Dr. A. H. Buck, Politzer, Hessler,† and others; Mr. Field's case has been already mentioned.

The **Diagnosis** of gummatous ulceration may present some difficulties, unless signs of syphilitic disease are discovered in other parts, such as the throat, skin, or bones. It is distinguishable from epithelioma by the fact that in the latter ulceration is early, and the ulcer presents everted edges, and is covered with a thin bloody discharge. Epithelioma is, moreover, attended with more or less pain. Ulceration due to lupus may be mistaken for syphilitic disease, but differs therefrom in several important respects. In the early stage of lupus small patches of papules or tubercles make their appearance, and after a time slowly break down and ulcerate. There is little discharge, but crusts and scales form, and some amount of cicatrization takes place.

Treatment.—The treatment of primary syphilis of the auricle is the same as that of chancres elsewhere. Mercury must, of course, be given internally, and black wash or an ointment composed of vaseline and Unguent. Hydrargyri, equal parts, should be applied to the sore. Condylomata likewise require the internal use of mercury. The best local remedies are calomel and oxide of zinc, in equal parts, applied by means of a brush. Nitrate of silver may be employed to reduce the size of granulations; and when many condylomata exist, a plug of lint, smeared over with mercurial ointment, should

* *The Ear: its Anatomy, Physiology, and Diseases*, p. 222.

† *Arch. f. Ohrenheilkunde*, vol. xx. p. 242.

be kept in the meatus. Gummatous ulceration will require iodide of potassium to be given internally.

Bony growths of the meatus, due to syphilis, will be considered in a subsequent chapter. The author is strongly of opinion that mercury should be administered in *all* cases of syphilis, irrespective of the stage, and that iodide of potassium should be given *in addition*, as long as the so-called secondary symptoms are present, and in the later stages of the disease. In order to prove efficacious, the internal exhibition of mercury should be continued from eighteen months to two years. The Pil. Hydrargyri and the Hydrarg. c. Cretâ are the best preparations, and the addition of iron is usually beneficial. The following is a good formula:—

Hydrarg. c. Cretâ, gr. i.

Ferri Redact., gr. i.

Glycerin. Tragacanth. q.s. to make pil. i.,

and two or three of these may be taken daily for many months without producing salivation or any undesirable result.

Unless there is serious inflammatory mischief present which renders it necessary to place the patient as quickly as possible under the full action of mercury, it is a mistake to give this drug in doses which produce salivation. The best results are obtained by giving small doses daily for a long period. I usually let the patient take two or three of the Hydrarg. c. Cretâ et Ferri Redact. pills daily for six or eight months; then discontinue them for a month, and subsequently take them for three months and discontinue them for one month alternately during another year or eighteen months.

CHAPTER XVIII.

NEW FORMATIONS OF THE AURICLE AND EXTERNAL MEATUS.

Angioma—Fibroma—Cysts—Sarcoma—Epithelioma—Lupus—Osteomata—Exostoses—Symptoms and Treatment—Case of Exostosis Removed by Drill and Screw.

NEW formations of various kinds, some being very rare, are met with in the external ear. They may be developed primarily in this part, or may spread thither from adjacent structures. Some kinds of growths are connected with the auricle and others with the meatus, while in a third class both portions of the external ear are the seat of disease.

I. THE AURICLE.—The principal new formations occurring in this portion of the ear may be classified under the headings of Angioma, Fibroma, Cysts, Sarcoma, and Epithelioma. Ulceration, due to lupus, will also require notice.

Angioma.—Vascular formations of this class are not uncommon in the auricle. Of the two kinds, simple or plexiform and cavernous angiomas, the former can scarcely be regarded as tumours, as they do not project above the level of the skin. They appear as bright red or livid patches, of varying size, and not marked off very sharply from the normal tissue. They are usually congenital, and may either remain stationary or increase in size; their colour is due to enlarged blood-vessels, which are seated in the corium or subcutaneous fat. The cavernous angioma forms a bluish-red tumour, made up of a series of cavities of various shapes, and separated from each other by incomplete fibrous partitions. These tumours are sometimes congenital, but

they may be developed from simple angiomas by continued dilatation of the enlarged vessels. The helix and the anterior surface of the auricle are the parts most commonly affected; but when the meatus is the place of origin, the growth may extend to the posterior surface of the auricle. The tumours vary in size, the largest observed being perhaps equal to a walnut; the surface is more or less irregular, and pulsation is occasionally manifest. Several tumours of this kind may exist in the same patient. Nothing definite can be stated with regard to their cause; in one instance, the tumour appeared after the auricle had been frozen. The rapidity of their growth varies, and when they are slowly developed they cause little, if any, pain. When, however, they grow quickly, and attain a large size, the pulsations are apt to be very disagreeable to the patients. Reflex cough has been observed in a case in which the angioma occupied the meatus, and deafness will of course result if the canal be occluded. Tinnitus may also be very troublesome. Hæmorrhage is, however, the most important symptom connected with these growths; it may be so profuse as to require ligature of the carotid.

The **Diagnosis** of angioma of the auricle or meatus can never be difficult; othæmatoma is the only other tumour with which it is likely to be confounded. The history of the case, the rapid development of the growth, and the uniform smoothness of the surface, will serve to distinguish tumours due to hæmorrhage.

Treatment.—This must depend upon the size and extent of the tumour. When small, vaccination of the surface and brushing it over with nitric acid are two measures that have been proposed; the resulting cicatrices cause more or less contraction. Politzer recommends that several aseptic silk threads, saturated with perchloride of iron, should be passed through the tumour, with the view of causing coagulation and atrophy. In larger growths the same results may be attained by means of the Paquelin or the galvano-cautery. Electrolysis may also be employed with advantage; the needle connected with the negative pole is passed into the tumour, and causes complete coagulation within a few minutes. Injections of the perchloride of iron are not to be recommended, inasmuch as there are several dangers connected with them. Suppuration may take place in the tumour, with pyæmia as a result; and if this danger be avoided, extensive sloughs may form, the separation of which may be followed by uncontrollable

bleeding. If all other means fail, removal of the tumour, with more or less of the auricle, may become necessary.

Fibroma.—Growths of this character most often occur in the lobule, as a result of the irritation caused by wearing earrings, or by piercing the ear for their reception. Instances of this kind are somewhat common among negresses in various parts of the world. The tumours consist of spindle cells and connective tissue, and are to be considered as resulting from hypertrophy of the cicatrix. They are more or less rounded in form, and frequently project on each side of the lobule; the surface is either smooth or furrowed; they vary in size, some being as large as a hen's egg. Tumours of the same nature are occasionally seen on other portions of the auricle.

It is only when they cause deformity that these growths require surgical treatment. Small tumours may be removed by means of a **V**-shaped incision, the edges being afterwards carefully brought together by sutures. If the tumour be pedunculated, it may be cut off with scissors, and when a growth projects from each side of the lobule it is well, after using the scissors, to destroy the remains of the pedicle with the galvanocautery. In dealing with a large growth, careful dissection is necessary, in order to retain as much of the integument as possible.

Cystic Formations, occurring in the auricle, are in most cases the result of glandular dilatation and accumulation of sebaceous materials. They appear as roundish soft tumours of variable size. In one case recorded by Gruber, the tumour was more than an inch in diameter, and was situated on the posterior surface of the auricle. It had existed for five years, and had remained without increase for two years.

Serous cysts occasionally become developed in the auricle, and more or less closely resemble othæmatoma. They differ therefrom, however, in containing a clear yellow sero-mucous fluid, and in not producing deformity at a later stage. It is also worthy of note that no masses of detritus and no shreds of fibrine are found in the fluid. The persons affected are for the most part robust and healthy; only one case occurring in a female has as yet been reported. With regard to their origin, they sometimes appear after slight injuries to the part; in such cases they are rapidly developed, but are not painful. In other cases they are developed spontaneously,

and also increase somewhat rapidly.* These cysts sometimes become inflamed, with suppuration and spontaneous cure as results. Small cysts on the auricle may be removed by suitable incisions; when large, they are best treated by making a free incision into the tumour, and after the escape of the fluid, filling the cavity with iodoformed gauze.

Sarcoma.—Tumours of this character are rarely seen in the external ear, and only a few cases have been placed on record. In one described by Hartmann,† the patient was a boy, aged three and a half years, who had suffered for some time from acute purulent inflammation of the tympanum. The tumour, a round-celled sarcoma, was as large as a goose's egg, and projected from the side of the head. Death ensued in seven months with cerebral symptoms.

Fibro-sarcomata and spindle-celled growths have also been noticed; these grow slowly, and may exist for years without giving rise to any marked symptoms; but the small-celled sarcomata rapidly increase in size, and are very painful, as they are apt to involve many sensory nerves, and to set up inflammation in neighbouring tissues. The parotid and mastoid regions are especially liable to be thus implicated.

The symptoms vary according to the variety of the growth; the sarcoma may appear as a circumscribed, reddish, more or less firm tumour, covered by normal cutis; in other cases the surface is eroded, or ulcerated and irregular, and covered with offensive muco-purulent matter. When the growth is of the round-celled variety, its increase is very rapid; masses of fungous granulations sprout from its surface. In a case recorded by Dr. Orne Green,‡ a spongy, highly vascular, fleshy mass occupied the left meatus, to the walls of which it seemed to be adherent. The tumour eventually measured eight inches in length, and six in breadth. Evidences of glandular irritation and of inflammation in adjacent parts may be present or absent; in the stage of ulceration hæmorrhage is liable to be profuse; metastatic growths are sometimes seen in other organs. Paralysis of the facial nerve is likely to occur as a result of the extension of the growth.

* See an article on "Cyst Formations in the Auricle," by Dr. Arthur Hartmann, *Archives of Otology*, vol. xv. p. 133; and another paper by the same author, vol. xvii. p. 233. A case is also recorded by Dr. Seligmann, *Archives of Otology*, vol. xvi. p. 41.

† *Zeitschrift f. Ohrenhlde.*, Bd. viii. S. 213.

‡ *Archives of Otology*, vol. xiii. p. 153.

The **Diagnosis** can be positively determined only with the aid of the microscope, a fragment of the tumour having been removed for examination. A round-celled sarcoma is usually white on section, and a milky juice exudes from the cut surface. The structure consists almost entirely of round cells and vessels, the former being small and fragile, and inclosing a rounded vesicular nucleus. Fibro-sarcomata contain much intercellular substance, and the tumours are firm and coarse-grained.

The **Prognosis** depends upon the nature of the growth and the rapidity of its development. The small-celled sarcomata increase rapidly, and death may soon result from extension to the brain.

Treatment.—The tumour should be removed as soon as possible. Fibro-sarcomata may be dealt with by the knife or the galvano-cautery loop; and round-celled tumours with the wire loop. After removal, the galvano-cautery should be applied to the surface, in order to destroy, as far as possible, all remains of the growth. Sometimes partial removal is all that can be achieved, and such an operation may be necessary to provide for the escape of purulent matter from the meatus.

Epithelioma.—This form of growth may have its starting-point in the auricle (usually in the upper half), or in the external meatus, or it may spread to these parts from adjacent structures. Only a few cases have been placed on record.* In the auricle the disease commences in the form of one or more hard nodules situated in the skin or subcutaneous connective tissue. At first, and for some time, their growth is a slow process, but afterwards it becomes more rapid; the surface sooner or later breaks down, and an ulcer results. Both surfaces of the auricle would appear to be equally liable to cancerous growth. Sometimes warty growths are the starting-point of epithelioma. The surface becomes fissured and the cracks form ulcers with indurated edges and roughened surfaces. As the growth enlarges, epithelial nests, made up of large multiform squamous cells, may sometimes be pressed out of it. Fresh formation of new tissue, to be followed by disintegration, goes on at the margin of the ulcer, and thus the process of destruction spreads, until not only the entire auricle and meatus may be involved, but the mischief may extend

* See Moos, *Archives of Otology*, vol. xiii. p. 239; Fougerey, *Annal. des Mal. de l'Oreille*, April, 1890; and Spalding, *Archives of Otology*, vol. xxi. p. 299.

to neighbouring parts and to the bones of the skull. In some cases the appearance of epithelioma in the meatus is preceded by some other affection of the ear, such as purulent inflammation; but in others the disease attacks a perfectly healthy canal. Epithelioma of the meatus may also begin with symptoms of eczema, or as a small crust beneath which an ulcer is developed. The process extends and involves the tympanum and bones of the head.

The development of the nodules on the auricle is unattended with pain, and some months may elapse before any glandular enlargement appears. When disintegration commences the pain becomes a prominent symptom, and it increases with the progress of the disease. As the deeper parts of the ear are gradually involved, the pain becomes excruciating. In addition to symptoms of irritation of the auditory nerve, the course of the disease will be further marked by profuse hæmorrhage, great swelling and induration of the glands of the neck, and facial paralysis; the fatal issue may be due to meningitis, thrombosis of the lateral sinus, or to cerebral abscess. Septicæmia is another cause of death in these cases.

Treatment.—As soon as the malignancy of a growth confined to the auricle has been determined, removal of the portion should be at once effected. The application of caustics is not advisable; extension of the growth is the ordinary result of the irritation. Removal of the entire auricle may be necessary, and in such a case the meatus must be carefully kept open during cicatrisation. An artificial ear can afterwards be adapted. If the growth be seen in an early stage and before it has reached any great size, it may be possible to scrape it away with a sharp spoon; but care should be taken to remove all the affected tissue. Dr. Spalding suggests that, after the growth has been thus removed, the resulting cavity should be covered with a skin graft from some healthy portion of the body. As, however, it is impossible to be certain that all affected tissue has been removed, excision of the growth, together with a wide margin of apparently healthy tissue, is the safer mode of treatment. In circumscribed epithelioma of the meatus, an attempt may be made to destroy the growth and a portion of the surrounding structure, by means of the galvano-cautery; but it is better not to interfere unless the whole of the ulcer is within reach. When this condition cannot be fulfilled,

the case must be treated in the ordinary manner. Remedies to relieve the pain, and local deodorant or antiseptic applications are always required.

Lupus.—Lupous ulceration confined to the auricle and meatus is extremely rare; but extension of the process from adjacent parts of the face is not uncommon. The ulceration of the auricle presents the usual appearance; the surface of the sore is covered at intervals with thick crusts of pus and blood; the margin is livid and swollen, and contains small nodules of granulation-tissue. The entire auricle may be destroyed, and the ulceration may extend along the meatus to the membrana tympani. The pain varies in degree in different cases; it is apt to be very severe when the deeper portion of the canal is involved. There is a variety of the disease termed *maculosus*, and characterised by the formation of brown tubercles, as large as a pin's head or a lentil. These have been observed on the lobule, in the hollow of the concha, and on the posterior surface of the auricle. They seldom ulcerate, but shrivel up, and cause atrophy and puckering of the integument. The spots are covered with minute scales, resembling those of psoriasis, but less abundant than in that complaint. There is yet another form, termed *lupus hypertrophicus*, which is sometimes observed as a consequence of lupous ulceration (Politzer). It is characterised by the formation of glandular and papillary outgrowths from the tissue of the granulations in the floor of the ulcer. These outgrowths are spongy in texture and readily bleed; in some instances they are said to have become hard on the surface, suppuration continuing at the base. The destruction of the integument goes on in the usual way; the development of lupous nodules in the corium is followed by their disintegration, and large portions of the auricle, or even the whole of the organ, may be thus destroyed.

The **Treatment** of lupus of the auricle, as recommended by Politzer, is as follows:—In the non-ulcerated form, a pointed piece of nitrate of silver should be thrust into each nodule, so as thoroughly to cauterise the interior, and this treatment is to be repeated until all nodules have disappeared. Hebra recommends that the affected spots should be brushed over with a thirty per cent. solution of caustic potash, so as to remove the epidermis; this is to be followed by the application of a twenty-five per cent. solution of nitrate of silver, and any excess of fluid is to be

quickly wiped off with moist cotton-wool. The caustic attacks and destroys the infiltrations, while the healthy skin is left untouched. The application is rendered comparatively painless by applying a five per cent. solution of cocaine before using the nitrate of silver.

In the treatment of the ulcerative form the main object is to check the spread of the mischief, and this may sometimes be effected by destroying the floor and edges of the ulcer by caustic applications. When the granulations are spongy and exuberant, the object will be more speedily attained by scraping them away with a small sharp-edged spoon; after any hæmorrhage has been checked, the floor of the ulcer should be cauterised either with nitrate of silver or by means of the galvanocautery. Several applications may be required, for although separation of the slough may be followed by a healthy granulating surface and cicatrisation, fresh nodules are likely to form in the surrounding parts. In the author's opinion all forms of lupus affecting the auricle are best treated by scraping the diseased tissues and then applying the electro-cautery or Paquelin's cautery freely to the edges of the wound. Considerable deformity, due to cicatrisation, often remains after the disease has been arrested by energetic local treatment; but if left to itself the ulceration invariably extends and causes frightful destruction. For *lupus maculosus*, painting with tincture of iodine, diluted with one-fourth the quantity of glycerine, is the best local remedy.

II. THE EXTERNAL AUDITORY MEATUS.—Most of the new formations just described as affecting the auricle likewise occur in the meatus, and generally as the result of extension; but there is one form of growth which necessarily implicates only the meatus, and requires to be described at some length.

Osteomata.—Osseous growths occur in several forms in the external meatus (1) as a diffused thickening of the normal osseous tissue, or *hyperostosis*; (2) as small pointed or rounded projections, which are due to inflammatory processes, and may be termed *osteophytes*; and (3) as circumscribed rounded tumours or *exostoses*.

(1) **Hyperostosis** of the external meatus is due to chronic periostitis, and consequent increased formation of osseous tissue, and is generally connected with chronic purulent or other disease of the middle ear. The deposit of bone is of uniform thickness, and involves more or less of the osseous part of the canal; it may

be confined to one side. The surface is slightly rough, and the integument is redder than natural and swollen. As a result of the deposit, the meatus is more or less contracted, and hearing may be impaired. The deafness, however, is more often due to the morbid changes in the middle ear, or to accumulation of secretion behind the narrowed portion. Examination with the probe will detect the nature and length of the stricture.

(2) **Osteophytes** are likewise the results of chronic inflammation, but the enlargement, instead of being diffused, takes the form of small elevations, extending for some distance over the surface. The *treatment* consists in cleansing the meatus by syringing, and in applying proper remedies to the swollen integument (*see* Treatment of External Otitis, page 185). Soothing ointments (*e.g.*, Unguent. Acid. Boric.) may be applied to the meatus, while tincture of iodine is painted over the mastoid process. When success has been attained, any disorder of the middle ear should be carefully treated. As the contraction is apt to return, it may be necessary to repeat the local treatment from time to time.

(3) **Exostoses** are somewhat common in the external meatus. These are little masses of either compact or spongy osseous tissue, and more or less globular in form; they are most prone to affect the posterior wall of the canal. With regard to their etiology, some authorities believe that local sources of irritation, and especially sea-bathing, are the most important factors. They are sometimes of syphilitic origin, and are associated with similar growths from other bones. They also occur in cases in which there is no venereal taint; sometimes they are associated with gout and rheumatism, but more often with inflammatory processes in the meatus or tympanum.* Flat and mammillary exostoses, of moderate size, are not uncommon in chronic catarrhal and purulent otitis. Another mode of origin is from cartilaginous and connective tissue growths, such as chondromata and polypi, which become partially ossified. Growths thus caused are for the most part single, and consist of a very hard nucleus, from the surface of which trabeculae of bone project into a layer of fibrous tissue, the whole being attached to the outer edge of the osseous meatus by a bony

* See notes of a case of pedunculated bony growth in external meatus, the result of prolonged suppuration, *Archives of Otolaryngology*, vol. xii, p. 59.

pedicle (Pritchard). The association of exostoses with obliteration of the Eustachian tube has been noticed in some cases, the obstruction in the latter part being probably due to osseous growths. Toynbee states that exostoses in the meatus are sometimes connected with similar formations in the deeper structures of the ear. Aural growths are much more common in males than in females.

Two bony prominences are sometimes seen in the upper wall of the meatus, close to the membrana tympani, one being in front of the other, and both ears being affected. These correspond with the line of union between the annulus tympanicus and the temporal bone, and probably depend upon the occurrence of irritative processes in early life.

Symptoms.—The development of exostoses is not attended with pain; only after some time, when the growth impinges against the opposite wall of the meatus, is any inconvenience experienced. In the not very uncommon case of multiple growths, their surfaces may soon come into contact, when much pain will be felt. Impairment of hearing will also depend upon the size of the growth and the extent to which the meatus is obstructed. When examined with a probe, the growths are sometimes found to be very tender. In a case recorded by Dr. H. Knapp,* fits of coughing were induced by touching the growth with a probe. Complete obstruction of the meatus may be due to accumulation of cerumen between the growth and the wall of the canal, and under such circumstances the deafness will vary in degree from time to time.

On examining the ear, an exostosis appears as a globular or elliptical swelling connected with the wall of the meatus, and either sessile or somewhat constricted at its point of attachment. Unless it be covered with granulations, the tumour is hard and firm, and its size varies from that of a hemp-seed to that of a small nut. It may extend to the opposite wall, and when two or more exostoses are present, their convex surfaces may so approximate as to leave only a small chink. Polypoid excrescences not infrequently appear on the surface. The growths are sometimes found in both ears, exhibiting a remarkable degree of symmetry in their form and position. Their structure is that of perfectly formed bone-tissue. They increase very slowly in size,

* *Archives of Otology*, vol. xi. p. 203.

and may remain for years without undergoing any further change in dimensions. In a few cases, the growths have been noticed to decrease in size and finally to disappear.

Exostoses of the auditory canal, when associated with chronic suppuration of the middle ear, may cause retention of the discharges and grave consequences within the cranium. Their presence is always a serious complication of chronic suppurative otitis. In a case recorded by Dr. Munson,* of Albany, N.Y., chronic otorrhœa had led to the formation of an exostosis, which, with polypoid tissue, almost completely occluded the canal. The patient refused to submit to any operation, although there were symptoms indicative of cerebral mischief; delirium supervened, followed by coma, and death ensued in less than twenty-four hours. Post-mortem examination revealed an abscess as large as a hen's egg in the middle lobe of the brain, caries of the

FIG. 68.

EXOSTOSES IN RIGHT MEATUS occurring in a lady now thirty-eight years of age. When the patient was first seen, eight years ago, the four growths were the same size that they are at the present time. The hearing of the right ear was then normal, and it still remains so.

superior wall of the petrous bone immediately above the semi-circular canals, and a corresponding perforation in the meninges.

Diagnosis.—The history of the case, the appearance of the growth, and an examination with a probe, will serve to distinguish an exostosis from other tumours of the meatus. Its hardness, slight tenderness, and the absence of redness, contrast with the symptoms of an abscess; moreover, the latter is further distinguished by the changes it undergoes. When the meatus is inflamed and swollen, and the projecting growth is covered with secretions, or presents granulations, it might be mistaken for a polypus, but an examination with the probe will detect the hardness of an exostosis.

Treatment.—Unless the meatus be considerably obstructed, an exostosis need not be interfered with; but care should be taken to prevent accumulation of cerumen and epithelium in the

* *Archives of Otology*, vol. xi. p. 29. See also the records of another case in which the cerebral symptoms were completely relieved by removal of the exostosis, *Ibid.*, vol. xix. p. 144.

deeper portion of the canal. If the meatus be much diminished in calibre, or completely obstructed, and especially if there be an accumulation of pus behind the growth, as would occur in suppurative otitis media, measures must be adopted for the removal of the latter. The local application of remedies to produce absorption, and the introduction of tents with the same view, are very rarely successful, their effects, if any, being mostly confined to the soft parts. All operative measures for the removal of exostoses require the greatest care, and should be undertaken only by those who are accustomed to deal with diseases of the ear. For sessile exostoses, Dr. Mathewson, of New York, was the first to suggest the use of the American dental drill, and the plan has been adopted by Mr. Field,* and others. The operation should be performed as follows:—The patient is placed on a high couch (about forty-two inches from the ground), with pillows under his head, so arranged that a strong light may be reflected into, or fall upon, the ear to be operated upon. An anæsthetic having been administered, an assistant holds round the exostosis or against the walls of the meatus, according to the position of the outgrowth, a copper or steel guard, to prevent injury from the drill slipping whilst in action. Although a steel guard is the better of the two, on account of its greater hardness, a copper one is often the more serviceable, as its curve can be readily altered to enable it to be placed in different positions. In all cases the guards should be previously tried, in order to ensure that they fit well against the parts which they are intended to protect. Three or four assistants are necessary, one to give the anæsthetic, a second to work the treadle of the drill, while a third holds the guards in the ear. It is necessary also to sponge or syringe away the blood which flows into the meatus. When dealing with **sessile exostoses**, it is well to begin with a small drill, and to widen the opening with a larger instrument. The hole should be commenced midway between the base and summit of the growth, and in the early stages of the operation too great care cannot be taken to prevent the drill slipping. Firm pressure should never be made with the drill, for if it slips whilst this is being done, serious injury may be caused to the middle and internal ear. It is necessary frequently to take out the instrument in order to remove the blood, so that a view can be obtained of the tumour. As the operation

* *Diseases of the Ear*, 3rd Edit. p. 75.

should never be hurried, from one to two hours may be required to drill through the growth; and if, after this has been done, it is considered undesirable to prolong the operation, the remainder of the exostosis may be removed on another occasion. After a few days the opening may be enlarged with other drills until the growth has been removed. This treatment is applicable to very hard exostoses, and for cases in which the tumour is composed of soft bone; but when dealing with the latter, an attempt may be made to break away the growth with a pair of suitable forceps, after a hole has been drilled into it. For multiple growths operations of this kind are, as a rule, unnecessary, inasmuch as a triangular channel is usually found which may be kept open by the use of graduated styles.

For the removal of aural exostoses, Dr. Urban Pritchard* suggests the use of a minute trephine, instead of a solid burr. The instrument is applied as near the base of the growth as will permit its circumference to rotate freely above the apex, the object being to cut off a portion, rather than to make a hole in the swelling. Dr. Pritchard claims that the trephine causes less débris and hæmorrhage, and removes a far larger portion of bone than when a hole is drilled.

For the removal of a **pedunculated exostosis** I consider the safest method is to drill a hole into it, by means of a dental engine, and then insert the tapering screw (Fig. 73) until a firm hold has been obtained. Gentle traction should then be made, and the growth broken off at its pedicle and removed from the meatus attached to the screw. If traction alone fails to break the pedicle, the direction of the force should be varied. Before beginning the operation several drills of different sizes should be provided, and a tapering screw made for each, with its end slightly smaller, and its broadest part larger, than the hole made by the drill. Care should be taken not to insert the screw too far into the growth, in case it should split it, and thus prevent a firm hold being obtained.

As I am unaware that a pedunculated exostosis has been removed previously by this method, I mention the following case, and insert woodcuts of the instruments used :—

M. C., a Dutch Jewess, aged twenty-two, was admitted into the London Hospital in November, 1892. There was a purulent

* *Archives of Otology*, vol. xx. p. 45.

discharge from her left ear, which had been present for some time, but she came on account of a pain in the right ear, which had existed for about six months, and was of daily and frequent occurrence.

FIG. 69.

THE EXOSTOSIS BEFORE REMOVAL.

FIG. 70.

SELF-RETAINING GUARD.

There was no discharge from the right meatus, but the hearing on this side was considerably impaired, and had been defective since the commencement of the pain. On making an

*b*

FIG. 73.

THE SCREW
EXTRACTOR.

examination a hard, smooth, whitish mass, with a rounded outline and tender to the touch, was seen filling the meatus, its outermost part being about an eighth of an inch from the entrance.

A very fine probe could with difficulty be passed between the exostosis and the walls of the canal for about a quarter of an inch, but no attachment could be felt.

The patient having been anaesthetised, the meatus was well illuminated by a strong light reflected from a frontal mirror, the lateral walls protected by the self-retaining guard (Fig. 70), and its roof and floor by two copper guards (Fig. 71), held by an assistant. A hole was then carefully bored into the exostosis with the drill (*a*, Fig. 72) attached to a dental engine, and when this had been made of a sufficient depth to enable a firm hold to be obtained, the screw (*b*, Fig. 73) was inserted. On traction being made, the pedicle was felt to break, and the exostosis firmly fixed to the screw was withdrawn from the meatus.

Examination of the growth (Fig. 74, natural size) showed that it had been attached at (*a*) to the junction of the upper and anterior wall. Hearing was restored on removal of the growth, and stated to be as good as it was before the onset of the pain.

The use of a small mallet and chisel has been recommended for detaching a pedunculated exostosis; but this method of treatment presents obvious disadvantages. When the tumour is large, on account of its close proximity to the walls of the meatus,

FIG. 74.

THE EXOSTOSIS AFTER REMOVAL.

it is often extremely difficult, and sometimes impossible, to discover the position of the pedicle, and in the latter case, if it is to be broken, the whole growth must be forced inwards, a procedure which cannot be recommended, as the size of the growth, and consequently its position as regards the tympanum, are unknown. When the chisel can be directly applied to the pedicle, it is evident that a blow sufficient to break it is liable to drive the chisel against deeper structures immediately the resistance ceases which has been offered by the growth, and if the exostosis is large and situated deep in the meatus, there may be considerable difficulty in removing it after it has been detached. In most cases where the mallet and chisel have been used, the auricle and cartilaginous portion of the meatus have previously been dissected off and held aside.

The removal of a pedunculated exostosis by an electric snare is another method of treatment which has been recommended. In many of the cases it seems probable that traction did more to sever the pedicle than the heat of the wire, the latter serving principally to destroy the tissues in contact with the growth, and thus allow the loop to be passed over it.

CHAPTER XIX.

FOREIGN BODIES IN THE EAR.

Classification of Foreign Bodies : Vegetable, Animal, Mineral—Symptoms caused by Insects in Meatus—Treatment—Symptoms caused by Non-living Bodies—Reflex Symptoms—Symptoms often Aggravated by Attempts at Removal—Diagnosis—Prognosis—Treatment, Various Methods and Precautions—Substances Liable to be Swollen by Moisture—Various Instruments for Extracting Foreign Bodies from Meatus—Course to be Pursued when Extraction Impossible—Partial Separation of Auricle.

A CONSIDERABLE number of substances, of very different kinds, find their way into the external auditory meatus, where they are apt to give rise to symptoms and disturbances varying both in kind and degree. On the other hand, they sometimes remain, even for years, without causing obvious inconvenience. To enumerate the articles that have been found in the external meatus would be a work of some length; they may be conveniently divided into several categories according to their nature.

(1) **Vegetable Substances.**—A large number (about 75 per cent. of all cases) are derived from the *vegetable* kingdom. It is sufficient to mention seeds of various kinds—peas, beans, cherry-stones, grains of wheat and barley—fragments of straw, pieces of wood, pencils, cork, plugs of cotton, pieces of india-rubber, etc. These, again, may be divided into two classes, according to their liability to swell, or the contrary. It is obvious that this distinction is a very important one, especially as regards treatment.

(2) **Animal Substances.**—Articles of *animal* origin are found in about 15 per cent. of all cases; the list includes various

insects, as flies, cockroaches, fleas, bugs, caterpillars, etc.; bacon-rind, ivory, bone, teeth, and wax.

(3) **Mineral Substances.** — Among *articles* of mineral origin (10 per cent. of all cases) come buttons, shot, beads, pebbles, rings, pieces of chalk, slate-pencil, glass, pin-heads, etc.

Children constitute the majority of patients, and in most cases the articles are introduced intentionally, either by the child itself or by a companion. Insects occasionally wander into the ears both of children and adults; but other foreign bodies are much more frequently met with. In the case of persons suffering from discharges from the meatus, flies are apt to be attracted to the part and to deposit their eggs. In the absence of any local disease, however, a fly has been known to crawl into the meatus and deposit its eggs. In one case,* fifteen larvæ had been present, of a yellowish-white colour and filled with blood, which showed through their bodies. The larvæ of the *muscida sarcophaga* soon become vigorous, and as their mandibles are furnished with strong hooks, they attach themselves very closely to the walls of the meatus, and are dislodged with difficulty. As many as 200 larvæ have been counted in one ear.

The **Symptoms** caused by insects in the meatus vary according to the amount of irritation which they set up in the canal and membrane. There may be only the sensation of something moving in the ear. Fleas, by jumping against the membrane, will cause loud and strange noises to be heard. Considerable irritation is caused by bugs, which are apt to attach themselves to the walls of the canal. Such insects as are provided with hooks will produce much irritation and severe pain. The earwig has been so named on account of its supposed propensity to crawl into the ears, but its reputation in this respect is undeserved. Though common in many parts of the country, and its numbers sometimes constituting a serious nuisance, it is not prone to crawl over the person, though it has a habit of creeping into tubes.

Professor Hedinger,† of Stuttgart, reports one case in which an earwig was found in the ear, its head imbedded in cerumen, and states that, so far as he knew, only one other case is mentioned in literature.

Other symptoms, besides pain and noises in the ears, are

* *Archives of Otolaryngology*, vol. xx. p. 11.

† *Ibid.*, vol. xv. p. 242.

sometimes caused by the presence of insects in the meatus. In rare cases headache, giddiness, vomiting, epileptiform attacks, and partial paralysis have been witnessed, their origin being demonstrated by the fact that they ceased after the insects were removed. On the other hand, the irritation may be so slight as to cause little, if any, annoyance. When pain is complained of in such cases, the cause is generally discoverable without much difficulty. Sometimes, as in the case of fleas, the movements of the insect may be detected. Small bugs are apt to adhere closely to the walls of the meatus, or to the membrana tympani, and may be difficult of discovery when partially covered up with secretion and epithelium. The larvæ of flies sometimes crawl out of the meatus, and are seen in the secretion in cases of otorrhœa. When the membrane is perforated or destroyed, these creatures readily gain access to the tympanum. They may be detected by their movements, and the dark colour of the posterior extremity.

The **Prognosis** in all these cases is for the most part favourable, inasmuch as insects can readily be removed from the ear. If there be already suppurative inflammation of the tympanum, the prognosis must depend upon its severity and previous course.

The **Treatment** consists in destroying or removing the insect by means of the syringe or forceps. Most insects are speedily killed by pouring water into the ear and allowing it to remain for a few minutes; they can then be easily removed by syringing. A little alcohol is still more efficacious, and oil of turpentine is also recommended for the same purpose. When the creatures are closely adherent to the walls or to the tympanum, their removal is less easy. A little tobacco-smoke or vapour of chloroform will suffice to stupefy or kill them, and they will then fall off; but if these means are not at hand, they can always be detached with the aid of fine forceps.

The **other foreign bodies** already mentioned are far more frequently met with in the ear. The symptoms they cause depend upon the amount of force with which they have been introduced; and secondly, upon the physical and chemical peculiarities of the substances themselves. It is not uncommon to meet with cases in which foreign bodies have remained for long periods in the ear without causing any appreciable symptoms.*

* In one case, two apple seeds had remained in the ear for forty years—*Archives of Otology*, vol. xviii. p. 194; see also vol. xx. pp. 218, 338.

Some degree of deafness and feelings of pressure or tension are, however, generally produced, and if the substance is pressed against the membrane, there will be noises in the ears of various kinds. When the foreign body is hard and rough, and especially if violent but fruitless efforts be made to remove it, more or less severe pain will be almost certainly present. In the majority of cases, the foreign bodies are found in the osseous portion of the meatus. Occasionally they are so far down as to injure the tympanic membrane, and in rare cases pass through it into the tympanum.

Various reflex symptoms are often caused by the presence of foreign bodies in the ears; some of them take an acute and others a chronic form, and those belonging to the first of these categories are sometimes intermittent and sometimes continuous. Among the acute reflex symptoms may be mentioned laryngeal irritation and violent cough, nausea and vomiting; and in one recorded case,* rigors, followed by febrile attacks, were due to the presence of a foreign body in the ear. Reflex symptoms, chronic in their duration, have been noticed in the form of epileptiform attacks,† contractions of the limbs, paralysis, dizziness, disordered equilibrium, convulsions, and spasmodic dysphagia. Hyperæsthesia and anæsthesia are of less common occurrence. Salivation has been known to occur as a result of retention of a plug of cotton-wool for several years; it ceased after removal of the plug. Disorder of the cerebral functions has been found to depend upon the presence of a foreign body in the ear. Thus, in the case of a schoolmaster, both of whose ears were plugged up with ceruminous secretion, there were such severe attacks of mental confusion, that he was often compelled to cut short the lessons he was giving. The symptom disappeared after removal of the plugs. The absence of giddiness and of noises in the ears was a notable feature in this case. Whatever form the symptoms may take, they are wont to subside after the foreign body has been removed.

In the majority of patients brought to the surgeon with foreign bodies in the ear, the symptoms have been aggravated by the attempts made to remove the offending substances. The latter are apt to be pushed inwards against, and even through, the

* *Berlin. Klin. Woch.*, April 10, 1876.

† *Archives of Otology*, vol. xiii. p. 208

membrana tympani; while the walls of the meatus are often lacerated by the instruments employed. Hence swelling, bleeding, and inflammation of the meatus are not uncommon. If several hours have elapsed, the parts may be so swollen as to conceal the foreign body from view. If the substance has been introduced into an ear already diseased, as in a case of purulent otitis, the symptoms of the latter will likewise exist.

The **Diagnosis** of a foreign body in the ear is sometimes quite easily made, and at other times it is very difficult. In young children especially, inflammatory swelling is soon set up, and the meatus becomes occluded. If the foreign body has been pushed through the membrane into the tympanum, it may elude discovery for a considerable time, during which serious mischief may be done. In some cases the shape of the canal makes detection difficult. The anterior wall sometimes bulges out considerably, so as to hide from view any substance lying against the tympanum. After foreign bodies have remained for some time in the meatus, they generally become coated with a layer of cerumen.

Prognosis.—In cases of foreign bodies in the ear, the *prognosis* is generally favourable, except when there are complications, or when the body is situated deeply in the tympanum and has set up profuse suppuration, or when the pus is prevented from escaping and head-symptoms have appeared. Under such circumstances, the prognosis must be very guarded. The seriousness of the case may be due to the rough and violent attempts at removal of the substance, quite irrespective of its nature, and cases of this kind, in which fatal meningitis or cerebritis has been set up, are by no means infrequent.

In not a few cases, foreign bodies, especially smooth ones, introduced into the ear, fall out without causing pain or other trouble; and in a somewhat numerous class, the substances remain for years without interfering with the patient's comfort.* In 1879 a child was brought to me on account of earache of one or two days' duration. On examination, a small piece of white substance was seen lying against the membrana tympani, and on removing it by syringing it was found to be a portion of

* See Hedinger's table in *Archives of Otology*, vol. xv. p. 228, and the papers referred to on page 218.

a shell. More than a month previously the child had been at the sea-side and played at being partially buried in the sand. The pain did not return after the piece of shell was removed. Rough pointed bodies are most likely to cause irritation and inflammation. In a few instances needles have been known to pass through the tympanum and Eustachian tube into the throat, whence they were discharged in the act of vomiting. In still rarer cases, the foreign body (*e.g.*, an oat-husk) has entered the pharynx from the mouth, and passed through the Eustachian tube and tympanum into the external auditory canal.*

Treatment.—The first step is to ascertain whether a foreign body is present, for it is not uncommon for patients to assert that such is the case when subsequent examination proves that they are mistaken. Serious injury has been inflicted in attempting to remove foreign bodies stated by patients to be in the meatus, but not visible on inspection. In one such instance,† fracture of the tympanic plate of the temporal bone was the result of attempting to remove a pin supposed to have passed into the meatus. In many cases, simple examination with the naked eye is sufficient; but for the detection of small bodies, a speculum will generally be required. Care must be taken not to push the object deeper into the ear. Substances which have passed into the osseous part of the meatus are much more difficult to extract than those which are situated in the cartilaginous portion. Too much gentleness cannot be exercised in carrying out any operative measure that may be required, and in all cases it is essential that the meatus should be thoroughly illuminated.

When a foreign body is detected, injections of warm water should be employed to remove it. As a strong current is generally desirable, a powerful syringe (holding three to four ounces) should be used, with a fine nozzle, so that the stream can be watched and accurately directed between the substance and the wall of the meatus. Whilst this is being done the auricle should be drawn upwards and backwards (in children downwards and backwards). For heavy articles, *e.g.*, shot, it is recommended that, whilst the ear is being syringed, the patient's head should be placed in a position to facilitate the foreign body falling out. Injections are contra-indicated when the

* *Berlin. Klin. Woch.*, 1878, S. 728.

† *Archives of Otology*, vol. xiv. p. 239.

foreign body is cup-shaped and the concavity presents itself, and when there is a perforation in the *membrana tympani*, they may have to be discontinued on account of the coughings produced or the loss of power resulting from the escape of the fluid into the throat through the Eustachian tube, or its presence in the tympanum causing giddiness.

When the foreign body is visible, but firmly resists all efforts at extraction by means of injections, it has been recommended to adopt the following method:—The point of a camel-hair brush is dipped in a strong solution of glue and carefully applied to the surface of the object, previously dried. A solution of mastic in spirit, or some one of the cements used for mending glass, would probably be more tenacious than glue. The brush is to be kept in position until the glue or cement is dry, when the foreign body can sometimes be drawn out with it.

In cases in which, owing to previous attempts at extraction, the meatus is swollen and inflamed, it will be best to adopt measures to relieve this condition before attempting to remove the foreign body, and except in the case of a substance which will absorb moisture there is a decided advantage in adopting this course. An ice-bag should be applied to the ear, and a little morphine may be injected hypodermically. A warm ten to twenty per cent. solution of cocaine dropped into the ear is at times desirable. When the swelling subsides, the foreign body is sometimes found to be comparatively loose. More active measures are requisite when there are symptoms of irritation of the brain, violent pain in the head, rigors, and vomiting, but even these, as well as the local symptoms, may often be relieved by the application of cold.

Substances liable to swell under the influence of moisture are apt to prove very troublesome when attempts are made to remove them, and those which possess this property are, unfortunately, often introduced into the meatus. Peas and beans are the foreign bodies most commonly met with, and when pushed deeply into the meatus, and swollen from imbibition, they get firmly fixed and are very difficult to extract. Hedinger recommends that oil or glycerine should be used in the attempts to syringe out foreign bodies of this class. If this plan fail, it will be necessary to use instruments for their removal, such as a small sharp-pointed hook (Fig. 75), or a stiff needle bent at a right angle near its point;

these are fitted with appropriate handles. When used, the hook or needle is to be passed along the upper wall of the meatus, between it and the foreign body, until the apex of the instrument is behind the latter. It is then to be turned round so that the point is directed towards the surface of the foreign body. By raising the handle the point is depressed and enters the substance to be extracted: slight traction of the handle may then prove sufficient. If the foreign body be deeply placed in the osseous portion of the meatus, it is better to pass the hook along the anterior and inferior wall; for if it be passed along the upper surface, there is risk of injuring the superior and posterior portion of the membrana tympani. Two hooks, one on each side of the substance to be removed, are sometimes required. When the handle of the instrument is circular, it is well to have a mark on it to denote the direction of the hook.

Instruments with a screw at the extremity are seldom of much use in extracting a foreign body other than wool. They are liable to drive the substance deeper into the ear, and the screw is apt to tear its way out when traction is made. The screw (Fig. 76) is, however, very useful in breaking up peas, beans, and similar soft substances, and enabling them to be subsequently removed by syringing or by other instruments. Forceps are not serviceable for extracting round hard bodies which are firmly fixed in the meatus. If injections fail, a fenestrated curette may be tried (*see* Fig. 27, p. 75), a wire loop, or a blunt hook, or sometimes a bent

Fig. 75.

HOOK FOR THE EXTRACTION OF FOREIGN BODIES.

Fig. 76.

DOUBLE SCREW FOR THE EXTRACTION OF FOREIGN BODIES.

probe is the most efficacious instrument. Dr. Ward Cousins has devised the extractor shown at Fig. 77. It consists of two loops, which can be approximated by slipping forward the ring in the centre of the handle. This instrument would be useful for removing beads, buttons, etc. In order to break up a hard body, the use of the galvano-cautery has been suggested, but the effect of heat upon the walls of the meatus is likely to be mischievous. Politzer thinks that it might be tried for such an object as an impacted cherry-stone, in order to burn a hole for the passage of an extraction-hook. Dr. Guye, of Amsterdam, has invented a small forceps* for the removal of cherry-stones and similar bodies from the meatus. In the case of a large bead firmly fixed in the meatus, its extraction was accomplished by means of a laminaria tent passed through the aperture. This was allowed to remain for some hours, and when removed, it brought the bead with it.

When the membrana tympani is perforated, and also when

FIG. 77.

WARD COUSINS' EXTRACTOR.

the foreign body has passed into the tympanum, and other measures have failed, its removal may sometimes be effected by injecting air or fluid through the Eustachian tube.

Cases in which foreign bodies are present in the external auditory meatus differ exceedingly in many particulars, and necessitate different methods of treatment. The nature and shape of the foreign body, its size, and especially its position in the meatus, are the points of most importance. Removal is generally easy if the body be placed in the cartilaginous portion of the canal, and if there be no hæmorrhage or swelling caused by attempts at extraction. On the other hand, difficulties will often present themselves, when the foreign body is in the osseous section, and firmly impacted.

When extraction is impossible, and symptoms of cerebral irritation are developing, it is advisable to make an incision behind the ear, and partially separate the auricle from its

* *Archives of Otology*, vol. xv. p. 32.

posterior attachment. In children, the superior wall of the meatus should be detached from its insertion, and a curved hook should be passed from above behind the foreign body. In adults, it is best to detach a portion of the posterior and inferior wall, and attempts should then be made to remove the foreign body with the aid of hooks, bent at various angles, or suitable forceps. After removal, the parts should be carefully readjusted and sutures applied.

CHAPTER XX.

AFFECTIONS OF THE MEMBRANA TYMPANI.

Injuries of the Tympanic Membrane—Indirect and Direct Causes—Symptoms—Subjective Sensations—Alterations in Hearing-Power—Objective Symptoms—Rupture of the Membrane from Sudden Condensation of Air—Mechanical Injuries—Rupture of the Membrane by *Contre-Coup*—Prognosis—Treatment—Inflammation of the Membrana Tympani or Myringitis—Symptoms—Abscesses in the Membrane—Formation of Vesicles—Diagnosis—Prognosis—Treatment—Chronic Inflammation of the Membrana Tympani—Causes—Symptoms—Course and Treatment.

INJURIES.

Injuries of the Membrana Tympani constitute about seven per 1000 of aural affections in general, and are therefore somewhat rare. The membrane is to a great extent protected by its position and mode of attachment to the surrounding bone. It may, however, be torn or ruptured as the result either of *indirect* or *direct* injury. Examples of the *former* kind are (*a*) cases in which the membrane is torn as the result of concussion, due to blows or falls; and (*b*) those in which the mischief is due to the effect of suddenly condensed air, *e.g.*, in violent explosions. Forcible condensation of the air in the tympanic cavity has been known to cause rupture of the membrane. Thus the accident is occasionally due to violent coughing, sneezing and blowing of the nose, and also to the injection of air by Politzer's method and by the catheter. Such a result, however, could scarcely occur in the absence of pathological changes in the affected membrane. *Direct injuries* are caused by foreign bodies coming in contact with the

membrane, by chemical agents, and by fractures of the surrounding bone. Cases due to unskilful attempts to remove foreign bodies from the meatus are by no means uncommon. In all cases of injury from violence, pre-existing morbid conditions of the membrane more or less affect the result. Perforation is not infrequently due to intra-tympanic disease. Thus, exudations within the cavity and morbid growths extending outwards are liable to cause absorption of portions of the membrane. Lastly, it must not be forgotten that the membrane is occasionally injured by bougies, passed along the Eustachian tube.

Superficial Injuries, or excoriations involving only the external layer, are often caused by the introduction of hard, pointed bodies for the purpose of cleansing the ear or relieving irritation. Owing to the oblique position of the membrane, injuries of this kind generally affect its upper half and the superior wall of the meatus. The symptoms are for the most part of a mild character, provided that the membrane is not torn through. There is more or less pain, and perhaps a little hæmorrhage, which, however, soon subside.

When the membrane is completely divided, as, for example, by falls upon pointed objects, the symptoms are apt to be severe; they depend upon the nature of the injury, the force employed, and the previous condition of the part. Laceration of a healthy membrana tympani causes sudden and very severe pain, but if there has been any previous disease, with fatty degeneration as a consequence, laceration may be easily produced and cause little pain to the patient. With a membrane previously normal, the pain may be so severe as to cause faintness and even attacks of syncope, and in hysterical subjects convulsions are liable to occur. In most cases, giddiness is an immediate result of the injury; it may be so severe that the patient falls down or staggers like a drunken man. Nausea and vomiting may be superadded; but these symptoms pass off unless the labyrinth be involved. The pain also soon subsides in the absence of inflammation of the membrane; if it continue beyond a few hours, complications may be looked for.

Subjective Sensations.—In addition to those already mentioned, various other subjective sensations are liable to be produced by rupture of the tympanic membrane, and the hearing-power is certain to be more or less affected. At the moment of the occur-

rence of the injury, a loud noise is usually heard, resembling that of an explosion; this generally lasts for a few seconds only, though it may be replaced by a slighter and continuous sensation. If inflammation be set up, the sound will be altered in character. The loud noise, first heard, is due to the rupture of the fibres; it resembles that which is caused when a tense membrane gives way. The subsequent and continuous noises may be due to several causes, *e.g.*, effusion within the tympanum, hæmorrhage in the labyrinth, or concussion of the auditory nerve. The noises heard after inflammation has set in are dependent upon the alterations produced in the tympanum. When rupture of the membrane is caused by condensing the air in the cavity (as in employing Politzer's method), the crack can generally be heard by the surgeon.

Various alterations in hearing-power are immediate results of the injury; the form they take depends upon the nature of this latter and on the previous condition of the membrane. Auditory hyperæsthesia is an occasional result, sometimes evinced towards sounds in general and sometimes towards special notes. In the majority of patients, however, there is marked diminution of hearing-power, and this rule obtains whenever the membrane was previously normal. It is rare for the diminution to be so great that a watch can be heard only when in contact with the auricle. When this symptom is present, lesion of the internal ear may be inferred to exist. In all such cases the other ear should be carefully examined, in order to compare the hearing-power.

When the injury has been inflicted upon a membrane altered by disease, the effect upon the hearing-power may be of an altogether different character. When the membrane was previously in a state of abnormal tension or adherent to the walls of the cavity, its condition may be so changed by the force which caused the rupture, that temporary improvement in hearing-power may actually result, though as a matter of course aggravation of the disability is only too likely to occur.

Another symptom is sometimes noticed in cases of injury of the tympanic membrane; the power of distinguishing the direction whence sound comes is impaired or altogether lost on the affected side. The power is apt to be restored before the wound in the membrane is healed. Some patients complain of a sensation of fulness and pressure in the ear; these symptoms are

probably due to effusion within the tympanum or between the layers of the membrane. Blowing the nose sometimes causes a hissing sound, due to the air which escapes through the opening.

The **Objective Symptoms** vary with the cause and extent of the injury. The membrane is more or less reddened and swollen, but when the rupture has been caused by a sharp instrument, only the edges of the wound may present these appearances. With regard to their seat, perforations due to indirect force are usually found in the posterior inferior quadrant and towards the central portion of the membrane; the peripheral part is thicker and more capable of resisting force applied to it. Sometimes the edge of the perforation corresponds with that of the handle of the malleus, and the margin of the wound is not infrequently excoriated. There is seldom more than one opening, and it is generally roundish in form. It varies in size between a mere fissure or cleft (which looks dark when seen through the speculum), and a gap involving the greater part of the membrane. In rare cases, from two to five perforations have been caused by indirect injuries. When the edges of the wound are far apart they are often covered with coagulated blood, and this may be so firmly adherent as to be very difficult of removal. Portions of the membrane at some distance from the opening are sometimes covered with ecchymoses. In some cases, the layers of the membrane are unequally involved in the injury (Gruber), and whenever a blunt instrument has been used, the margins are apt to be irregular. The amount of blood in the meatus depends upon the extent and character of the wound; in the absence of complications there is seldom profuse hæmorrhage. When the perforation is very large, it may be possible to see the mucous membrane of the tympanum.

A punctured wound of the tympanic membrane may be complicated by escape of cerebro-spinal fluid. Thus, in a case reported by Professor Schwartz*, a knitting needle passed through the membrane in the region of the stapes, and the injury was followed by transient syncope, vomiting, no hæmorrhage, but escape of cerebro-spinal fluid from the ear. This flow lasted for eight days, and was so profuse as to cause continuous trickling. The most violent headache, earache, and vertigo at once set in, and were followed by other symptoms of cerebral irritation, which lasted for four weeks. It was doubtful whether there had been

* *Archives of Otology*, vol. xi. p. 82.

a lesion of the labyrinth from the penetration of the needle into the fenestra ovalis, or into some other part of the wall. It was also possible that the cerebral fluid might have been evacuated through the tegmen tympani, after its perforation by the needle, with simultaneous rupture of the mucous membrane and the dura mater.

Injuries involving rupture of the tympanic membrane are sometimes associated with fracture of the ossicles, especially of the malleus, and lesions of the deeper structures. Union of the fractured ends is the rule in such cases; but the normal position of the parts is seldom preserved.

Owing to its deep-seated position, the tympanic membrane is seldom injured as a result of concussion from falls or blows, unless the bone be simultaneously fractured. Cases of perforation of the membrane are sometimes attributed to blows or shocks; but it will generally be found that some diseased condition of the membrane has previously existed.

Effects of Condensed Air.—Rupture of the membrane may undoubtedly be caused by sudden condensation of air in the external meatus, produced either by blows upon the ear,* or by explosions of gunpowder. Such cases are, however, extremely rare, and in most of the recorded instances there was a history of previous disease of the membrane. Gruber† relates the case of an officer who was struck down at Königgrätz by the bursting of a shell. On recovering consciousness, he became aware of a loud noise in the left ear. There was also deafness on that side, moisture in the meatus, and escape of air when he blew his nose. A few hours afterwards pain set in, and other symptoms of inflammation. On examination a roundish opening was discovered in the anterior inferior segment of the membrane; there were no evidences of any previous disease, and the structures of the other ear were quite normal. This was the only case of rupture of the membrana tympani that occurred during the war, in which many hundreds of the soldiers who were engaged doubtless suffered from some disease of the ears. Deafness is not uncommon among artillerymen, but it is only in very rare cases that perforations of the membrane have been discovered,

* See summary of a paper by Dr. Sexton, *Archives of Otolaryngology*, vol. xvi. p. 360, and a paper by Dr. Treitel, *Ibid.*, vol. xix. p. 110.

† *Lehrbuch der Ohrenheilkunde*, S. 311.

and these are more likely to have been caused by disease than by explosions. Dr. Sexton,* however, had the opportunity of examining the ears of eight men, who had been in the vicinity of an exploding shell. In six men the membrana tympani was found to be ruptured; in some, rather extensively. In all, there was serious impairment of hearing. In the cases of persons who have become deaf, as a result of sudden condensation of air, the condition is generally due to lesion of the nervous structures. As a result of various morbid processes, the membrane may become comparatively fragile, and will then give way under the operation of slight causes, as during coughing, straining, blowing the nose or sneezing. In some cases of this character, the rupture is followed by the escape of muco-purulent fluid from the meatus, thus demonstrating the existence of disease in the tympanum (Gruber).

Dr. Roosa† states that in America, during the late Civil War, only one case of rupture of the tympanic membrane occurred from the explosion of artillery. He has also met with one case in which firing of a pistol near the ear produced this result. The accident is sometimes due to another cause, viz., "the force of condensed air found in passing through the lock of a caisson used in excavating for the foundations of bridges, or the making of tunnels under rivers." In most of such cases, however, the permeability of the Eustachian tubes had been previously impaired by disease. The injury is caused by the pressure of the condensed air upon the membrana tympani; if the external meatus be hermetically plugged, no unpleasant sensation is experienced. The rupture may be caused directly by the pressure; but in another class of cases, congestion and inflammation of the membrane are the first effects, and perforation ensues later on. If those engaged in the work adopt from time to time Politzer's method of inflating the ears, all bad consequences will be prevented.

Mechanical Injuries to the head, causing fracture of the temporal bone and of the base of the skull, may of course produce rupture of the tympanic membrane. The prominent symptom of such an injury is hæmorrhage from the meatus or more or less serous discharge from the ear. The membrane may, however,

* *Archives of Otology*, vol. xvi. p. 360.

† *Diseases of the Ear*, Seventh Edition, p. 260.

escape even in severe fractures of the temporal bone, attended by considerable hæmorrhage. The latter symptom is sometimes indicative of rupture of the lateral sinus, but the blood may come from the tympanic artery. When the injury is immediately followed by the escape of clear, slightly albuminous fluid from the meatus, there is reason to suspect fracture of the petrous portion of the temporal bone, involving the roof of the tympanum, and the osseous part of the external meatus, with laceration of the cerebral membranes and rupture of the membrana tympani. If the discharge first appear twenty-four hours or more after the injury, it is in all probability not cerebro-spinal fluid, but inflammatory exudation produced within the tympanum. In a fracture involving the petrous portion of the temporal bone, and attended by the above symptoms, paralysis of the muscles supplied by the facial nerve may be expected to occur. Loss of taste on the same side of the tongue may also result from injury to the chorda tympani.

Rupture of the membrana tympani on each side is a very rare accident, and is generally accompanied by fatal injuries of other parts. In one case, however, reported by Dr. J. M. Ray,* both membranes were ruptured from a fall on the head. Hæmorrhage from the ears went on for four days, and then gave place to a straw-coloured fluid. Notwithstanding the serious character of the injuries, the patient made a good recovery, and was reported "well" three months after the accident.

Rupture of the membrana tympani sometimes occurs by *contre-coup*, that is to say, the injury to which it is due is inflicted on a part of the head at some distance from the membrane. Thus falls on the forehead, vertex, and occiput, have caused an injury of this character. Such cases are less common than those in which the injury is on the same side of the head as the blow. In one instance recorded by Dr. C. Williams,† of Minnesota, the injury consisted of fracture of the left external auditory canal and rupture of the membrana tympani. The patient, a man aged thirty-seven, had fallen backwards on a slippery path, and struck the back of his head against the ice with such force as to produce unconsciousness, which lasted for some time. That the back of his head was the part struck was shown by the fact that the

* *Archives of Otology*, vol. xv. p. 192.

† *Ibid.*, vol. xiii. p. 157.

corresponding portion of "his stiff felt hat was broken off and lay under his head." In a case under the care of Dr. Eitelberg,* of Vienna, after a fall down some steps, the greater part of the tympanic membrane on the right side became detached and came away. Two months later, the loss of substance was entirely replaced.

Prognosis.—In rupture or traumatic perforation of the membrana tympani, the prognosis depends upon the nature of the injury, the presence of complications, and the previous condition of the ear. In many cases, ruptures of the membrane, due to traumatic causes, heal up in a few days, the process being effected either by adhesion of the margins of the wound, or by the development of membranous tissue between them. The hearing-power is but little, if at all impaired. Ecchymoses of the membrane are apt to change their position in the course of time, and to pass towards the periphery. In their later stages, they are often found at the upper and posterior part, and project slightly from the surface. Sometimes yellow spots remain, due to metamorphosis of the hæmoglobin. The subjective sensations generally pass away after the perforation has closed.

When the injury has affected the labyrinth, the prognosis must be guarded. Restoration of the hearing-power is likely to be incomplete. In the presence of such complications as injuries to the osseous walls, dislocation or fracture of the ossicles, complete recovery is not to be expected; the hearing-power is certain to be seriously impaired, if not altogether lost. Purulent inflammation of the middle ear sometimes results from injuries to the membrana tympani. It is not infrequently caused by the injudicious treatment of such cases. The symptoms of such a complication are increase of pain in and about the ear, elevation of temperature, and marked hyperæmia of the membrane. The opening becomes larger, and more or less purulent secretion escapes. In unfavourable cases portions of the membrane are destroyed, granulations or polypi form, and the process becomes one of chronic suppuration of the middle ear, with all its dangers.

In complicated cases, the tuning-fork sometimes aids in determining the extent of the injury. If the bone-conduction on the affected side be better than conduction through the air, injury to the labyrinth may be excluded.

* *Archives of Otology*, vol. xix. p. 12.

The general health of the patient will influence the prognosis. In tuberculous subjects, healing of a perforation is often very incomplete.

Treatment.—As a general rule, slight injuries to the tympanic membrane quickly become healed. All that is necessary is to introduce into the meatus a small plug of cotton-wool carrying a little carbolised oil, and to apply a bandage so as to protect the ear. Simple ruptures of the membrane require similar treatment. The patient should be kept quiet, and should avoid doing anything likely to cause cerebral congestion. Forcible sneezing and blowing the nose violently are certain to interfere with the healing process. The desire to sneeze may sometimes be checked by rubbing the bridge of the nose with the finger. Any little masses of coagulated blood in the meatus and foreign bodies should be carefully removed with the forceps or scoop, and the parts should be cleansed with a little cotton-wool attached to a probe; the instillation of fluids and syringing are never advisable. Such procedures are only too likely to cause severe inflammation of the membrane and tympanum. If there be severe pain in the ear and hyperæmia of the membrane, a few leeches may be applied with advantage either over the mastoid process or in front of the tragus. Cold applications are also likely to be serviceable. After all active symptoms have subsided, if the discharge from the ear become sero-purulent, warm antiseptic solutions should be cautiously tried. Boric acid (2—3 per cent.) and carbolic acid (1 per cent.) are the best remedies for this purpose. Other details will be found in the chapter on the Treatment of Chronic Suppuration of the Middle Ear.

INFLAMMATION OF THE MEMBRANA TYMPANI—MYRINGITIS.

Primary acute inflammation of the membrana tympani very seldom occurs; but the membrane is liable to be implicated in various inflammatory processes of the external and middle ear. The majority of cases of acute myringitis are of a secondary character. Inflammation of the meatus, due to fungi, is apt to spread to the membrane, with perforation as an occasional result in neglected cases.

Primary acute myringitis is almost invariably confined to one ear, and follows directly upon some form of injury. The most

common causes of this character are: foreign bodies, the application of irritating or caustic fluids, and exposure to cold.

Symptoms.—In acute cases, especially when due to direct injury, the first symptom is more or less severe pain, of a pricking or tearing character, which increases in intensity, and subsides with the appearance of a serous discharge. The patient also complains of a feeling of pressure and fulness in the ear, and of noises of various kinds, often of a pulsating character. Hearing-power is somewhat lessened. More or less fever is generally present, and delirium may occur in young subjects. The pain and the other symptoms are usually worse at night.

The **Objective Symptoms** depend upon the exciting cause and the degree of inflammation, and likewise upon the previous condition of the membrane. In most cases the membrane is not uniformly affected; but the signs of inflammation are especially marked in the upper portion and along the handle of the malleus. The principal changes occur in the external layer of the membrane, which becomes hyperæmic and yellowish-red in colour; these appearances commencing near the handle of the malleus, and gradually becoming diffused over the whole surface. In a subsequent stage, which rapidly supervenes, the membrane, especially in its upper part, becomes opaque and much swollen, so that it projects into the canal. The handle of the malleus is no longer distinguishable, being covered up by the infiltrated tissue; its position is marked by injected vessels. Beneath the epidermis, more or less sero-purulent fluid is exuded, and sometimes vesicles are distinguishable. During the further progress of the case, separation of the epidermis is a marked feature, and the exudation becomes more copious and purulent. The deep portion of the external meatus is reddened and swollen, sometimes to such a degree as to obliterate the periphery of the membrane, which may be still further covered up by accumulated secretion.

In the subsequent course of the disease, after detachment of the epithelium, the exudation gradually diminishes in quantity and the swelling subsides. Some weeks, however, pass before the signs of inflammation eventually disappear. The redness becomes less and less marked, and the normal translucency and lustre of the membrane are gradually restored, unless fatty degeneration or partial calcification has occurred.

Abscesses in the Membrane.—In rare instances, instead of exudation beneath the epidermis, abscesses form in the substance of the membrane. Such formation is most often seen in the early stages of middle-ear inflammation. In those cases in which vesicles and abscesses are developed without obvious cause, they may possibly be dependent upon irritation of nerve-centres, and thus resemble herpetic eruptions. Their formation is attended by more or less severe pain; but the subjective sensations and loss of hearing-power are for the most part slight. Such abscesses are generally found in the posterior superior quadrant, and extend from the membrane to the wall of the meatus. They contain clear yellowish exudation; are more or less rounded in form, and are surrounded by a reddened margin in which enlarged vessels are distinctly visible. They usually burst externally, leaving small, flat, yellowish-red ulcers, which have a tendency to perforate the membrane. Sometimes, however, the contents of the abscess become absorbed, and the process comes to an end with the detachment of a yellowish crust. Partial calcification is sometimes observed, and one or more whitish chalk-like patches are seen on the membrane. Such a result is not infrequent in the case of abscesses of the membrane connected with acute middle-ear inflammation. The deposition of tubercle sometimes leads to the formation of abscesses, with perforation as a consequence.

Formation of Vesicles.—Acute inflammation of the tympanic membrane occasionally gives rise to other changes than those already noticed. In one variety described by Politzer* as *myringitis bullosa*, in addition to increased vascularity near the handle of the malleus, and scattered ecchymosed patches, one or more transparent vesicles, as large as hemp-seeds, pearly white in colour, and filled with serous fluid, appear on the surface. These vesicles either burst, or disappear owing to the absorption of their contents.

In another form, which has of late been somewhat frequently observed in connection with influenza,† ecchymosed patches are accompanied by the development of bluish-black, tense vesicles, containing blood, which are apt to extend to the wall of the meatus and to bleed very freely on bursting. Their development is accom-

* *Lehrbuch der Ohrenheilkunde*, II. Aufl. S. 192.

† Gruber, *Allgem. Wiener Med. Zeitung*, 1890, No. 10.

panied by very severe pain. The origination of these vesicles is attributed to capillary thrombosis, said to be due to a peculiar micro-organism found in the blood of influenza patients.

Diagnosis.—The diagnosis of acute inflammation of the membrana tympani is seldom difficult; the complaint may, however, be confounded with acute middle-ear inflammation. In myringitis, the impairment of hearing is slight in comparison with the objective appearances; the air-douche causes pain, but no abnormal sound on auscultation. The pain is relieved by pressing the finger gently into the ear. When abscess exists, it may be detected with the probe; its surface will be found to pit on pressure. It must be remembered that acute inflammation of the tympanic membrane is very seldom of primary origin, whereas it frequently accompanies acute suppuration of the middle ear.

Prognosis.—The prognosis in cases due to injury varies with the degree of the inflammation and the general condition of the patient. If the injury be slight and the patient's health good, recovery within a few days is the general rule. If, however, there be any constitutional dyscrasia, *e.g.*, scrofula, the complaint may prove very obstinate and tedious.

In severe cases, perforation is not uncommon, and this when not caused by the injury may be due to a gradual process of absorption or to ulceration, and openings may take place at one or more spots. Abscesses formed in the membrane generally burst externally, but the pus may break through into the tympanum as well, with a large perforation as the result. In other cases, a different course may be noticed; the pus becomes partly absorbed, and in process of time is converted into a calcareous mass. Atrophy of the membrane is a common result of inflammation; but in some cases, thickening or hypertrophy remains behind.

Treatment.—Careful treatment is required not only to relieve pain, but to prevent injurious consequences. The first step is to protect the meatus and membrane by the introduction of a plug of cotton-wool. Injections of any kind are not to be recommended, inasmuch as they are liable to act as irritants and increase the hyperæmia. For the relief of the latter, several leeches should be applied below the ear and over the mastoid process. In severe cases a small bladder of powdered ice may be placed over the ear, care being taken to prevent water from

trickling into the meatus. If the leeches fail to relieve the pain and hyperæmia, it is well to try the effect of a few superficial incisions through the integument of the deep part of the meatus, as recommended by Gruber. These should be about $\frac{1}{8}$ inch long, and parallel to the margin of the membrane, so as to divide some of its blood-vessels. The bowels must be relieved by means of saline purgatives. If the pain prove very severe, lukewarm water containing anodynes in solution may be dropped into the ear; of these, cocaine is the most efficacious, used in the form of a 10—20 per cent. solution. When an abscess has formed in the membrane, it should be opened as soon as possible with a myringotome.

As the acute inflammation subsides, serous fluid escapes from the ear, and the pain is much mitigated. The meatus may then be syringed out thrice daily with a 3 per cent. solution of boric acid, after which a plug of cotton-wool charged with perchloride of mercury is to be introduced. The ear should be carefully examined in order to see whether perforation exists. This may be difficult to detect at first, inasmuch as the swollen and softened state of the membrane prevents an aperture from gaping. The best evidence is obtained by employing Politzer's method; or the Eustachian catheter. If a perforation exist, the air passing through it will give rise to a blowing, whistling sound.

Another sign of perforation is to be found in the discharge from the ear. When the tympanic mucous membrane is involved, the matters discharged will be mucous in character, and hence if after the use of the syringe threads of mucus are found in the fluid, the existence of a perforation may be inferred. Later on the secretion becomes purulent in character. As a matter of course, involvement of the tympanum lengthens the duration of the case, and influences the prognosis. Adhesions of the sound-conducting parts are certain to take place, with more or less impairment of hearing as a necessary consequence.

CHRONIC INFLAMMATION OF THE MEMBRANA TYMPANI— CHRONIC MYRINGITIS.

Chronic inflammation of the membrana tympani is generally the result of an acute attack, and may continue for weeks or even for months. It is, however, but rarely an independent affection;

in most cases it occurs in connection with inflammation of the middle ear or of the meatus. Even if the morbid process commence in the membrane, perforation is the ordinary result in chronic cases, with subsequent implication of the tympanic cavity. When both parts are involved, it is impossible to determine the course and starting-point of the disorder.

The **Symptoms** of chronic myringitis are less marked than those of the acute disorder. They consist of noises in the ears, a sensation of fulness and pressure, more or less deafness, with itching or sharp pricking pain from time to time. The discharge from the ear is muco-purulent and variable in quantity, being sometimes very abundant, and sometimes very scanty. On examining the meatus, the deeper parts are seen to be swollen, red, and covered with epithelial debris. The membrane itself is grey or greyish yellow, thickened, and devoid of transparency; the short process and the handle of the malleus are indistinguishable. The surface of the membrane may be covered by exudation in the form of crusts. Ulcers and granulations are sometimes present, and the latter, in the course of time, may attain the size of a pea, and project like a polypus into the meatus; their presence does not necessarily indicate perforation of the membrane. Ulceration of the membrane is sometimes due to syphilis.

Chronic myringitis is not always associated with purulent discharge from the meatus. When the membrana propria is especially involved, increase of the connective tissue is the general result. This produces thickening and rigidity of the membrane, with considerable impairment of its functions.

A villous condition of the membrane has been noticed, as a result of chronic inflammation. Small projecting growths of connective tissue, inclosing a capillary loop, and covered with pavement epithelium, occupied the surface of the membrane, while the membrana propria was much thickened.* Such villous growths resemble mucous polypi; in some cases the adjoining part of the meatus has been found similarly covered. In all these forms of chronic inflammation, the whole membrane may be affected, or only certain portions thereof, leaving intermediate spaces free.

Course of the Disease.—Chronic inflammation of the membrana tympani runs a very tedious course, and rarely ends in

* *Arch. f. Ohrenheilkunde*, Bd. V. S. 250.

complete recovery; thickening, opacity and calcareous deposits often remain, and in other cases there is atrophy with perforation. The chronic stage which often follows acute inflammation is sometimes characterised by oft-repeated desquamation of the epidermic layer. In such cases the discharge mainly consists of thick yellowish-white flakes of epithelium, with a little purulent fluid. The membrane is covered with epithelial scales, and sometimes dotted over by minute granulations.

Treatment.—In comparatively slight cases the meatus should be carefully syringed in order to remove purulent secretion and epithelial débris, both of which irritate the parts, and maintain the hyperæmic condition. After syringing and careful drying, powdered boric acid may be applied by means of an insufflator. If this prove insufficient, we may have recourse to solutions of zinc sulphate (gr. iij. to ℥j.), of which a few drops warmed may be poured into the ear once daily. A solution of acetate of lead, of similar strength, may also be tried. In the desquamative form, the crusts should be softened by dropping in a solution of carbonate of sodium (1 to 5 each of glycerine and water). The ear is then to be syringed, after which astringents (zinc or lead) will prove useful. In very obstinate cases, a 2 per cent. solution of nitrate of silver may be used with advantage. When granulations and ulcers exist on the membrane, they should be touched with a solution of chromic acid, or with solid nitrate of silver, or with its solution (10 per cent.), applied by means of a brush, or absorbent wool twisted on to the end of a probe. It is well to syringe the ear after applying the caustic, which may be repeated every third or fourth day. For the destruction of granulations, a solution of chromic acid will generally be found more efficacious than the nitrate of silver; it is to be carefully applied on a chromic acid carrier or wool every three or four days. I consider the galvano-cautery is very rarely necessary for the destruction of granulations; but Politzer recommends a simple platinum point, and that each cauterisation should last only two or three seconds; the circuit is to be closed when the growth is touched by the electrode, which must be withdrawn after each application. The pain caused may be somewhat lessened by the previous application of a 5—20 per cent. solution of cocaine.

Various conditions of the tympanic membrane, associated with middle-ear suppuration, will be described in subsequent chapters.

CHAPTER XXI.

DISEASES OF THE NOSE, PHARYNX, AND NASO-PHARYNX,
CONNECTED WITH DISEASES OF THE MIDDLE EAR.

Influence of Diseases of Nose and Naso-Pharynx on Condition of Tympanum—Acute Nasal Catarrh—Causes and Symptoms—Extension to Eustachian Tubes—Objective Appearances—Treatment—Chronic Catarrh of the Naso-Pharynx—Causes and Anatomical Appearances—Condition of the Mucous Membrane—The Secretions—Symptoms Caused by Swelling of the Mucous Membrane—Nervous Disorders—Course and Changes sometimes produced in Mucous Membrane—Ulcerative Processes—Connection between Chronic Naso-Pharyngeal Catarrh and Aural Diseases—Treatment—Local Applications—The Nasal Douche—The Syringe—Politzer's Method of Applying Solutions to the Nares—Use of the Spray-Apparatus—Inhalation—Ointments—Caustics in Solution—Insufflation of Fine Powders—Nasal Bougies—The Galvano-Cautery—Chemical Caustics—Treatment of Ozæna—Treatment of Enlargement of Posterior Extremity of Inferior Turbinate Body—Treatment of Nasal Polypus—Treatment of Enlarged Tonsils—Granular Pharyngitis—Morbid Growths in the Naso-Pharynx and their Treatment—Removal of Tip of Uvula—Measures for Restoring the Functions of the Muscles of the Tubes—Adenoid Growths—The Pharyngeal Tonsil—Literature on the Subject of Adenoid Growths—Their Anatomical Structure—Etiology—Symptoms, Subjective and Objective—Disorders of Middle Ear resulting from these Growths—Methods of Examination—Digital Examination—Inspection with the Mirror—Diagnosis—Treatment—Method of Removing Adenoid Growths.

OWING to the anatomical relations of the parts and the manner in which they are connected by means of the Eustachian tubes, diseases of the nose and naso-pharynx are in many cases the starting-points of disorders of the tympanum, and they exercise a

very decided influence upon the course and termination of the latter complaints. Thus, catarrh of the naso-pharynx may extend through the Eustachian tube, and produce a similar condition, and possibly one of greater severity, in the middle ear. Moreover, when there is no extension of the original process beyond the Eustachian tube, the obstruction may prevent the proper interchange of air in the tympanic cavity, with catarrhal and other changes as probable results. Any condition which seriously interferes with nasal respiration tends to produce injurious effects in the tympanic cavities.

A knowledge of nasal and naso-pharyngeal disorders is therefore necessary for the treatment of aural affections, and the present chapter will be devoted to a consideration of such diseases as are closely connected with the subject of this work.

The methods of examining the nose and naso-pharynx by anterior and posterior rhinoscopy have been already described (*see* p. 97). Digital examination may be necessary for the purpose of discovering the existence and extent of adenoid growths, a fruitful source of middle-ear disease.

The affections of the nose which require description are: acute and chronic nasal catarrh, morbid growths of various kinds, and adenoid growths.

Acute Nasal Catarrh.—This well-known complaint is generally attributed to catching cold; it is most common when the temperature exhibits sudden changes, and sometimes prevails as an epidemic. Nasal catarrh often attacks in succession several members of one family, and in such instances it is highly probable that micro-organisms (streptococci) play an important part in causation. Such organisms are often to be found in the naso-pharynx, where they appear to cause no disturbance so long as the tissues are in a normal condition. When, however, local disorder of circulation is set up as a result of cold and damp, the micro-organisms are capable of exerting a specific influence. Some persons are especially liable to nasal catarrh, while others are seldom affected. Sometimes the cause is purely local; thus, ulcers in the nose, foreign bodies and tumours of various kinds are apt to cause catarrh, and in the same category must be placed those cases in which the symptoms are due to inhalation of powdered ipecacuanha, and of the pollen of various grasses. Iodine taken internally often causes nasal catarrh, and the same

symptom is frequently observed in connection with acute and chronic infectious disorders.

Symptoms.—These are so well known as scarcely to require description. In severe cases there are generally febrile symptoms accompanied by headache, pains in the limbs, loss of appetite, and depression. The local symptoms take the form of a feeling of dryness and a pricking sensation in the nose, while smell and taste are impaired or perverted. In from twenty-four to forty-eight hours a thin watery secretion is poured out, and becomes more and more plentiful; the fluid is of an irritating nature, and often causes more or less inflammation of the orifice of the nose and upper lip. After two or three days the secretion becomes purulent and thick, and crusts form.

The tendency of the catarrh to spread to adjacent cavities is a point of special importance. Thus, it often involves the frontal sinuses and the antrum, and extends backwards to the mucous membrane of the throat. The Eustachian tubes are very liable to be involved, the patients complaining of deafness, pain or fulness, and noises in the ears. The mouths of the tubes are swollen and covered with mucus, and this condition may spread along the canals, and involve the tympanic cavity on one or both sides. Catarrh of the tympanum often results from a similar affection of the naso-pharynx.

Objective Appearances.—On examining the nose, the mucous membrane is observed to be reddened, and covered with secretion; in severe cases there are often erosions and discharge of blood. When posterior rhinoscopy is practised, the pharyngeal tonsil is found to be enlarged, and stands out prominently; and as a result of swelling of the adenoid tissue, Rosenmüller's fossa appears filled up, while the pharyngeal orifice of the tube on one or both sides is reduced to a mere cleft, and is covered with secretion. The posterior wall of the pharynx is reddened and swollen in places, and the surface of the soft palate has an uneven, granular appearance. The mucous membrane of the posterior extremities of the inferior turbinate bodies sometimes projects from the posterior nares in the form of gelatinous greyish tumours, which may extend as far as the pharyngeal orifices of the Eustachian tubes. The septum is often thickened, and in contact with the turbinate bodies, so that the nares are much reduced in width.

Treatment.—In most cases, acute naso-pharyngeal catarrh runs

a tolerably definite course, and comes to an end in from ten to fourteen days without any special treatment. It is especially necessary that the patient should avoid the causes of the complaint, such as exposure to cold and draughts, and this precaution is very desirable for patients who are prone to suffer from ear-symptoms during the progress of the catarrh. In order to mitigate the severity of the symptoms, the patient may be directed to inhale the vapour of water charged with ammonia or carbolic acid; the application of a 2—5 per cent. solution of cocaine to the mucous membrane tends to diminish the swelling and discomfort. In some patients, camphor inhaled or taken internally has a decided influence on nasal catarrh. It is useful only at the beginning of an attack, which it sometimes cut short, or, should it fail to do this, it diminishes the violence of the symptoms. When the irritation is very great, and the pain in the forehead is severe, relief may be procured by insufflating morphine in fine powder, about an eighth of a grain at a time, mixed with one grain of starch. Some patients derive great benefit from a few grains of Dover's powder taken at bed-time for three or four nights; other diaphoretics, warm baths and purgatives are all serviceable in different cases. If the throat be considerably involved, a borax gargle or spray containing the same drug will tend to relieve the catarrh. The best remedy, however, for most cases, is the ammoniated tincture of quinine taken in drachm doses every three or four hours. A double dose should be taken immediately the early symptoms are noticed, and a single dose continued at the intervals mentioned above. If taken with twenty drops of spirits of chloroform the disagreeable taste is considerably diminished.

Chronic Catarrh of the Naso-Pharynx may succeed the acute disease, or it may become gradually developed as an independent disorder. In the former case it is most often seen in debilitated or scrofulous persons who have suffered from some acute infectious disorder, or are the subjects of pulmonary disease. It may last for months or even years, improvements alternating with relapses. In some patients the condition of the naso-pharynx is maintained and aggravated by the nature of their occupation. Many instances of this kind are to be met with among omnibus drivers, cabmen, engine drivers, furnace-men, cooks, and others exposed to great changes of temperature, or those who have to work in dust or irritating vapours. The immoderate use of

alcohol and tobacco too often helps to intensify and perpetuate the naso-pharyngeal complaint. Gastric derangement is a frequent source of this affection, and nasal obstruction due to any cause is also an important factor in maintaining this disease. In children the presence of intestinal worms may cause the continuance of this malady. Enlarged tonsils and an elongated uvula also act as sources of irritation.

Anatomical Appearances.—The changes are not confined to the naso-pharynx, but almost invariably extend to the accessory cavities and adjacent parts. When the condition has existed for some time, the Eustachian tubes and tympanic cavities are rarely found to be normal. On examining by posterior rhinoscopy, the parts are seen to be relaxed and swollen; the pharyngeal tonsil, the orifices of the Eustachian tubes, the middle and inferior turbinate bodies, the soft palate and the uvula are the parts especially involved. An œdematous condition is not infrequent. The colour varies; it may be pale red, greyish red, or brownish red. In drunkards the naso-pharynx is often of a deep red colour, and the mucous membrane presents many tortuous dilated vessels and small patches of extravasated blood. In severe cases of this kind, and especially when complicated by hepatic or cardiac disease, copious hæmorrhage from the throat is a not infrequent symptom.

In chronic naso-pharyngeal catarrh, the swollen condition of the mucous membrane is due to vascular dilatation, serous infiltration, and deposits of cellular elements in the connective tissue, with hypertrophy and induration as further results. Retiform or adenoid tissue, in some places diffused, and in others forming small masses, is very abundant in the naso-pharynx, and rapidly increases under the influence of irritation. The enlarged lymphoid follicles project above the surface of the mucous membrane, and give rise to the appearances peculiar to granular or follicular inflammation. The swollen condition of the nasal mucous membrane is liable to frequent variations, in great measure due to the existence of the cavernous tissue in the sub-mucous layer of the membrane covering the turbinate bones, and especially the inferior. Patches of this tissue are often in a varying state of engorgement during catarrh, and are also liable to chronic induration. Such changes are apt to be most marked in the posterior extremity of the inferior turbinate body, which

then projects into the posterior nares, and occupies more or less space in the upper part of the pharynx. The treatment of this condition will be referred to presently.

Changes in the Secretion.—In cases of naso-pharyngeal catarrh, the secretion is always more or less increased and altered in quality. It consists of mucus mingled with pus in various proportions; and has a yellowish or yellowish-green colour. It often forms tenacious masses, which appear behind the uvula, or dry up into dark yellowish or brown crusts, which adhere somewhat firmly to the posterior wall. In the nares, the dried secretion may either coat the surface of the mucous membrane or may form plugs, completely obstructing the passages and exciting sensations similar to those caused by foreign bodies. Flakes of dried secretion accumulate in the nostrils; efforts at their removal not infrequently cause erosions and ulcers. Earthy concretions, "rhinoliths," are sometimes formed. On examination under the microscope, the most prominent changes are seen to be as follows: dilatation of capillary vessels, enlargement of the glands, infiltration of the tissue with lymphoid cells and consequent increase in bulk, and suppuration of the follicles. These appearances are often very marked near the pharyngeal orifices of the tubes.

Subjective Symptoms.—Many of the symptoms of naso-pharyngeal catarrh are due to the impediment to respiration; the patient complains that the nose is stopped up, and that he has to keep his mouth constantly open. As a result of this attitude, the expression after a time is liable to become changed; the patient acquires a dull, stupid look. Pain or a feeling of heaviness in the forehead and temples is often troublesome, and may be so severe as to incapacitate the sufferer for mental occupation. The voice is altered, and the senses of smell and taste are more or less blunted, and sometimes quite abolished. The patients frequently cough and hawk, in order to get rid of the tenacious secretion, and to lessen the feeling of dryness, irritation, and discomfort at the back of the throat. After a few hours' sleep, the dryness of the tongue and pharynx is apt to be very annoying. There is often temporary deafness, from obstruction of one or both Eustachian tubes, and increased secretion in the external meatus.

In addition to the above-mentioned symptoms, there are certain nervous complaints which sometimes appear to be more or less

closely connected with chronic affections of the nose. The phenomena are of reflex origin, and those which are most important take the form of paroxysms of asthma and spasmodic cough, migraine, vertigo, and facial neuralgia. It is supposed by some authorities that turgescence of the inferior turbinated body often plays an important part in the causation of these disorders; but other forms of intra-nasal disease are credited with a similar power of originating nervous symptoms.

Course and Changes Produced.—Chronic naso-pharyngeal catarrh may continue for indefinite periods, and is liable to produce marked changes in the mucous membrane. In one class of cases, hypertrophy is the prevailing feature, and is accompanied by polypoid outgrowths (*see* page 245). In children, proliferation of the adenoid tissue, with serious consequences in the Eustachian tubes and tympana, is a common result. In another class of cases, the mucous membrane becomes atrophied, the nasal cavities are enlarged and contain accumulations of crusts which give rise to an offensive odour. This process of atrophy sometimes follows the opposite condition, in which swelling and inflammatory thickening of the mucous membrane have been prominent symptoms. Ulceration is another consequence of naso-pharyngeal catarrh, and is often seen in syphilitic cases. It may be confined to the mucous membrane, or extend to the periosteum and the bones, producing more or less severe caries and necrosis. These processes are always accompanied by fœtid discharges from the nose, and often cause extensive destruction of the soft parts.

The connection between chronic naso-pharyngeal catarrh and aural disease may be thus described. The swelling of the mucous membrane is liable to extend to the pharyngeal openings of the tubes, which may also be occluded by masses of secretion; the catarrhal process may extend to the middle ear and cause deafness, subjective auditory symptoms, and pain. In addition to these causes, the tympanum may be indirectly affected by loss of power of the muscular apparatus of the tube; and when a catarrhal condition is superadded, the difference must be very considerable, inasmuch as there is not only loss of power, but greater difficulty to be overcome. Atrophy of the muscles would appear to result from long-continued catarrh.

Treatment.—In dealing with chronic naso-pharyngeal catarrh, there are at least three objects to be attained: 1, removal of the

secretion; 2, restoration of the mucous membrane to a normal condition; 3, stimulation of the muscular apparatus of the tubes. But before local measures are employed, it is necessary to ascertain whether there be any constitutional dyscrasia requiring attention. Syphilis, scrofula, and anæmic conditions must be dealt with by appropriate general remedies, without which local treatment will prove unavailing. Dyspepsia and constipation must also not be overlooked.

Removal of Secretion is best effected by thoroughly washing out the nares with an alkaline solution, to which an antiseptic may be at times added with advantage. It is often well to begin with a weak solution (3—10 grains to the ounce) of chloride of sodium, to which may be added the same quantity of bicarbonate of soda and borax, and two or three times the quantity of powdered white sugar. The last ingredient, by increasing the specific gravity of the solution, makes it less irritating, and at the same time causes it to be more pleasant to the taste. Chlorate and bicarbonate of potash may be used in the same proportion as chloride of sodium. In some cases of chronic catarrh, menthol is of service after the secretion has been removed by an alkaline lotion. The following formula is suitable for its application in the form of a spray:—

R Menthol gr. 5—15, Ol. Adepsin. Alb. ad ℥j. ft. sol.

Urbantschitsch recommends equal parts of milk and warm water to be used as an injection. Astringents are not well borne by the nasal mucous membrane, and when used should be very weak. According to Wendt, quoted by Politzer, solutions of alum are to be avoided, inasmuch as permanent loss of smell has been noticed after their use. As antiseptics, the sulpho-carbolate of zinc (gr. $\frac{1}{2}$ —2 to ℥j.), salicylic acid (gr. $\frac{1}{2}$ to ℥j.), and boric acid (gr. 5 to gr. 15), are suitable remedies, and as a stimulating application chloride of ammonium (gr. iij.—v. to ℥j.) may be employed. When the secretions are very foetid stronger antiseptic solutions, such as carbolic acid, $\frac{1}{2}$ —2 grains to the ounce, or Liq. Potass. Permangan. (℥v.—xv. to ℥j.) may be used.

A large number of medicinal substances are recommended for improving the condition of the mucous membrane. With regard to them all it must be said that their efficacy varies much in different cases, and that a remedy which has acted very beneficially in one case may prove useless in another. Hence the necessity of

being provided with several applications which can be tried in succession as required. The remedies in question may be used in several ways; thus, to begin with, they may be applied either in solution, or in the dry state as fine powders, or as ointments.

Solutions are best applied to the nose and naso-pharynx by means of a spray producer, and failing that, by sniffing them through the nostrils from the hand or a small vessel made to fit the opening. I never recommend the employment of a nasal douche, because its use is liable to be followed by acute inflammation of the middle ear caused by some of the lotion having

FIG. 78.

SINGLE BALL SPRAY PRODUCER.

passed along the Eustachian tube; or by severe and persistent headache, consequent on some of the fluid having forced its way into the frontal sinuses. Roosa's* experience is by no means unique, and yet the dangers attending the employment of this instrument appear to be comparatively unknown or disregarded. If a spray-producer were insufficient to clear inspissated mucus from the nostrils or naso-pharynx, there would be grounds for resorting to another method; but I have always found that the instrument shown in Fig. 78 accomplished all it was intended to do. At my suggestion, Messrs. Mayer and Meltzer made this spray-producer with only one ball, which, in my opinion, is more serviceable than

* Dr. Roosa (*Diseases of the Ear*, p. 389) gives a list of sixteen cases in which injury to the ear resulted from the use of the nasal douche.

a similar apparatus fitted with two balls. In the case of the latter, the spray cannot be readily checked if the patient coughs, or, for any reason, wishes the application of the lotion to be quickly stopped; whereas with the former, the strength and duration of each jet of spray can be accurately regulated by the force used to compress the single ball.

Although disapproving of the employment of the nasal douche I will now refer to that instrument, and repeat the precautions considered necessary by those who advocate its use.

The Nasal Douche was invented by Weber; it consists of a jar, capable of holding a pint of fluid, and of a piece of india-rubber tubing fitted at one end with an olive-shaped nose-piece. The tube acts as a syphon, and the vessel must therefore be placed on a higher level than the patient's head. When the tube is exhausted of air, a continuous flow takes place; the nose-piece is placed in one nostril, and when the fluid touches the upper surface of the soft palate, the latter rises and closes the passage into the throat; the fluid passes round the septum and escapes by the other nostril, thus washing out the naso-pharynx, and removing mucus and crusts. The patient should be directed to breathe quietly through the mouth while the douche is in action.

According to Politzer, the following precautions are necessary in using the douche. First, the vessel containing the fluid must not be too far above the head, and the flow should be occasionally interrupted by pinching the tube. Secondly, the head should be kept erect, directed neither forwards nor backwards; the patient must breathe through the mouth, and it will aid the closure of the throat if he keeps pronouncing the vowel sound "ah." Thirdly, if one nasal cavity be narrower than the other, the stream must be directed into it. Fourthly, tepid, non-irritating solutions of weak strength should always be used. Fifthly, if on any occasion fluid has passed into the middle ear, the douche must be laid aside; and in any given case, before allowing a patient to use it himself, it is necessary that he should be fully conversant with the necessary manipulations, and with these precautions.

The solutions most often used in this manner are as follows:—Solutions of boric acid or of common salt, 5—15 grains to the ounce. Politzer especially recommends a 10 per cent. solution of acetate of alumina, which he states has proved useful in

several cases in which other remedies failed. Störk recommends a solution containing a tea-spoonful of a mixture of the following salts in a litre of water—the salicylate, bicarbonate, and chlorate of sodium, of each, twenty parts.

The Syringe affords a somewhat safer means than the douche of applying solutions which may be required to be injected into the anterior nares, or into the naso-pharynx. For the former purpose an olivary nose-piece is required, and the syringe should contain not more than two ounces of fluid; it should be held horizontally, and the fluid should be directed straight backwards. When it is wished to wash out the naso-pharynx recourse may be had to a syringe furnished with a long tubular nozzle, with a curved extremity, so that when passed through the mouth, the point can be turned upwards behind the soft palate; but an ordinary syringe used through the anterior nares is generally sufficient to remove all secretion, and, moreover, causes the patient less discomfort. When the post-nasal syringe is used the head should be directed forwards, so that the fluid may escape through the nostrils. Only a slight amount of force must be used, as there is some danger of driving the solution into the tympanum.

When it seems desirable to apply a solution to the general surface of the mucous membrane of the nose and naso-pharynx, Politzer recommends the use of a **boat-shaped glass vessel**, by means of which two table-spoonfuls of fluid can be poured into the nostrils when the head is inclined backwards. In order to prevent the solution from escaping into the lower part of the throat, the patient should breathe quickly through the mouth while it is being poured in; when the fluid is felt in the pharynx, the head must be quickly bent forwards, so that escape may take place through both nostrils; for the fluid, in consequence of the shutting-off of the lower part of the pharynx, will have passed into the other half of the nose. To ensure the action of the remedy upon the mucous membrane, and to prevent the passage into the tympanum of any that may remain, the patient should be prohibited from blowing his nose until a quarter of an hour has elapsed. When any of these methods is practised the injected fluid will reach the pharyngeal orifice of the tube, and is liable by attraction to pass into the tube itself, and thus act indirectly upon the tympanum.

Inhalation is another method of applying remedies to the mucous membrane of the nose and naso-pharynx, and an ordinary inhaler with an india-rubber nose-piece fitted on the mouth-piece will answer the purpose. Steam from hot water relieves the feeling of dryness and tightness which sometimes accompanies chronic catarrhs when secretion is very scanty, and it also softens layers and plugs of inspissated secretion. The vapour of *chloride of ammonium* in the nascent state has a good effect as a stimulant when the mucous membrane is relaxed and swollen. There are many different kinds of inhalers for generating these fumes—Basdon's and Godfrey's may be mentioned as acting efficiently. Other remedies are (1) *Creasote*, used as follows:—℞ Creasoti ℥80, Magnesiae Carbonatis Levis ʒss., Aquam ad ʒj.; a tea-spoonful to be added to a pint of water at 140° for each inhalation. (2) *Tinctur. Benzoin. Comp.*, a tea-spoonful to be used in a similar manner, and its stimulating properties may be increased by adding ℥v. Ol. Pini Sylvestris to each ʒj. As a more stimulating remedy, the following may be employed:—℞ Ol. Pini Sylvestris ℥40, Magnes. Carbonat. Levis gr. 20; Spirit. Camphoræ ℥40, Aquam ad ʒj. A tea-spoonful to be added to a pint of water at 140° for each inhalation.

Application of Ointments.—Remedies can also be applied to the nasal mucous membrane in the form of ointment, and it is sometimes desirable to apply them in this manner after the use of the douche. The boric acid ointment is antiseptic and sedative in its action, and relieves irritation in cases of subacute and chronic catarrh, and menthol ʒss.—ʒj., mixed with oil of sweet almonds ʒj., is also sometimes of use. When excessive secretion is a prominent symptom, belladonna ointment is useful, and a more efficacious preparation is composed as follows:—℞ Liq. Atropinae Sulphat. ʒss.—ʒj.; Vaselinei ʒj. When dryness of the membrane is a marked symptom, the following will relieve discomfort:—℞ Eucalypti Olei ʒj., Vaselinei ʒj. An ointment containing five grains of hydrochlorate of cocaine to the ounce will prove serviceable when the mucous membrane is hyperæmic, relaxed, and swollen. In some cases in which abrasions or ulcerations exist, an ointment containing five to ten grains of iodoform to an ounce of vaseline is a suitable application. This ointment may be applied to syphilitic ulceration, and may be replaced after a time

by the weak nitrate of mercury ointment, further diluted with four or six parts of vaseline.

If the catarrhal condition of the nose and pharynx prove very obstinate, and unaffected by the remedies just described, Politzer recommends the application of a concentrated solution of nitrate of silver (1—10). This acts as a strong cauterant to the mucous membrane; it can be applied to the diseased portions by means of a camel-hair brush, or on a piece of absorbent wool. When the membrane is extensively affected, and the swelling obstructs the nose, a ball of cotton-wool, as large as a hazel-nut, and saturated with the solution, may be pushed as far as possible into each nostril by means of a pair of forceps, and the nose then plugged with dry wadding. The head is inclined backwards, and the solution squeezed out of the cotton-wool by compressing the nose with the thumb and forefinger; by this means the fluid is brought into contact with a large portion of the mucous membrane. After the cotton-wool has been removed, the skin about the nostrils should be washed with a weak solution of iodide of potassium.

The application of a strong solution of nitrate of silver causes a severe burning pain and increased secretion. If the action be very severe, it should be neutralised by injecting tepid water, or a weak solution of common salt. Politzer states that the treatment is often followed by rapid improvement; the breathing through the nose becomes freer, and the patient feels much more comfortable. The application should be made twice or three times a week, and may have to be repeated as many as ten times. If it be desired to apply the solution to the naso-pharynx, a brush is required, fixed to a suitably bent handle. This can be passed behind the soft palate, and applied to the roof and walls of the naso-pharynx. In cases of atrophic rhinitis, a feeling of dryness at the back of the throat is often very troublesome. It may be relieved by the application of a solution of iodine gr. vj., iodide of potassium gr. xij., in glycerine \mathfrak{z}_{ss} .

Insufflation is another method of applying remedies to the nose and naso-pharynx. Very fine powders are required, and only small quantities should be used at one time. As but little good can be expected from the patient's attempts to "snuff up" powders, a proper instrument is always necessary. Kabierskie's insufflator (Fig. 79) is a good apparatus. It works best when the

powder is below the india-rubber valve in the centre of the bottle. Besides Kabierskie's there are various other forms of insufflators, by means of which the powders can be introduced into the nose or throat; but with these instruments the powder is not so evenly or so finely distributed as with Kabierskie's insufflator. A piece of india-rubber tubing, furnished with an elastic ball at one end, and a narrower tube at the other, is suitable for most cases. The powder is introduced through an opening in the wall of the tube, which is then closed with a slide or the finger. Tubes of different curvatures may be required for different cases; but an instrument with an arm about half an inch long, bent at a right angle with the stem, will be found suitable in most cases for applying powders to the naso-pharynx.

The insufflation may be made through the nostrils, whether

FIG. 79.

KABIERSKIE'S INSUFFLATOR.

the nose or the naso-pharynx be the seat of disease, and this method is especially preferable when both regions are affected; but in some cases, when the naso-pharynx alone is diseased, it is best to apply the remedy directly to that region through the mouth. Boric acid is best mixed with oxychloride of bismuth or sugar of milk. Grains 20 to 30 of boric acid to 2 drachms of the latter make a suitable mixture. Menthol may be used as follows:—Menthol, grain 1, oxychloride of bismuth, grains 24, powdered starch, grains 25. Iodoform may be mixed with half its weight or more of starch, or added to the mixture of boric acid and bismuth. Hydrochlorate of morphia one-sixteenth to one-eighth of a grain, mixed with about a grain of starch, is useful for allaying pain. For some syphilitic cases sublimated calomel is serviceable when blown into the nostrils by means of a suitable appliance (Fig. 80) with lamp attached.

Nasal Bougies.—There is yet another way of applying remedies to the nasal mucous membrane, viz., the introduction of bougies, having a gelato-glycerine basis, with which the drug is incorporated. Iodoform (gr. $\frac{1}{6}$ — $\frac{1}{2}$), carbolic acid (gr. $\frac{1}{2}$), hydrochlorate of cocaine (gr. $\frac{1}{6}$), sulphate of copper (gr. $\frac{1}{10}$), and sulphate of zinc (gr. $\frac{1}{10}$) can be applied in this manner. As the basis gradually liquefies, the action of the remedy is maintained for some time. The disadvantage of this mode of treatment is that the bougie, when partially melted, is liable to slip down the patient's throat or out of the anterior opening of the nostril.

Cauterisation.—When the mucous membrane is much swollen, and ordinary treatment has failed to produce the desired effect, the careful application of the galvano-cautery will sometimes prove very efficacious. The extremity of the electrode should be adapted to the part to which it is to be applied. Sometimes it is desirable to produce a somewhat large superficial slough, but more

FIG. 80.

FUMIGATOR, WITH SPIRIT LAMP.

often linear cauterisation will produce the best effect. The use of the cautery should be preceded by the application of a solution of cocaine (10—20 per cent.), and as some individuals are easily affected by this drug, and a feeling of faintness in consequence quickly supervenes, no more than is necessary should be used. It is sometimes advisable, when both nostrils require to be cauterised, to anæsthetise one, and then determine whether the other shall be treated at that interview or on another occasion. When the part to be cauterised is within view, it is best anæsthetised by rubbing it with a piece of absorbent wool twisted on to the end of a probe and wetted with the solution. If a spray producer is used, I prefer one made of vulcanite (Fig. 53, page 120), as this material is not acted upon by the drug. Before applying cocaine, the part to be cauterised must be carefully determined, because the swelling of the tissues will disappear as

soon as the drug takes effect. Finding that Schech's cautery handle was frequently getting out of order, I had a handle made, Fig. 81, with the connections on the surface, and the movable pole arranged as a long spring, so that it could be easily depressed.

Before using the cautery, the anterior orifice of the nostril should be dilated with a speculum having solid blades, in order to press aside the hairs usually found in that region in adults. Should it be necessary to introduce the cautery into the nasopharynx, the soft palate should be previously painted with a solution of cocaine, and, when anæsthetised, held forward by means of a soft palate tractor. The danger of inflammation extending along the Eustachian tube and producing suppuration in the middle ear must not be forgotten. When cauterising a

FIG. 81.

THE AUTHOR'S ELECTRODE HANDLE.

nostril, care is necessary to prevent two opposite parts of the cavity being touched with the electrode, because if both surfaces have been burned, they are liable to unite when they come in apposition, as a result of the swelling of the tissues which always follows the operation. It is usually advisable to wait about a fortnight before again applying the cautery, so as to allow all inflammatory swelling to subside and healing to be thoroughly completed.

As substitutes for the galvano-cautery, various chemical agents are available for the destruction of hypertrophied portions of the mucous membrane, but the objection to their use is that their action cannot be precisely limited. The most efficacious of these are: chromic acid, glacial acetic acid, nitrate

of silver, chloride of zinc (a concentrated solution), and nitrate of mercury. If a proper chromic acid carrier (Fig. 82), is not at hand, a silver probe, grooved near its apex, is a convenient instrument for applying this remedy, and also nitrate of silver.

Whilst the application is being made, the nostril should be kept dilated by means of a speculum. A solution of cocaine should be previously applied, and after the cauterisation (with chromic acid) has been effected, it is well to use the spray-apparatus with a strong solution of bicarbonate of soda. The fluid caustics, according to their nature, may be applied on a small glass or camel-hair brush, or on a strip of cane having one end slightly crushed, so as to be capable of taking up a small amount of fluid, provided the chromic acid carrier, Fig. 82, is unsuitable for the purpose. Before the application, any superfluous liquid should be removed with a piece of absorbent wool or blotting-paper. Various modifications of the instruments will be required when

FIG. 82.

CHROMIC ACID CARRIER.

the naso-pharynx is especially affected. When the mucous membrane is much swollen, especially in the neighbourhood of the pharyngeal orifices of the tubes, Politzer recommends circumscribed cauterisation of the latter parts. He uses for this purpose a large slightly curved vulcanite catheter, containing a long wire, the extremity of which carries a little ball of nitrate of silver. This latter is withdrawn within the catheter when the instrument is introduced, and is pushed out when the extremity is in contact with the parts near the orifice of the tube. Cauterisation is accomplished by moving the catheter in various directions, and the caustic is to be withdrawn before removal.

When *ozæna* exists, the free use of an alkaline lotion and the application of antiseptic remedies are necessary parts of the treatment. By means of the former, masses of inspissated secretion and crusts are removed, and deodorants are required to destroy the fœtor. Benefit may also be derived from the inhalation through the nostrils of iodised spray from a Siegle's

apparatus, or of iodine vapour, a few drops of Tinct. Iodi being placed in a suitable inhaler filled with warm water.

Some authorities strongly recommend Gottstein's method of treating ozæna. This consists in the introduction into the nostrils of plugs of wadding, either dry or moistened with glycerine, and about two inches in length. These are allowed to remain in position for several hours, or even for an entire day. The wadding absorbs the secretion and prevents the formation of crusts, and the odour is more or less diminished. This plan is of course to be regarded as only a palliative measure. It may be advantageously combined with insufflations of powdered boric acid diluted with oxychloride of bismuth or of aristol. The plugs of wadding are changed twice or three times a day, and the remedies are blown into the nostrils before the wadding is replaced. The application of the electro-cautery is at times beneficial.

For syphilitic ozæna special treatment will, of course, be required, and the calomel fumigator (Fig. 80) directed to the nasal cavities will be the most suitable method. The action of the mercury must be carefully watched, especially in cases in which there are signs of osseous lesions. Under such circumstances, iron and cod-liver oil will probably be indicated.

Hypertrophy of the Posterior Extremity of the Inferior Turbinated Body.—The posterior extremity of the inferior turbinated body is sometimes considerably hypertrophied. There is no distinct pedunculated tumour, and the growth appears to be due to hyperplasia of connective tissue, infiltration with lymphoid cells, and formation of new vessels. It more or less resembles a raspberry in appearance, and may attain a considerable size, filling up the choana and reaching the pharyngeal orifice of the Eustachian tube.

This enlargement is best removed by means of a wire snare, which can be worked with one hand, and as the region is sensitive an anæsthetic is desirable. Nitrous oxide gas with the addition of a little ether is the most suitable, but cocaine may be employed. The drawback to the use of the latter is the contraction it produces of the tissues with which it is brought in contact. The posterior surface of the soft palate should be anæsthetised as well as the nostril. The instrument which I use for these cases is my modification of Sir Morell Mackenzie's nasal snare (*see* Fig. 83, p. 260).

The operation should be performed as follows :—A wire loop placed vertically should be passed through the nostril, and the forefinger of the left hand then introduced into the naso-pharynx. The loop should then be pressed outwards as far as possible by this finger whilst it is being tightened, and the hypertrophied tissue will be felt to become tense if it has been caught in the snare. The loop should not be tightened too quickly, as occasionally free hæmorrhage follows removal. When the extremity of each inferior turbinated body is enlarged, both should be removed at the same operation. It is desirable to have two, if not three, snares at hand, so that time may not be lost in remaking a loop if the hypertrophied tissue is not at once seized. For a few days after the operation it is well to spray through the nostrils occasionally a solution of boric acid, five to ten grains to the ounce.

Treatment of Nasal Polypus.—When a polypus exists in conjunction with catarrh or chronic suppurative inflammation of the middle ear, it is especially desirable to remove it without delay. In all cases cocaine (5—10 per cent. solution) should be applied either by means of a spray-producer or on absorbent wool; the latter method is convenient when the polypus is small or the part to be anæsthetised can be easily reached. In some cases a fifteen or twenty per cent. solution of cocaine is preferable. As soon as the parts are insensible, a good light should be reflected into the nostril and a loop of wire sufficiently large to pass easily over the polypus to be removed, should be introduced by means of a snare (Fig. 83), and worked gently backwards and forwards, whilst it is being raised to the attachment of the pedicle to the part from which it is growing. The loop should then be carefully contracted until it closely embraces the pedicle at its origin, when it should be further tightened until the pedicle is severed. When more than one polypus exists, each must be removed separately as above described. It often happens, after a nostril has apparently been cleared, that in the course of a day or so other polypi make their appearance. These probably have been wedged by the polypus which has been removed into a position in which they could not be seen, and on its pressure being taken away, they have gravitated into the region which it occupied. When a polypus is attached far back in the nostril, it is sometimes necessary to insert the left forefinger into the naso-pharynx

and push the polypus through the loop of the snare. During this manipulation, the finger should be protected with the india-rubber guard (Fig. 42, page 104).

After a polypus has been removed, its base should be anaesthetised with cocaine, and then destroyed with the electro-cautery to prevent its recurrence. As a rule, the bleeding which is caused by the operation obscures more or less a view of the parts,

FIG. 83.

THE AUTHOR'S MODIFICATION OF SIR MORELL MACKENZIE'S NASAL SNARE.

The modification consists of the following additions:—The flange A, to prevent the wire getting twisted round the axle. The shoulder B to the pawl C, to prevent the latter being forced off the ratchet. The cross-bar D attached directly to the axle to give increased cutting power when required. The screw E to fix the revolving barrel F in the necessary position. The adoption of the movable end G fitted at its extremity with a pin which separates the two sides of the loop of wire. When the end G is drawn off the barrel F the wire is unwound from the axle and the loop reformed, thus saving the time spent in fitting another wire.

and therefore the cauterisation is best done after an interval of a few days has elapsed, to allow the subsidence of any swelling of the tissues which may have resulted from the irritation of the operation.

Small mucous polypi not infrequently disappear under the steady use of a saturated solution of chromic acid; finely powdered tannin applied daily for a few weeks by an insufflator is sometimes employed for the same purpose. Both these methods, however, are less certain and slower in their action than the use of the electro-cautery.

It is a matter of regret that some surgeons—presumably ardent admirers of one or more of the surgical celebrities who have long since passed away—still adhere to their primitive and violent method of tearing polypi from the nostrils with forceps. In olden times, this painful procedure was unhappily justifiable because the frontal mirror was unknown, and consequently the treatment of intra-nasal affections by the aid of reflected light could not be practised. At the present day, however, a surgeon's neglect to make himself efficient with this instrument is no excuse for a method of operation which not only causes unnecessary pain, but which, in many cases, is less efficacious than the removal of the polypus by the snare, and subsequent destruction of its attachment with the electro-cautery. Moreover, the forceps never obtains a result which the employment of the humane and painless method advocated would not have achieved. Still more unpardonable is the performance of an operation which reflects the cartilaginous portion of the nostril, in order to obtain a better view of the growth and facilitate the removal of a polypus with forceps because it has recurred after a portion of it had been evulsed with that instrument. In such a case it might have been foretold before the first operation was performed, that recurrence would take place unless only one polypus existed attached by a narrow pedicle, and the operator happened to seize it near its origin.

Not only does the attempted removal of a polypus with forceps cause unnecessary pain, but the result is far less certain than that obtained by the use of a snare and subsequent destruction of the attachment of the growth with the electro-cautery. Furthermore, by the former method healthy tissues and structures are frequently not only injured but even torn away.

Treatment of Enlarged Tonsils.—It has been previously mentioned that enlargement of the tonsils and granular pharyngitis are frequently found in patients who are suffering from middle-ear catarrh; and although these affections cannot be regarded as direct causes of this complaint, their treatment must not be neglected, as the presence of the former tends to keep up the conditions which immediately produce it, and the latter, if it does not always have this effect, is nevertheless attended by changes which produce this result. For the removal

of tonsils, I consider Morell Mackenzie's modification of Physick's tonsillotome, Fig. 85, the most suitable instrument. It is usually sold in a set of three sizes, but as it is important that the tonsil,

Fig. 84.

THE DIMENSIONS OF THE AUTHOR'S SET OF TONSILLOTOMES.

to ensure its complete removal, should be closely embraced by the ring, I use a set of five sizes, the diameters of which are shown at Fig. 84. When operating, I always hold the tonsillotome in my right hand, and therefore have a pair of each size, because it is better for the blade to be held towards the mesial line, so that the flat and immovable portion of the instrument may be in contact with the pillars of the fauces. Fig. 85 represents a tonsillotome for the removal of the right tonsil, and the dotted handle as attached to the instrument represents a tonsillotome for the left tonsil, but placed upside down. The fork which is attached to some forms of tonsillotome is unnecessary, and, moreover, is liable to cause injury to the soft palate or other parts, if the patient resists the introduction of the instrument.

It is inexpedient to remove tonsils whilst they are inflamed, and after an attack of tonsillitis, it is advisable to wait until they have resumed their normal condition before the operation is undertaken; in some cases it is desirable for an astringent to be applied daily for a week or ten days before they are excised. In cases of syphilis, it is best to postpone the removal of tonsils until the mucous

patches have disappeared from the mouth and fauces, unless there are circumstances which require the tonsils to be excised without delay. In the latter case, too much care cannot

be exercised in thoroughly disinfecting the instruments after use.

I am strongly of opinion that a general anæsthetic should not be administered for this operation, as I consider it is not only unnecessary but entails needless complications, and also introduces a possible source of danger. When properly performed, the removal of tonsils is almost painless, provided the guillotines are in good condition. In the case of adults and some children,

FIG. 85.

MORELL MACKENZIE'S MODIFICATION OF PHYSICK'S TONSILLOTOME.

the fauces may be sprayed with a 2—5 per cent. solution of cocaine a few minutes before the operation is begun, but in young and nervous children this drug is best dispensed with, as its application and the peculiar sensation it produces cause as much alarm as the operation itself. Although I consider the use of a general anæsthetic for the removal of tonsils unnecessary, I am satisfied that it is essential for the thorough removal of post-nasal growths.

For the operation, the patient should be seated either with

his back to the window, or by the side of a powerful lamp, and it is desirable to protect the front of his clothes by pinning a towel round his neck. The surgeon will do well to adopt a similar precaution, especially in the case of a child. One assistant, standing behind the patient, should support his head by allowing it to rest against his chest, whilst he steadies it laterally by placing a hand on each side, and he should put the second finger over the region of the tonsil in readiness to make pressure with it whilst the tonsil is being removed. In the case of a child, another assistant should sit by the side of the patient, and hold both his hands, to prevent him from dragging the tonsillotome from his mouth during the operation. The surgeon, wearing a frontal mirror to reflect the light into the fauces, should seat

FIG. 86.

Natural size.

THE LEFT TONSIL REMOVED FROM A MAN, AGED 21 YEARS.

himself in front of the patient, taking care to draw his chair against the patient's legs in order to prevent him kicking. As soon as the tonsil to be excised has been well illuminated, the tonsillotome should be slipped over it; care being taken not to include the tip of the uvula, and to carry the stem of the instrument as far as possible from the mesial line (*see* Fig. 87), before the blade is driven home by the thumb of the hand which is holding the tonsillotome. The object of thus carrying the stem of the instrument away from the mesial line is to ensure the removal of the whole of the anterior surface of the tonsil, the external portion of which is often left uncut when this procedure is omitted, on account of the outer portions of this surface of the tonsil lying on a plane external to the corresponding portion of

the posterior surface. Fig. 86 shows an enlarged tonsil removed from a man aged twenty-one years, and well illustrates the condition usually present, viz., that only a portion of the external surface of an enlarged tonsil is attached to the fauces.

It has been previously mentioned that in order to ensure the complete removal of the projecting portion of a tonsil, it should be closely embraced by the rings of the tonsillotome. This cannot be done in the case of a large tonsil, unless its attachment (as shown in Fig. 86) is borne in mind. Fig. 87 shows diagrammatically the positions in which the tonsillotome should be placed for the operation:—1. The ring below the tonsil. 2. The tonsillotome raised until its outer border comes in contact with the lower edge of the attachment. 3. The tonsillotome in position for excision. The dotted line between 2 and 3 shows the course taken by the upper border of the tonsillotome between the second

FIG. 87.

DIAGRAM SHOWING THE METHOD OF APPLYING A TONSILLOTOME.

and third positions, the lower border of the instruments at the time being pivoted at *a*. In the actual application of a tonsillotome it need not be placed in the positions shown in the diagram, as it is only necessary to turn the lower border of the instrument sufficiently outwards to enable the pendent portion of the tonsil to pass through the ring.

It sometimes happens, when the blade of the tonsillotome has been driven home, that the tonsil is still held to the fauces by an undivided piece of mucous membrane. When this occurs, the blade should be kept firmly pressed against the further side of the ring, and the tonsil dragged off by the index finger of the hand which is not holding the tonsillotome. It is a mistake, when this happens, to withdraw the blade and remove the tonsillotome from the mouth, because the tonsil is then left hanging,

and must be removed with scissors—a procedure often difficult in the case of a child.

When a patient will not open his mouth, no attempt should be made to force the jaws apart by twisting the tonsillotome, as the teeth are liable to be broken or loosened by this method; but the tonsillotome should be held horizontally, and slipped as far back as possible into the pharynx. This causes the patient to retch, and in so doing he opens his mouth widely; the tonsillotome should then be quickly slipped into position, and the operation performed.

In most cases merely rinsing the mouth with cold water is sufficient to check any bleeding which may follow the operation; but sometimes other measures, such as cold or the application of astringents, are required. Ice held in the mouth is often all that is necessary, and it is preferable to an astringent, as it interferes less with the healing processes. When, however, it is not sufficient to stop the bleeding, astringents should be used. The following gargle of tannic and gallic acids in the Throat Hospital Pharmacopœia is very useful in such cases:—

R Tannic acid, ʒvj.
Gallic acid, ʒij.
Water, ʒj.

Rub the acids to a fine powder, and mix with the water.

Directions.—The patient should be directed to sip the mixture slowly, or hold it passively in the mouth till the hæmorrhage is stopped.

When the bleeding is coming from a small artery, the vessel should be squeezed with a pair of torsion forceps. It occasionally happens that severe hæmorrhage follows the operation, and the common carotid artery has been tied, in order to arrest it, in more than one case. From the experience which I have gained of these cases during the last eighteen years, I am led to believe that this operation is unnecessary, unless a large vessel has been wounded, if the measure is adopted which I am about to describe.

I have successfully used it when cold, pressure, and astringents, including iron, applied in the ordinary way, were useless to check the bleeding; and although I have had to deal with some severe cases, I have never known it to fail.

To Arrest Severe Hæmorrhage, mix together tannic acid, 3 parts; gallic acid, 1 part; and add a few drops of water.

Then knead the powder until it is a *hard* mass, and from it take a piece sufficient to form a ball the size of a small marble. Place this on the forefinger of the hand, corresponding to the side of the patient from which the hæmorrhage is occurring, and by this means introduce it into the patient's mouth, and rub it *firmly* against the bleeding surface, making counter pressure with the palm of the other hand, placed on the side of the head over the region of the tonsil.

Note.—It will be found, on continuing to knead the powder, that it requires less water than at first appeared necessary to make it into a mass, and it is important to bear this in mind, because unless only a few drops of water are added the mass will be too soft to be of use, as the saliva or blood quickly moistens it when introduced into the mouth.

It is advisable for the patient to suck ice for several hours after tonsillotomy, as it lessens the pain, and checks any tendency which may exist for the neighbouring tissues to become inflamed. The marshmallow lozenges of the Throat Hospital Pharmacopœia are useful in the case of children, and for adults the bismuth and morphia pastilles of the same Pharmacopœia are often of service. In spite of the patient's sucking ice, œdema of the soft palate and uvula sometimes ensues, and I have known acute suppurative inflammation of the middle ear to follow the excision of the tonsil on the same side, in the absence of any apparent cause for this severe inflammation following the operation. When œdema occurs, the application of ice should be continued, and considerable relief will be afforded, and the duration of the attack lessened, if the swollen tissues around the uvula be scarified. For this purpose I use the instrument shown at Fig. 88, which I had made by Messrs. Mayer & Meltzer, to fit into my pocket case. Each of the ends A has a T-shaped piece (*a* and *a'*) projecting from their inner surface, which pass through the apertures (*c* and *c'*) in the blades of an ordinary pair of dissecting forceps B. As will be seen in the figures, the top of the T in A and C is at a right angle to the blade of the instrument, which must therefore be placed at a right angle to the forceps in order to allow the T-piece to pass through the aperture *c*. On twisting the blade A to its position shown in C, the pin (*b*) slips into the hole (*d*), and

holds the blade securely in position. The total length of the instrument, as shown at C, is eight inches. With this instrument the uvula is easily scarified, as it is pierced on each side simultaneously by the points. The previous application of a solution of cocaine makes the procedure painless. A good deal of pain in the fauces is sometimes experienced during the act of swallowing for a day or so after the tonsils have been removed, and in the case of delicate children it may be advisable to adopt some measure for its relief.

FIG. 88.

THE AUTHOR'S UVULA SCARIFIER.

The following simple **Method for Relieving Odynphagia** deserves to be better known, as it is applicable to all cases whether the cause be malignant disease, scarlet fever, diphtheria, tonsillitis, or any other affection. It is performed as follows:—A person standing behind the patient, who should be seated on a chair or in bed, places the palm of each hand, with *the fingers pointed directly upwards*, over the ear on the corresponding side, and then makes firm pressure towards the mesial line. The greater the pressure the greater will be the relief from the pain during swallowing.

Granular Pharyngitis* is often found associated with catarrh of the middle ear, and when the side of the pharynx behind the posterior pillars is involved, it is especially prone to

* For further details see a paper by the Author, *Medical Press and Circular*, October 19, 1892, p. 391.

keep up the ear-mischief in the corresponding ear. When the pharynx is much congested, it is well to direct treatment to the catarrh of that region which probably coexists, and defer the application of the electro-cautery until the parts have assumed a more healthy appearance.

In slight cases, the application of a weak alkaline lotion to the naso-pharynx by spraying or sniffing it through the nostrils may be a sufficient local measure to effect a cure; but when the affection has existed for some time, or is well marked, it is best at once to destroy the hypertrophied tissue by means of the electro-cautery. In the treatment of this disease, attention must not be confined to the pharynx, as the condition of the general health is an important factor in its causation. Although many cases are the result of an improper use of the voice, there are numerous instances in which the affection is due to totally different causes. Amongst these may be mentioned residence in a damp climate, dyspepsia, and hepatic derangement, chronic constipation, or any condition which tends to long-continued congestion of the pharynx. Amongst the cases due to an improper use of the voice, there are many in which the general disorder intensifies the local trouble. When the disease is established, it is very difficult to cure if the general health is also impaired; and in these cases local treatment, even by the cautery, frequently gives but temporary relief. Some of the worst instances of this affection which I have seen have occurred in women who were suffering from an uterine derangement.

In cases of chronic middle-ear catarrh, associated with granular pharyngitis, the increase in the symptoms during damp weather is probably partly consequent on the aggravated condition of the granular pharyngitis which has resulted from the climatic condition.

A 10—20 per cent. solution of cocaine should be applied to the granules which are to be touched with the cautery, and for the former purpose I prefer to use a brush or piece of absorbent wool on a probe, rather than a spray-producer, because by the former methods less cocaine is swallowed, and therefore there is not so much liability to the unpleasant sensations produced by this drug.

Congestion of the pharynx is sometimes partly the result of the irritation produced by an elongated uvula, and when this is

the case the superfluous mucous membrane should be removed. This operation is best performed by seizing the tip of the redundant portion of mucous membrane with a long pair of mouse-toothed forceps after the part has been anæsthetised with cocaine, and removing it with suitable scissors (Fig. 89). The incision should be made to pass obliquely from side to side immediately below the azygos uvulæ muscle, and to terminate about an eighth of an inch above that point.

Morbid Growths of various kinds are found in the nasopharynx, and may be divided into two principal classes, (*a*) innocent and (*b*) malignant. To the former class belong (1) fibromata, (2) enchondromata, and (3) mucous polypi, springing from various parts of the posterior nares. The polypoid degeneration of the inferior turbinated body previously mentioned (page 258)

FIG. 89.

NUNN'S UVULA SCISSORS.

may also be again referred to as projecting into this region. Malignant growths (carcinoma and sarcoma) less frequently affect the naso-pharynx.

All these growths are liable to occlude the mouths of the Eustachian tubes and to cause more or less deafness. The fibrous growths spring from the periosteum and rapidly increase in size. Enchondromata are very rare. Mucous polypi are frequently found in the naso-pharynx, but usually in connection with similar growths in the nostril. Their place of origin varies; sometimes they spring from the middle or inferior turbinate and extend backwards and downwards. In other cases they are attached to the lateral wall, between the pharyngeal orifice of the Eustachian tube and the extremity of the inferior turbinate. In a third class of cases, they are attached to the margin of the choanæ.

The **Treatment** of growths in the naso-pharynx, other than

adenoid growths, requires only a brief description in this work. Fibrous growths, on account of their size and prolongations, and the adhesions they are apt to form, may present many difficulties to the operator. For the procedure necessary for their removal, a work on general surgery must be consulted. Mucous polypi can generally be removed through the nostrils by means of a wire snare, if the loop is guided by the forefinger of the left hand when introduced into the naso-pharynx. It is well to wear an india-rubber finger-guard whilst this is being done, to prevent injury from the teeth. In the case of large polypi attached by broad bases, it is advisable to cauterise the surface freely and deeply, so as gradually to destroy the tissues, if the growth cannot be removed with a snare. A solution of cocaine should be applied some minutes before the cautery is used, and five or six days, or more, should be allowed to elapse between each operation. After removal of a polypus, it is generally necessary to destroy with the electro-cautery the remains of the base, from which otherwise new growth may become developed. Chromic acid or nitrate of silver may be used instead of the cautery in some cases.

It remains to add a few words on the third indication, viz., to restore the functions of the muscles of the Eustachian tubes. This effect is in some measure achieved by all remedies which improve the condition of the mucous membrane of the naso-pharynx.

Gargling the Throat, performed in the manner suggested by v. Tröltsch,* is an efficacious method of cleansing the naso-pharynx and of exercising and strengthening the muscles of the tubes. It is performed as follows:—The patient having taken a mouthful of the fluid, allows it to pass into the lower part of the naso-pharynx, and throws his head well back. The muscles of the palate and throat are then caused to contract, so that the fluid is forced upwards, and the motion of swallowing is then performed, but the fluid is not allowed to pass downwards. With a little practice, the same mouthful of water can be moved upwards and downwards before it is finally expelled from the mouth. A few tea-spoonfuls of brandy or a little borax may be added to the water. In order to show that this process causes the fluid to wash the pharynx, Dr. Roosa has suggested the

* *Lehrbuch der Ohrenheilkunde*, Aufl. 6, S. 372.

following simple experiment:—Let the posterior wall of the pharynx be painted with tincture of iodine, and then a gargle of starch-water be used in the manner described; the characteristic reaction will be found in the ejected fluid. The process causes forcible contraction of the muscles of the tubes; the glandular structures are compressed, and the muscles themselves are stimulated and strengthened.

Electricity is sometimes useful in these cases, and either the galvanic or the induced current may be employed. One electrode is passed either through the nose or into the mouth, and applied to the pharynx, while the other is placed on the side of the neck or in the meatus. (See last paragraph in chapter on Electricity in the Treatment of Diseases of the Ear.) In order to act directly upon the muscles of the tube, a suitable electrode may be passed into the orifice through the Eustachian catheter.

Adenoid Growths in the naso-pharynx play a very important part in the causation of diseases of the middle ear, and will therefore be described somewhat minutely. These growths generally spring from the pharyngeal tonsil, and are due to hyperplasia of its tissue. Owing to the nature of their structure, the term "adenoid" was applied to them by Dr. W. Meyer, of Copenhagen.

The pharyngeal tonsil was described by Kölliker in 1859, and he also discovered masses of glandular tissue around the openings of the Eustachian tubes, near the posterior nares and on the posterior part of the soft palate. Luschka states that the pharyngeal tonsil occupies the roof of the pharynx, extends thence to the posterior wall, forms the base of Rosenmüller's fossæ, and coats the surface of the swellings caused by the projecting mouths of the Eustachian tubes. Its normal maximum thickness is 7mm. It contains many roundish follicles and racemose glands; its structure is the same with that of the tonsils. In 1860 Czermak observed two small growths on the left side of the upper part of the naso-pharynx. In 1864 Sir Andrew Clark published a paper on naso-palatine gland disease, in the London Hospital Reports, and observed that fœtid cheesy masses were sometimes contained in the cavities of these glands. A year later, Löwenberg described three cases of deafness with vegetations in the naso-pharynx. Voltolini also reported the case of a man, aged forty, under his care during two years for deafness.

He discovered stalactite-like growths projecting into the free cavity of the naso-pharynx. In 1868, Dr. Wilhelm Meyer, of Copenhagen, gave a full account of adenoid growths in the *Medico-Chirurgical Transactions*, vol. liii. He described the symptoms and progress of the affection, the microscopic character of the growths and a mode of surgical treatment. He had then examined 2,000 children in national schools, and had discovered the affection in one per cent. of this number. In a London school containing 700 children, 13, or 1·8 per cent. were found by Dr. Meyer* to exhibit the "dead pronunciation." Digital examination proved that this was based throughout upon adenoid growths in the naso-pharynx. The close causal connection of ear-affections with these growths was likewise clearly ascertained by Dr. Meyer; he found 130 cases of ear-disease among 175 patients suffering from adenoid growths. A few years ago, Dr. Gustav Justi published an essay on this subject; it forms No. 125 of Professor Volkmann's "Sammlung."

Anatomically, the growths consist of adenoid tissue. They vary in form and consistence; sometimes being solid and firm—sometimes soft, highly vascular, and prone to bleed. They may be either almost uniformly distributed over the roof and posterior wall of the naso-pharynx, or collected so as to form several conical or comb-shaped projections. Dr. Meyer described them in one case "as giving the finger the sensation of soft masses, which, yielding to pressure, felt very much like a bunch of earth-worms, and, hanging down from the roof of the pharynx, completely closed up the posterior nares." On close examination, the surface of the growths is seen to be split in different directions, and dotted over with sieve-like lacunæ, which are formed by the openings of the excretory ducts of the mucous and follicular glands. The mucous membrane covering them varies in thickness; the epithelium is usually ciliated. Great vascularity is a characteristic of most of these growths; in some cases, the bulk of the tumour is made up of connective tissue. Microscopic examination reveals networks of delicate connective tissue, which in part contain lymphoid corpuscles, and in places are surrounded by them.

Etiology.—Adenoid growths are more common in young subjects than among adults. The great abundance of lymph-follicles in the naso-pharynx of children explains the frequent occurrence

* *Archives of Otology*, vol. xiv. p 267

of the disease in early life. During childhood this lymphoid tissue is very easily excited to take on active growth. Similar examples are seen in the tonsils and cervical glands. The amount of tissue sufficient to cause marked symptoms in children might produce none in adults. The excessive development of the tissue in question is probably often due to very slight catarrh of the nasopharynx. It may be produced by prolonged congestion of this cavity, and hence the frequent development of growths after scarlet fever, measles, and whooping-cough. The absorption of septic matter by Luschka's tonsil may account for the frequent occurrence of growths after the two former diseases, and also for their occurrence in weakly or underfed children, who pass much time in an overcrowded school, or who live in a small and badly ventilated room. *Sex* is apparently without influence in the production of the disease. *Heredity* is a doubtful factor, it being far more probable that the children affected have been exposed to similar predisposing conditions to those to which their parents were subjected. Struma is said to cause these growths, but they are not usually accompanied by other marked signs of the diathesis. The growths are not infrequently associated with deformities of the throat, such as cleft palate.

The **Symptoms** of adenoid growths may be divided into two classes—subjective and objective. The prominent subjective symptoms are (1) obstruction to nasal respiration; breathing through the nose is either impossible or very difficult. In the latter case, the mouth can be kept closed, but only for a time, and it is more convenient to keep it open. The degree of obstruction depends upon the size and position of the growths, also upon the amount of swelling of the mucous membrane which they cause. When an infant is suffering from post-nasal growths he is unable to suck for more than a short time, and throws the teat out of his mouth frequently in order to breathe more freely. (2) Inability to blow the nose properly. The cause of this symptom is easily intelligible: air cannot be driven with sufficient force through the nares, so as to expel secretion. (3) The patient complains of dryness of the throat on waking; this is due to breathing through the mouth, the moisture of which is removed by the air. (4) Headache, which is doubtless due to the pressure or tension caused by the growths upon the mucous membrane, closely adherent to the base of the skull. To a like cause may be due

the feeling complained of by many patients, that there is something at the back of the throat, which no attempts can remove. Meyer observed that this pain was increased in some cases by digital pressure on the growths; also that it was sometimes continuous, sometimes remittent, its locality varying in different cases. (5) Symptoms referable to the ear, viz., deafness, ear-ache, and tinnitus.

A few years ago Dr. Guye,* of Amsterdam, drew attention to a symptom often associated with disorders of the nose and adenoid growths, and termed by him *aprosexia*, or inability to fix the attention on any definite more or less abstract subject. Most of the cases observed by him occurred among boys or young men at school or universities. In order to explain this symptom, Dr. Guye points out that large lymph-vessels leave the cerebral cavity together with the fibres of the olfactory nerve. Structural changes in the nasal mucous membrane, and especially such as exert pressure on the lymphatics, will prevent or hinder the current of the lymph, and cause retention of the products of metabolism in the cerebral tissues. Pressure on the lymphatics may likewise be caused by local hyperæmia, due to reflex action, which may serve to account for paroxysmal attacks of *aprosexia*.

A somewhat large percentage of disorders of the middle ear result from adenoid growths of the naso-pharynx. The catarrhal process accompanying the growths is very apt to extend through the tubes, especially when the growths are situated upon the lateral walls, close to the pharyngeal openings. Both ears are not always equally affected; the symptoms may diminish or even disappear for a time. The process in the middle ear is either acute or chronic, and corresponds with the intensity of the symptoms. When the ear-complication occurs, swelling of the mucous membrane of the Eustachian tube and interference with the passage of air to the tympanum are the first symptoms; afterwards the mucous membrane of the tympanum becomes involved. The patient often complains of auditory hallucinations of all kinds, such as ringing, buzzing, humming, and other noises in the ears; sometimes there are twinges of pain; range and sharpness of auditory perception are diminished.

Objective Symptoms.—The patient has a heavy look, and appears dull and stupid (Fig. 90, page 276). The speech is decidedly affected;

* *Brit. Med. Journ.*, 1889, vol. ii. p. 709.

the sound of *b* is substituted for that of *p*, and *d* for *t*. In some cases the nasal sounds cannot be pronounced, but *b*, *d*, and *l* are uttered instead. The alteration in the voice is due partly to the closure of the nose, partly to alteration in the uvula, and diminution of the naso-pharyngeal space. Czermak was the first to show the importance of the uvula in the formation of vowel-sounds. He stated that when these are uttered, changes take place in the direction of the velum, and therefore at the level at which it closes the pharynx above. When adenoid growths exist, the velum is often thickened, partly in consequence of diffuse swelling of the follicular glands and partly from œdema. The weak, dull,

FIG. 90.

A BOY, AGED 14, THE SUBJECT OF POST-NASAL GROWTHS.

monotonous voice is mainly due to the impediment to free movement, and to the thickening of the velum. After removal of the growths, the nasal twang may completely disappear, while the other features of the voice remain—probably as a result of thickening of the velum. As a matter of course these growths interfere with singing, and may render it quite impossible. In addition to the mechanical obstruction which they cause, there is often paresis of the palate, due to the chronic congestion of the palatine glands and muscular tissue. In extreme degrees of enfeeblement of the muscles, the impairment of speech closely

resembles that which occurs in patients suffering from cleft palate.

Other prominent symptoms, some or all of which may be present according to the severity of the case, are:—Noisy respiration when awake, snoring and sometimes also mucous dribbling from the mouth during sleep; the lips prominent and expressionless, and moving feebly, owing to partial abolition of the functions of the orbicularis oris, buccal respiration being often noticeable; the nostrils narrow, and the cavities of the nasal fossæ ill-developed; the alæ of the nose depressed at the junction of the superior and inferior lateral cartilages; distension of the transverse nasal vein, caused by obstruction to venous outlet through sphenopalatine foramina and pharyngeal collaterals. In severe cases the patients are often pigeon-breasted and present signs of anæmia. Nocturnal incontinence of urine is sometimes found in patients, especially girls, who are the subjects of adenoid growths.

Dr. William Robertson, of Newcastle-on-Tyne, has called attention to the presence or past existence of adenoid growths in cases of inflammation of the lymphatic glands in the neck, and considers the latter affection to be directly due to the absorption of septic matter in the naso-pharynx. On examining the throat the hard palate is seen to be arched; its mucous membrane and that of the posterior wall of the pharynx are often swollen and almost œdematous in appearance. The growths in the naso-pharynx secrete a tough mucus, sometimes of greenish colour, which may be mixed here and there with blood; this runs down the posterior wall and the back of the uvula. In adults the secretion is most abundant in the morning, having accumulated and become dry during the night. Exposure to cold causes increased secretion, which, if retained, is apt to become offensive, as a result of decomposition. The amount, colour, and consistence of the mucus found in the pharynx vary in different cases. The mucous membrane, as a rule, is deeper in colour than normal; the uvula is often twisted to one side. The back of the pharynx may present enlarged glands and vessels, projecting beyond the surface of the mucous membrane. *Pharyngitis sicca* may be found in cases where the obstruction affects only the upper and middle meatus. The larynx is often more or less congested.

On examining the ear the membrana tympani is generally seen to be dull and depressed, often to an extreme degree; the bright spot is either diffused or absent. The membrane is sometimes congested, sometimes perforated; otorrhœa is not uncommon, and the cavity of the tympanum is sometimes occupied by granulations. The Eustachian tubes are generally closed to Valsalva's inflation.

Diagnosis.—In many cases the aspect of the patient is sufficient to enable a diagnosis to be made; but if there is a doubt, it may be removed by examining the naso-pharynx with a laryngeal mirror, or, failing that, with a finger. Digital examination is safe, easy, and practicable, and requires no preparation; it should never be neglected in any case at all suspicious. It is necessary to guard the finger from injury by the patient's teeth, and as I found the jointed metal-guard in ordinary use unsuitable, I made a guard for myself, figures and description of which will be found on page 104. Whilst the examination is being made the patient's head should be thrown a little backwards, and steadied with the surgeon's hand, and the patient should breathe quietly and deeply through the mouth. This digital exploration is practicable in patients of all ages. In the case of children, and in adults with small growths, not much interfering with the movements of the velum, the latter sometimes approximates to the posterior wall and impedes the passage of the finger. When this occurs the tip of the finger should be placed behind the lower part of the posterior pillar of the fauces on the side on which the surgeon is standing, and slipped upwards in the space between it and the posterior wall of the pharynx. By this means it will easily pass behind the soft palate. Digital exploration informs us as to the consistence, size, and extent of the growths, which are more common than is generally supposed. Some amount of hæmorrhage usually follows the examination.

Inspection with the Mirror.—To diminish the irritability of the throat, the part should be first sprayed or painted over with a solution of cocaine, 2—5 per cent., according to the age of the patient. The mirror should then be passed behind the velum, to the front of the posterior wall of the pharynx, which should not be touched; it is then carefully turned, depressed, or raised so as to get a view of the whole space.

In some cases it is necessary to depress the tongue, but usually the examination is best borne when this is not done. By gently pulling the soft palate forward with a tractor the whole of the contents of the naso-pharynx can be seen. But this instrument is not well tolerated by children. If growths are present, and depend from the roof of the pharynx, their lower free border and posterior surface are all that can be seen. A better view can be obtained when there are only small growths on the roof and on the posterior wall. In adults with large growths, and in children, pharyngoscopy often partially or completely fails, from want of sufficient illumination, or on account of the narrowness of the space between the velum and posterior wall of the pharynx. Enlarged tonsils usually prevent a good view being obtained. When the nasal cavities are very large, it is sometimes possible to see the naso-pharynx by simply lifting up the tip of the nose. Such a view, however, can be obtained only in very rare cases. Zaufal's naso-pharyngeal speculum is sometimes useful, but difficulties in passing it are often encountered.

Adenoid growths may be mistaken for *nasal polypi*, *polypi filling the posterior nares*, and *retro-pharyngeal abscess*. Nasal polypi are generally accompanied by symptoms of nasal catarrh, sensations of fulness and discomfort in the nostril and snuffling respiration. The sense of smell is deadened, and the nostril may become completely obstructed. Polypi can usually be detected on looking into the nostrils. The tumour presents a shining surface, and is greyish or greyish-yellow in colour; on touching it lightly with a probe, it is found to be soft, elastic, and movable; this last condition definitely distinguishes it from swollen mucous membrane. When the patient blows his nose, the growth is forced lower down. More or less of the tumour can be seen with a mirror or felt on digital examination, when it projects through the choana. Fibrous polypi cause symptoms of obstruction in the nose, and epistaxis is not uncommon. The tumour is apt to project into the pharynx as a hard, rounded mass, and afterwards manifests its presence in the nostrils. Such a growth usually springs from the roof of the pharynx and of the nasal fossæ, or from the inferior turbinated bone, but sometimes from the whole basilar surface of the sphenoid and occi-

pital bones. The tumour has a firm consistence, and when visible is denser and more opaque than a mucous polypus. The symptoms of retro-pharyngeal abscess are sufficiently distinctive; the posterior wall of the pharynx is pushed forward by a collection of pus, which forms a tense elastic tumour, usually fluctuating distinctly and situated close behind the soft palate. It is generally caused by caries of the vertebræ, or suppuration of lymphatic glands at the back of the palate. In addition to pain and fever, there is more or less dyspnœa and cough, and frequent choking sensations. The rapid onset of the symptoms is sufficient to distinguish them from those of adenoid growths.

Treatment.—It is not necessary to operate when the growths are so few and so small that they produce no marked symptoms, and the hearing is unaffected; but when the symptoms become prominent an operation is imperative, irrespective of the age of the patient. I have removed growths from a child only four months old who was unable to suck properly on account of the nasal obstruction. This infant, before the operation, used to throw the teat out of its mouth at short intervals in order to breathe. It has been stated that it is unnecessary to operate on patients who have passed the age of puberty, on account of the retrogressive changes which are taking place in the growth. This view is erroneous, because as long as the abnormal conditions remain which the growths cause, so long will the mischief which has been produced progress. I have operated with marked benefit on several patients of more than twenty-one years of age. Shortly after operating on a gentleman twenty-seven years of age, he told me that since the operation his voice had been more clear than he ever recollected it to have been previously, and that for the first time in his life he was experiencing the comfort of being able to breathe through his nose. When a patient has enlarged tonsils as well as post-nasal growths, I am decidedly of opinion that the tonsils should be removed previously to the growths, and without a general anæsthetic being administered. (*See* page 263.) Furthermore, if the two operations have to be performed at one interview, that the anæsthetic should not be administered for the removal of the growths until the hæmorrhage consequent on the tonsillectomy has practically ceased. It is my custom, when possible,

first to remove the tonsils, and on a subsequent occasion to take away the growths. An anæsthetic should always be given, as the operation is somewhat painful, and children are naturally alarmed at the sight of the blood. Owing to the frequency with which this disease occurs, a large number of patients have to be operated upon at hospitals, and on account of the time occupied by the administration of the anæsthetics, there is a tendency amongst some surgeons to remove the growths without the patient being anæsthetised. If the object aimed at was merely to re-establish nasal respiration, no great amount of harm would be done by adopting this course, but as the middle ear is very frequently affected, it is most important to remove the source of the naso-pharyngeal catarrh which usually co-exists. This end will not be gained if portions of growth are allowed to remain, and I am well aware that this usually occurs when the operation has been performed without the patient being anæsthetised. At the present time, sufficient attention is not paid to the ear-complications associated with post-nasal growths by surgeons who do not make a special study of aural diseases; but it is to be hoped that they will soon awaken to the fact that the establishment of free nasal respiration should not be the only object for which the operation is performed.

With regard to the choice of anæsthetics, it is best in most cases to place the patient fairly deeply under ether, and to keep up the anæsthesia with chloroform whilst the actual operation is in progress. An exception must be made, however, when dealing with infants, and in their case chloroform or the A.C.E. mixture should be employed in preference to ether. Many surgeons prefer chloroform throughout for all cases; and, at first sight, this anæsthetic appears to be specially indicated. But in addition to the greater safety of ether as a routine anæsthetic, it is certainly far safer than chloroform in operations about the naso-pharynx, involving free hæmorrhage. The deep and audible breathing under ether; the tendency to occasional coughing and swallowing which attends its administration; the remarkable manner in which the circulation holds out when, as occasionally happens, respiration becomes temporarily interfered with during the operation; and the rapid and permanent cessation of hæmorrhage after the anæsthetic has been withdrawn; are all weighty

reasons for selecting this agent. It is true that patients breathe more easily under chloroform, and hæmorrhage may be less during the operation; but the noiseless manner in which breathing may become obstructed under chloroform; the rapidity with which the circulation runs down should any embarrassed breathing take place; and the greater liability to secondary hæmorrhage when the circulation becomes brisk with returning consciousness; are all unfavourable points against the use of this anæsthetic throughout the operation. When the patient has been placed well under ether, however, small quantities of chloroform may with great advantage be given to keep up the anæsthesia.

When circumstances permit, nitrous oxide should first be given; then ether, and then chloroform. Nitrous oxide has the great advantage of rapidly destroying consciousness and cutting short the initial phenomena of anæsthesia; a point of some importance when, as is often the case, friends of the patient are near at hand.

Should nitrous oxide not be available, a small quantity of the A.C.E. mixture may be used, upon lint or a Skinner's mask, before the ether is given. Should neither nitrous oxide nor this mixture be at hand, ether should be given from the commencement by means of a Clover's inhaler.

In giving gas and ether to children a very small quantity of the former is needed. When the signs of nitrous oxide narcosis come on, the face-piece should be removed; one breath of air given; and an Ormsby's ether inhaler previously charged with ether, applied. In the case of children it is best to pass quickly from gas to ether, and for this purpose an Ormsby's inhaler is better than a Clover's inhaler, because the former gives off more ether in a given space of time than the latter. In dealing with children, it is also an advantage to have the gas inhaler distinct from the ether inhaler, because this arrangement ensures the mouth-piece first applied being free from the smell of ether; and as, in this case, the gas bag can be kept out of sight, the child is less likely to be alarmed than if it were in front of his face as when Clover's apparatus is used. For adults and adolescents, Clover's inhaler is preferable, because with it, when required, a certain amount of ether can be mixed with gas from the beginning of the administration, and if ether only is required,

the amount given can be better regulated than with an Ormsby's inhaler.

When there is more or less complete nasal obstruction, it is a good plan to place a small mouth prop between the teeth before beginning the administration: this is especially advisable in young adults and grown-up persons.

Whatever plan be adopted, the patient should be placed fairly deeply under ether before the operation is begun. The jaw muscles should have become relaxed, the conjunctiva almost insensitive, and the breathing regular and deep. The laryngeal and pharyngeal reflexes, as evidenced by slight, but not inconvenient, cough and swallowing movements, should, however, always be allowed to persist in a minor degree. In cold weather seven to ten minutes may be needed to secure the proper degree of narcosis. The gag being introduced and the operation begun, the tube leading from a Junker's chloroform apparatus should be hooked inside the corner of the mouth by the side of the arms of the gag. A word or two may be said as to the introduction of the Mason's gag. The pillow should be so arranged that it does not project beyond the neck on the side upon which the gag is inserted, otherwise the gag may be dislodged by the pillow. Care must be taken not to injure the teeth when introducing the gag, the blades of which should be guarded with stout india-rubber tubing, carried for some distance along the arms, beyond the angle, to prevent the possibility of its slipping off.

When anæsthetising young adults and grown-up persons, a Hewitt's modification of Mason's gag is useful, *i.e.*, a gag with metal tubes soldered to its arms for the transmission of chloroform vapour to the back of the throat. By this plan greater room in the mouth is secured. When the conjunctival reflex commences to reappear, *but not before*, the chloroform vapour should be pumped in to the back of the mouth. The conjunctival reflex should not, as a rule, be allowed completely to disappear. An occasional cough or act of swallowing should be encouraged; but muscular movement or retching should be met by giving more chloroform. When the breathing becomes bubbling in character, less chloroform should be administered. Moderate hæmorrhage can easily be met by sweeping round the back of the throat with a sponge. Should the bleeding be profuse, or

should the vomiting of fluids or solids take place, the head should be turned to the side for half a minute or so. Should the operation be longer than usual, the anæsthesia may be allowed to become less and less profound. Moderate duskiness of the features need not cause alarm; but any increasing blueness should be taken to indicate less chloroform till coughing has occurred or the colour has improved.

Immediately the operation is at an end, it is best to remove all pillows, to turn the patient on to his side, and to allow fluid to drain away from his mouth. The Mason's gag should not be removed till some few minutes after the operation. Patients should never be allowed to lie with the face turned upwards after the administration of the anæsthetic has been discontinued, and it is best for the administrator to stay by his patient till retching has taken place and distinct signs of recovery have been observed. Before leaving the subject of anæsthetics, it will be well to mention that when about to operate on post-nasal growths before 10 a.m., I arrange for the patient to be kept without food after the last meal on the preceding evening; but if a time be fixed for later in the day, I direct that some beef-tea be taken six hours before the operation. This arrangement ensures an empty or almost empty stomach, and vomiting is thereby either entirely prevented, or very materially lessened. The anæsthetic takes effect more quickly, and consequently less is required, and the after effects are thereby considerably diminished.

Great variety of opinion exists as to what is the best position for the patient whilst being operated on, the main object aimed at being to prevent blood getting into the trachea, a danger which, in my opinion, has been much exaggerated, and is not likely to occur unless the anæsthetic has been pushed to an improper degree. I invariably operate with the patient lying on his back on a low sofa, with a small, soft pillow under the neck to keep the occiput lightly resting on the flat surface of the couch. I consider it a great mistake to throw the head far back, because in this position there is pressure upon the veins of the neck, and consequently hæmorrhage is increased. If the patient is not placed in a position which thus produces unnecessary hæmorrhage, provision for the overflow of blood through the nostrils is unneeded.

For the removal of the growths various cutting* and scraping instruments are employed, but I consider the latter should not be used, and that of the former, forceps are decidedly the best. I do not recommend the use of a ring-knife, because this instrument, in any of its forms, does not remove the growth as thoroughly as forceps. A large-size ring-knife, in consequence of its dimensions and shape, is especially liable to leave untouched growths attached to the upper border of the choanæ and other parts to which it cannot be applied. An instrument for scraping, whether attached to a handle or fitted to the finger, I am of opinion should not be used, because of the injury to the surrounding healthy tissues which is liable to result from its employment, and also the unnecessary damage caused to the tissues lying beneath the surface to which the growths were attached. If the growths are small, soft, and few in number, they may be removed with a finger nail, the tactile sensibility of the finger enabling the operator to distinguish the growths from the healthy tissues. In all other cases I consider that they are best taken away with forceps.

In order to avoid unnecessary hæmorrhage, the edge of this instrument should not be too sharp. Löwenberg's forceps and the various modifications thereof appear to present two defects. In the first place, only a portion of the end of the instrument has a cutting edge, and hence it is often impossible to cut off the piece of growth held between the blades. The portion not cut away has to be torn off, and when the growth is thick and tough, the tearing sets up more inflammation than would otherwise have occurred. It is generally stated that the cutting edge is made only on the upper and posterior part because the growths are, as a general rule, attached exclusively to the upper and posterior walls of the naso-pharynx, and that a sharp edge is required only in those situations. The statement as to the attachment of the growths is quite correct, but the deduction drawn therefrom is erroneous, because the piece of growth grasped by the forceps is frequently larger than the end of the instrument, and has an attachment greater than the length of its cutting edge, and a larger surface from before backwards than that covered by the

* Dr. Meyer invented a ring-shaped knife for the purpose; Dr. Guye, of Amsterdam, suggests a similar instrument, but elliptical in form, *Archives of Otology*, vol. xv. p. 30.

blades. It is therefore evident that such a piece cannot be entirely removed, without being partially torn away, by the instruments hitherto employed. The second defect is that the two cutting edges are made to strike against one another, and consequently soon become extremely blunt. In the instrument which was manufactured for me by Mayer & Meltzer, in 1887, and exhibited that year at the meeting of the British Medical Association at Dublin, both the defects mentioned above have been remedied; the first by the entire circumference of the blades being made with a cutting edge; the second, by one cutting edge being made to pass inside the other, so that the piece of growth grasped by the forceps is completely detached by the action of the instrument. The end of the latter has also

FIG. 91.

THE AUTHOR'S POST-NASAL FORCEPS.

The screw which is represented as holding the blades together is now replaced by a pivot, an arrangement having been added which allows the two blades to be taken apart for the purpose of cleaning them.

been fenestrated to prevent a thick piece of the growth from interfering with the close approximation of the blades.

When the proper amount of anæsthesia has been produced, the surgeon, standing on the right side of the patient, should insert the first finger of his left hand, with the palm upwards, into the naso-pharynx, and feel the growth. The forceps, held in the right hand, should then be introduced, the left forefinger not only holding forward the soft palate out of the way of the forceps, but also serving as a guide to the growth to be removed. The blades should then be opened, and the growth gripped, the left forefinger, if necessary, pushing the growth between them. Unless it is of firm consistence, it is best partly to cut and partly tear it from its attachment by a slightly oscillating movement of

the forceps, the tip of the forefinger of the left hand at the same time gently assisting to separate the growth from its attachment should it not readily come away. Care should be taken to prevent traction on any portion of mucous membrane which may happen to remain unsevered, for I have seen strips torn away in consequence of this detail being neglected.

When that piece of growth has been removed, the forceps should be again inserted into the naso-pharynx, the left forefinger being still in that region. The remainder of the growth should then be felt for with the finger, and removed by the forceps, until all has been taken away. The left finger should remain on each piece of growth until the closure of the blades of the forceps makes its removal necessary; by this means no injury

FIG. 92.

POST-NASAL GROWTHS.

can be done to healthy tissues. Each piece of growth, as it is removed, is most easily detached from the forceps by shaking the latter in water.

As the pharyngeal extremities of the Eustachian tubes are at the sides, no harm can be done to them if the patient's face looks directly upwards, and the curved end of the forceps is kept in the mesial line. Two cases have come to my knowledge in which the vomer was injured, but this is an accident which could not occur if ordinary precautions were taken.

Before completing the operation the left forefinger should be inserted into each choana in order to ensure that no portion of growth is left attached to its upper border, each fossa of Rosenmüller should also be examined, and any small piece of growth

which remains in the naso-pharynx should be removed by scraping it off with the finger nail.

It may be necessary to stop during the operation in order to take away the blood which has collected, and for this purpose it is best to use pieces of soft honey-comb sponge, about two to two-and-a-half inches in each diameter. A fine sponge is comparatively of little use for this purpose, as its surface becomes coated with mucus. About a dozen pieces of sponge are required. Each piece should be carried to the back of the mouth on the first and second fingers of the right hand, then swept across the back of the pharynx and removed. If an assistant passes a clean sponge with one hand, and takes the used one with his other hand, several sponges can be used in very quick succession. Sponge-holders are not only unnecessary but inconvenient, as the pharynx can be more effectually and more rapidly sponged out as above described. When operating at a patient's home, it is well to take precautions to ensure the clothes and couch being left unsoiled. With this object, a mackintosh should not only be laid beneath the head and shoulders, but also over the patient, and the centre of a towel should be placed behind the neck, and the two ends brought round one on each side, then spread out and crossed in front. By this means the upper part of the clothes will be kept clean. Whilst operating on girls, I have placed over their heads, in order to protect their hair, a waterproof cap made of hat lining, and fitted with elastic, similar to a bathing cap.

The hæmorrhage which takes place during the operation generally quickly subsides as soon as the growths have been removed. In the rare cases in which it continues, the nostrils should be filled with ice, and in the event of that failing to arrest the bleeding, pressure should be made with a sponge on the place from which the growths have been taken away. Ergotine may also be administered hypodermically. As soon as the patient recovers consciousness after the operation, it is well to let him suck ice, as this tends to arrest any inflammatory tendency which may arise in consequence of traction on the soft palate. In the rare event of the uvula becoming cedematous, it should be painted with a 5—10 per cent. solution of cocaine, and pricked with the uvula scarifier (Fig. 88, page 268).

For a week or ten days after the operation, a solution of boric

acid (5—10 grains to the ounce), may be sprayed through the nostrils into the naso-pharynx several times daily, in order thoroughly to cleanse that region. Subsequently, the ordinary treatment for naso-pharyngeal catarrh should be adopted. In many cases, tonics containing iron are administered with benefit for a few weeks after the operation.

The hypertrophic rhinitis which often accompanies post-nasal growths usually subsides when the latter have been removed; but should it continue to produce nasal obstruction, the lax tissue may be touched with the electro-cautery with advantage. Recurrence of the growths after removal is the exception and not the rule; and when it occurs, the growths are but rarely developed to the same extent which they were originally. Recurrence results from a continuance of the congestion of the naso-pharynx, and is more common in delicate children than in those of robust health. As the fresh growths tend to keep up naso-pharyngeal catarrh, their removal may be rendered necessary on account of the condition of the ears, and in this case the operation must be performed as on the first occasion. The largest number of recurrences (four) which I have heard of occurred in my own practice, in the case of a young lady who had been twice operated upon before she came under my care for deafness, accompanied with profuse naso-pharyngeal catarrh.

The patient should be directed to discontinue the habit of keeping the mouth open, and made to practise breathing through the nose. Some amount of perseverance is necessary in some cases for this change to be effected; but it must be borne in mind that the continuance of the symptom may be due to the recurrence of its original cause, and not to forgetfulness or obstinacy on the part of the patient.

CHAPTER XXII.

AFFECTIONS OF THE EUSTACHIAN TUBES.

Extension of Morbid Processes through the Eustachian Tube—Injuries to the Eustachian Tube—Foreign Bodies—Inflammation of the Eustachian Tube—Anatomical Appearances—Symptoms—Examination of the Throat and Ear—Treatment—Constrictions of the Eustachian Tube—Diagnosis—Complete Atresia—Undue Patency—Ulceration of the Eustachian Tube—Diphtheria, Small-pox, Tuberculosis, and Syphilis—Treatment of Constrictions, Abnormal Patency, and Ulceration.

EACH Eustachian tube consists of two portions, a cartilaginous and an osseous (*see* p. 47), and these are connected by an isthmus, the narrowest part of the tube. The cartilaginous portion may be regarded as a prolongation of the naso-pharynx; its mucous membrane is continuous with that of the latter cavity, in which its disorders are wont to originate. The osseous portion is similarly connected with the cavity of the tympanum, and hence disease of one structure is usually associated with a similar condition of the other. The Eustachian tube is the only channel of communication between the tympanum and the external air, and by it, also, in the majority of cases, morbid matters gain access to the cavity. There are two ways in which disease may spread from the naso-pharynx to the tympanum: (1) by extension of inflammation along the mucous membrane of the tube; (2) by the passage, in a similar direction, of infectious secretions during forced expiratory movements. On the other hand, as a far less frequent occurrence, disease may extend in the opposite direction, viz., from the tympanum to the Eustachian tube.

INJURIES TO THE EUSTACHIAN TUBE—FOREIGN BODIES.

Owing to its sheltered position, the Eustachian tube is rarely the seat of injury; its mucous membrane is sometimes torn during unskilful attempts to pass a catheter. A few cases of gunshot wound have been placed on record. Obliteration of the canal is, of course, the ordinary result. In a case of punctured wound,* the knife passed through the cartilaginous portion of the meatus, below the articulation of the jaw, into the pharynx, dividing the cartilaginous portion of the Eustachian tube. Recovery took place, with atresia of the tube as the result.

Foreign bodies very seldom gain access to the Eustachian tube. During the act of vomiting, matters from the stomach have been known to pass into the pharyngeal orifice. Breakage of bougies, used to dilate the tube, has in a few cases been followed by the lodgment of fragments. These set up vomiting, which may cause their expulsion. In one case, a barley-corn was found in the tube on post-mortem examination.† The man had complained of noises in the ear for some time before his death. In a very remarkable case, under the care of Dr. Urbantschitsch,‡ an oat-husk, 3cm. in length, passed into the pharynx and thence along the Eustachian tube into the tympanum, where it set up purulent inflammation. Nine weeks afterwards it was discovered in the external meatus, the membrana tympani having become perforated. While the husk was passing along the tube, the patient experienced very severe pain in moving the jaw, and for several weeks could take only fluid nourishment. There was also total loss of appetite, possibly due to irritation of the branches of the pneumogastric supplying the tube.

Foreign bodies of another kind are occasionally found in the tube. Intestinal worms have been known to pass upwards into the throat, and thence along the Eustachian tube into the tympanum§ and external meatus.

INFLAMMATION OF THE EUSTACHIAN TUBE.

Catarrhal inflammation of the Eustachian tube often accompanies catarrh of the naso-pharynx. The process is then most severe in the cartilaginous portion, and may be confined to it. Less frequently inflammation spreads from the tympanum to the osseous portion of the tube. As a matter of fact, the tubes are affected in almost all affections of the middle ear; they are, indeed, the channels through which infection extends, and hence inflammation of these parts is of very common occurrence. It rarely happens that the process is confined to the tubes; but cases of this kind do sometimes occur, and usually in children. In young subjects the mucous membrane is thick and the cartilage ill-developed, and hyperplastic processes are easily set up. In addition, the pharyngeal orifice is narrow, and secretion is very liable to be retained. Scrofula is a predisposing cause, and this condition is frequently associated with adenoid growths and hypertrophy of the tonsils.

The **Anatomical Appearances** are redness, swelling, and increased secretion. The tube is filled with a muco-serous or more or less purulent fluid; the blood-vessels are enlarged and tortuous, and the mucous membrane is swollen, owing to cellular and serous infiltration. In some cases the secretion is very tenacious in character, and closely adheres to the walls of the tube, so as completely to obstruct it. Sometimes a whitish-yellow plug may be seen projecting from the pharyngeal orifice, and a complete cast of the tube may be formed by inspissated secretion. In other cases, the exudation is fluid in character, and more or less purulent. It always contains cylindrical epithelial cells, some being ciliated; and micro-organisms of various kinds are frequently present.

Symptoms.—A patient suffering from inflammation of the Eustachian tube on one side complains of a sensation of pressure and fulness in the ear, and of more or less deafness. These symptoms are well-known accompaniments of an ordinary cold. The patient is apt to regard the deafness as more severe than is really the case; he feels as though the meatus were plugged up. When the inflammation is very severe, pain in the ear is generally superadded; it may extend to the angle of the lower jaw and

side of the neck, and it is made worse by movements of swallowing. Giddiness and nausea are sometimes observed. Sudden disappearance of all the symptoms is occasionally noticed; it generally occurs during eating, and is caused by the opening of the membrano-cartilaginous portion of the tube, or perhaps by the escape of inspissated secretion. The improvement, however, is only temporary; the symptoms connected with the ear speedily return. Not infrequently, the opening of the tube is accompanied by a crack, of which the patient is conscious.

On examining the throat by posterior rhinoscopy, the appearances are those already mentioned, viz., circumscribed redness of the mucous membrane with increased secretion, swelling, and contraction of the orifice, which is sometimes occluded by a plug of tenacious secretion. Considerable resistance is offered to the passage of the Eustachian catheter, and when the beak of the instrument is within the lips of the tube, several compressions of the bag may be required before air begins to pass. The obstruction may be caused by swelling or by folds of the mucous membrane, by thick, tenacious secretion, or by adhesion of the walls of the tube. When it is overcome, the sound heard on auscultation is weak, distant, and interrupted; but by degrees it becomes stronger, nearer, and more continuous. If the obstruction be completely removed, the sound approximates to its normal blowing character.

On examining the ear, in cases in which the Eustachian tube has been for some time impermeable to air, the position of the tympanic membrane is seen to be materially changed. The funnel-shaped depression is increased in depth, and the handle of the malleus is decidedly shortened. These alterations are due to the rarefaction of air in the tympanic cavity; the atmospheric pressure on the external surface of the membrane is greater than on the internal. Besides the increased concavity of the membrane and the shortening of the handle of the malleus, the folds (especially the posterior one) passing from the short process are rendered more prominent, while the cone of light is much diminished in size or even obliterated. As the membrane is drawn inwards, the angle between the handle of the malleus and the posterior fold becomes more and more acute, and the short process is caused to project downwards, like a peg, towards the external meatus. In very marked cases, the promontory, the long

process of the incus, and the chorda tympani nerve sometimes become visible.

Treatment.—Measures must be adopted to cure or relieve the morbid condition of the naso-pharynx. For this purpose, the various remedies, as described in a preceding chapter, may be employed in the form of gargles, inhalations, sprays, and pigments. Constitutional treatment is always required; cod-liver oil, iodide of iron, arsenic, and other tonics are likely to be useful. To relieve the condition of the Eustachian tube and tympanum, the catheter and air-douche must be employed. If the local treatment of the naso-pharynx prove insufficient, weak lotions should be injected into the Eustachian tube through a catheter. To ensure the fluid being warm, it is well to make the solution which is to be employed of double strength, and dilute it with an equal quantity of hot water before use. Care should be taken that the nozzle of the syringe does not fit the catheter too closely, otherwise the fluid may be forced along the Eustachian tube into the tympanum, and produce inflammation of that cavity. The patient's head should be placed, if possible, against a rest, and held straight, so that the stem of the catheter when in position may be horizontal. Two or three drops of fluid should then be put into the catheter from the syringe, and blown into the Eustachian tube by a handball previously attached, ready for use, to the button of the coat. The auscultation tube should be in use whilst this is being done, so that the pressure to the air-bag may be properly regulated according as to whether or not the fluid is passing readily into the Eustachian tube. The injection should be repeated two or three times a week, or daily for a short time in severe cases. If a two per cent. solution of cocaine is sprayed through the nostril before the catheter is passed, the discomfort which sometimes attends its passage will be prevented. In many cases alkaline solutions are best. Iodide of potassium about 10 grains to the ounce is very useful. Bicarbonate of soda 3—5 grs. to the ounce may also be employed with advantage. When an astringent is required it should be weak. I have found a solution of sulphate of zinc, one grain to the ounce, beneficial.

CONSTRICTIONS OF THE EUSTACHIAN TUBE.

The calibre of the Eustachian tube may be diminished at various points and from a variety of causes. Thus the pharyngeal

opening may be partially closed by enlargement of the pharyngeal tonsil, and by the cicatrization of ulcers due to syphilis, tuberculosis, or diphtheria. Constrictions in the tube are the result of thickening of the submucous connective tissue, as may occur after repeated attacks of inflammation. Apparent constriction is sometimes due to an abrupt bend in the tube, or to projection of the carotid canal into the osseous portion. Constriction in this latter may be due to hypertrophy of the mucous membrane, to connective tissue formation during middle-ear inflammation, or to bands of the same tissue extending between the walls of the tube. Besides these causes of constriction, the osseous portion may be more or less blocked up by bony deposit and exostoses.

The **Diagnosis** of constriction of the Eustachian tube is effected by means of rhinoscopy, the air-douche, and also by inspection of the membrana tympani. The use of bougies for this purpose is not recommended by the author (*see* page 129). The condition of the pharyngeal orifice should always be carefully examined; adenoid growths, enlargement of the pharyngeal tonsil, and growths from the inferior turbinate bone may constitute the obstacles to the passage of air. It must also be remembered that constriction in the tube itself may coexist with any of these impediments. There are other conditions which play a more or less decided part in diminishing the patency of the Eustachian tube. Among them may be mentioned atony and insufficient action of the muscles of the palate, due to over-exertion of these parts, or the result of paralysis after diphtheria. A similar condition of the muscles is sometimes noticed during recovery from exhausting illnesses, in cases of anæmia, and occasionally as a result of old age.

Complete Atresia of the tube is a rare condition; it may be caused by those processes which produce constriction. In the majority of cases, the occlusion exists at the pharyngeal orifice. Cicatricial stricture and complete obliteration of the canal have been observed in cases of syphilitic and diphtheritic ulceration. The symptoms are similar to those of severe inflammation of the tube: there is an unpleasant sensation of fulness and pressure in the ear, together with tinnitus, headache, giddiness, and loss of hearing-power. The membrana tympani is drawn inwards, and no sound is heard on injecting air through the catheter. Various alterations may be discoverable on posterior rhinoscopy.

An opposite condition of the tube, viz., undue patency, is

sometimes present. It may be due to senile atrophy of the parts, to atrophy of the mucous membrane following chronic catarrh, or to destructive ulceration. It is sometimes temporarily present in cases of extreme debility, but is most often associated with atrophic conditions of the nose and pharynx. Partial dilatation most often occurs at the pharyngeal orifice. In one case, recorded by Urbantschitsch,* the tip of the little finger could be easily introduced into the mouth of the tube. As results of the undue patency, air passes more or less freely into the tympanum during respiration, and the patient is conscious of increased resonance of his own voice (autophony). This latter phenomenon is most often observed in debilitated patients; not only their own voices, but other sounds produced near them, appear louder than natural, so that the sensation becomes very disagreeable. Dr. Sexton explains autophony as due to the fact that vocal sounds, instead of being heard after passing through the mouth and external air to the drum of the ear, gain access to the auditory nerve by traversing the tissues between the mouth and ear in a more or less direct line, and are thus heard *false* in comparison with normal hearing. In some cases the increased resonance is no longer perceived when the patient either bends the head forwards or lies down.

As a result of free communication between the tympanum and the outer air, the respiratory movements are sometimes accompanied by corresponding vibrations of the membrana tympani, especially if the membrana propria is absent as a result of previous inflammation, and only the mucous and epithelial layers remain. During inspiration the membrane bulges outwards, and is withdrawn during expiration. Associated movements of an opposite character have been occasionally observed. When the patency of the tube is very marked, the surgeon may hear a blowing sound during ordinary breathing.

Ulceration of the Eustachian Tube.—This process occurs at the pharyngeal orifice in connection with diphtheria, small-pox, tuberculosis, and syphilis. In *diphtheria* of the naso-pharynx the pharyngeal orifice is prone to be attacked; a tubular false membrane or a semi-solid plug may form in the tube, and be subsequently cast off, leaving an ulcerated surface. Necrosis and gangrene of the cartilaginous portion of the tube have been

* *Lehrbuch der Ohrenheilkunde*, III. Aufl. S. 197.

observed in rare cases. In *small-pox* the tube is frequently involved; the cartilaginous portion is filled with tenacious mucus, sometimes mixed with blood. The lymphoid elements of the mucous membrane are considerably increased, and infiltrated with blood. Superficial ulcers likewise form, but generally heal without cicatrisation, and do not cause adhesion of the lips of the orifice.

Tuberculous ulcers of the naso-pharynx may extend to the tissues bounding the pharyngeal orifice and lead to their destruction. In like manner tuberculosis of the tympanum may extend to the osseous portion of the tube. Prof. Habermann states that he has several times seen tuberculous processes in the Eustachian tube. In one case the cartilaginous portion contained deposits of miliary tubercle with characteristic bacilli, and similar deposits, some partially caseous, were found in neighbouring portions of the pharynx.

Primary syphilitic affections of the pharyngeal orifice are occasionally observed, the infection having been conveyed by the Eustachian catheter. Secondary and tertiary manifestations of syphilis are not uncommon; they take the form of condylomata, gummatous deposits, and ulceration. The cicatrisation of syphilitic ulcers sometimes leads to occlusion of the tube. Exostoses in the osseous portion are occasional results of syphilis.

Treatment.—In the treatment of constriction of the Eustachian tube, the condition of the naso-pharynx is the first point to be attended to. Chronic hyperæmia, thickening and excessive secretion must be dealt with by the application of the remedies already described. It sometimes happens that the pharyngeal orifice is occluded by crusts or plugs of inspissated mucus, and that after these are removed the function of the part is completely restored.

Constrictions of the tube, the result of swelling of the mucous membrane, should be treated by means of the air-douche, the effect of which is to remove secretion and to distend the cartilaginous portion of the canal. Should the air-douche fail to afford relief, injections of a warm solution of iodide of potassium (*see* page 294) should be made into the tube, and iodide of potassium given internally. An alkaline lotion should be sprayed through the nostrils into the naso-pharynx

several times a day. The amount of success will depend upon the character of the stricture.

Abnormal patency of the tube may sometimes be relieved by astringent injections (such as sulphate of zinc, gr. i.—ij. to ℥j.). Gargles containing common salt may also be tried. V. Tröltzsch's method of gargling the throat (*see* page 271) is likely to prove serviceable. In cases presumably due to pathological conditions of the muscles of the tube, the faradic current should be used. One electrode is placed within the tube and the other on the side of the neck. In ulceration affecting the pharyngeal orifice, the treatment must be directed according to the nature of the case. In tuberculous and syphilitic subjects, constitutional remedies are always necessary,

CHAPTER XXIII.

DISEASES OF THE TYMPANIC CAVITY—INTRODUCTION.

DISEASES of the tympanum constitute by far the largest class of aural affections. Statistics * show that about two-thirds of these disorders (66·9 per cent.) occur in the middle ear. *Men* are more liable to suffer than *women*, the proportion per cent. being 58·4 : 41·6. With regard to *age*, we find that children constitute nearly half the total number of patients. As compared with adults the numbers are 48·2 : 51·8 per cent.

Their numerical preponderance would amply suffice to denote the importance of diseases of the middle ear; but their liability to affect the hearing-power to a very serious extent and to produce complications of an exceedingly grave character constitutes a still greater claim upon the attention of surgeons. The relations of the tympanum to the contents of the cranium are of a very intimate character; it is not to be wondered at that diseased conditions of the tympanic cavity are attended with more or less risk to the brain, to its membranes, and blood-vessels. Serious constitutional disorder may likewise result from intra-tympanic disease.

The most common middle-ear affections are caused by catarrhal and inflammatory processes involving primarily the mucous membrane, and often confined thereto, though liable, in many cases, to spread to adjacent structures. In typical cases, these affections may be divided into three classes, the classification being based upon the anatomical changes and the

* See papers by Bürkner and Bezold in *Archiv für Ohrenheilkunde*, xx. 81; xxi. 240; and xxv. 211.

clinical symptoms. The first class includes catarrh (acute and chronic) of the middle ear; the second, suppurative inflammation, likewise subdivided into two sub-classes; while the so-called "dry" or "adhesive" catarrh, or sclerosis of the middle ear, has so many special characteristics, that it must be placed in a separate category. Before giving particular descriptions of the various forms, it seems desirable to take a general review of the catarrhal and inflammatory affections of the middle ear.

Morbid Appearances.—**Catarrh** of the lining membrane of the tympanum is characterised by hyperæmia and swelling, due to enlargement of vessels, serous transudation, and cellular infiltration of the connective tissue. In addition to these changes, there is more or less abundant exudation of a mucous, colloid, or serous character on the surface of the membrane. In the earliest stage, the secretion consists of mucus, formed in the lining epithelial cells, and in the cells of the mucous glands. In a later stage, the mucous secretion is checked, and replaced by a more or less abundant serous exudation.

Suppurative Inflammation involves the deeper periosteal layers of the lining membrane; besides the hyperæmia and the serous and cellular infiltration, the exudation contains a considerable percentage of white blood-cells, and though new formation occurs, the processes decidedly tend to the destruction of tissue. Caries and necrosis are frequent consequences of acute and chronic suppurative inflammation within the tympanum. In some cases, and notably in tuberculous patients, there is abundant purulent exudation, but the other signs of inflammation are either very slight or altogether wanting.

"Dry" or "Adhesive" Catarrh is accompanied by changes of which only the final stages are well known. In some cases they are preceded by the symptoms of catarrh; in others no such history is obtainable. When the condition is fully developed, the mucous membrane becomes thickened and rigid, various parts of the sound-conducting apparatus lose their elasticity, and the movements of the ossicles become impaired or altogether abolished.

The **Symptoms** are in some degree a guide to the nature of the case. In catarrh of the middle ear, the pain is most often slight or moderate; and, if severe, it is generally intermittent. In children, the fever and constitutional disturbance are usually

prominent symptoms. So long as the process is purely catarrhal, it does not involve the middle and external layers of the tympanic membrane. They may, however, even in the early stage, be somewhat hyperæmic, and the membrane itself is apt to assume a diffuse bright red colour, by reflection from the reddened mucous membrane covering the promontory. But little change occurs in the thickness and translucency of the membrane, so that in purely serous exudations, the level of the fluid can be easily distinguished. The normal curves of the membrane may, however, undergo decided alterations. Perforation is by no means a necessary result.

Acute Purulent Inflammation of the middle ear often sets in with one or more distinct rigors; the pain is severe and continuous; there is much constitutional disorder and often high fever; perforation of the tympanic membrane is the almost invariable result, and the inflammatory process may extend to the labyrinth. The acute disease often passes into a chronic form.

"Adhesive" or "Dry" Catarrh of the middle ear comes on insidiously; tinnitus is often the first symptom noticed by the patient. After a time, perhaps not until the hearing-power has been decidedly impaired, the patient is conscious of deafness, easily discoverable on applying the usual tests. In "dry" catarrh, accompanied by sclerosis, the membrana tympani is comparatively normal. The appearance through the membrane of a dull-red or orange-coloured spot, corresponding to the promontory, is characteristic of this form of disease.

The brief sketch just given of the various inflammatory processes which take place in the middle ear is sufficient to show that great differences exist, both in the structural changes and in the symptoms to which they give rise. Their course also varies, being sometimes acute or subacute, and sometimes chronic; the termination in some cases is favourable; in others, it is just the opposite; while in a very numerous class, more or less permanent alteration of structure is associated with a corresponding impairment of function. There is no foundation for the view that the various forms of middle-ear inflammation are stages of one and the same morbid process. Some of these forms may pass into others, *e.g.*, a catarrhal process may be succeeded by purulent inflammation, and this in time may subside, and the secretion

may become serous in character. A superficial form of inflammation may be so far changed as to invade the deeper structures, and this alteration is apt to occur when the process continues for any length of time. Clinical experience, however, shows that certain forms of inflammation of the middle ear exhibit certain typical peculiarities, which they often retain throughout their course.

Besides those already mentioned, other forms of inflammation occur in the tympanum. In one of these, the exudation contains fibrinogenic and fibrino-plastic elements, and undergoes coagulation. Thus the surface of the mucous membrane becomes coated with an adherent film or croupous false membrane. In another form, the membrane is diphtheritic in character, and the deeper layers are especially involved. In a third variety, termed "desquamative" inflammation, epithelial cells are formed and shed in vast numbers, and are mingled with the secretion. The cylindrical cells are replaced by others having a tessellated arrangement and form.

Impairment of Function, a common symptom of these affections of the middle ear, is caused by anatomical and physical changes in the sound-conducting apparatus. The most important of these changes are those which interfere with the movements of the ossicles and of the structures closing the fenestræ. When such morbid conditions tend to subside or can be removed by appropriate treatment, as in acute catarrh and in many cases of acute purulent inflammation, restoration of function is the ordinary result. In the chronic forms of these diseases, much improvement can often be effected, whereas in chronic adhesive catarrh, the hearing-power usually becomes less and less as time goes on, and the results of treatment are often very unsatisfactory.

The fact that the mastoid cells and the Eustachian tubes frequently participate in tympanic inflammations is one of great importance. The same morbid process, however, does not always prevail in these parts at the same time. Thus the disease in the tympanum may be of a purulent character, while the process in the mastoid cells may be catarrhal in type. Chronic purulent inflammation of the tympanum is not infrequently followed by acute disease in the mastoid cells.

CHAPTER XXIV.

ACUTE CATARRH OF THE MIDDLE EAR.

Frequency and Causes of the Disease—Affections of the Throat—Part Played by Micro-organisms—Channels of Access—Morbid Appearances—Subjective Symptoms—Impairment of Hearing—Subjective Sensations—Autophony—Increased Temperature—Objective Symptoms—Appearance of the Meatus and Membrane—Effects of the Air-Douche—Auscultation and Sounds Heard—Diagnosis—Prognosis—Treatment—Attention to the Naso-Pharynx—Relief of Pain—The Air-Douche—The Operation of Paracentesis—Spontaneous Perforation and its Treatment—Treatment of Adenoid Growths and of Enlarged Tonsils, when Present.

ACUTE catarrh of the middle ear is of somewhat frequent occurrence; thirteen per cent. of aural diseases are of this nature. Children are more liable to suffer than adults, and males are more often affected than females. In rather more than half the number of cases both ears are affected; when the complaint is unilateral, it occurs as frequently in the right ear as in the left.

Causes.—Catarrh of the middle ear is often attributed to exposure to cold; the complaint is more common in wet and cold weather and in damp localities, than under opposite conditions. The special liability of children to suffer from this disorder is due to several causes. In early life, the lips of the pharyngeal orifice of the Eustachian tube are but slightly developed, and closure is very apt to result when the pharynx is affected with catarrh. In patients of all ages, catarrh of the middle ear is most often due to disorders of the naso-pharynx. Thus it may come on during an ordinary cold in the head, or an attack of pharyngitis; or it may complicate chronic affections of the naso-pharynx, such as rhinitis

and chronic pharyngitis, hypertrophy of the tonsils, and adenoid growths. All febrile and other disorders which are apt to be complicated by nasal and pharyngeal affections may be regarded as predisposing causes of middle-ear catarrh. Among such diseases, scarlet fever, measles, diphtheria, typhoid fever, influenza, and syphilis are those in which the tympanum is especially liable to suffer; but the resulting inflammation is more often of the suppurative kind. Scrofula is likewise a predisposing cause of catarrh of the middle ear.

The affection of the throat which is most often associated with middle-ear catarrh in children and young adults is adenoid growths. They form a constant source of irritation to the mucous membrane; moreover, they may press upon the mouths of the Eustachian tubes and impede the circulation of blood and the escape of the secretion. Prof. Gruber suggests that they may also act in another way, viz.:—by preventing the action of those muscles of the tubes which are contained in the soft palate, and thus interfering with the ventilation of the tympana. In adults obstructions in the nostrils, narrowing and occlusion of the nasal passages and enlargement of the inferior turbinate body, are often associated with middle-ear catarrh, and require careful treatment. When these conditions occur in children, they are often the result of post-nasal growths, and disappear when the growths have been removed.

Adenoid growths in the naso-pharynx have been already described in the chapter on Throat Affections connected with the Ear. It is sufficient to repeat that these growths vary in size, and occupy more or less of the naso-pharyngeal space. They may completely occlude the posterior nares, obstruct the orifices of the tubes, and cause the soft palate to protrude forwards into the mouth. When these growths are present, slight causes are often sufficient to excite attacks of pharyngeal catarrh, with extension to the tympanum as a possible result.

In the cases above described, the propagation of catarrh from the naso-pharynx to the tympanum takes place through the Eustachian tube; but when the orifice of the latter is occluded, the tympanum is affected in another way. The air contained in the cavity is to some extent absorbed by the blood-vessels; rarefaction takes place, and causes an indrawn condi-

tion of the membrane, hyperæmia and swelling of the mucous lining, and effusion of fluid (*hydrops e vacuo*).

The part played by **micro-organisms** in causing and maintaining catarrh and inflammation of the middle ear cannot as yet be positively estimated. It may, however, be regarded as certain that many of these organisms are closely connected with the development of the processes referred to. The following paragraphs contain a summary of the most recent investigations on this subject.

The micro-organisms most often found in tympanic exudations are the *diplococcus pneumoniae* and the *streptococcus pyogenes*. Next in frequency come the *staphylococcus pyogenes albus* and *aureus*, and the *bacillus tuberculosis*; less commonly the *pneumobacillus* of Friedländer, the *bacillus pyocyaneus*, the *staphylococcus cereus albus*, and the *micrococcus tetragenus*. It is doubtful whether the two last are pathogenic in character. Several kinds of micro-organisms are often present at the same time; it is therefore difficult to assign to any one of them a principal share in the causation of inflammation. Mr. Kanthack's* researches show that in cases of acute otitis media pure cultivations of the *diplococcus pneumoniae* are rarely obtainable; in most cases the *diplococcus* is associated with the *staphylococcus*, and that even where the membrana tympani is entire, other non-pathogenic organisms (bacilli) are found. "We need not wonder that saprophytes and other bacilli find their way into the middle ear, when we consider that the latter communicates with the nasopharynx, and thus with the air; and again, that the *bacillus saprogenes* I. is often found in normal saliva." It is worthy of note that similar organisms were found in seven other cases in which exudation was present in the tympanum, without evidence of any decided symptoms of inflammation. In cases of chronic otorrhœa, the *diplococcus pneumoniae* was not discovered. It would, moreover, seem that various kinds of micro-organisms may occur in succession, and that inflammatory processes about to subside may be rekindled by the advent of other forms of bacteria. Thus Zaufal's investigations show that a pathogenic micro-organism, exciting otitis media, may be succeeded by another kind of organism having the same properties. The *diplococcus pneumoniae* may be succeeded by the *staphylococcus*

* *Archives of Otology*, vol. xix. p. 29.

pyogenes albus. Such a change is believed to be the main cause of the chronic character of suppuration of the middle ear. The original excitant perishes, but has left the soil prepared for other germs. Zaufal's investigations have also shown that in rabbits the normal tympanum is not free from germs, and that various micro-organisms are abundant in the naso-pharynx.

As a general rule, it is impossible to draw any conclusions as to the degree or course of the inflammatory process from the kind of micro-organism contained in the exudation. One and the same form may be associated with very different degrees of the inflammatory process. No doubt the virulence of micro-organisms varies greatly from time to time, and great differences exist in the conditions which influence their development. The actual presence of bacteria is not enough to excite inflammation; other circumstances, favourable to the development and multiplication of the organisms, must likewise exist.

Channels of Access.—There are several routes by which pathogenic micro-organisms may gain access to the tympanum. As a general rule, the Eustachian tube is the channel through which inflammation is propagated. It is possible that pathogenous bacteria may pass through the tube during vomiting, along with a minute quantity of the contents of the stomach, and that any that may remain in the throat or nose may be forced into the tube during violent expiratory efforts. There is a second route by which micro-organisms may pass into the tympanum, viz., through the blood-vessels. It is possible that in some cases of middle-ear disease connected with infectious disorders, the excitants of inflammation may take this course, but actual demonstration has not yet been afforded. It is easy to understand that when the tympanic membrane is perforated, pathogenous and non-pathogenous bacteria may pass into the tympanum and undergo further development. It far less commonly happens that inflammatory processes extend to the tympanum from neighbouring parts, such as the external meatus, the labyrinth, and the base of the skull.

Morbid Appearances.—The tympanum contains more or less serous exudation mixed with mucus, the proportion of these constituents varying in different cases. Besides mucus, the exudation contains a large number of epithelial cells, much swollen and otherwise altered; pus corpuscles are likewise often

present. The mucus is formed from the goblet cells of the epithelium; the mucous membrane itself contains but very few glands. Many of the epithelial cells are in a state of complete mucoid degeneration. The mucous membrane itself is reddened and swollen, either on distinct spots or throughout its extent. The tympanic membrane is often transparent, and permits the level of the exudation to be seen through it; but when the inflammatory processes are severe, its tissues become infiltrated and opaque, and the lustre of its surface is diminished or altogether lost. An excessive amount of exudation may cause the membrane to bulge into the meatus. On microscopical examination, the epithelial layer is found to be thick and swollen, the vessels are enlarged and distended with blood, and superficial patches of infiltration are noticed. Leucocytes are mingled with the secretion in the neighbourhood of these patches. Perforation of the membrane rarely occurs, notwithstanding the pressure of the exudation; but when the membrane is severely implicated its tissues may give way, and the fluid will then escape into the meatus. In the majority of cases of acute catarrh absorption takes place, and the process completely subsides. The symptoms, however, are liable to return, and the complaint not infrequently assumes a chronic form. When this stage has been reached, slight causes will often bring on acute attacks. In scrofulous children an exudation, at first serous or mucous, is liable to become purulent; perforation of the membrane is then likely to ensue.

Subjective Symptoms.—In the majority of cases the first symptom of acute middle-ear catarrh is a feeling of pressure and fulness in the ear; this sensation rapidly becomes more and more marked. The patient, however, notices that the feeling passes off at times, particularly after swallowing and blowing the nose. The improvement is due to the opening of the Eustachian tube, and its advent is often accompanied by a crackling noise. Pain is soon experienced, but this symptom varies greatly in character. Sometimes it is very slight; in other cases its severity is described as almost unbearable. It is generally of a pricking, boring character, not confined to the ear, but spreading over the side of the head. The pain, which may be continuous or intermittent, is mainly due to increased tension of the membrana tympani, as a result of the exudation within the cavity. It is

aggravated by such movements as tend to shake the membrane, and notably by coughing, sneezing, and blowing the nose, and by movements of the jaw. It sometimes extends to the mastoid region. The pain of catarrhal middle-ear inflammation is sometimes very severe in children, and exacerbations are very apt to occur at night. As a general rule, the pain subsides after a few days; it may recur, but with diminished severity. In some cases the affection runs such a mild course that fluid may collect in the tympanum, and escape by perforating a previously healthy tympanic membrane without pain being produced.

The hearing-power is more or less affected, but if the catarrh be unilateral the loss may not be noticed by the patient. In some cases impairment of hearing is present from the commencement of the attack; in others it comes on later. It is due either to the condition of the sound-conducting apparatus, or to implication of the labyrinth. In the former case conduction is impaired by the swelling of the mucous lining, and subsequently by the thickening of the tympanic membrane, impeded movement of the ossicles, and accumulation of secretion. The deafness varies greatly in degree, being sometimes very slight, and sometimes almost complete. When the fenestræ are covered up by exudation the hearing is certain to be much impaired.

Subjective auditory sensations are due to the same causes as produce the deafness, and are very variable in character. Adult patients are seldom free from them, but it rarely happens that children mention them. It may be that in young subjects the intra-labyrinthine tension is less liable to vary.

Autophony is another symptom which is often noticed. The patient complains of the loudness of his own voice as heard in the affected ear. Not only the voice, but sounds produced on touching the head annoy by their loudness; brushing and combing the hair are disagreeable to the patient. This altered sensation is due to closure of the Eustachian tube. Double hearing and modifications of various sounds are occasional symptoms.

Increase of temperature is frequently present, especially in children. The fever may be either continuous or intermittent, and may not altogether subside until the exudation has become absorbed. More serious symptoms, such as giddiness, violent headache, insensibility, and epileptiform attacks are far less

common than in acute purulent inflammation, but they may occur during the progress of catarrh of the tympanum. Giddiness is due to pressure upon the structures of the labyrinth, and it may also be caused by extension of the hyperæmia of the tympanic vessels, through the petro-squamous fissure to the meninges. There is another possible cause, viz., transference of the irritation of the sensory nerves to the centres which regulate the equilibrium. Symptoms of facial paralysis are occasionally noticed during the course of middle-ear catarrh; they are due to escape of effusion into the Fallopian canal through small apertures in the posterior wall of the tympanum. Other symptoms, rarely observed, are due to implication of the chorda tympani nerve, and take the form of increased secretion of saliva and perversions of taste. Neuralgia of some branches of the fifth nerve is sometimes complained of.

Objective Symptoms.—In the examination of a patient the surgeon's attention should be first directed to the state of the nose and naso-pharynx, for it is in these parts, and especially in the latter, that lesions are often found to which catarrh of the tympanum is due, and which therefore require treatment. Hence posterior rhinoscopy should never be neglected, and the state of the naso-pharynx should be carefully noted. When the aural catarrh is connected with some constitutional disorder, such as scrofula or syphilis, the glands about the ear will generally be found swollen.

The appearance of the meatus and membrane varies in different cases and in different stages of the complaint. Sometimes the meatus appears normal, but more often the integument lining the osseous portion is hyperæmic and swollen.

On examining the membrane, the earliest visible changes are diminution of lustre and increased concavity. The surface is usually dull, like glass that has been breathed upon; the cone of light is less distinct than usual; the short process projects, and the anterior and posterior folds, but especially the latter, become more tense and prominent. The vessels which are contiguous to the handle of the malleus are considerably enlarged, and tortuous vessels extend from the periphery towards the centre. Sometimes the membrane has a more decided polish than normally belongs to it; its colour, especially at its lower and anterior part, is darker than usual, or perhaps has a reddish tinge

communicated to it by the lining membrane of the tympanum. The handle of the malleus remains visible, unless obscured by the congested vessels, or covered by the posterior fold. The colour of the tympanic membrane soon becomes changed; the red tinge disappears, and gives place to a yellowish-white or yellowish-green hue. The change is owing in part to the subsidence of the congestion, but mainly to the exudation in the cavity of the tympanum. When the secretion is copious, and the membrane is inflamed, it may bulge out towards the meatus; otherwise it may be in its normal position, or even depressed. The latter condition is the result of atmospheric pressure acting on it after the air which was in the tympanum has been almost or entirely absorbed, and more cannot enter on account of the swollen condition of the Eustachian tube. The colour of the membrane, as above described, is very marked in its lower

FIG. 93.

FIG. 94.

FIG. 95.

Fig. 93. The right ear of a gentleman, aged 56, showing the tympanum filled with fluid, with the exception of the space occupied by a bubble in the upper anterior segment, and another in the posterior segment.

Fig. 94 shows the appearance of the same ear after a little air had been injected, and before the bubbles had time to rise to the top of the fluid and coalesce.

Fig. 95. The same ear a few days after the membrane had been punctured and the fluid evacuated, showing the fluid beginning to re-accumulate.

segment. Sometimes yellowish specks are visible; these are caused by tiny patches of exudation adherent to the internal surface of the membrane. Sometimes a line corresponding with the surface of the fluid is clearly discernible; this is usually more or less curved, with the concavity directed upwards. In other cases the highest point of the exudation is at the umbo, whence the surface slopes towards the periphery on each side. Below this line the yellowish or greenish tint of the membrane is more pronounced. It less frequently happens that without any decided change in the lower part of the membrane its surface appears to be crossed by one or two very fine lines, resembling hairs. When the exudation is visible, movement of the head forwards or backwards will cause an alteration in the level of the fluid and in the colour of portions of the membrane.

Effects produced by the Injection of Air.—The exudation,

as visible through the membrana tympani, presents a different appearance when air is introduced by means of a Politzer's bag, or through a catheter (Fig. 94). The surface line is no longer visible, and the yellow colouration is succeeded by a number of small, dark circles which may move about and then disappear. These are air-bubbles, produced by the inflation. At the same time the hearing-power is decidedly improved, unless the tympanic cavity be quite filled with exudation. As tested by the watch, bone-conduction, which may have been much impaired by the exudation, is likewise restored after air has been injected. The tuning-fork test, when the affection is unilateral, gives the following results—increased perception on the affected side with Weber's experiment, and "negative" with Rinne's test.

On auscultation whilst air is being injected, rattling sounds or râles are generally heard. These seem to originate near the ear of the observer; their character varies according to the quantity and quality of the secretion. When the latter is thin and serous, the sounds may be described as "crackling;" when it is mucous and viscid, "bubbling" sounds are heard. No sound is produced when the tympanum is completely filled up with exudation, or when the Eustachian tube is impermeable to air. Even when exudation is present no bubbling sound will be caused by the entrance of air, unless the fluid be thrown into agitation. This result is also noticed when the exudation is small in quantity, and just covers the floor of the tympanic cavity. It must be remembered that several injections of air may be required, before any sound is produced; the first attempts may only suffice to overcome the resistance of the walls of the Eustachian tube. The sound is likely to be of a very indefinite character when the tympanum contains a little tenacious secretion; in such cases, a distinct pop may sometimes be heard after the air-bag has been emptied several times.

The **Diagnosis** of acute middle-ear catarrh is for the most part easily made; the objective symptoms are sufficiently characteristic. In doubtful cases the results following upon the injection of air will establish the diagnosis.

Prognosis.—This is favourable in the majority of recent cases, provided that suitable treatment be adopted. When the catarrh has lasted for some time, the prospect is less favourable; adhesions may have formed and the changes in the mucous membrane may

be but slightly influenced by treatment. The following conditions may be regarded as unfavourable: a decided tendency towards relapse and chronic stages; the supervention of purulent inflammation; complications in the labyrinth; syphilis; tuberculosis, anæmia, and exhausting diseases in general.

The tendency towards relapse is apt to be very marked in cases of chronic disease of the nose and pharynx. The results of inflation of the middle ear greatly influence the prognosis. If hearing-power be considerably improved when this method is employed, the prospect is decidedly good; if there be little or no alteration, the chances of recovery are proportionately doubtful. When there are evidences of labyrinthine mischief, little if any improvement can be expected.

The duration of the disease in ordinary cases is from two to six weeks. Pain is usually the first symptom to subside; later on the hearing-power is recovered, and tinnitus ceases to be troublesome. This last symptom may, however, continue for some time after all other signs of the disease have disappeared. The habits of the patient, especially as regards alcohol, and the general state of health, must be borne in mind in estimating the chances of recovery. In all cases of acute middle-ear catarrh, the patient should be made aware of the possibility of recurrence, and of the supervention of a chronic stage.

Treatment.—In the treatment of acute middle-ear catarrh there are two principal objects to be kept in view, viz., to cure the local affection, or to diminish the severity of the process; and secondly, to prevent relapses. Confinement to the house is always desirable, and should be prescribed even for mild cases. When there are any signs of fever, the patient should be kept in bed. All causes tending to produce congestion of the head must be carefully avoided; the diet should be of a light, non-stimulating character, and alcoholic fluids and tobacco should be forbidden. The state of the bowels requires attention; purgatives, and especially salines, are generally indicated. For the direct treatment of the catarrh a careful examination of the nasopharynx should be made, inasmuch as the starting-point of the disease is often to be found in that part. The treatment of the antecedent disorder has been described in a previous chapter, which dealt with the affections of that region.

Treatment must next be adopted for the relief of the pain in the ear. For this purpose two or three, or even more, leeches may be applied in front of the tragus and in the sulcus behind the lobule immediately beneath the meatus. Cold compresses may be placed over the auricle and side of the neck. Leiter's apparatus is convenient for the application of cold. Various anodyne solutions are sometimes serviceable. Those most likely to prove efficacious are a 20 per cent. solution of hydrochlorate of cocaine, a solution of acetate or hydrochlorate of morphia—two grains to one drachm, or a 2—10 per cent. solution of atropin and cocaine, four or five drops of which may be used at a time. The effects should be carefully noticed. (See page 139 for method of warming drops.) Politzer* recommends a mixture of acetate of morphine and olive oil (1 to 50) to be warmed and introduced into the meatus on cotton-wool, or a mixture of olive oil and chloroform (equal parts) to be dropped on a piece of wadding and applied over the ear. Glycerine of carbolic acid (introduced into the meatus on cotton-wool) will also tend to relieve the pain. Bendelack Hewetson, of Leeds, strongly advocates the employment of this remedy, and his experience is confirmed by that of Rohrer and Hartmann. The former recommends the introduction of a tampon, with one drop of glycerine of carbolic acid. Warm poultices, warm fomentation, steaming the ear, etc., must never be employed; they are liable to cause softening and disintegration of the membrana tympani. In the case of children the pain may be relieved by expiring into the ear.

The Introduction of Air.—The most important part of the local treatment consists in the introduction of air, the effects of which are to modify the condition of the tympanum by restoring the permeability of the Eustachian tube, relieving the pressure on the ossicles and membrane, scattering accumulated secretion and promoting its absorption. The prevention of adhesions between various structures of the tympanum is another result to be desired. These objects may be attained either by Politzer's method, or by means of the Eustachian catheter. The former should be reserved for children; the latter is more suitable for adults. When pain is a prominent symptom, and the tympanic membrane is reddened and swollen, the air-

* *Lehrbuch der Ohrenheilkunde*, Aufl. II. p. 269.

douche should be employed with great caution, lest the membrane should be ruptured or the symptoms of inflammation aggravated rather than improved. The possibility of forcing micro-organisms into the tympanum must not be forgotten; this drawback appertains especially to Politzer's method, which acts upon the air in the naso-pharynx. When only one ear is affected, the use of the catheter is decidedly preferable; the force of the injection can be accurately graduated, and no injury is likely to be produced in the sound ear. A two per cent. solution of cocaine should, as usual, be previously sprayed into the nostrils.

Besides, however, being suitable for children, Politzer's method should be adopted whenever, for any reason, the catheter cannot be employed; in some cases, it may be practised by the patients themselves. Air should be injected daily, and thus continued until the improvement produced in the hearing-power remains unaltered after the lapse of twenty-four hours, and the tympanic membrane resumes its normal appearance. As a general rule, this treatment should be continued daily for ten or twelve days, and afterwards less frequently.

In the majority of cases the introduction of air, aided by the other measures already described, will suffice to bring about complete recovery. When, however, the symptoms appear to be unaffected by treatment, it may become necessary to make an opening in the membrana tympani. The operation is indicated when the cavity contains secretion, and when the symptoms are accompanied by severe deep-seated pain and fever. Under the latter circumstances, neither Politzer's method nor the use of the catheter will prove efficacious; on the other hand, the injection of air into the ear will tend to aggravate the pain and inflammation. Moreover, not only treatment of this character, but even the act of blowing the nose somewhat violently may drive exudation from the tympanum into the mastoid cells, and there set up violent inflammation. In these severe cases, the exudation is rarely absorbed; as a general rule, the membrane speedily becomes ruptured.

The Operation of Paracentesis.—If the accumulation be not very great, and the membrane not much reddened nor very tense and bulging, and especially if the pain be only slight or moderate, the operation of paracentesis may be deferred, while treatment is directed to the nares and throat, as already described. A

blister* or mustard plaster, or if symptoms are only very slight the liniment or tincture of iodine may be applied to the mastoid process, and a few drops of a 10—20 per cent. solution of cocaine may be placed in the ear. The advice already given as to diet and general regimen must be strictly followed. Under this treatment, the quantity of exudation may be expected to diminish in a few days; the bulging of the posterior part of the membrane then becomes less prominent, and at the same time a gradual detachment of the epidermis may be observed to take place, whereby the membrane assumes a mottled appearance. After the inflammation has subsided, the epidermal layer of the tympanic membrane sometimes becomes detached as a whole, and fills up the meatus. This layer may be mistaken for the membrane itself; but it may be distinguished by its funnel-shaped form and dull appearance. It readily gives way when touched with a probe.

FIG. 96.

A MYRINGOTOME.

When the accumulation is considerable and the membrane is tense and bulging, and especially if there be high fever and any sign of implication of the meninges, the operation of paracentesis should not be delayed. A small lance-shaped knife is the best instrument for this purpose; it should be thoroughly disinfected by holding it for several minutes in boiling water or in absolute alcohol, and then drying it with sterilised cotton-wool. In order to provide for the escape of the secretion, it is desirable to make an incision rather more than the sixteenth of an inch in length, the best spot to select being in the inferior half of the membrane, between the umbo and the posterior inferior margin of the meatus. The incision into the membrane sometimes causes sharp pain, and some anæsthetic is therefore necessary. Cocaine is usually sufficient; a few drops of a warm 20 per cent. solution may be

* The blistering fluid (*Emp. Cantharidinis Liquid.*), which has been used for many years at the Royal London Ophthalmic Hospital, is a very good preparation; and, in consequence of its greater consistency, is much less liable to run from the place to which it has been applied than the B.P. form. It is manufactured by T. and H. Smith & Co., 12, Worship Street, London, E.C.

dropped into the ear, or the meatus may be filled with the same fluid. Before using the cocaine, however, the meatus should be thoroughly syringed out with a solution of perchloride of mercury ($\frac{1}{10}$ per cent.). It should then be dried with cotton-wool, after which the cocaine solution may be introduced and allowed to remain for about five minutes. If the cocaine be insufficient, chloroform must be administered. A good light must be thrown upon the membrane, and the patient's head carefully held while the incision is made.

The incision is followed by the discharge of muco-serous secretion, sometimes in considerable quantity. Its escape may require to be expedited by air-propulsion; for this purpose a Politzer's inflation may be given, or, what is better, air injected through a catheter. A piece of absorbent wool should be previously placed against the opening in the membrane to take up all the fluid which escapes. The advantages of a catheter are that the force of the air injected can be regulated according to the consistence of the fluid, and the sound produced by the air indicates whether or not all the secretion has been removed. Whilst fluid remains in the tympanum, a bubbling sound will be heard through the auscultation tube whenever air is injected; but as soon as the cavity is emptied only a blowing sound will be perceived.

As a general rule, scarcely a drop of blood escapes after the puncture, unless there be considerable hyperæmia of the membrane. In a few cases, the operation has been attended with very considerable hæmorrhage. In one of these,* the knife passed through the floor of the tympanum into the commencement of the internal jugular vein. The hæmorrhage was arrested by a tampon of iodoform gauze. With ordinary precautions such an accident could not occur.

When the operation is completed, the parts should be carefully dried with carbolised cotton-wool, and a plug should be retained in the meatus. The patient must be kept in bed, or at rest in his room, until the wound in the membrane has healed. Air should be injected several times daily in order to prevent a too rapid closure of the opening and to remove secretion from the cavity. The wound generally heals in three or four days, but it may do so in a few hours. Injections of air should be continued for

* *Archiv für Ohrenheilkunde*, xxix. p. 234.

some time afterwards, and until the hearing-power is restored. Should the exudation continue after the wound has healed, it will be necessary to make another opening. When this occurs, the opening should again be made in the position of the former one, in order to prevent unnecessary injury to the membrane.

In a large majority of cases, paracentesis of the tympanic membrane does not give rise to any inflammatory symptoms; but occasionally the operation is followed by evidences of acute purulent otitis. So undesirable a result has caused the operation to be regarded with disfavour by some authorities; but there can be no doubt as to its beneficial effects as a general rule. The possibility of aggravating the condition should, however, be borne in mind, and should emphasise the necessity of adopting anti-septic and other precautions.

Spontaneous Perforation of the Membrane.—In some cases of acute catarrh of the tympanum, rupture of the membrane occurs spontaneously, and the surgeon, when first consulted, finds that there is a muco-purulent or purulent discharge from the ear. When this is the case, the pain and sensation of fulness will have greatly diminished, but the deafness and the noises in the ear may have become more marked, owing to increase of exudation, and secondary inflammation of the membrane. In such cases, after removing the discharge by syringing and drying the meatus with cotton-wool, the membrane may be seen to be much reddened, so that the parts usually observable, such as the handle and short process of the malleus, can no longer be made out. The perforation appears as a yellowish-grey spot, pulsating simultaneously with the pulse at the wrist. This phenomenon is due to the fact that the impulse of the pulse-wave in the dilated vessels of the hyperæmic tissue of the tympanum and membrane, or in the internal carotid, is transferred to the layer of fluid covering these parts, and when they are illuminated the movement becomes manifest.

When a discharge from the ear has become established, as a result of spontaneous rupture of the membrane, the meatus must be cleansed once or twice daily by syringing with lukewarm water. An alkaline solution (Sodii Bicarb. gr. iv. to $\mathfrak{z}\text{j}$.) is more efficacious than plain water; and boric acid in solution may also be used with advantage (gr. v.—xv. to $\mathfrak{z}\text{j}$.). The latter drug reduced to a fine powder should be blown into the ear after the

meatus has been thoroughly syringed out and dried with cotton-wool. When the discharge is purulent it is sometimes advisable to syringe the ear with a solution of carbolic acid, 1 in 60 to 80, or of perchloride of mercury, 1 in 1,000 to 2,000.

In exceptional cases, when the exudation is very tenacious, it may be advisable to syringe out the meatus with a warm solution of bicarbonate of soda or chloride of sodium (one or two per cent.), and to inject this fluid through the Eustachian catheter and wash out the tympanum. The tympanic mucous membrane, although very sensitive when in a normal condition, is not irritated by these injections when its tissue is relaxed and swollen after an attack of inflammation. On the other hand, in favourable cases, this treatment is followed by closure of the perforation and cessation of all symptoms in from ten to fourteen days.

When the opening in the membrane, whether spontaneous or made by the knife, proves too small, so that the exudation is still retained, it must be sufficiently enlarged. This operation will be followed by escape of secretion, restoration of the membrane to its normal position, and cessation of the pain in the ear and side of the head.

The external meatus often participates in the inflammation, becoming red, injected, and swollen, and this condition is apt to be maintained by the irritating discharge. The inflammation, however, subsides under the use of the remedies applied to the tympanum; the insufflation of powdered boric acid generally has a good effect; but if it irritates, the drug may be applied in the form of a saturated solution.

In children especially, adenoid growths are frequently present, and these growths are common causes of aural catarrh. If found they must be removed in the manner described in the previous chapter (*see* page 280) as soon as convenient after the present affection has subsided.

Hypertrophy of the tonsils is another cause of middle-ear catarrh. The treatment consists in the removal of the tonsils (*see* page 261), or of a portion thereof, by means of the guillotine. If the patient will not submit to this treatment, an attempt may be made to diminish the size of the tonsils by the daily application of Tinct. Iodi on a camel-hair brush, and by the internal administration of the Syrupus Ferri Iodidi.

CHAPTER XXV.

CHRONIC CATARRH OF THE MIDDLE EAR.

Chronic Catarrh of the Tympanum—Frequency and Forms, Catarrhal and Adhesive—Causes—Affections of the Eustachian Tube—Anatomical Appearances—Subjective Symptoms—Deafness, Noises in the Ear, Giddiness, Autophony, Paracusis, etc.—Objective Appearances—Condition of Membrana Tympani—Use of the Catheter and Air-Douche—Effects on Appearances—Perforation of the Membrane—Course—Diagnosis and Prognosis—Treatment—Attention to State of Naso-Pharynx—The Air-Douche, Politzer's Method, the Catheter—Chloride of Ammonium Vapour and Remedies in Fluid Form—The Use of Siegle's Speculum—Paracentesis and Plicotomy—General Treatment of Chronic Middle-Ear Catarrh.

Chronic Catarrh of the Tympanum is a decidedly common disease; about twenty per cent. of all cases of aural affections come under this heading. Adults form the majority of patients, and both sexes are equally liable to suffer. As a general rule, both ears are affected; when the complaint is unilateral, the left ear is more often attacked than the right.

A chronic stage often follows an acute attack of middle-ear catarrh; but in a considerable proportion of cases, there is no history of any definitely acute symptoms. Chronic catarrh appears in two principal forms: in one, the process is mainly catarrhal, *i.e.*, accompanied by more or less abundant secretion; in the second, the process is marked by hyperplasia of the mucous membrane, adhesions between various parts, and thickening and condensation of tissues. To this latter form, the term "dry catarrh" has been applied. There is no strict line of demarcation between these two types, inasmuch as the strictly catarrhal form may pass into the adhesive or sclerotic type of the disorder, and

mixed forms often occur. Nevertheless, it seems advisable to consider separately the catarrhal form, and to devote another chapter to the description of the adhesive processes and their consequences.

Causes.—As already stated, a chronic stage may follow an acute attack, or the symptoms may be gradually and slowly developed. In the latter class of cases they are, for the most part, due to extension from the naso-pharynx, and may occur in the course of scarlet fever, measles, syphilis, and scrofula. In some patients, the aural affection is associated with obstructive diseases of the heart or lungs. Exposure to cold and wet is often mentioned as the probable cause of the complaint. In some patients, excessive indulgence in tobacco and alcohol seems to have provoked the disease. Hereditary predisposition is often traceable in this as in other affections of the ear, and several members of a family are not infrequently found to be suffering from chronic aural catarrh. Hereditary predisposition to naso-pharyngeal catarrh is often noticed, and when this exists the development of aural disease is only too probable. According to some authorities, certain anatomical peculiarities of the tympanum, *e.g.*, abnormal smallness of the cavity and of the fenestræ, are hereditarily transmitted, and these abnormalities are thought to favour the development of aural catarrh.

Affections of the Eustachian tube play a considerable part in the causation of chronic middle-ear catarrh. If this channel for the ventilation of the tympanum be occluded, the air in the cavity becomes rarefied, and the same effect is produced when the tympanic orifice of the tube is blocked up by swelling of the lining membrane. Under such circumstances, the membrana tympani is drawn still more inwards, and becomes less transparent, and serous fluid may be exuded into the cavity. When the exudation is mucous and viscid, the membrane usually remains depressed; it tends to bulge into the meatus only when its tissue is softened or the quantity of fluid contained in the tympanum is very large. In severe cases, the tympanic cavity and the mastoid cells are filled with exudation. The adhesive form of chronic catarrh may constitute another stage of the process.

Anatomical Appearances.—In the early stages, the tympanum contains more or less exudation, which may be serous, mucous, or

muco-purulent in character. It is usually viscid and tenacious, and adherent to the surface of the lining membrane. The mucous membrane is decidedly thickened, this change depending partly upon small-celled infiltration and increased supply of blood, but mainly upon proliferation of the cellular elements of the membrane itself. The connective tissue is increased in quantity and contains a large number of spindle-shaped cells; later on, the tissue becomes more fibrous in character and the cells are less abundant. The mucous membrane in the neighbourhood of the fenestræ, and the mucous covering of the ossicles are especially affected; and there is often marked thickening of the membrane lining the floor of the cavity. With the development of the process, the ossicles become embedded in the swollen tissue, and the fenestræ are almost completely hidden from view. Mucous surfaces thus come into contact, and adhesions take place; as the swelling subsides in consequence of retrogressive metamorphosis, bands and membranes extend between the surfaces. The ossicles themselves undergo various changes of an inflammatory character, and the process not infrequently extends from the inner wall of the tympanic cavity to the labyrinth. The formation of exostoses is another result, and ankylosis of the base of the stapes is perhaps the most frequent consequence of disease of the ossicles. The condition is due either to calcareous deposit around the base of the bone or to proliferation of the cartilaginous covering; in other cases, there is true osseous union (synostosis). Similar changes are sometimes found in the articulation between the malleus and incus.

The **Membrana Tympani** is always more or less involved. The change most commonly observed is thickening as a result of hyperplasia of its mucous membrane. When, however, owing to persistent closure of the Eustachian tube, the membrane remains indrawn for a long period, it is liable to become thin and atrophied. When thickened, the membrane appears dull and more or less opaque, and loses its elasticity; these changes are usually most marked at the periphery. Calcareous deposits are sometimes observed.

Subjective Symptoms.—Unless the complaint has supervened upon an acute attack, the early symptoms, in many cases, are of an indefinite character, and the patients are unable clearly to indicate their duration. Deafness is always present; but when

only one ear is affected, the loss of function may be unnoticed for a considerable period, and in the case of children, impaired hearing on both sides may be attributed to inattention. Even adults, with both ears affected, are often unaware of any loss of function until the condition has become very pronounced. They unconsciously supplement their hearing-power by lip-reading, and by filling up gaps in conversation by guesswork. It is, moreover, a common habit of deaf persons to attribute their incapacity to imperfect articulation on the part of the speaker, rather than to any defect in their own organs of hearing. Sooner or later, however, in these cases of chronic catarrh, the hearing-power becomes decidedly impaired, so that the patients cannot fail to be aware of their loss. Implication of the cochlea causes loss of hearing-power for high notes. Absolute deafness seldom or never occurs, except as a result of the further stages. Pain is sometimes complained of; it is generally due to exacerbation of the catarrh.

Noises in the Ear constitute another symptom which is almost invariably present. In many cases the tinnitus is the first indication of aural mischief, and the one that causes the patient to seek relief from treatment. In another class, almost or quite as numerous, the tinnitus accompanies the later stages of the affection, and proves very obstinate and troublesome. The noises vary in character and intensity; they are described by different patients as "singing," "whistling," "buzzing," "blowing," "roaring," etc. They are either continuous or intermittent; sometimes they are synchronous with the cardiac pulsations, and sometimes altogether irregular in rhythm. Sounds either of a very high or of a very low pitch for the most part indicate an advanced stage of the disease, with implication of the labyrinth. When only slight, they may give the patient but little trouble; but when loud and constant, they prove very distressing. It is often noticed that they are aggravated by excitement, and by severe bodily or mental exertion, by conditions of exhaustion, and by excessive indulgence in alcohol and tobacco.

Entotic sounds, *i.e.*, those originating in the ear itself or in its immediate neighbourhood, are less often complained of. They are due to clonic spasms of the tensor tympani and the muscles of the Eustachian tube, and can be heard on auscultation. They are synchronous with movements of the soft palate and tympanic membrane.

Giddiness is another somewhat common symptom of chronic aural catarrh. At first the attacks are slight and transient: as the disease progresses, they are apt to become severe and prolonged. They are then often associated with nausea or vomiting, and with increase of the tinnitus. They, in common with the noises, are presumably due to extension of the processes in the tympanum to the external semi-circular canal and cochlea. In some cases, loss of memory, inability to concentrate the attention, and a sensation of fulness in the head, are superadded to the giddiness.

Variations in the intensity of the symptoms, and especially in the degree of deafness, are characteristic of the disease, and are sometimes traceable to changes of weather, and alterations in the condition of the naso-pharynx. As a general rule, the patients are worse in all respects in cold damp weather. The bodily health of the patients often has a decided influence on the symptoms.

Autophony and Paracusis.—Other symptoms, occasionally present in cases of chronic aural catarrh, are *autophony* and peculiarities of hearing (*paracusis*). The former, which has been already described (*see* page 296), consists of reverberation of and echo-like additions to the patient's own voice; and other sounds sometimes undergo like modifications. It is often associated with abnormal patency of the Eustachian tube, which is prone to occur in "dry" catarrh of the middle ear. It is also noticed in cases in which the tube has become impermeable, and may then be attributed to increase of osseous conductivity.

Paracusis Willisii, or hearing improved by noise, is sometimes noticed in cases where the movements of the ossicles are interfered with by swelling and exudation. An increase of stimulus is necessary to cause sufficient vibration; when this is provided, the hearing-power becomes much improved. Such patients can hear better when travelling by railway or in a closed conveyance than when all around them is quiet.

Objective Appearances.—The condition of the tympanic membrane varies in different cases; when the morbid process is mainly confined to the inner wall of the cavity, it may be but little changed. As a general rule, however, the membrane is more or less drawn inwards; the short process projects and the posterior fold is tense and well-defined. The handle of the malleus is

drawn inwards and backwards, and sometimes almost covered by the posterior fold, only its extremity remaining visible; the posterior superior quadrant of the membrane is much reduced in size. The cone of light appears smaller, less bright and distinct, and sometimes is interrupted; it may, indeed, be altogether absent. Various alterations are observed in the appearance of the membrane, opacity being the most common change. This may be either uniformly diffused, or scattered in patches over the surface; in the latter case, the posterior segment, between the umbo and the periphery, is apt to be especially affected. Sometimes the opacity is especially marked at the periphery. The colour of the altered portions is bluish-white, and in later stages leaden-grey; the margin is not very clearly defined. The spots may be so thick and dense as to resemble calcareous deposits, which, moreover, are sometimes found associated with chronic aural catarrh. These deposits are decidedly white in colour and crescentic in form, and have well-defined margins.

An opposite condition, viz., a peculiar transparency of portions of the membrane, is sometimes noticed in long-standing cases; it is due to atrophy and loss of substance. When a large portion of the membrane is thus affected, several intra-tympanic structures—*e.g.*, the promontory, long process of the incus, and even the stapes—may become visible.

When the tympanum contains free exudation, which is generally the result of a subacute attack, the opacity of the membrane prevents the fluid from being clearly distinguishable; there may be a light yellowish tinge of the lower half, or one or two dark lines. When the secretion is viscid and mucous, the opacity will be still more pronounced. When cicatrices exist in the membrane and exudation is abundant, the pressure of the latter may cause them to bulge out from the surface of the membrane and form whitish or greenish-grey projections. If the membrane be in a state of atrophy, the level of any existing exudation will be very clearly made out.

The **Injection of Air** affords material assistance in determining the state of the tympanum. Râles of various kinds are heard when exudation is present and air is injected through the catheter. If the Eustachian tube be permeable, absence of sound on injecting air indicates that the secretion is very tenacious and adherent to the walls of the tympanum, or else that it entirely fills the cavity.

A rough, interrupted sound indicates that the mucous membrane is relaxed and swollen, and coated in places with tenacious mucus. When some force is required to inject the air, and the sound, at first weak and shrill, becomes stronger and lower in pitch after one or two swallowing movements, some obstruction in the Eustachian tube may be inferred to exist. Complete impermeability is extremely rare. If the sound heard on auscultation be comparatively normal, and the hearing-power be much diminished, the case is probably one of adhesive or "dry" catarrh.

In most cases inflation of the tympanum is followed by decided improvement of hearing-power, which, however, soon passes off. The compressed air forces the membrane outwards, and overcomes, for the time, the secondary contraction of the tensor tympani muscle. On examining with the speculum immediately after inflation, the normal condition of the parts is seen to be restored to some extent: the membrane is less concave, it may even bulge out into the meatus; the short process and the posterior fold are less prominent, and the handle of the malleus is more conspicuous and less horizontal. When exudation is present in the tympanum, the injection of air causes its dispersion; the yellowish tinge disappears, and the line marking the upper surface of the fluid is no longer visible or else is altered in position. These changes are less distinct when the exudation is of a tenacious character.

In cases of chronic catarrh with perforation, after using the syringe, the short process and the handle of the malleus are usually visible, the membrane is seen to be thickened, whitish-grey in colour, and coated with patches of epithelium; the perforation, which is usually situated in the anterior inferior quadrant, is small, roundish in form, and has its margin everted; through the opening, the mucous membrane of the tympanum appears reddened and thickened.

Bone-conduction.—Unless there be some disorder of the labyrinth, osseous conduction is found to be increased on the affected side; and if both ears be involved, the sound is most distinct on the side on which the symptoms are especially pronounced. Rinne's experiment gives negative results, with diminished air-conduction and increased length of time during which the sound is heard through the bones of the skull. There is sometimes

considerable difference between the results of testing by the watch and by speech; but various patients differ very much in this respect.

Course of the Disease.—Chronic aural catarrh always runs a protracted course, and the complaint is apt to prove very obstinate when it has supervened upon disease of the naso-pharynx, or is associated with constitutional disorders. The hearing-power is observed to be more and more impaired; the change for the worse is sometimes slow and sometimes rapid in its progress. Not infrequently, the condition remains stationary for some time, and then becomes worse; spontaneous improvement is seldom noticed. In the absence of treatment, the processes upon which the condition depends go on either intermittently or continuously; thickenings of the mucous membrane, adhesions between various parts, induration and chalky deposits are the ordinary results.

Diagnosis.—Chronic aural catarrh is for the most part easily recognisable. The symptoms already described, and especially the condition of the membrana tympani; the state of the naso-pharynx; the sounds produced and the improvement in hearing when air is injected—these, taken together, indicate the real nature of the case.

Prognosis.—More or less improvement in hearing-power may generally be anticipated, provided that proper treatment be submitted to; and the greater the change for the better after the injection of air, the more favourable the prospect. Several examinations are, however, desirable, before any definite opinion is expressed; the air-douche may at first produce results which are subsequently unattainable. A somewhat lengthened trial is therefore necessary. Politzer's inflation or injection of air through a catheter should be used twice or three times a week for about three weeks, and if no improvement result, the outlook is by no means promising, though much may be done to prevent the condition from becoming worse. If the injection of air fails to improve the hearing, but lessens the subjective symptoms (the noises and the feeling of pressure and fulness in the head), there is reason to hope for satisfactory results. The hearing-power should, it may be noted, be thoroughly tested for various sounds, both before and after the employment of the air-douche; differences may be noticeable in the perception of some sounds and not in that of others. When any improvement is detected,

its duration should be noted; the prognosis is generally favourable in proportion to the latter.

Certain other circumstances tend to render the prognosis more or less favourable, and may be briefly summarised as follows:—The adoption of treatment in an early stage of the disease, and before marked symptoms have set in; intermittency of the tinnitus; maintenance of bone-conduction; hearing-power for speech and high notes not much impaired; variations in the intensity of the symptoms from time to time, and absence of hereditary predisposition. In cases in which a cure is impossible, much may often be done to cause, at least, temporary improvement, and to prevent the condition from becoming decidedly worse.

Treatment.—Any existing affection of the naso-pharynx must be carefully attended to in the manner already described (*see* page 247). The local treatment of the middle ear has for its objects the absorption of exudation and the diminution of swelling and thickening of the mucous membrane.

Inflation of the Tympanum is the most important therapeutical measure. It tends to break up adhesions, to remove exudation and to stimulate absorption; it likewise acts mechanically on the membrana tympani and chain of ossicles, and lessens the pressure on the fenestræ. Air may be injected into the tympanum either by Politzer's method or with the aid of the catheter. The former is suitable for children and for mild cases of bilateral disease; the catheter is required whenever there is considerable swelling of the Eustachian tube, and also when remedies are to be injected into it. The carrying out of Politzer's plan is sometimes entrusted to patients themselves or to their friends. In such cases, very careful instructions should be given as to the method of employment. On the whole, air injected through a catheter yields better results, but certain precautions are necessary. The instrument should be used daily or every other day for two or three weeks, and afterwards at longer intervals, provided that the symptoms show some improvement. If, after a month's trial, the result be negative, the catheter should be given up, at least for a time. Another attempt should be made a few weeks later, when the result will probably be better. As a general rule, the use of the catheter is followed by decided improvement of hearing.

Application of Vapours.—In some cases, the absorption of the

exudation is promoted by chloride of ammonium introduced in the gaseous form into the tympanum. The method of using this remedy has been already described (*see* page 144). Care must be taken that the ammonium is perfectly neutralised, otherwise much irritation may be caused. Decided benefit is not infrequently witnessed in cases that have been little, if at all, improved by the injection of air; the remedy is indicated in cases of this kind, and when râles continue to be audible after prolonged treatment with the catheter. The vapour should be applied twice or three times a week, and for three or four minutes at a time. Air impregnated with turpentine may be used in a similar manner. A few drops are poured into the air-bag and allowed to volatilise; the air, thus charged with the vapour, is then injected through the catheter. A better plan is to have a small vulcanite box fitted on to the delivery tube of the Politzer's bag, in which can be placed a piece of wool moistened with the medicament.

Remedies, in a Fluid Form, may likewise be applied to the mucous membrane of the middle ear (*see* page 294). At first these should be of a comparatively mild character, *e.g.*, solution of iodide of potassium 5—10 grains to the ounce, or solution of borax, alum, carbonate of soda, or chlorate of potash 2—3 grains to the ounce. Afterwards, when the condition has become less acute, solutions of nitrate of silver 3—5 grains to the ounce, or of sulphate of zinc 1—3 grains to the ounce, may be carefully tried. Of these solutions, about two or three drops should be injected with very slight pressure: with larger quantities and stronger solutions, severe pain and some amount of inflammation may be set up. These injections, when they are well borne, may be used twice or three times a week, and continued for several weeks. Alkaline remedies, thus injected, render the secretion less viscid and more capable of absorption.

Besides inflation of the tympanum, there is another method whereby the membrane and ossicles may, in some measure at least, be restored to their original positions. This plan consists in rarefying the air in the external meatus by the aid of Siegle's speculum (Fig. 30, page 81). The larger end of this speculum is closed by a glass disk; an india-rubber tube connected at its other extremity with an elastic bag, opens into the side of the instrument, which closely fits the meatus. Before introducing the speculum the bag is compressed; its expansion, when the

instrument is in position, rarefies the air in the meatus, and draws the membrana tympani outwards. When this method is practised, the patients sometimes assert that the hearing-power is increased, and that the subjective sensations are less troublesome.

The **Operation of Paracentesis** (*see* page 315) is sometimes advisable in cases of chronic catarrh of the middle ear, and especially when the symptoms threaten to become acute. It may be practised with advantage when other methods of treatment have failed to remove the exudation from the tympanum, and also when the cavity appears to be completely filled with tenacious secretion.

For the relief of the subjective symptoms, and with the view of improving the hearing-power, **plicotomy**, or division of the posterior fold, is recommended by some authorities. The operation has been done when the fold projects and forms a sharp ridge, and when other measures have failed to produce relief. A perpendicular incision is made with a paracentesis knife, through the fold in its anterior half, at a distance of 2—3 mm. from the short process. It is better to cut from below upwards than in the opposite direction. The hæmorrhage is easily stopped with a little cotton-wool; a plug of carbolised gauze should be placed in the meatus. In order to avoid wounding the chorda tympani, the knife should not be thrust too far inwards.

Various other operative measures, having for their objects the relief of tension and the separation of adherent parts, will be described in the chapter on Adhesive Inflammation of the Tympanum.

In all cases of chronic middle-ear catarrh, it is not sufficient to treat the local disease; the patient's general condition always requires attention. Change of air is often beneficial, and is always desirable whenever there is a pronounced tendency to bronchial or pharyngeal catarrh. Residence in a mountainous district, sheltered from high winds and possessing a mild climate, often suits these patients. In winter special care is necessary; if the patient's means permit, change to a warm climate should be advised. Any special constitutional disorder—*e.g.*, tuberculosis or syphilis—will require appropriate treatment. The diet in all cases should be of a nourishing character; tobacco is generally hurtful, and strict moderation should be enjoined in the use of alcoholic stimulants. Baths of various kinds, with the water at

a suitable temperature, are useful accessories in the hygienic treatment of these cases ; if the weather and the patient's general condition permit of sea-bathing, Ward Cousins' india-rubber ear

FIG. 97.

WARD COUSINS' EAR PROTECTORS.

protectors (which are manufactured in four sizes), Fig. 97, must be introduced in order to prevent the water from getting into the meatus.

CHAPTER XXVI.

CHRONIC ADHESIVE CATARRH OF THE MIDDLE EAR—OTITIS
MEDIA CATARRHALIS SICCA—SCLEROSIS OF THE
MIDDLE EAR.

Nature of the Disease—Origination and General Consequences—Pathological Appearances—Causes—Symptoms—Impairment of Hearing—Subjective Sensations—Hyperæsthesia Acustica—Paracusis—Objective Appearances—The Membrana Tympani—Contraction of Tensor Tympani Muscle—Condition of the Naso-Pharynx and Eustachian Tubes—Testing the Hearing-Power—Course and Termination—Diagnosis—Prognosis—Treatment—Attention to Naso-Pharynx—The Air-Douche—Application of Remedies to the Tympanum—Rarefaction of Air in the Meatus—Politzer's Plan—Lucae's Spring Pressure-Probe—Hommel's Method—Treatment of the Tinnitus—The Eustachian Tubes—General Hygienic Rules—Operations Proposed—Removal of Tympanic Membrane and Ossicles—Establishment of an Opening in the Membrane—Division of the Posterior Fold of the Tympanic Membrane—Division of the Anterior Ligament of the Malleus—Multiple Incisions into the Tympanic Membrane—Division of the Tendon of the Tensor Tympani Muscle—Indications for Operation and Various Methods—Results.

THIS form of catarrh is characterised by a great variety of symptoms and morbid appearances. The processes developed in the tympanum tend especially to the formation of adhesions between many parts of the middle ear, and thus lead to serious impairment of hearing. The various changes do not always originate in abnormal secretory processes. Politzer* lays great stress upon the fact that in the absence of any previous catarrh, an insidious interstitial inflammation may become developed in the mucous membrane, with thickening and subsequent contrac-

* *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 229.

tion as results. The ligamentous apparatus is similarly affected, and, as a consequence, the ossicular chain becomes more or less rigid, and the stapes frequently becomes ankylosed. It is not, however, possible to draw a sharp line of demarcation between secretory catarrh and adhesive processes as a further development. The anatomical changes which are at the base of the latter may be developed during the catarrhal stage, and continuously with it, as well as after its subsidence.

This form of middle-ear disease, whether originating or not in catarrh, is especially prone to be accompanied by symptoms indicative of disorders of the labyrinth. Those insidious forms which result in ankylosis of the stapes are more often associated with the latter affections than adhesive processes originating in catarrh. It is quite true that in the course of chronic exudative diseases of the middle ear, secondary changes in the labyrinth are not infrequent complications, but in connection with purely adhesive processes labyrinthine disorder may exist from the very beginning. In such cases it is fair to assume that the disease in both portions of the ear is attributable to the same cause; as a matter of fact, indeed, the labyrinthine disorder is sometimes so prominent at an early stage, that it would appear to have been developed prior to the origination of the disease in the tympanum.

We are not as yet able to separate those forms of the disease which begin in catarrh from such as are independent of that condition. The prominent symptom, impeded conduction of sound, is common to both cases.

Pathological Appearances.—These have been especially studied by Politzer, who has given a very minute description of them in the second and third editions of his work. The following account is mainly derived from Politzer's statements:—The changes are either diffused over the whole of the mucous membrane, or are confined to certain parts of it. The former condition would seem to result from secretory catarrh, while the latter is produced by interstitial inflammation, and the parts most liable to be affected are the fenestral structures and recesses. The changes in the mucous membrane consist of partial or complete conversion of the proliferated round cells into cicatricial tissue, and of increase in the substance of the mucous membrane, followed by regressive metamorphosis, shrinking, sclerosis, atrophy, and calcification.

When the secretory stage is still in progress, the mucous membrane is hyperæmic, irregularly swollen, of a yellowish red colour, spongy in texture, and infiltrated with serum; its surface is uneven, and marked by glandular or villous projections. The concavities, and particularly the fenestræ, are levelled and less apparent, and the cavity as a whole is more or less diminished. The tympanic portion of the Eustachian tube is narrowed, and the mastoid cells are filled with secretion. The mobility of the ossicles is lessened, but not as yet abolished. Partial recovery is possible as a result of fatty degeneration of the proliferated round cells.

In another class of cases the secretory processes have come to an end, and the conversion of the hypertrophied elements into fibrous connective tissue has already taken place. The mucous membrane is smooth, thickened, pale, and stiff, closely adherent to the underlying parts, and presenting calcareous patches. These changes affect not only the lining membrane, but also its folds and the ligaments and the tissue covering the articulations; the thickening is generally most marked at the points of contact between the ossicles and the walls of the cavity. The functions of the tympanum are still further impaired by the formation of membranous cords and bands, running in various directions and connecting together the ossicles, the tympanic membrane and the tendon of the tensor tympani muscle. Some of these cords can be traced to the wall of the cavity, and are sometimes partially ossified. Another serious change is the adhesion of the membrane to the inner wall; and if this be accompanied by the formation of bands and cords and the development of exostoses, the tympanic cavity will be almost or quite obliterated.

The general result of all the above-described changes will be: diminished vibrating power of the tympanic membrane and ossicles, and impeded conduction of sound. The most serious consequences result from adhesions of the ossicles to the tympanic walls and ankylosis of the articulations, and especially of the stapes to the fenestra ovalis. In some cases the morbid process appears to be confined almost entirely to the fenestræ, and especially to the upper one and its union with the stapes. On the other hand, the changes in these parts may be, and often are, associated with adhesions and the formation of bands of membrane, as already described.

The ankylosis of the stapes may be caused by the union of the footplate with the margin of the fenestra, or by adhesion of its crura to the lower wall of the niche. The occurrence of this latter condition is favoured by the fact that the two parts are often connected by minute filaments, the remains of the gelatinous substance of foetal life. The ankylosis of the footplate is due either to calcification of the ligamentous ring, to proliferation of cartilage at the margin of the fenestra, or to deposit of osseous matter on the inner surface of the plate, and over the fenestra itself. The fenestra rotunda is also liable to important changes. The niche is often filled with connective tissue, or much contracted and closed up; the membrane itself is thickened, but seldom calcareous. In addition to the ankylosis between the stapes and its fenestra, a similar condition sometimes exists between the incus and malleus, the articular surfaces being incrustated with calcareous deposit and adherent to each other.

The **Changes in the Eustachian Tube** vary in different cases. When the process is of a diffused character and connected with chronic affections of the naso-pharynx, the canal is apt to be narrowed as a result of hypertrophy of the mucous membrane and thickening of the connective tissue. In interstitial inflammation, limited to circumscribed spots in the tympanum, the Eustachian tube is generally normal in appearance and calibre. Structural alterations sometimes occur in its muscles, whereby the ventilation of the tympanum is interfered with. Thus fatty degeneration, atrophy, and cicatricial contraction are occasionally observed. The internal muscles of the ear are liable to present signs of atrophy, as a result of inflammation of the adjacent mucous membrane, and of impeded action due to ankylosis of the joints of the ossicles. A normal state of the muscles may, however, exist in cases of chronic ankylosis of the stapes.

This description of the morbid anatomy of adhesive catarrh of the middle ear sufficiently exhibits the differences which exist between this affection and the catarrhal and purulent forms of the disease. In these latter, in addition to increase of the intercellular fluid, there is always a mucous, serous, or purulent exudation, the quantity of which is generally proportionate to the intensity of the inflammation. In adhesive inflammation, the intercellular fluid may be slightly increased, but the exudation in the tympanum may not exceed the normal quantity. In mixed forms, when

hyperplasia of the connective tissue elements is superadded to exudative inflammation, the tympanum may contain more or less mucous or purulent secretion.

Causes.—Adhesive middle-ear inflammation is due to much the same causes as the catarrhal form, but the process is always chronic. It differs from the catarrhal inflammation, inasmuch as it generally attacks persons in middle or advanced age. With regard to antecedent conditions, the complaint sometimes follows chronic naso-pharyngeal catarrh, and conditions involving paralysis of the muscles of the Eustachian tubes, whereby the ventilation of the tympana is interfered with. Sometimes there is a history of syphilis, scrofula, gout, or rheumatism; hereditary predisposition to aural disease is often traceable. The patients, however, are more often plethoric and robust than in cases of catarrhal inflammation. Exposure to cold and wet, to the action of dust, as in certain occupations, frequent and prolonged sea-bathing, and excessive indulgence in alcohol and tobacco, are more or less potent causes of the disease, and they certainly aggravate the condition, when once set up. All classes of persons are equally prone to suffer from the complaint. As in the case of catarrhal inflammation, the adhesive process generally affects both ears simultaneously (86 per cent.), or in rapid succession: in rare cases, one ear is thus affected, while the other is the seat of catarrhal inflammation. In unilateral cases (14 per cent.) the left ear is more often affected than the right (8·2 : 5·8).

Symptoms.—When the parts concerned in the conduction of sound are not primarily involved, the process may go on slowly for months or years without causing any decided symptoms. If, however, the vibrations of the membrana tympani and ossicles are impeded, the patient will be conscious of impairment of hearing, of a feeling of pressure and fulness in the ears, and of subjective auditory sensations. There is no particular pain, but giddiness and mental and nervous disturbance may be very troublesome. The symptoms once established steadily progress, and herein they differ from those of the catarrhal form. In some cases the symptoms correspond with those of Ménière's disease.

As time goes on the hearing becomes more and more impaired, and the noises in the ears louder and more annoying. Not infrequently the patients complain that whereas they can hear simple sounds, they fail to hear words addressed to themselves,

and are therefore unable to carry on conversation. The advance of the symptoms is due in part to the continuous formation of tissue in the tympanum, and partly to the secondary changes which become developed. Contraction and shrinking take place, with increased rigidity of the joints of the ossicles and abnormal position of these bones. Thus the function of the conducting apparatus is seriously impaired, and secondary changes are liable to occur in the labyrinth, though, as already pointed out, the internal ear may have been implicated from the commencement. Labyrinthine disorder cannot fail to aggravate the impairment of hearing which results from changes in the tympanum, and the deafness is influenced to some extent by the condition of the Eustachian tube; if the mucous membrane be swollen or thickened, the hearing-power will be diminished. The deafness is also liable to be aggravated by excesses of all kinds, and by fatigue and debility.

The **Subjective Sounds** vary in character, and are variously described by different patients as "humming," "buzzing," "knocking," "whistling," "blowing," "ringing," etc. The noises may appear to emanate from outside the head, or in the ear itself, or in some part of the skull. In some patients noises of various character co-exist, or succeed each other. They are generally continuous and uniform; but sometimes they cease for short intervals. The distress caused by the noises is very severe in some cases.

There are no other definite symptoms of a subjective character. Pain in the side of the head, giddiness, a feeling of confusion or heaviness, or of pressure about the occiput, may be complained of from time to time. The defective hearing and the subjective sounds are the marked symptoms. In some cases, in the early stages of the disorder, but still more frequently after the hearing has become much impaired, great sensitiveness is evinced towards various sounds, especially high notes and loud talking (*Hyperæsthesia acustica*).

There is another symptom which is not infrequent in this form of ear-disease, viz., improvement of hearing during a noise, the so-called "paracusis" of Willis. This author described a case in which a man's voice could be heard by his deaf wife only while a servant was beating a drum. This phenomenon will be further described in the chapters on Affections of the Labyrinth; its cause

may here be briefly alluded to. Politzer* thinks that improved hearing in a noise is due to the severe shaking of the ossicles, the articulations of which have become stiff. Their normal condition is in some measure restored, and they are rendered more capable of conducting sonorous vibrations. Löwenberg thinks that the shaking produces increased excitability of the auditory nerve, and consequent augmentation of hearing-power.

Objective Symptoms.—These exhibit differences according to the stage of the complaint, the parts principally affected, the intensity of the process, the previous condition of the part, and the predominating character of the inflammation. The symptoms caused by purely adhesive processes differ from those in which the catarrhal element has been more or less prominent.

On inspection, the external meatus is generally found to be very dry; there is little, if any, ceruminous secretion. The patients themselves often notice this deficiency, and regard it as the cause of their symptoms.

The appearance of the membrana tympani varies greatly; its sensitiveness is often much reduced. There may be little, if any, change in position, lustre, or transparency; in other cases, the membrane is seen to be cloudy, dull, and either thickened or atrophied and parchment-like. Abnormal transparency is associated with atrophy. An almost normal appearance of the membrane may co-exist with very serious impairment of hearing; in such cases, the morbid process is confined to the fenestræ and ossicles. The membrane is generally drawn inwards or sunken, and obviously adherent to parts situated on its inner side. Hyperæmia of the inner wall of the tympanum often imparts a characteristic tint to the membrane, causing it, in some cases, to assume a peculiar dry, dusky-red appearance. In others, a reddish-yellow spot, with a diffuse red areola, corresponding with the promontory, is seen behind the handle of the malleus. Such evidences of hyperæmia may remain unchanged for several years; and even after the membrane has become dull and opaque, traces of the reddish tint may be discoverable here and there. Sometimes the reddish tinge is especially marked in the posterior inferior quadrant, near the umbo, and this appearance is apt to be associated with injection of the vessels of the handle of the malleus. This condition of the parts often accompanies synostosis

* *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 239.

of the stapes ; but its existence cannot be detected when, as is often the case, the membrane is thickened and opaque. In exceptional cases, the peripheral part of the membrane appears as a whitish ring, while the remainder is normal in colour. Calcareous deposit, causing a decided white opacity, is sometimes visible in front of the handle of the malleus. Less frequently, a similar spot exists behind that part.

Another change, more or less frequently observed in cases of sclerosis of the tympanum, is a peculiarly white colour, sharp definition, and roughened surface of the handle of the malleus. A pit-like depression of Shrapnell's membrane is also regarded by some writers as characteristic of sclerosis and the adhesive processes. These appearances are, however, by no means constant, and they have been noticed in association with other morbid processes.

When Siegle's speculum is used, the central part of the membrana tympani is found to be decidedly movable in some cases and fixed in others. The former condition is often the result of atrophy, while the latter is caused by interstitial deposit and induration of the mucous membrane. It must be remembered that other processes in the middle ear often precede the development of sclerosis or adhesive inflammation, and produce changes in the membrane and other parts, which complicate the appearances due to the latter process.

Proneness to contraction is exhibited not only by the newly-formed bands of connective tissue, but by the tendinous structures within the tympanum, and the condition of the tendon of the tensor tympani muscle is of serious import during the course of the disease. The entire chain of ossicles is acted upon by the increased tension and rigidity of the muscle, and the intra-labyrinthine pressure is considerably raised.

Gruber has pointed out that as a result of the contraction of the tensor tympani muscle and also of shortening of its tendon, the malleus is not merely drawn inwards, but turned round upon its long axis, this latter movement being due to the fact that the tendon is inserted into the inner margin and anterior surface of the handle. The direction thus given to this surface is somewhat internal, while the opposite surface is directed outwards, thus making the handle appear broader when viewed from the external meatus. This alteration in the appearance is of dia-

gnostic value, but it may be absent when the tendon is contracted. Individual peculiarities in the insertion of the tendon and in the structures connected with the malleus, to some extent influence its movements and the secondary consequences of retraction of the tendon. Thus, even when this latter condition is present, some portions of the membrana tympani remain normal as regards their tension, while others are abnormally stretched, and others again relaxed and thrown into folds.

The **Naso-pharynx** is always more or less affected. In the earlier stages, the mucous membrane covering the posterior wall is frequently swollen, dark red in colour, and dotted over with granulations of various sizes, either isolated or in patches. In other cases, the membrane is smooth, dry, and shining. When the condition has existed for some years, the mucous covering of the pharynx is seen to be abnormally pale and thin. It adheres closely to the parts beneath, and patches of brownish secretion are scattered over the surface, which is traversed by a few enlarged vessels.

The nasal mucous membrane is dry, and sometimes presents the appearances of atrophic rhinitis. The patients assert that they seldom require to use a pocket-handkerchief; the secretion from the nose is reduced to a minimum.

Various changes are likewise noticeable in the **Eustachian tube**. In young subjects with granular pharyngitis, the mucous membrane of this part is apt to be similarly affected; the tube is narrowed, the auscultation-sound when the catheter is used is weak and high, and more force is required to compress the air-bag. In later stages, the mucous membrane is dry and the tube easily permeable; slight force is necessary to propel the air, and the sound is distinct and hard. As a result of the air-douche, either the hearing may be unaffected, or the patient may be conscious of slight and transient improvement, while the subjective sounds are often considerably diminished, and the feeling of dulness and heaviness is much ameliorated. If the hearing-power be *decidedly* increased by catheterism, we may safely conclude that the affection is comparatively slight. On examining the membrana tympani after inflation, no particular change may be discernible. If the force of the air has really acted on the membrane, there will probably be more or less bulging of the posterior superior quadrant, with a diffuse pale reflex of light there, and also injection of the vessels along the handle of the malleus.

Results of Testing the Hearing-power.—In the early stage of the complaint, when perhaps occasional tinnitus in one ear causes the patient to seek advice, the impairment of hearing is often so slight as to be scarcely recognisable on testing with the watch and speech. In such a case, however, on applying the tuning-fork to the vertex, the patient not infrequently asserts that he hears the sound more distinctly on the side on which the tinnitus exists. It may then be inferred that some obstacle to conduction is present in the middle ear, though perhaps of so slight a nature that no difference can be detected between the two ears when the tuning-fork is held in front of them.

Rinne's test may give a positive result, because the slight obstacle to the transmission of sound is easily overcome by the force of the vibrations conducted by the air to the ossicles, and the duration of perception is not appreciably shortened. As time goes on, the disorder of function becomes much more decided in the ear first attacked, and the other ear is more or less involved, as shown by the diminution in hearing-distance. On the one side, the watch may be heard only when in close contact with the auricle; or the other, perhaps at one-half or one-quarter the usual distance. Bone-conduction may be good on both sides, or weak on the more affected side, or entirely abolished. The hearing-power for speech may be such that with the worse ear very loud talking is heard at a distance of three or four yards, while with the other ear whispers are heard at the same distance. The tuning-fork on the vertex is best heard by the more affected ear; but when held in front of the ears by the less affected organ. Rinne's test may still give a positive result; but the duration of perception (with the fork held in front of the ear) is more or less diminished. If, moreover, the labyrinth be not implicated, the duration of perception through the air will be lessened relatively to the duration of bone-conduction.

In a subsequent stage, the hearing-power becomes more and more impaired, and this is the ordinary course of the complaint. In a small proportion of cases, the condition having advanced to a certain point remains stationary for some years, or even up to the end of life. The watch is unheard, even when in close contact with the auricle, on the side most affected; loud speech is inaudible at a greater distance than two or three feet. On the other side, the hearing-power may be less impaired.

In comparing the two sides it is often difficult to exclude the better ear, as some amount of sound reaches it even when stopped with the finger. In order to determine the side on which loud speech is really heard, a hearing-tube should be placed in the worse ear, while the other is stopped as closely as possible with the finger. A few words are then uttered in a moderately loud voice close to the mouth of the tube, and then at a little distance from and at the side of the latter. If these last are repeated by the patient, it is evident that he has heard them with the better ear.

When the deafness has become so marked in the ear first affected as to be almost absolute, the process, as a general rule, goes on much more rapidly in the other ear, and before long the impairment is found to be much the same on both sides. When this stage is reached the watch is inaudible, and loud talking is heard only close to the ear. If, however, the ossicular chain is not quite rigid or the fenestræ completely blocked up, the patient will hear words spoken through a hearing-tube. It sometimes happens that the final stage of ankylosis supervenes very rapidly; words spoken through a tube are then no longer heard, but bone-conduction may still exist, as shown by the power of the patient to repeat words spoken close to the side of the head.

In this final stage Weber's test gives doubtful results. If, however, the obstacle in one ear be increased by plugging the meatus tightly with the finger, the tuning-fork on the vertex is generally best heard on that side, unless the auditory nerve be decidedly implicated. Rinne's test gives negative results on both sides; shortened duration of perception when the tuning-fork is applied to the mastoid process indicates disease of the labyrinth.

Course and Termination.—In the large majority of cases, the symptoms become more and more marked as time goes on. Differences in their progress are noticed in different individuals, and are sometimes dependent upon pathological conditions of the naso-pharynx, upon the influence of climate and hygiene, and the presence of constitutional disorders. The degree in which the hearing is impaired depends upon the special localisation of the morbid processes. The loss is generally gradual and slow in its progress; in some cases the process is rapid, and a severe degree of deafness is the corresponding result. Implication of the labyrinth is always a serious feature.

During the course of the symptoms there are often intervals,

of varying lengths, during which little if any change can be detected. So long as tinnitus and other subjective symptoms are absent, it may be inferred that the labyrinth is not involved; but even in cases of this kind the hearing may rapidly become impaired. In a case recorded by Dr. Hedinger,* in which the autopsy showed ankylosis of all the ossicles of the right ear, the hearing-distance had been tested and found normal only a year before death. The rapid development of the process was thought to explain the absence of subjective sensations, which would not have been wanting had the labyrinth been correspondingly affected.

In syphilitic subjects, and in persons with hereditary predisposition to aural disease, adhesive catarrh sometimes causes total deafness, which results from implication of the labyrinth. The aural complaint may accompany the development of secondary symptoms, or may supervene at a much later period.

Politzer† draws special attention to the fact that in cases of adhesive catarrh with impairment of hearing on one side only, the still normal ear is very liable to become affected. When this extension occurs, the progress of the disease in the latter ear is seldom chronic, but generally very rapid. After a short interval, the impairment is more marked in the ear last attacked than on the other side, in which the symptoms had existed possibly for several years.

In adhesive catarrh of the middle ear spontaneous improvement is extremely rare; when it occurs, it is due to disintegration and absorption of the newly-formed tissue. Sometimes the condition is complicated by the supervention of acute inflammation, either catarrhal or suppurative, and this is accompanied by aggravation of all the symptoms.

Diagnosis.—This is based upon an examination of the membrana tympani and the Eustachian tube, upon the history of the case, the subjective symptoms, and the results yielded by testing the hearing. With regard to the tympanic membrane, the changes to be looked for are an indrawn or sunken condition, alterations in tension, partial or general thickening, atrophy, or calcareous deposits. The condition of the Eustachian tube, and, to some extent, that of the tympanic cavity, can be determined

* *Archives of Otology*, xiii. p. 47.

† *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 241.

by auscultation during the injection of air, either by means of Valsalva's or Politzer's method, or with the aid of a catheter.

It is all-important to distinguish between adhesive catarrh, and its results upon the sound-conducting apparatus and labyrinthine affections. The diagnosis is sometimes attended with great difficulties, and the frequent co-existence of the two affections must always be kept in mind. When adhesive inflammation alone exists, osseous conduction is unimpaired; but when the labyrinth is involved, the vibrations of the tuning-fork applied to the head are either not heard at all, or very indistinctly perceived. If, with this loss of osseous conduction, there be increasing deafness and continuous noises in the ear, disease of the nervous apparatus may be affirmed to exist.

The methods of using the tuning-fork in diagnosis have already been described (*see* page 89). When a positive result is obtained with Weber's experiment—that is, when a tuning-fork applied to the head is heard best on the affected side—disease of the middle ear is indicated. Rinne's test (page 93) is of less value than Weber's (page 90), though opinions differ considerably on this point. Gruber* takes as an example a case in which, as a result of hyperplasia, there is rigidity of the fenestra ovalis and rotunda, with disorder of sound-conduction, but the labyrinth remains intact. In such a case, Rinne's "positive" experiment is successful; but the tuning-fork held before the meatus is heard for a shorter time than under normal circumstances. Gruber asks whether exactly the same result may not be obtained from a patient with labyrinthine disease not far advanced, and he answers this question in the affirmative. And if a negative result be yielded, it is evident that the same might be expected in both diseases, so that as a means of positive diagnosis Rinne's test is not to be relied on.

Bezold and Rohrer, who have investigated this question, state that a negative result with Rinne's test, in all bilateral affections of the ear, with no great difference in the hearing-power on the two sides, is indicative of changes in the sound-conducting apparatus. On the other hand, a normal positive result with Rinne's test, with great impairment of hearing and negative results from the speculum and air-douche, excludes any essential participation of the sound-conducting apparatus, whether the disorder be on

* *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 480.

one or both sides. This statement holds good in many cases, but the exceptions are too many to admit of its being universally applicable. Gruber thinks that disease in the sound-conducting apparatus can be inferred with absolute certainty when Weber's test gives positive results, and Rinne's a result which is either negative or nearly so—that is to say, when the sound is heard for a very short time. The latter is therefore in some measure to be considered as a test of the diagnosis, based on Weber's experiment, of a lesion in the sound-conducting apparatus. The converse of this proposition does not hold good—that is to say, if, in a given case, the result yielded by Rinne's test be positive, and that by Weber's be negative, disease of the sound-conducting apparatus cannot always be excluded.

In order to test the condition of the *membrana tympani*, to ascertain how far it is adherent, and likewise the state of tension of the ossicular chain, the parts are examined while air is forced into the tympanum, and when air is rarefied in the meatus by means of Siegle's apparatus. Portions of the membrane which are drawn inwards or sunken, but not adherent, are bulged out when the tympanum is filled with air, and are seen to move when Siegle's speculum is used; they return to their former position when the pressure is taken off. No such changes are observable after adhesions have taken place. Strands of tissue stretched between the membrane and the inner wall of the tympanum cannot be thus detected; Politzer states that the attached parts of the membrane possess a certain amount of mobility, and may yield to pressure.

It would appear that alterations of the tension in the sound-conducting apparatus may exist to some extent without leading to obvious functional disorder. As regards the membrane itself, such alterations cannot be ascertained by inspection alone. When the membrane is drawn inwards and dull, it may appear when examined with Siegle's speculum to be much relaxed, and a membrane apparently normal on inspection may prove to be in a state of tension. Slight alterations in this latter condition cannot be diagnosed by means of the pneumatic speculum; but excessive mobility and an opposite state of the membrane point respectively to diminution and increase of tension, and free movement of the handle of the malleus excludes the possibility of ankylosis between this bone and the incus. There is one clinical

fact of considerable importance, viz., that only slight deafness is often observed associated with great tension, and still more often with decided relaxation of the membrane, and an altered position of the handle of the malleus, this part of the bone being drawn decidedly backwards and inwards (Politzer).

Prognosis.—The prognosis in adhesive middle-ear catarrh is for the most part unfavourable, only in a small proportion of cases can any improvement be effected by treatment. A return to the normal condition, or even a cessation of the morbid process, is very exceptional. In most cases, notwithstanding treatment, the symptoms steadily grow worse, until the deafness becomes very marked, as a result of ankylosis of the ossicles. Many years may, however, elapse before this stage is reached. Absolute deafness does not occur unless the labyrinth be profoundly implicated. The prognosis is unfavourable in cases in which Ménière's group of symptoms is observed, and in which the noises in the ears are very troublesome, and are not relieved by the use of the air-douche. If the subjective sensations be continuous, and accompanied by impairment of bone-conduction, improvement is all but impossible. There are, of course, many grades in the disease, and the prognosis is influenced by the circumstances connected with individual cases. A previous history of naso-pharyngeal catarrh renders the prospect more favourable than it must be in the absence of such symptoms, when the case is probably one of insidious adhesive inflammation, coupled with disease of the labyrinth. The prognosis is *comparatively* favourable when the hearing is not much impaired; when the subjective sensations are either absent or not very marked; when osseous conduction is not diminished, and when the symptoms are decidedly improved after the air-douche. It is unfavourable under opposite circumstances, especially when these are accompanied by a normal appearance of the membrana tympani and permeability of the Eustachian tube. Rapid diminution of osseous conducting power is of evil import. With regard to general and individual conditions as affecting the prognosis, it may be stated that the prospect is unfavourable in old persons, and in the subjects of cachexia, and especially in those with a syphilitic history. The prognosis is likewise bad in drunkards, and in persons whose avocations expose them to cold and damp. Hereditary predisposition to aural disease is another unfavourable circumstance.

In a large number of cases a trustworthy prognosis cannot be given until the patient has been seen several times and the result of treatment carefully noted. The surgeon may then be able to form an opinion as to whether improvement may be expected, whether the disease will go from bad to worse, or whether the patient's condition as regards hearing and other symptoms is likely to be maintained.

Treatment.—In cases of adhesive catarrh of the tympanum, the throat should be examined in order to see whether any symptoms of catarrh are present in the naso-pharynx. If the mucous membrane be hyperæmic, swollen, and relaxed, an endeavour should be made to effect an improvement by the remedies mentioned in a previous chapter (*see* page 247). In most cases, however, no evidences of any recent affection will be found in the throat, and the treatment must be directed to the tympanum itself. The condition of the Eustachian tube and the general state of the patient will, of course, require attention.

In adhesive inflammation of the middle ear, restoration of the mobility of the affected parts and arrest of the progress of the disease are the primary aims of treatment, and these results may sometimes be achieved by the employment of the air-douche. Improvement of hearing-power and lessening of subjective sensations and other head-symptoms are certainly feasible in some cases. Valsalva's method of forcing air into the tympanum is not to be recommended for the purposes above mentioned; the choice lies between Politzer's plan and the employment of the Eustachian catheter. According to its inventor, the former may be tried whenever the tubes are pervious; the catheter is indicated when there is obstruction to the passage of air. Politzer states that in cases of the latter kind the injection of air through a catheter may not only improve the hearing, but also considerably relieve the subjective symptoms, and that its efficacy in these respects is often greater than that of his method.

Great caution and gentleness must be exercised in using the air-douche; a prolonged course of such treatment may have a very prejudicial effect upon the condition intended to be relieved. The douche should be used every second or third day, and thus continued for about four or six weeks. The patient must then be examined from time to time, and if there are evidences of renewed progress of the symptoms, another course of the air-

douche should be recommended. This plan should have a fair trial; whenever possible, the air-douche ought to be used in short courses, extending over many months, or even several years. As a matter of course, if the symptoms are aggravated by this method of treatment it is useless to persevere with it. It not infrequently happens that Politzer's method decidedly increases the subjective sensations, and especially the feeling of pressure within the ear. Under such circumstances its use is altogether contra-indicated.

Application of Remedies to the Tympanum.—The effects of the air-douche are purely mechanical; the application of remedies to the tympanum is the next subject for consideration. Such remedies may be employed either in the form of solution or in that of vapour; solutions are now generally preferred. Their effects are, to a considerable extent, due to the force of the current of air which conveys them to the tympanum; but some of the remedies have a relaxing effect upon the stiffened tissues, and thus facilitate the action of the injected air. It is also possible that some amount of absorption may result from the irritation set up by the remedies. Before using the injections in the manner about to be described, the air-douche should be employed to dilate the Eustachian tube, and to remove any mucus which it may contain.

Fluid should not be injected directly into the tympanum on account of its liability to set up acute inflammation of that region. When a lotion is used, one or two drops of the warmed solution should be injected into a catheter—held horizontally after it has been placed in position—and then propelled through the Eustachian tube by means of an air-bag. By this method the fluid is carried into the middle ear in the form of spray, and all the beneficial action of the lotion is obtained without the risk attending the injection of several drops of fluid into the tympanum.

Many drugs have been employed for injection into the middle ear; the principal are borax (1—2 per cent. solution); bicarbonate of soda (1—10 per cent.); chloride of ammonium (1 per cent.); nitrate of silver (.5 per cent.); perchloride of mercury (1 per cent.); iodide of potassium (3 per cent.); chloride of sodium (3 per cent.); and caustic potash (.25 per cent.). Politzer recommends the following solution:— R Sodii Bicarb. .5; Aquæ Destill. 10.0; Glycerin. pur. 2.0. This solution causes

but little irritation, either of the tympanic mucous membrane or of the throat. The same author states that he has obtained satisfactory results in several cases from injections into the tympanum of five or six drops of a two per cent. solution of pilocarpin. The injection is often followed by slight salivation and increase of perspiration. In cases of syphilis the solution of the iodide of potassium should be employed, appropriate constitutional treatment being at the same time adopted.

In applying remedies to the tympanic mucous membrane, those which produce a marked reaction must be scrupulously avoided. Experience shows that inflammation thus set up is wont to be followed by bad results, and notably by rapid impairment of hearing-power. There is always risk of producing hyperæmia in the tympanum and a congested state of the diseased portions.

If this treatment be continued for from four to eight weeks, or even for a shorter period, the injections being used every second or third day, considerable improvement in the hearing-power will frequently be noticed, and when this is not the case the subjective sensations and the unpleasant feelings in the head will often be ameliorated. As a general rule it may be stated that if no improvement take place after two to three weeks' treatment no benefit can be expected from this method.

Remedies can also be applied in the form of vapour, the medicines most often used in this way being chloride of ammonium, turpentine, carbonate of ammonium, iodine, acetic acid, and various balsams. Politzer states that he has obtained the best results from iodic ether. He uses the vapours of chloride of ammonium and turpentine by way of experiment in cases in which injections have proved useless, owing to a swollen condition of the Eustachian tubes. The method of applying vapours to the tympanum has been described in a previous chapter (*see* page 144).

It would appear that the air injected with the fluids and vapours is the main factor in causing an improvement. In many cases, however, the combination of fluids or vapours much increases the effect of the air-douche. Fluids, as already stated, would seem to be more effective than vapours; von Tröltsch recommends a combination of the two methods; after injecting steam for a short time he employs a stimulating fluid.

When the method of treatment by injections is being pursued,

the state of the symptoms must be carefully watched. If any change for the worse take place, either the injections should be altogether discontinued or the air-douche alone used.

Rarefaction of the Air in the external meatus will sometimes assist in rendering the membrane more capable of movement and improving the hearing-power. The process is effected by means of a small india-rubber bag, about $2\frac{1}{2}$ inches in diameter and connected with a tube, about a foot long, terminating in an olive-shaped nozzle, fitting closely into the meatus. To use the instrument, the bag is compressed so as to drive out the air, when the nozzle is fixed tightly in the meatus; pressure is then taken off the bag, with the effect of producing rarefaction of the air in the auditory canal and exerting traction on the membrane. This process may be repeated four or five times at one sitting. Politzer also recommends a gradual rarefaction of the air, effected by the hermetical occlusion of the external meatus. When this has been accomplished, the action of the atmospheric pressure upon the membrane is suspended and the inward collapse of the latter is prevented. A plug of cotton-wool, as large as a hazel-nut and moistened with oil, is passed into the external part of the cartilaginous portion of the meatus. When the canal is properly occluded, a watch will be heard only on contact with the auricle. The plug should be introduced in the evening and allowed to remain till the morning, and this plan should be persevered with for two or three weeks. Lucae's method* appears to be also of service in some cases in which the membrane is much drawn inwards. He employs a small instrument which he terms "a spring pressure-probe," the extremity of which is so applied to the tympanic membrane as to press inwards the short process of the malleus. The movements are repeated several times in succession, and it is claimed that, in suitable cases, the rigidity of the chain of ossicles will be mechanically removed. According to Lucae the treatment by means of the probe is adapted only for the cases in which Rinne's experiment gives negative results in connection with marked diminution of hearing for speech, and other symptoms of disease of the sound-conducting apparatus. The instrument is introduced in a direction parallel with the anterior superior wall of the meatus, and perpendicularly to the base of the short process, to which the ball of the probe is applied. From one to ten

* *Archiv. f. Ohrenheilkunde*, xxi 84.

pressure-movements are then made in succession. Great care and gentleness are necessary, and in some cases this method of treatment is followed by slight temporary improvement. It has, however, the drawback of often causing severe pain, and the results as regards the hearing-power are sometimes decidedly mischievous. The effect on the subjective symptoms is similar to that produced by massage in like cases.*

Another plan, resembling massage in its action, is that devised by Hommel.† The tragus is pressed by the finger into the meatus and then allowed to return to its place, thus causing alternately condensation and rarefaction of the air in the canal. The manipulations are repeated four or five times daily for about a minute and a-half; the tragus is pressed inwards about 150 times on each occasion. It is claimed that in the early stages of the disease, in cases not benefited by the air-douche, these manipulations sometimes result in a decided improvement of the hearing. It is improbable that they act directly upon a rigid malleo-incudal articulation; but they may cause rhythmical movements of the membrane and prevent increase of rigidity and adhesions. No harm can result from practising Hommel's method; in some cases, it certainly relieves the subjective sensations.

The improvement which may be effected by the above-described methods of treatment is rarely of a permanent character; after a time the hearing is apt to grow worse and the subjective sensations become aggravated. The advent of relapses may be delayed by short courses of treatment from time to time. Recourse should be had to the air-douche and injections, the method and remedy selected being determined by the amount of success previously experienced. It is well to recommend a course of treatment extending over three or four weeks, and repeated twice or three times a year, or even more frequently.

The **Subjective Symptoms**, the noises in the ear, often cause much distress, and for their successful treatment it is all-important to discover the condition with which they are connected. Tinnitus is a common symptom in a large number of aural diseases, and therefore admits of no special treatment; it subsides with the disappearance of the original lesion, which may be situated in some part not directly connected with the ear. Thus there may

* See a paper on Lucae's method by Dr. Eitelberg, *Archives of Otology*, xv. 36.

† *Archiv f. Ohrenheilkunde*, xxiii. 17.

be a primary or secondary affection of the labyrinth, a disease of the brain or of some cerebral nerve, and in these cases electricity may possibly be of service. On the other hand, there may be a history of syphilis or of debility the result of some other cachexia, and in such cases the sensation in the ear will probably be relieved by constitutional treatment. When there are no such indications, and when local measures fail to afford relief, recourse may be had to such remedies as chloral, the bromides, hydrobromic acid, iodide of potassium, and morphine. Narcotics are sometimes requisite in cases where the tinnitus prevents sleep. The relief obtained from any of these medicines is for the most part temporary. These subjective sensations will be again referred to in the chapters on Diseases of the Labyrinth.

As already mentioned, the Eustachian tubes are rarely normal in cases of adhesive inflammation of the tympanum. Their condition, however, varies; in some cases, the mucous membrane is swollen and relaxed, and the calibre is more or less narrowed, while in others, the condition is one of atrophy and the tubes are abnormally patent. For details of treatment the reader is referred to a previous chapter (*see* page 105). The employment of bougies for the purpose of dilating the tubes is not to be recommended. The author believes that this practice is fraught with serious risk, and that the result asserted to have been obtained, viz., restoration of patency, may be more safely achieved by the use of the air-douche and catheter and the injection of solutions.

In addition to local remedies, there are various general rules which should never be neglected in dealing with patients suffering from adhesive middle-ear catarrh. All details connected with the mode of life and condition of general health should be carefully attended to. Thus the patient should be protected, as far as possible, from all injurious influences, and especially from damp and cold, and from loud noises. His rooms should be well ventilated, and in bright dry weather plenty of exercise in the open air is likely to prove beneficial. The diet must be adapted to the state of the individual; alcoholic liquors and tobacco may be allowed in strict moderation to those accustomed to them, and this rule must be very carefully observed. Excessive mental strain and excitement are almost invariably mischievous, and must therefore be avoided as far as possible. The state of the skin should be attended to; a warm bath once or twice a week will

prove beneficial. Cold bathing and the application of cold water to the head are to be avoided, except by strong and vigorous individuals with no tendency to catarrh.

Change of air and a prolonged residence in mountainous regions often have a good effect upon the course of adhesive catarrh. Politzer states that he has seen many cases thus benefited after a lengthy but fruitless course of local treatment. A change to a hilly district is especially indicated for weakly, anæmic, and scrofulous subjects. In cold weather, a change to a warmer climate is generally advisable, and particularly for those who are prone to suffer from naso-pharyngeal catarrh. The state of the patient's constitution should be considered in making choice of a health-resort. Gouty subjects should be sent to Carlsbad, Marienbad, Vichy, or Kissingen; for rheumatism, Bath, Buxton, or some one of the Continental Spas should be selected, while iron-springs are indicated for anæmic subjects. As a general rule, internal treatment of any kind is useful only as an adjunct to local measures, and for cases exhibiting evidences of marked dyscrasia. When there is a history of syphilis, the administration of mercury or iodine should be combined with local treatment, and should be perseveringly continued until the remedies have been thoroughly tried.

Operative Treatment.—It remains to describe various operations, having for their object the amelioration of the symptoms of adhesive catarrh. In many cases of this disease, no permanent improvement is effected by local treatment; the ossicles become more and more firmly ankylosed and incapable of movement, and deafness and subjective sensations are very prominent symptoms. Some twenty years ago, Professor Schwartze proposed to relieve this condition by excising the tympanic membrane and the malleus. In some cases thus treated, the subjective symptoms were either decidedly improved or altogether removed; but the permanence of the result was prevented by reproduction of the tympanic membrane. Many operations of this kind (fifty-five on forty-seven patients) were subsequently performed by Lucae, who described the operation as free from danger, but not altogether satisfactory. Another German surgeon, Kessel, showed that regeneration of the membrane might be prevented by detaching the tendinous ring in the posterior superior portion of the circumference.

Excision of the Tympanic Membrane and Ossicles.—The indications for the operation are by no means clear. It cannot yield any good results if the labyrinth be involved or if the stapes be firmly adherent to the fenestra ovalis. If, however, there be only a certain amount of rigidity in the structures closing the fenestra, accompanied by an indrawn membrane and firm adhesions between the malleus and incus, the operation may be attended with more or less success. Removal of the membrane and of one or both of these bones will lessen the obstacles to the conduction of sound.

The details of the operation are as follows:—An incision through the membrane is made with a paracentesis knife at the middle of the lower border. A blunt-pointed knife is then passed through the opening thus made and carried upwards, first on one side and then on the other, to the highest point in the upper border, so as to effect complete separation from the *sulcus tympanicus*. At the posterior and upper part, the tendinous ring is likewise removed. After dividing the tendon of the tensor with a tenotome, and cutting through the malleo-incudal joint, the handle of the malleus, together with the membrane, is seized with a pair of forceps and carefully drawn out. The forceps should be applied as high up as possible; some authorities recommend that the removal should be effected by means of Wilde's polypus-snare. The incus is generally removed at the same time; if loosened from its attachment to the stapes, it will not interfere with sound-conduction. It may be detached, if necessary, by means of the snare. Sometimes the head of the malleus is firmly fixed to the roof of the tympanum; it is then advisable to cut through the adhesions with a synechotome, while the bone is held in the loop of the snare.

An operation, such as that above described, is practicable only when the calibre of the meatus is perfectly normal. General anæsthesia is always necessary; the operation requires some time for its performance, owing to the minuteness of the parts to be dealt with and the hæmorrhage which is liable to occur. Syringing should not be practised as a preliminary step, inasmuch as it always causes more or less hyperæmia of the membrane and internal portion of the meatus. A few minutes before the operation, the canal may be filled with warm sublimate solution (1 : 1000), which is allowed to remain for a minute, and then

removed. In spite of this precaution, and the employment of antiseptics after the operation, suppurative inflammation of the middle ear is a somewhat frequent result. When the membrane is much retracted, though still movable to some extent, it is well to give a Politzer's inflation or inject air through a catheter before the operation, in order to increase the tympanic space as much as possible. In order to gain more room, some authorities* have recommended preliminary detachment of the auricle and cartilaginous portion of the meatus, followed by the removal of the external wall of the "attic," and of the upper and posterior part of the osseous canal.

Excision of the Stapes is another operation which was suggested and practised by Kessel. The necessary manipulations must, however, be very difficult, and they involve the risks attendant upon opening the labyrinth, *e.g.*, purulent internal otitis and meningitis. It has also been proposed, as a less serious operation, to loosen the stapes† when firmly adherent to the fenestra. The posterior superior quadrant of the tympanic membrane is partially excised, and through the opening thus made a small hook or bent probe is passed. The attempt is then made to pass the instrument between the crura of the stapes, and to move the bone in various directions.

Nearly all the surgeons who have performed these operations are fain to admit that the general results are far from satisfactory. It may well be doubted whether such severe measures are really justifiable while the indications for their adoption are so imperfectly defined as they are at present. It is only fair, however, to state that some aural surgeons of repute, and notably Dr. Sexton,‡ of New York, recommend and practise removal of the tympanic membrane with one or more of the ossicles in certain cases of progressive sclerosis, in which other forms of treatment have failed to arrest the advance of the disease. When there is a difference in the hearing-power of the two ears, Dr. Sexton usually chooses the worse ear for the operation, which he regards as entirely free from danger. If regeneration of the membrane takes place, the newly-formed tissue should be carefully cut away with as little irritation as possible. In some cases, this operation

* Stacke, *Archiv f. Ohrenheilkunde*, vol. xxxi. p. 201.

† Miot, *Otol. Congress*, Paris, 1889; *Archiv f. Ohrenheilkunde*, vol. xxix. p. 306.

‡ *Archives of Otology*, vol. xx. p. 95.

has to be repeated several times. "A rigid enforcement of dietetic rules which almost, or quite, exclude meat, seems to lessen regenerative action." Dr. Sexton concludes his remarks by stating that the permanent removal of the membrana tympani requires for its success patience and gentleness in the necessary manipulations; but when this obstruction to the entrance of sound to the round window and base of the stapes is no longer present, deafness is removed; and where rigidity of the ossicles gives rise to tinnitus, etc., these phenomena also cease with the removal of the malleus or malleus and incus.

Artificial Perforation of the Tympanic Membrane.—Another plan of mitigating the results of chronic adhesive catarrh is to make a perforation in the tympanic membrane, and thus to provide a channel for the passage of sonorous undulations to the labyrinth. The establishment of a permanent opening in the membrane is, however, scarcely feasible. Politzer states that if this difficulty could be overcome, the operation would be indicated in the following cases: (1) When the membrana tympani is much thickened, and has lost its elasticity in consequence of calcareous deposits. (2) When the movements of the malleus and incus are prevented by adhesions between these bones and the walls of the tympanum. (3) When the Eustachian tube is the seat of irremediable strictures. (4) It might be tried, as a last resource, in cases of severe tinnitus which all other means have failed to relieve.

As a means of restoring the hearing-power, the operation is, of course, useless, whenever the labyrinth is seriously affected, as shown by loss of osseous conduction. It is also unavailing when the stapes is firmly adherent, and when the membrane of the fenestra rotunda is either thickened or covered with calcareous deposit. For the operation to be successful, the footplate of the stapes and the membrane of the fenestra rotunda must be capable of a certain amount of mobility.

Methods of Operating.—Many plans have been proposed, but nearly all of them have fallen into disuse; the employment of the galvano-cautery offers the best chance of success. An aperture the size of a hemp-seed can be made in a second by the application of an ordinary button-ended point. A full-sized speculum must be previously passed into the auditory canal, and the membrane illuminated by the aid of a forehead mirror.

Politzer emphasises the necessity for the point to become red hot at the moment the circuit is closed, and for the closure to be made immediately the cautery point touches the membrane. As a preliminary step the patient should be directed to inflate his ears, or the air-douche is employed by an assistant. The cauterisation should be only momentary, for otherwise a large portion of the membrane may be destroyed. No pressure must be employed, as the point of the instrument might easily penetrate to the inner wall of the tympanum, and set up inflammation of the mucous membrane. The most suitable spot for making the opening is the inferior portion of the membrane, because it is at the greatest distance from the inner wall. The steam which is evolved during the operation must be blown away as soon as possible (Politzer).

The effects of the production of an artificial opening vary in different cases. There may be little or no improvement as regards either the hearing-power or the subjective sensations, and in such cases it may be inferred that the stapes is immovably fixed, and that the fenestra rotunda has lost its elasticity. On the other hand, in a fair proportion of cases, more or less improvement is experienced; though the change is seldom permanent, for the opening generally closes in the course of two or three weeks, and the symptoms recur. This result has caused many attempts to be made to preserve the patency of the opening; but none have been really successful. Politzer, some twenty years ago, suggested the insertion of a vulcanite eyelet into the opening. It was found, however, that in the course of a few days or weeks the membrane showed signs of purulent inflammation, which extended to the tympanum. The eyelet was thus expelled, and the aperture sooner or later closed by cicatrisation.

The results of this method would seem to show that it is likely to prove useful rather for diagnostic than for remedial purposes. It might be tried as a preliminary to more serious operations: if followed by some degree of improvement, the question of removing the membrane might be entertained. Possibly some method of keeping open an artificial perforation may yet be discovered; but up to the present time all attempts in that direction have resulted in failure.

An Incision through the Posterior Fold of the tympanic membrane is another method of treating certain conditions of this structure. A brief account of the operation has been given

in a previous chapter (*see* page 329). It is sometimes performed in cases of adhesive catarrh, with the object of relieving tension of the membrane, thereby improving the hearing-power and lessening the subjective sensations. As necessary conditions for its success, the Eustachian tube must be patent, and there must be no accumulation of secretion in the tympanum; absence of adhesions between the membrane and the wall of the labyrinth and comparative soundness of the nervous structures must likewise be demonstrated. The operation was suggested by Politzer in 1871. It is indicated in cases in which the membrane is much drawn inwards, and where the lower extremity of the handle of the malleus appears to be displaced in a direction inwards and backwards, while the short process and the posterior fold project towards the external meatus. Under these conditions the membrane is generally indurated and but little sensitive, and is therefore far more suitable for incision than when in an hyperæmic and swollen state. As a matter of course ordinary treatment should first be tried, and if no relief be obtained, recourse may be had to this operation, under the conditions already specified.

The operation (*see* page 329) consists in dividing the posterior fold perpendicularly, either from above downwards or in the opposite direction, the most suitable spot being immediately behind the short process, but the incision may be made midway between this and the peripheral end of the fold. The division is generally accompanied by a grating sound; the wound in the membrane gapes, and the handle of the malleus assumes a more normal position. Hæmorrhage is generally slight, and can be easily arrested.

There is some risk of injuring the chorda tympani nerve, though Lucae states that, in 140 cases in which he performed the operation, he never witnessed any symptoms of this accident. If, however, the nerve be cut through, the ends generally unite in the course of a few weeks, and its function is restored. If the fold be divided nearer to the periphery, there is some risk of injuring the long process of the incus and the articulation with the stapes. The general result of the operation is to diminish the severity of the subjective symptoms; but the improvement is in most cases transitory, though it may last for several weeks. Sometimes the hearing-power is slightly increased.

Division of the Anterior Ligament of the Malleus is another

operation devised and performed by Politzer,* with the view of improving the hearing-power, and lessening the subjective sensations, in cases in which this band is contracted and abnormally adherent. Under such circumstances, the membrane is much drawn inwards, and the air-douche causes a considerable improvement, which soon passes off. In the performance of this operation, an incision $1\frac{1}{2}$ mm. long is made in the membrane, immediately in front of the short process of the malleus, and directed from above downwards. Through the opening thus made, the surgeon passes a small knife bent at a right angle near its extremity, pushes it under the upper border of the membrane, and cuts outwards and downwards through the anterior ligament and the long process of the malleus. A grating sound is heard as these parts are divided.

Multiple Incisions into the Membrane.—In cases of extreme tension of the membrana tympani, as a result of pathological changes in its tissue, Gruber† recommends multiple incisions. The wounds of course heal, but this process should be retarded as much as possible by the frequent employment of the air-douche in the after-treatment. Gruber makes four, five, or more incisions, and unites them by cross-cuts at right angles. As a general rule the chief incisions are made from the malleus towards the periphery; but their position should be modified according to the conditions of each case. Before resorting to the operation, it is necessary to ascertain the condition of the labyrinth, and the following is the method recommended by Gruber. He first alludes to the fact that a vibrating tuning-fork held in front of the ear is not so well heard when Valsalva's method is being practised, as it is before and after; the increased tension of the membrane lessening the conduction of sound. On the other hand, under similar circumstances, a tuning-fork applied to the head is better heard.

Deviations from these rules are of diagnostic importance. When the membrane is unduly relaxed, Valsalva's experiment causes the tuning-fork held in front of the ear to be better heard, but osseous conduction is diminished. In cases of abnormal tension, the experiment either makes no alteration in the sound of the fork in the first position, or causes it to be less distinctly

* *Lehrbuch der Ohrenheilkunde*, S. 259.

† *Lehrbuch der Ohrenheilkunde*, S. 549.

heard. The sound of the fork placed on the head is likewise not altered unless the tension be increased, in which case it is more distinctly heard.

In this method of examination, the patient's statements serve as a test of each other. For example, if a patient, with a relaxed membrane, asserts that a vibrating tuning-fork in front of the ear is heard better during Valsalva's experiment than either before or after it, he ought to hear the sound less distinctly when the fork is placed on the head during inflation.

Absolutely correct inferences cannot, however, be always drawn from the results of Valsalva's experiment when employed for purposes of diagnosis as above described. Thus when the membrane is abnormally relaxed, Valsalva's experiment may cause an undue degree of tension, and the vibrating tuning-fork held in front of the ear will be less distinctly heard, whereas an improvement will be noticed when the air is driven into the tympanum with only slight force. Besides, it is quite possible that when Valsalva's method is practised, other structures in the ear may be so affected that the hearing-power is improved irrespective of any change in the membrana tympani. The fact is that this method of diagnosis must be taken in conjunction with others; agreement in results serves to determine the nature of the case.

The after-treatment consists in carefully removing any blood which may have escaped and applying iodoform gauze. A few days afterwards the air-douche should be employed, and this should be continued every other day for some time after the incisions have healed. If inflammation be set up, it must be treated in the manner described in a previous chapter. Such a complication is, however, very rare.

Gruber, in opposition to Politzer, asserts that the cicatrization of incisions in the membrane does not increase its tension, and that multiple incisions are not suitable for cases in which its tissue is atrophied and relaxed. After incision, union generally takes place by first intention, without any secondary changes; in other cases a cicatrix forms, the appearance of which indicates that the tension of the membrane would be lessened by the formation of several cicatrices.

Division of the Tendon of the Tensor Tympani muscle is another method of treatment which has been recommended for adoption. It was first performed on the living subject by Weber-Liel in

1868. Abnormal contraction and shortening of the tendon produces excessive tension of the membrana tympani and of the joints of the ossicles, and increases the pressure in the labyrinth. This condition of the tendon is not peculiar to adhesive inflammation; it is often associated with suppuration in the middle ear with perforation and retraction of the membrane. The object of dividing the tendon is to relieve the tension and the symptoms which it causes. A satisfactory result is attainable only when other serious pathological changes are presumably absent from the middle ear and labyrinth.

There are no positive signs clearly indicative of contraction of the tendon. An indrawn condition of the membrane is always associated with it; but may be produced by other changes of common occurrence, *e.g.*, occlusion of the Eustachian tube, atrophy of the tympanic membrane, and adhesions to deeper parts in the cavity. It has been supposed that improvement of hearing after the use of the air-douche and lessening of subjective sensations after the rarefaction of air in the meatus point to contraction of the tendon. Such changes, however, are just as likely to result from relaxation of ossicular tension, stretching of bands of false membrane, etc. It is sometimes stated that contraction of the tendon may be inferred to exist when the handle of the malleus is not only drawn inwards (and, therefore, seems shortened when viewed from the meatus), but also made to revolve slightly on its long axis, so that it appears to be broader than usual. This change is due to the mode in which the tendon of the tensor is inserted into the handle of the malleus. It has, however, been shown by Urbantschitsch* that the place of insertion varies considerably, and it may well be doubted whether contraction of the tendon always causes the handle of the malleus to revolve on its long axis. Some persons are able to cause voluntary contraction of the tensor tympani, and they find that low notes are then less distinctly heard, and that a humming-sound is perceived. It remains to be seen whether this fact can be utilised for purposes of diagnosis.

Professor Gruber† thinks that contraction of the tendon is an indication for tenotomy, provided that the subjective sensations are relieved by the use of the catheter. He believes that the

* *Lehrbuch der Ohrenheilkunde*, Aufl. III. S. 233.

† *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 562.

subsequent union of the divided ends does not tend to increase the contraction, but rather has a contrary effect. Tenotomy is found to be beneficial when simple paracentesis of the membrane has proved useless.

Kessel* lays down the following indications for performing tenotomy of the tensor:—

1. Paralysis of the stapedius muscle with unrestrained action of the tensor.

2. Permanent spasm of the tensor.

3. Perforations involving the "cone of light," and when the openings are reniform or heart-shaped.

4. In catarrh with swelling, so long as the stapes is movable, and excessive pressure in the labyrinth admits of diminution. Also, when the sounds are continuous, and the excessive pressure in the labyrinth is obviously dependent upon changes in the internal muscles of the ear.

Dr. Sexton,† of New York, warmly advocates tenotomy of the tensor in cases of sclerosis with relatively good bone-conduction, and thinks that the operation often improves the functions of the intra-tympanic and muscular apparatus for the perception of sound, words, and speech. The indications, he states, to be as follows:—

1. Progressive deafness, with neuropathic sclerosis; the operation, however, is not likely to be successful unless one-fourth of the normal duration of perception is still preserved.

2. The operation should be performed on the worse ear if a positive result of Weber's and a negative of Rinne's experiment make us suspect permanent obstacles to conduction in this ear, while there is no trace of this condition in the better ear.

3. If one ear be quite deaf, and the other becoming so, the operation should be performed upon the latter, on the ground that reduction of tension on one side of the muscular apparatus will benefit that of the other.

Method of Operating.—In the normal condition, the exposed portion of the tendon is only 2 mm. in length, and, when the membrane is considerably indrawn, the space for the incision is very limited. As a general rule, it should be made just behind the handle of the malleus, but the exact spot must depend upon

* *Archiv für Ohrenheilkunde*, vol. xxxi. S. 238.

† *Archives of Otology*, vol. xix. p. 151.

the circumstances of the case. The steps of the operation are as follows:—A paracentesis knife is used to make an incision 1mm. behind and parallel with the handle of the malleus. A tenotome, adapted to the side to be operated upon, is passed through the opening with its rounded point turned upwards and forwards towards the roof of the tympanum, until it touches the head of the malleus or the malleo-incudal articulation. The instrument is then turned at a right angle, so that its edge is brought immediately above the tendon, which is then divided by drawing the knife backwards and forwards, and from above downwards; a grating noise is audible as the resistance is felt to be overcome. By drawing out the handle of the malleus with the tenotome, the operator can determine whether the tendon is completely divided. The hæmorrhage is usually slight. If, after complete division of the tendon, the handle of the malleus retains its former position, adhesions in the tympanum may be inferred to exist.

In so-called neuropathic sclerosis, the tympanic membrane is always far less sensitive than usual; but, during the operation, it is generally advisable to use local or general anæsthetics. Dr. Sexton recommends a little ether on absorbent cotton-wool, to be placed upon the membrane and left to evaporate. He advises that the incision should be made *in front* of the short process. The difficulties of the operation are increased by narrowness of the meatus, great retraction of the membrane, and by adhesions between it and the labyrinth. After the operation, the patient should remain in bed, and powdered boric acid on cotton-wool should be kept in the ear. The wound usually heals by first intention in the course of a few days. Any blood effused into the tympanum is more or less rapidly absorbed. If there be symptoms of otitis, the ordinary treatment must be adopted. When the wound in the membrane has quite healed, it is well to inject air through a catheter every second or third day, or to rarefy the air in the meatus.

Gruber directs that when the incision is to be made behind the handle of the malleus, the concavity of the tenotome is to be directed forwards, and in the opposite direction when the spot chosen for the incision is in front of that process of bone, on a level with the upper third of which the knife is passed through the membrane. When the tympanum is reached, the concave

surface of the tenotome is applied to the handle of the malleus, and an incision parallel with it is made upwards so as to divide the tendon which runs obliquely from within outwards through the tympanum. When the instrument is introduced behind the malleus, its point should be carried forwards to a corresponding extent, so as to be certain of dividing the tendon, which is sometimes considerably in front of its ordinary position. Care must be taken to give to the edge of the tenotome a somewhat lateral direction by turning the point slightly upwards, so as to avoid the wall of the carotid canal. Gruber states that the direction and form of the external meatus must determine the spot for the incision in the membrane. As a general rule, this should be made in front of the malleus; but in many cases the convexity of the anterior wall of the meatus is very marked, and hides the anterior segment of the membrane, so that the portion behind the malleus must be selected.

The **Results of the Operation** vary considerably in different cases; the subjective symptoms are sometimes much improved, the tinnitus ceases or becomes less troublesome, and the giddiness has been known to disappear. The effects upon the hearing-power are far less marked, and in not a few cases no improvement is perceptible. According to some authorities any good results which may be noticed are due to the incision in the membrane. The condition of the patients several weeks or months after the operation is the best test of its value. Aggravation of all the symptoms has been observed in a few cases, and severe suppurative inflammation has been known to follow. Politzer asserts that all trustworthy accounts are of an unfavourable character. With few exceptions, any improvement in the hearing-power completely subsides, while the subjective sensations recur and even become more troublesome. In several patients who came to him some months after the operation had been performed, there was complete deafness on that side, the condition having rapidly become worse since the operation. Division of the tendon is, therefore, an operation of a very doubtful benefit; any advantage is but slight, and its results are not infrequently mischievous. It may prove of advantage in some cases; but positive indications for its performance have not as yet been discovered.

CHAPTER XXVII.

ACUTE SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR.

Nature of the Disease—Causes—Micro-Organisms—Frequency as affected by Age, Sex, Climate, etc.—Reasons for Frequency in Young Subjects—Symptoms—Subjective, as Pain, Impairment of Hearing, etc.—Objective, Changes in Tympanic Membrane—Perforation, Signs of, and Methods of Discovering—Character of Secretion—Course and Results—Diagnosis—Prognosis—Treatment—Antiphlogistics—Paracentesis—The Air-Douche—Local Remedies—Treatment of Cases of Spontaneous Perforation—Mastoid Complications.

Acute Suppurative Inflammation of the tympanum may come on suddenly, without any previous local symptoms, or may follow an attack of catarrhal inflammation of the cavity. It is characterised by rapid effusion of purulent fluid, hyperæmia and swelling of the lining membrane, and by inflammation of the membrana tympani, which often becomes perforated. The pus is formed either on the surface of the mucous membrane or within its substance, and sometimes between it and the bone. More or less marked destruction of the tissues is the almost invariable result, and in severe cases the process extends to the bony walls. The inflammation likewise spreads to the Eustachian tube, and often backwards to the mastoid cells, which contain purulent or sero-purulent exudation. The labyrinth may become involved, but is seldom seriously affected; hyperæmia and serous exudation are the ordinary changes.

Causes.—These are generally the same as those of ordinary catarrhal inflammation; but micro-organisms would seem to play a very important part in the causation of suppurative inflammation. The channels by which they may gain access to the tympanum

have been already described (*see* page 306). Zaufal's researches* show that organisms of the following kinds have been found in the middle ear in cases of suppurative inflammation. The pneumonia-bacillus of Friedländer; the diplococcus pneumoniæ; the streptococcus pyogenes, pyogenes albus, pyogenes aureus, cereus albus and tenuis; bacillus tenuis; bacillus pyocyaneus; micrococcus tetragenus and saccharomyces albicans. Various kinds of micro-organisms often appear in succession, one set preparing the way for another, and thus maintaining the suppurative process. In the primary form of suppurative otitis media, the diplococcus pneumoniæ very often occurs; in secondary forms, the streptococcus pyogenes is more common. Rohrer† states that the non-fœtid secretions contain only cocci; whereas bacilli are abundant and cocci comparatively few in fœtid discharges. Streptococci would seem to indicate a severe form of inflammation, and the probability of extension to the mastoid cells.

Whether micro-organisms are essential to the development of suppuration within the tympanum is not as yet definitely settled. The aural complaint is, however, often secondary to acute and chronic inflammatory processes in the naso-pharynx, and many of these disorders are associated with a profuse development of micro-organisms. It is a not infrequent complication of many infectious diseases, *e.g.*, scarlet fever, measles, small-pox, diphtheria, typhus and typhoid fevers, influenza, tuberculosis, syphilis, erysipelas, and puerperal affections. With regard to scarlet fever and measles, it would appear that aural complications are very frequent during some epidemics, and rare in others. In one series of cases of scarlet fever cited by Burckhardt-Merian,‡ 33 per cent. of the patients suffered from middle-ear disorders; and in another, the proportion was 22 per cent. Middle-ear suppuration is sometimes attributable to exposure to cold; to injuries of various kinds, as blows on the ear, falls on the head, and operations on the membrana tympani; to the presence of foreign bodies in the meatus, and to the efforts made to extract them; to burns and scalds, and to the effects of caustic applications.

In another class of cases, the inflammation results from the passage of fluids along the Eustachian tube, as sometimes occurs

* *Archiv für Ohrenheilkunde*, vol. xxxi. p. 180.

† *Zur Morphologie der Bakterien des Ohres und des Nasen-Rachenraumes*, S. 9.

‡ *Volkmann's Sammlung Klin. Vorträge*, No. 182.

during the employment of Weber's douche. Plugging the posterior nares has been known to set up inflammation of the tympanum; either the blood passes along the tube and acts as a foreign body, or the plug causes pharyngitis, which extends in the same direction. Suppurative inflammation of the middle ear sometimes occurs after the removal of adenoid growths. In such cases it is due either to the irritation caused by blood lodging in the Eustachian tube, or to the extension of inflammation consequent upon the operation. Some years ago I saw a man, between thirty and forty years of age, suffering from suppurative inflammation of the middle ear, which came on shortly after the removal of a tonsil with the ordinary guillotine. A few cases have been placed on record in which foreign bodies of various kinds have passed along the Eustachian tube and even reached the tympanum. In one such instance, a portion of a vulcanite catheter became detached and found its way into the middle ear, causing acute inflammation, for the relief of which the membrana tympani was incised. The foreign body was removed through the opening, and the case progressed satisfactorily. In another case, recorded by Urbantschitsch,* an oat-spikelet passed from the pharynx along the tube, and caused suppurative inflammation in the tympanum. This was followed by circumscribed inflammation in the external meatus, with polypoid growths. After a time the foreign body escaped through a perforation in the membrana tympani, and the symptoms then subsided.

In a few rare cases suppurative inflammation of the tympanum has resulted from purulent formations within the cranium. The pus finds its way into the tympanum through some fissure or canal in the temporal bone, and causes inflammation of the cavity and perforation of the membrane. Caries of the osseous roof may be another step in the process; an opening results, through which the pus enters the tympanum.

Suppurative inflammation of the middle ear is more common in children than in adults (in the proportion of 70 : 30), and in spring and autumn than in summer. Males and females are equally liable to be attacked. Climatic conditions alone, *e.g.*, heat, cold, and moisture, appear to exercise no special influence upon its development: according to Politzer, it constitutes from 6—7 per cent. of all cases, the proportion being the same in the

* *Lehrbuch der Ohrenheilkunde*, 3 Aufl. S. 202.

United States as in Germany. The complaint is generally unilateral (80 per cent.); but when due to scarlet fever or typhus, both ears are liable to be affected.

The occurrence of the complaint in children is favoured by a variety of circumstances; *e.g.*, the special liability of young subjects to the acute exanthemata, to severe affections of the nose and pharynx, and to various forms of pneumonia. Congenital syphilis is another cause of ear-disease. Some authorities consider that dentition may excite suppurative inflammation of the tympanum: the continuous irritation of the peripheral branches of the trigeminus is transmitted to the vagus and glosso-pharyngeal, and produces vaso-motor disorder, with inflammation as a result. Whether this theory be correct or not, it is probable that in very young children the occurrence of inflammation in the middle ear is favoured by the hyperæmia and swelling which are associated with the retrogressive metamorphosis of the mucous membrane. To this may be added, according to Urbantschitsch, the passage of liquor amnii into the tympanum during futile inspiratory efforts, and of the contents of the stomach during vomiting.

With regard to the infectious fevers as a cause of middle-ear inflammation, it must be remembered that the deafness so common in typhus may be due either to nervous disorder or to catarrhal or suppurative inflammation of the tympanum. In the early stages of the disease, the impairment of hearing ordinarily results from functional disturbance.

There is one other complaint, *viz.*, relapsing fever, which is not infrequently accompanied by middle-ear inflammation. In an epidemic of this fever, recorded by Dr. Luchau,* aural complications occurred among 180 out of 300 patients, the majority suffering from purulent inflammation of the tympanum. Additional details with regard to the connection between various constitutional disorders and affections of the ear will be given in a subsequent chapter.

Symptoms.—From the beginning of the attack, the subjective symptoms are different from those of any other form of middle-ear inflammation. The disease is sometimes ushered in by a distinct rigor, and is always accompanied by elevation of temperature. Acute pain in the affected ear is an early symptom; it

* *Ueber Ohren- und Augenerkrankungen bei Febris Recurrens. Virch. Arch., Bd. 82, 1880.*

is variously described by different patients as "burning," "tearing," "pricking," "boring," etc. It extends over the side of the head, and particularly to the occiput and neck. It seldom remits altogether; but is apt to become worse at night and somewhat less severe in the morning. It is increased by pressure over the auricle, and over the mastoid process, when this portion has become implicated. It is likewise aggravated by coughing, sneezing, swallowing, bodily exertion, and mental excitement. Besides the pain, there are sensations of heat and fulness in the ear, and the neighbouring lymphatic glands are more or less swollen and tender. Redness of the conjunctiva and œdema of the eyelid on the affected side are sometimes present, and in rare cases paralysis of the facial nerve and neuralgia of the fifth pair have been observed to accompany the attack.

In children, suppurative middle-ear inflammation is often ushered in with vomiting and peculiar restlessness, and attended by marked fever, loss of consciousness, and epileptiform convulsions: the symptoms therefore closely resemble those of meningitis. In early life the mucous membrane of the middle ear is closely connected, anatomically, with the dura mater; a process of the latter membrane accompanied by vessels and nerves extends through a fissure in the roof of the tympanum, and becomes continuous with the lining membrane. Dehiscences are likewise frequent in the tympanic walls. The ears should always be examined in children presenting cerebral symptoms and high temperature. In such cases, the cause of the attack is sometimes not recognised until a copious discharge of pus takes place from the meatus, when the cerebral symptoms rapidly pass off.

In addition to the pain, the **Subjective Symptoms** consist of impairment of hearing, noises in the ears, giddiness, and a feeling of confusion; in some patients hearing-power is at first considerably increased, and the sensation known as autophony is experienced. There is nothing characteristic about these phenomena; they are also met with in catarrhal inflammation, and they are by no means constant in the purulent form of the complaint. They are due in part to increase of pressure, and in part to hyperæmia of the labyrinth and serous exudation, and their character is apt to become modified during the progress of the disease. The noises in the ears are variously described as "roaring," "singing," "hissing," "throbbing," etc. The degree in

which the hearing is impaired varies considerably. Some difference can always be detected, and before perforation has taken place, it is often very marked; but owing to the severity of the other symptoms, it may not be fully recognised. The deafness is generally proportionate to the amount of exudation, the swelling of the mucous membrane, the height of the fever, and the condition of the sensorium. It is likely to be complete if the labyrinth be seriously involved. As a general rule bone-conduction is preserved; in the early stages and before perforation has occurred it is often increased. According to Politzer, however, in scarlatinous, diphtheritic, and syphilitic cases, bone-conduction is often considerably impaired, or even altogether lost.

In children all the symptoms are wont to assume a severe type; but in adults they are not infrequently much less prominent. In these latter there is often no disorder of the sensorium; but a high temperature, a very rapid pulse, and a sensation of fulness in the head are sometimes very marked. On the other hand, in cases due to tuberculosis there may be neither pain nor any particular disturbance of the general system; the process goes on insidiously, and increase of moisture in the meatus or discharge of purulent matter therefrom is the first indication of mischief.

The **Objective** symptoms consist mainly of changes in the condition of the membrana tympani and of evidences of irritation in the meatus and surrounding parts. The glands in the neighbourhood of the ear are often more or less swollen, and, when the mastoid cells are involved, the soft parts covering that process are apt to become swollen and reddened. The cartilaginous portion of the meatus is similarly affected, while the lining of the osseous portion is still more decidedly inflamed.

The internal or mucous layer of the membrana tympani, being continuous with the lining membrane of the cavity, participates in the inflammation, and the process extends to the other layers. The membrane is at first reddened and swollen, and soon loses its lustre; as the hyperæmia increases, it becomes more convex externally, and yellowish-red or bluish-red in appearance. Owing to the redness and swelling of the deep portion of the meatus, the circumference of the membrane is not clearly defined. There is marked injection of the vessels near

the handle of the malleus; and later on, this part of the bone is often hidden by the swollen membrane, while a yellowish point indicates the position of the short process. When the exudation is profuse, the position of the handle of the malleus is marked by a furrow, on each side of which the membrane bulges out towards the meatus. The posterior portion is especially prominent; the epidermis often becomes detached at various spots, and the whole surface of the membrane is sometimes dotted over with little points, which more or less clearly reflect the light from the mirror. Ecchymoses, and the formation of minute abscesses between the layers, are sometimes noticed. Perforation occurs from the bursting of one or more abscesses, or from extension of ulceration. The opening is usually in the lower half of the membrane; and in three-fourths of the cases, in the anterior inferior quadrant. Illustrations of various forms of perforation will be found in a subsequent chapter on the Changes in the *Membrana Tympani* in various Affections of the Ear.

The spot at which perforation will finally occur may sometimes be accurately predicted. A small yellowish vesicle is seen to project into the meatus, and in the course of a few hours or a few days bursts and discharges its contents. In other cases there is no such distinct spot: the pus collected in the tympanic cavity bursts through the membrane, already softened by the inflammation, and is poured out into the meatus. Under such circumstances the opening is large and irregular in shape.

The progress of the case is somewhat less rapid than usual, and perforation is delayed, when the exudation occupies a nipple-shaped prominence in the posterior half of the membrane, and when the swelling forms in Shrapnell's membrane or close to the superior osseous margin. A crateriform opening in the posterior portion may indicate inflammation of the mastoid cells, the result of extension from the tympanum. In such cases the opening is usually very small, and the processes in the middle ear are apt to be very obstinate. When Shrapnell's membrane is involved, the secretion escapes with difficulty, and its retention may be accompanied by caries of the upper wall and of the incus and malleus. The loss of substance tends to increase as time goes on, and is liable to be accompanied by destructive changes in the ossicles, the formation of adhesions, and additional perforations in the tympanic membrane. When the perforation has been

caused by the bursting of an abscess between the layers of the membrane, the opening is generally small, and cannot be detected until air has been forced through the Eustachian tube. When formed under other circumstances, the opening may be difficult to recognise during the first few days; its margin is often obscured by the swollen membrane, and it may be covered up by shreds of detached epithelium. Sooner or later, however, the escape of purulent matter becomes distinctly visible, and a pulsating movement with a reflection of light can often be made out. The pulsation occurs in the minute but abnormally enlarged arteries of the swollen mucous membrane, and is transmitted to the exudation contained in the tympanic cavity, and to the fluid occupying the perforation. It is possible that the pulsations in the carotid artery may likewise be transmitted to the fluid.

Other means may be adopted for the discovery of a perforation. Thus, if the meatus be filled with fluid, bubbles will appear when the air-douche is employed, and a powder blown into the meatus will be expelled by the same means. Politzer has suggested the employment of the manometer, coupled with the air-douche, as a means of diagnosis.

As results of the escape of the exudation, the hyperæmia and swelling of the membrane gradually subside, and after the discharge has been wiped away with cotton-wool, the perforation appears as a dark opening, of variable size. In some cases the aperture becomes slightly enlarged during the next few days, but under ordinary circumstances the difference is never very great.

The secretion which escapes from the meatus varies in character and quantity; it is at first sero-purulent, greyish-yellow in colour, and tinged with blood. After a few days it becomes more decidedly purulent. If the secretion contain much mucus, little yellowish masses, flakes and threads will be found in the water after the syringe has been used. Pus, on the other hand, mingles more or less freely with the water. Blood is often mingled with the discharge in middle-ear suppuration occurring in cachectic subjects, and in cases due to injury. The escape of blood from the vessels is due, in some instances at least, to closure of the Eustachian tube. The resulting vacuum in the tympanum, or the approach thereto, produces hyperæmia and rupture of the vessels.

The changes discoverable in the nose, pharynx, and Eustachian tube are the same as those which accompany catarrhal inflammation. Obliteration of the canal of the tube, due to swelling of the mucous membrane, is often found in cases of suppurative middle-ear inflammation. In such cases the air-douche yields a negative result. In the absence of perforation, if the mucous membrane of the tympanum be much swollen, and the cavity be filled with tenacious secretion, the injection of air will cause little, if any sound, even when the tube is permeable.

Course and Results.—The first stage of the disease, comprising the interval between the outbreak of the symptoms and the perforation of the membrane, varies in length in different cases. In the absence of treatment (*i.e.*, paracentesis) an opening is usually formed in the course of four or five days. In some cases, however, the membrane gives way before twelve hours have elapsed; in others the opening is delayed for two or three weeks. These differences are due to the variations in the intensity of the inflammation, and in the kinds of bacteria that may be present, and likewise to the resistance which the membrane offers to the pressure of the exuded fluid. Rupture is apt to be delayed, if, as often happens in the case of adults, the membrane be thickened by calcareous or other deposits. It must also be remembered that in children the normal membrane is thicker than in after-life. The occurrence of perforation is generally followed by relief of all the symptoms, the change in this respect being very marked in young subjects. The patients' aspect becomes more natural; the restlessness or apathy is no longer prominent, and the head can be moved without signs of pain. If the former symptoms continue, with but slight abatement, after the perforation has taken place, there is reason to suspect that the osseous walls of the cavity have become implicated.

The second stage of the process, *viz.*, the interval between the occurrence of perforation and the closure of the opening, also varies in length in different cases. Its principal characteristic is the discharge which gradually ceases; while the subjective sensations become less and less troublesome, and the hearing-power is more or less improved. When the opening is very small and the general condition of the patient not unfavourable, closure may take place in the course of a few days. In most cases, however, cicatrization is not completed until several weeks have

elapsed, but the period depends chiefly upon the severity of the previous inflammation. The *membrana tympani* gradually re-assumes its normal appearance, and, in some instances, scarcely any trace remains of the opening. More commonly, however, the spot is marked by a cicatrix, or by opacity or calcareous deposit. Opaque patches are frequently visible in other portions of the membrane. Tinnitus is often the last symptom to disappear; it may continue to be troublesome for some months, and then pass off.

In a somewhat large proportion of cases, the local and general symptoms reappear to some extent a few days after perforation has occurred. The patient is feverish and complains of pain, noises in the head, and other unpleasant sensations. These symptoms are due to retention and accumulation of the secretion, as a result of closure of the opening either by adhesion of its margins or by masses of inspissated material. Such relapses may also be due to the influence of different kinds of micro-organisms. All these symptoms usually pass away under proper treatment; their persistence, in spite of local measures, would be suggestive of cranial complications.

The course above described is witnessed in favourable cases; there are, unfortunately, many others in which the progress of middle-ear suppuration is of a very different character. Instances of this type are not infrequent in connection with pharyngeal diphtheria and the acute exanthemata. The process in the ear is exceedingly rapid and intense; in the course of a few days, the tissues of the middle ear are partially or totally destroyed, the ossicles are detached and come away, and the membrane perishes in the suppuration. Complete deafness, or serious impairment of hearing, is the necessary result, and a history of this kind is attached to many cases of deaf-mutism, the children having lost their hearing power before they were able to speak. In adults also, severe suppuration of the tympanum, associated with marked cachexia, tuberculosis, scarlatina, or typhoid fever, often results in serious damage to the cavity and its contents, with grave impairment of hearing, or even complete deafness, as a permanent result. Complications of various kinds exercise a more or less decided influence upon the course of the disease. Extension of the inflammation to the mastoid cells, the development of granulations upon the membrane or walls of the tympanum, and chronic inflammation of the meatus, frequently retard the progress of the case.

The **Results** of acute suppuration of the middle ear vary considerably in different cases: they may be briefly summarised as follows:—

(1) The symptoms may subside after perforation; closure of the opening and restoration of function being completed within a few weeks, or perhaps several months.

(2) Impairment or total loss of hearing-power, the result of permanent lesions within the tympanum. The position of the ossicles with regard to each other and to the wall of the cavity is liable to many alterations; if the ligaments be destroyed, the bones are more freely movable. In other cases, abnormal adhesions take place, and these have an opposite effect. Increase of mobility is, however, more common; the bones, no longer held together by the ligaments, become dislocated, and this change is especially liable to occur after extensive destruction of the membrane. One or more of the bones may be completely separated from the remainder, and escape with the discharge. This, however, is a rare accident, when compared with the frequency of middle-ear suppuration. In other cases, the ossicles become carious or necrotic. The articulation between the incus and stapes is most often affected by destruction of the ligaments. Purulent exudation in the labyrinth may be associated with these lesions of the membrane and ossicles.

(3) Mastoid periostitis, or inflammation of the mastoid cells, terminating either in recovery or in abscess with discharge externally; caries or necrosis of the mastoid process.

(4) Purulent inflammation in the Eustachian tube, and pharyngeal abscesses as a result.

(5) Subsidence of the acute symptoms after perforation and the continuance of the discharge for an indefinite period, the condition being that of chronic suppurative inflammation of the middle ear, which will form the subject of the next chapter. The disease frequently takes this course in scrofulous and tuberculous cases, and when it occurs in connection with scarlatina.

(6) The disease occasionally proves fatal, by causing one or other of the following conditions: meningitis, thrombosis of the lateral sinus, pyæmia, opening of the carotid artery as a result of caries of the wall of the canal. A fatal result is less common than in chronic suppuration of the middle ear.

Diagnosis.—In the early stages of the disease, the symptoms resemble those of acute catarrhal inflammation; but they are usually more severe. The nature of the case becomes evident when the membrane bulges out into the meatus, and yellowish pus can be seen through it, or when a pustule occupies the most prominent part of the swelling. It must be remembered that portions of the inner wall of the tympanum can sometimes be seen through the membrane, and care must be taken not to mistake these for collections of pus. Behind and a little above the lower extremity of the handle of the malleus, a slightly yellowish spot is sometimes visible; this is due to the yellow rays reflected from the promontory (Politzer).

After perforation, the diagnosis is made (1) by ocular inspection and by observing the peculiarities of the secretion which escapes; (2) by injecting air into the tympanum and listening to the sound produced in the opening; (3) by condensing or exhausting the air in the external meatus. In examining the ear in order to detect a perforation, it is sometimes necessary to inject air, either by Valsalva's or Politzer's method, or through a catheter, in order to separate the margins of the aperture and to force out plugs of pus and débris. Syringing may also be employed for cleansing the meatus. Inflation of the middle ear, with auscultation, will confirm or establish the diagnosis. If the perforation be small, a whistling or hissing sound is heard as the air passes through it. Politzer's method is likely to be more efficacious than Valsalva's, as the air passes with greater force. When a perforation exists and air is condensed in the external meatus, as by the use of Siegle's pneumatic speculum, the air passes along the Eustachian tube into the throat, and the sound can be heard by means of a tube introduced into the nares. On the other hand, when the air in the meatus is exhausted by means of a Siegle's speculum, the fluid contents of the tympanum are drawn through the perforation, and may be seen flowing into the meatus.

Prognosis.—The complaint is not specially dangerous to life in persons otherwise healthy, and provided that suitable treatment be adopted from the commencement and throughout the progress of the disease. The most important favourable symptoms are: early occurrence of perforation and escape of secretion; rapid subsidence of fever and subjective sensations and absence of compli-

cations. Evidences of scrofula, tuberculosis, syphilis, or of general malnutrition are to be regarded as unfavourable. When the middle-ear affection is associated with scarlatina or diphtheria, the case is likely to be very serious, and the restoration of the affected parts to a normal condition is highly improbable. Other symptoms of an unfavourable character are : intensity and duration of the pain ; signs of cranial mischief ; frequent recurrence of rigors and fever ; evidences of mastoid inflammation and detachment of the ossicles. It seldom happens that *acute* middle-ear suppuration leads immediately to a fatal result. Such an ending is generally due to caries or necrosis and their consequences, and the patients are usually the subjects of some constitutional disorder, the presence of which materially affects the prognosis.

Professor Gruber has pointed out that the age of the patient has to be taken into account, and for the following reasons : In very young children, the lateral sinus is separated from the mastoid cells by a wall of osseous tissue, which is relatively thicker than in adults. In old age these cells are often obliterated, and hence the danger of extension of morbid processes from the ear to the cranial contents is less at the two extremes of life than during the intervening period. Both in young and in aged subjects the tendency of any extension of the mischief in middle-ear suppuration is rather towards the surface than in the opposite direction.

The hearing-power may be permanently more or less impaired, and on this subject a very guarded prognosis is always necessary. In many cases complete restoration ensues, but such a result cannot be definitely promised. Unfavourable symptoms in this respect are : persistent and profuse discharge, especially if hæmorrhagic in character ; persistent subjective auditory sensations ; considerable and rapid destruction of the membrana tympani ; detachment of one or more ossicles ; signs of mastoid inflammation and loss of bone-conduction. If improvement of the hearing-power takes place simultaneously with the subsidence of the inflammation, a favourable result may confidently be expected ; but in the absence of any such change the prognosis must be very guarded.

Treatment.—In the early stages the measures required are the same as those recommended for acute catarrhal inflammation. The

patient must be kept at rest and on low diet; stimulants of all kinds should be avoided, and if the bowels are confined, suitable purgatives should be administered.

Except in debilitated subjects leeches should be applied in front of and behind the ear, and internal to the lobule, with the object of lessening the pain and hyperæmia; and this treatment, if followed by relief, may be repeated several times. In the case of an adult, six or eight leeches may be applied. If a leech-glass is not at hand, a small test-tube answers the purpose very well. The part to which a leech is to be put should be washed with warm water, and if the leech will not bite, a drop of milk may be placed on it; or as a last resource, the part may be pricked with a needle, and a drop of blood smeared over it. The application of cold, by means of ice-bags, is sometimes recommended; but the effects are for the most part unsatisfactory. On the other hand, relief is generally obtained from moist and hot applications, such as a hot sponge or compress. These, however, should not be continued for more than two or three days; by hastening the destructive process, they are liable to act prejudicially upon the deeper parts of the ear. A little warm water poured into the ear from time to time will serve to relieve the pain; it should be allowed to remain for a few minutes and then removed. A few drops of tincture, or what is better, the liquid extract of opium, may be added to the water. Ten to fifteen drops of a 10—20 per cent. solution of hydrochlorate of cocaine, previously warmed (*see* page 139), may be used for the same purpose. Atropine sometimes acts satisfactorily in these cases; but its use requires great care. Three or four minims of the *Liquor Atropinæ Sulphat.* are instilled into the meatus every three or four hours, and allowed to remain for about ten minutes. If there be decided tenderness over the mastoid process, a blister or mustard plaster should be applied. As a valuable method of reducing the severity of the complaint in the early stages, Bendelack Hewetson, of Leeds, recommends the introduction into the meatus of tampons charged with a 20 per cent. solution of glycerine of carbolic acid. Rohrer,* Morpurgo, and Hartmann report very favourably of their experience of this method. When fever is a marked symptom, antipyretics are likely to prove useful; antifebrin, in doses of three or four grains or more every four hours, or

* *Lehrbuch der Ohrenheilkunde*, S. 129.

antipyrin in doses of ten grains or more at an hour's interval, are good remedies of this class.

When there are positive signs of purulent formation within the tympanum—that is, when the membrane bulges out into the meatus, and the swelling is greenish or yellowish in colour, and there is severe pain and high fever—the operation of paracentesis is strongly indicated. An incision into the membrane not only provides a suitable outlet for the escape of the pus, but reduces the hyperæmia of the tympanic vessels, relieves the tension and pain, and lessens the duration and risk of extension of the morbid process. Prompt mitigation of the pain is the almost invariable result. As a general rule the operation should not be delayed when the symptoms are manifest; the risk of damage to the structures of the tympanum rapidly becomes more serious. Moreover, the progress of the case, after the pus has been evacuated by an incision, is always more satisfactory than when the opening is allowed to take place spontaneously. As a general rule, the incision should be made in the lower half of the membrane, below the umbo, as the purulent collection gravitates towards the floor of the cavity. If, however, the yellowness be very marked at any particular spot, showing that the pus is nearer to the surface there than elsewhere, the incision should be made so as to involve that part. As a preliminary step, it is well to disinfect the meatus by pouring into it a one per thousand solution of perchloride of mercury. This may be allowed to remain for a few minutes, and then removed, the meatus being afterwards dried with absorbent cotton-wool. To produce local anæsthesia, a warm 20 per cent. solution of cocaine may be applied to the membrane. The operation of paracentesis has been already described (*see* page 314). When practised for the relief of acute purulent inflammation of the tympanum, the incision in the membrane should be made sufficiently large—from the $\frac{1}{16}$ to $\frac{1}{8}$ of an inch—so that the exudation may freely escape; this precaution is very necessary if the pus be thick and tenacious. The membrane is often swollen and infiltrated, and the paracentesis needle has to pass through a considerable amount of tissue before the cavity is reached.

Other circumstances, besides those mentioned above, may render the operation necessary. Thus, in the absence of any decided prominence of the membrane, if the pain be very severe,

and palliatives prove useless, an exploratory incision will generally be successful. It must be borne in mind that the membrane is sometimes thickened and indurated in consequence of previous disease, and under such circumstances a purulent collection may exist in the middle ear without causing any decided change visible from the meatus.

After the operation, which usually causes but little hæmorrhage, the purulent matter escapes more or less freely; if it be viscid and therefore retained, the meatus should be filled several times daily with warm water. Politzer recommends the instillation of ℥viii.—x. of a 2 per cent. solution of pilocarpine, for the purpose of making the secretion more fluid. If pain continue after paracentesis, or after spontaneous perforation, the anodynes cocaine and atropine (as described in a former paragraph) or warm liquid extract of opium should be dropped into the ear.

When an opening has been made, whether by puncture or by spontaneous rupture, the meatus should be thoroughly cleansed several times daily with pure warm water, or a warm solution of boric acid; the frequency with which the injections are used must be regulated by the amount of secretion. If the latter be very abundant, the meatus should be washed out every two hours. After the injections, the canal should be carefully cleansed and dried, and a plug of cotton-wool introduced.

The injection, however, of warm water into the meatus will not remove all secretion from the middle ear; other means must be adopted for this purpose, and the best plan is to inject air through the Eustachian tube by Politzer's method. There are, however, certain drawbacks connected with the employment of the air-douche. In the first place, micro-organisms are likely to be conveyed to the tympanum from the nose and naso-pharynx. This risk can, at least to some extent, be averted by a preliminary disinfection of these cavities. Rohrer recommends peroxide of hydrogen as a suitable disinfectant, to be followed by insufflations of iodoform, iodol, or aristol. There is another danger, viz., that of forcing particles of secretion into the mastoid antrum or into the pouches of the tympanic membrane, which were previously free from disease. When the tympanum is filled with tenacious secretion, even a strong current of air may only break up the mass, without forcing it through the opening in the membrane. The case is of course different when the secretion is altogether

fluid in character. If the pouches of the membrane be already filled with secretion, a current of air, passing upwards from the Eustachian tube, cannot clear these spaces, but the secretion is likely to be driven into the mastoid cells, and to aggravate the condition of those cavities.

These drawbacks are, however, more than counter-balanced by the results often produced by the employment of Politzer's method. If there be considerable obstruction in the tube, the catheter may be employed for the injection of air. When the exudation is very abundant and tenacious, the injected air may fail to propel it through the perforation. Under such circumstances, it is best to wash out the tympanum with a warm solution of common salt ($\frac{3}{4}$ per cent.) previously sterilised and injected through the catheter. This solution generally diminishes the tenacity of the exudation which is forced into the meatus, provided that the aperture in the membrane be sufficiently large. In the event of failure, the catheter should be laid aside for a few days, during which the meatus is to be frequently cleansed by the use of the syringe, as already described.

For the majority of comparatively mild cases, the injection of air into the middle ear is all that is necessary; in a few days the discharge ceases, and the aperture gradually closes. As a general rule, however, local remedies are required to check secretion and to restore the parts to a normal condition. The best remedy for this purpose is boric acid, reduced to a very fine powder. Before using it, the meatus should be washed out with warm water and carefully dried with absorbent wool. A small quantity of the powder is then blown into the meatus by means of an insufflator, and a plug of cotton-wool is introduced. This treatment is to be repeated several times daily, until no discharge appears on the cotton-wool which has remained in the meatus for twenty-four hours. Politzer recommends that, if no decided lessening of the secretion is observed within a few days, a little plug of iodoform or some cotton-wool dusted over with the same drug, should be passed down the meatus and kept in contact with the membrane, and that after this plan has been adopted for a short time, the boric acid should be again applied.

As the continuance of the discharge is frequently due to retention of pus in the tympanum, in preference to changing the application of boric acid for that of another drug, I usually have

the meatus syringed out, and then a Politzer's inflation given to force the discharge out of the tympanum. The syringing and Politzer's inflation should then be repeated alternately until the water which comes away is free from pus or mucus. In such a case it is better to syringe the meatus with a warm solution of carbolic acid (1 in 80) instead of with water or a solution of boric acid. When this treatment is adopted several times daily for a few days, the discharge usually diminishes greatly or entirely ceases. The Politzer's inflation is contra-indicated if it produces pain.

If the treatment by boric acid fail to check the discharge, astringent remedies should be tried; sulphate of zinc and acetate of lead are the most useful. Schwartze recommends the instillation of dilute *Liquor Plumbi Subacetat.* (℥i.—ij. to ℥x. warmed distilled water). This mixture is to be used thrice daily for a few days, and afterwards less frequently, and should be allowed to remain in the meatus for about ten minutes. It causes less irritation than other astringents, and often checks suppuration within a few days. After removal of the fluid, the meatus is carefully dried with absorbent wool. The sulphate of zinc is used in the form of a watery solution (2—5 grains to the ounce); twenty drops, warmed, are poured into the ear and allowed to remain for ten or fifteen minutes. The instillation is made once or twice daily, and continued for five or six days. A solution of acetate of lead, of the same strength, may be used in a similar manner. In some cases the addition of tincture or liquid extract of opium to the above-mentioned solutions, in the proportion of two drachms to each ounce, proves beneficial. As a general rule, astringents are not advisable so long as the patient complains of pain in the ear.

The treatment of cases in which spontaneous perforation has taken place is to be conducted in much the same manner as that already described. It is important that the exudation should freely escape, for if it be pent up within the cavity, complications are likely to occur. Extension of the process to the mastoid cells is by no means infrequent. Retention of secretion may be due either to smallness of the aperture or to its position in the upper part of the membrane. In the former case, the aperture should be enlarged with the paracentesis knife; and in the latter, a second opening should be made in the lower part of the mem-

brane if there is evidence that the retained secretion is keeping up the inflammation or causing its extension, otherwise time should be allowed for the symptoms to disappear in their ordinary course. The alternate syringing and injection of air, as just described, is often sufficient to keep the tympanum clear, although the perforation is in the upper part of the membrane. Implication of the mastoid cells is marked by local pain, tenderness, redness, and swelling. To relieve these symptoms leeches should be applied behind the ear, and followed by an ice-bag or cold compresses. When the redness and swelling have subsided, tincture of iodine painted over the process will help to promote resolution. If no benefit be obtained from these measures, or from the injection of warm water through the catheter, and if the mastoid region remain swollen and painful, the best plan to adopt is to make an incision through the soft parts covering the process. The incision should be about $1\frac{1}{2}$ inches in length, and should be carried down to the bone. The symptoms are almost invariably relieved even if no pus escapes. The treatment of inflammation of the mastoid process will be fully described in subsequent pages.

When the opening resulting from spontaneous perforation is sufficiently large and favourably situated for the escape of discharge, the treatment depends upon the nature of the secretion. If the latter be thin and serous, and escape freely, all that is necessary is to keep the meatus clean by syringing and careful drying, and to apply boric acid by insufflation. If the secretion be purulent and offensive, the air-douche or the use of the catheter daily, and antiseptic fluids for syringing into the meatus, will constitute the best treatment. It may be necessary to enlarge the opening in the membrane or to make a second. Excoriations or ulcers in the meatus generally heal as the character of the secretion becomes improved; the application of white precipitate ointment (1 : 20) will prove efficacious. Granulations sometimes form on the margin of a perforation; but they usually subside as the secretion diminishes. If they prove troublesome, they should be lightly touched with the point of a fine probe coated with nitrate of silver or with a solution of chromic acid, ten grains to the ounce.

After the opening in the membrane has closed, an interval of three or four weeks should be allowed to elapse; the air-douche

may then again be used with advantage, provided that the membrane is no longer swollen, especially in the neighbourhood of the short process. The air should be injected twice a week for four or five weeks, very slight force being used at first. The ear must be protected as far as possible from injurious influences; a plug of cotton-wool or gauze should be worn for several weeks, and all probable causes of a relapse should be scrupulously avoided.

The symptoms and treatment of mastoid complications supervening in acute middle-ear suppuration will be fully described in a subsequent chapter.

CHAPTER XXVIII.

CHRONIC SUPPURATIVE INFLAMMATION OF THE
MIDDLE EAR.

Statistics showing Frequency of the Complaint—Morbid Appearances in the Tympanic Cavity and Membrane—Caries of the Ossicles—Suppuration in the Upper Tympanic Spaces—The Eustachian Tube—Causes—Influence of Age, Sex, etc.—Subjective Symptoms—Impairment of Hearing, Tinnitus, Giddiness—Pain as a Symptom—Evidences of Nervous Disorders—Objective Symptoms—Discharges from the Ear—Micro-Organisms—Condition of the Membrana Tympani—Perforations, their Size, Form, etc.—Condition of Tympanum—Portions and Structures Visible through a Perforation—Perforation of Shrapnell's Membrane—Course and Results of Chronic Middle-Ear Suppuration—Diagnosis of Perforations—Prognosis—Treatment—Various Methods of Cleansing the Middle Ear—The Syringe, Inflation, Enlargement of the Opening—Aspiration, Condensation of Air, Dry Cleansing—Use of Antiseptics—Boric and Carbolic Acids, etc.—Caustics, Nitrate of Silver—Astringents—Gelatin Bougies—Constitutional Remedies—Methods of Improving the Hearing-Power.

THIS complaint is accompanied by a discharge from the meatus, and hence it is often described as "Otorrhœa." It is the most frequent as well as the most important disease to which the aural structures are liable. The statistics of 48,780 cases of ear-disease show that the middle ear was affected in 66·9 per cent.; the external ear in 25·5; while 7·6 represented the percentage of affections of the internal ear.* Of all middle-ear affections, 29 per cent. belong to the suppurative class. The Registrar-General's reports show that 300—400 deaths occur annually from what is

* As cited in a lecture delivered at the Royal College of Surgeons, June 3, 1889, by Prof. A. E. J. Barker.

vaguely termed "otitis." The mortality, however, is far greater than would appear from these figures. Not a few fatal cases of suppurative ear-disease are probably returned under the headings "Meningitis," and "Unclassified Brain-diseases." With respect to otitis, it may be regarded as certain that middle-ear disease is implied by this term when used in the reports. Suppuration of the external ear very rarely causes a fatal issue, while the internal ear is seldom, if ever, the seat of inflammation leading to suppuration. Acute inflammation even of the middle ear is comparatively seldom followed by cranial complications; the lymphatics are intact, and any septic matters which may find their way into the cavity are probably destroyed.

Morbid Appearances.—In chronic middle-ear suppuration, the continuance of the process is due to various causes, the most important of which are (1) the development of granulations on the mucous membrane of the tympanic cavity; (2) the retention of masses of exudation, and (3) lesions of the osseous walls of the cavity. One or all of these conditions may be present in any given case. The mucous membrane undergoes many changes, varying with the stage of the disease. It is generally thickened as a result of excessive infiltration with round cells, and of vascular dilatation with formation of new vessels. The surface is often dotted over with papillary excrescences or nodules, which amount to granulations, and are frequently polypoid in character. The epithelial cells lose their cilia, and either become indurated or undergo fatty degeneration. Atrophy of the lining membrane is another result of purulent inflammation, and may be regarded as due to a more severe type of the disease. In this form there is no increase of tissue; on the other hand, the normal elements disappear and are not replaced; the newly-formed cells do not become organised, but are rapidly detached and discharged with the pus. Thus it is, that when examining the tympanum from the external meatus, through a perforation, in some cases, a thick layer of connective tissue is seen to cover the inner wall; in others, the osseous surface is visible through a very thin layer of membrane.

Ulceration results from the replacement of the sub-epithelial layer by a mass of round cells, which form a granulating surface, traversed by dilated vessels. The lining membrane is of a deep-red or yellowish-red colour; the general thickening and the

papillary excrescences considerably reduce the size of the tympanic cavity, a large portion of which may be filled up by the hypertrophied mucous membrane. Important changes take place in the lymphatic vessels situated in the deeper layers; their trunks form an anastomosing network, and the radicles become varicose and constricted at intervals, and present many knob-like dilatations. Politzer also describes the formation of cyst-like cavities in the proliferated mucous membrane: those in the deeper layers are to be regarded as isolated lymph-spaces; while the minute sacs in the superficial granulation-layers are probably due to the cohesion of papillary excrescences, which thus shut off the little depressions contained between them. These cyst-like cavities are well adapted for the retention of infective matters, septic bacteria, etc. The part played by micro-organisms in the production of complications would seem to be of a very important character; it will be discussed at some length in subsequent paragraphs.

The changes, as above described, are not uniformly distributed over the mucous membrane of the middle ear; but different parts are often affected in different ways. Thus the formation of granulations in one part may be associated with the development of connective tissue, or with atrophy and loss of substance, in other portions of the membrane.

The **Membrana Tympani** is almost always perforated, and sometimes in two or more places; the size and shape of the openings vary considerably. In exceptional cases, the secretion escapes through fistulous channels in the bones, and the membrane may then be found intact. Such openings are usually found in the posterior and posterior superior walls of the meatus, and communicate with the mastoid cells or antrum. A perforation may at the same time exist in the tympanic membrane. With regard to the size of the perforation, it is sometimes very small, although it has existed for years. In cases in which the aural disease was associated with scarlatina or diphtheria, the opening is usually large; the destruction may indeed have involved the whole of the membrane, with the exception of a very narrow border next to the tendinous ring. Considerable alterations are often manifest in the remains of the membrane; thickening, opacities, and calcareous deposits are the most common changes. In most cases, the membrane is drawn decidedly inwards, and when the perforation

is central, its margin is often closely applied to the wall of the labyrinth. After a large perforation has remained open for a long time, the lining of the cavity sometimes becomes dermoid in character, owing to proliferation of epidermis from the external meatus.

The **structures contained** in the tympanic cavity are often bound together by layers and fibrils of connective tissue, extending in various directions, and sometimes these bands become indurated, calcified, or even osseous in texture. In another class of cases, destruction of tissue is the prevailing feature. The mucous membrane is ulcerated, and in some places the bone is exposed or perhaps hidden by granulations. The roof and inner wall of the tympanic cavity are the parts most often affected. Caries is another result, evidences of which are frequently seen in the ossicles as well as in the bony walls. This process, which may be confined to the malleus, renders the suppuration obstinate. The discharge, loaded with micro-organisms, trickles down to the floor of the cavity, the tissues of which are constantly exposed to reinfection. Prussak's space (*see* page 43) and the anterior and posterior tympanic pouches are sometimes filled with purulent matter, the presence of which leads to destructive changes, especially to perforation of Shrapnell's membrane, and to caries or necrosis of the malleus and incus. As stated by Politzer,* purulent processes in this system of cavities (with perforation of Shrapnell's membrane) may either localise themselves and not spread, or may involve the entire cavity. In the latter case, the suppuration in the middle ear may come to an end, while it continues almost indefinitely in the system of cavities between the body of the malleus, incus, and Shrapnell's membrane. Purulent processes may be very obstinate in a space occupied by a meshwork, from which stagnating secretion is difficult to be removed, and the hidden crevices of which are with difficulty accessible. In these cases, if the original perforation should heal, another opening is likely to form in Shrapnell's membrane. Chronic suppuration in the mastoid antrum is prone to occur simultaneously with purulent processes in the upper tympanic spaces.

The **Eustachian Tube** is always more or less affected in cases of

* *Anatomical and Histological Dissection of the Human Ear, in Normal and Diseased Conditions* (translated by George Stone), p. 86.

middle-ear suppuration. The mucous membrane is swollen and covered with secretion; the glands are enlarged and their excretory ducts dilated; the epithelium may be either thickened or detached. In some cases, the process is catarrhal in type; in others, decidedly purulent. Some amount of constriction often remains in the tube.

Causes.—Chronic suppurative inflammation of the middle ear is generally the result of an acute attack; in some cases, however, and notably in those due to tuberculosis, the disease is chronic in type from the commencement. The acute symptoms are apt to pass into a chronic stage in cases of scarlatina, small-pox, and measles; and in tuberculous, scrofulous, and syphilitic patients. A similar result may be caused by improper treatment, and is very liable to occur when the upper tympanic spaces are the seat of disease. The connection between scarlatina and diphtheria and affections of the middle ear is now thoroughly recognised; in both these diseases, the throat is often implicated, and the process extends through the Eustachian tube to the aural structures. As a general rule, it may be stated that from five to six per cent. of all diseases of the ears are due to scarlatina, the frequency with which the complication occurs being in proportion to that of the throat-affections and their severity. Diphtheria in children is liable to be followed by a very severe form of chronic purulent inflammation of the middle ear. There may be little or no pain or any acute symptoms, but in a few days a discharge appears in the meatus, abscesses form around the ear, and portions of the bone soon become necrotic. A separate chapter will be devoted to the consideration of those forms of otorrhœa which originate in diphtheria, scarlatina, tuberculosis, syphilis, and other constitutional disorders.

According to v. Tröltsch and other German writers, purulent collections are often found in the tympana of new-born children. This appearance is due to abnormal metamorphosis of the embryonic connective tissue; to the passage of liquor amnii into the tympanum during futile attempts by the fœtus at respiration; and possibly to the entrance of matters from the stomach during the act of vomiting. It must also be noticed that the vascular supply is more copious in the fœtus than in the adult. In forty-seven temporal bones taken from new-born children, v. Tröltsch found that the aural structures were normal only in

eighteen preparations; in twenty-six there were indications of purulent processes in the middle ear.

The complaint is most common in children; and both sexes are equally liable to suffer from it: in a majority of cases (58 per cent.) only one ear is affected. Many of the sufferers belong to the poorer classes, who are more exposed to cold and damp, and to other injurious influences. Dr. Burnett points out that among the well-to-do classes girls form the majority of young patients. They are more closely observed than boys, and therefore are more often placed under treatment. Boys are more liable to be neglected until impairment of hearing causes them to lag behind their schoolfellows.

Subjective Symptoms.—These vary in different cases; many patients appear to be almost free from them, and complain only of the discharge. There is usually more or less deafness; but it is sometimes so slight as to pass unnoticed, and especially if only one ear be affected. In some cases, however, the hearing is decidedly impaired; and this symptom may be due either to obstacles to conduction, or to changes in the labyrinth. The former is the more common cause; the comparative infrequency of labyrinthine complications is a distinguishing mark between chronic middle-ear suppuration and the adhesive processes. Bone-conduction is maintained; in cases of unilateral disease, the tuning-fork applied to the vertex is best heard on the affected side. Rinne's test gives negative results. The degree in which the hearing is impaired depends in some measure upon the position of the opening in the membrane. Perforations in the anterior portion are more likely to impair the function than similar openings in the posterior part. Comparatively slight alterations may be noticed even with large perforations involving the posterior superior segment, and exposing the articulation between the incus and stapes. When the cone of light is destroyed, the hearing-power is apt to be decidedly lessened. Most patients are conscious, from time to time, of considerable variations, which depend upon the state of the weather, the condition of the tympanum and Eustachian tube, and particularly upon the nature and quantity of the secretion. Warm and dry weather tends to improve the hearing. A thick tenacious secretion has a contrary effect, inasmuch as it impedes the movements of the ossicles. Sometimes the exudation is so

scanty that otorrhœa cannot be said to exist; in these cases crusts often form and emit a very disagreeable odour. The hearing-power is not uniformly affected by the cessation of suppuration; in many cases the deafness increases with the subsidence of the process, and is lessened when the discharge again becomes free. The change for the better is probably due to the relaxation of the connective tissue, and to the increased mobility of the ossicles under the influence of the liquid secretion. If the fenestræ are blocked-up by the hypertrophied mucous membrane, and the base of the stapes is fixed, cessation of the discharge is not likely to be followed by any improvement of function.

Subjective Sensations, noises of various kinds, are seldom very troublesome, and in many cases are altogether absent. Some patients are subject to occasional attacks, which depend upon the condition of the Eustachian tube and tympanic mucous membrane. Tinnitus is likely to be troublesome when the labyrinth is involved, and when there is ankylosis of the articulations between the ossicles. Giddiness is an occasional symptom; it may result from increased pressure in the labyrinth, or from extension of the hyperæmia of the tympanic vessels through the petro-squamous fissure to the meninges. An attack is sometimes produced by stooping, and by suddenly rising up from the recumbent position; syringing the ear with cold water, and with too great an amount of force, is likely to have a similar effect.

Pain is by no means a constant or prominent symptom in chronic middle-ear suppuration; usually patients complain only of uncomfortable sensations on the affected side of the head. The supervention of an acute attack will be accompanied by severe pain, which lasts until the parts have returned to their former condition. Occlusion of the perforation, preventing the escape of the discharge, is a common cause of the return of pain. Carious processes in the walls of the cavity may give rise to severe boring pain, extending over the side and back of the head. The sudden occurrence of severe pain renders a careful examination very necessary.

Various Evidences of Nervous Disorder are occasionally witnessed. Sometimes taste is impaired or even lost on the affected side,* and diminution of tactile sensation in the tongue has also been noticed. Facial paralysis is another symptom of this

* Urbantschitsch, *Lehrbuch der Ohrenheilkunde*, III. Aufl. S. 358.

character, and is most often due to carious processes involving the aqueduct of Fallopius, though it may be caused by pressure of exudation in the canal. Urbantschitsch mentions impairment of vision and nystagmus as occasionally due to the condition of the tympanum. In one case, recorded by Schwabach,* pressure upon the wall of the tympanum caused nystagmus, with movements towards the affected side. Psychical disorders of various kinds and epileptiform convulsions are sometimes due to chronic middle-ear suppuration; and an obstinate cough and frequent paroxysms of sneezing have been observed to accompany a chronic discharge from the ear.

Objective Symptoms.—On examining the meatus, it is generally seen to contain inspissated or fluid pus, and the walls of the canal are swollen and inflamed. When the discharge is only slight, the secretion may be confined to the deep part of the meatus or to the tympanum. The quality, as well as the amount of the discharge, varies considerably in different cases and at different times in the same case. Sometimes the secretion is thick and scanty, and only a few drops are discharged in the course of twenty-four hours, or perhaps it becomes dry in the meatus and forms crusts. In other cases the discharge is watery and profuse, or even so abundant as to trickle almost continuously from the ear. In a case recorded by Itard, 200 grammes (about seven ounces) of fluid were discharged in seven days. Abundant secretion is the rule in cases associated with scarlatina and diphtheria, and when the tympanum is decidedly granular or the temporal bone has become carious with subsequent formation of abscesses. The discharge often contains crumb-like masses of inspissated pus and of epithelial cells. Variations in the quality of the secretion are very numerous; thus the discharge is sometimes purulent, sometimes muco-purulent or serous and tinged with blood. Less frequently it is viscid, resembling a solution of gum. Stiff, tenacious crusts are then apt to form and to irritate the walls of the canal. The colour likewise varies; it depends upon the relative proportions of pus, mucus, serum, blood, débris, and vegetable organisms; it may be pure yellow, greenish-yellow, reddish, or brown; it is sometimes decidedly blackish. In rare cases, the discharge is blue or bluish-green in colour. Pus of this character is sometimes noticed covering

* *Deutsche Zeitung f. prakt. Heilk.*, 1878, 1.

granulating sores on various parts of the body. The colouring matter is contained in the serum and not in the albumen; it is due to micrococci, containing a blue material called "pyocyanin." These organisms (*M. pyocyaneus*) require for their development a temperature equal to that of the body and the presence of albumen; they are not found when the discharge is profuse. If a drop of this blue pus be placed in the meatus of a patient suffering from ordinary otorrhœa, the discharge, in a few days, will become similarly coloured. The organism is quite innocuous, and its presence does not interfere with the course of the healing process. Cholesteatoma will be subsequently described.

A highly disagreeable odour is another common feature of the discharge in cases of chronic middle-ear suppuration. The odour varies in character; sometimes it is described as "faint" or "sickly," sometimes as pungent and resembling decaying cheese. Mention has been already made (*see* page 365) of the various kinds of micro-organisms found in the middle ear in cases of suppurative disease. In 100 patients suffering from this disorder, and examined by Dr. Rohrer,* the discharge was more or less foetid in sixty-nine cases, and contained many forms of micro-organisms. In 317 examinations, micrococci were found in 130, and bacilli in 177 specimens. In sixty patients the symptoms were of a chronic character, and bacilli proved to be more common than micrococci in the discharge (154 : 121). In the nine acute foetid cases, bacilli were found in still greater proportions (23 : 9); in the cases (31) with non-foetid discharge, micrococci alone were discoverable. The investigations showed that the odour of the discharge in foetid otorrhœa was due to forms of putrefactive bacilli. The absence of bacilli from the non-foetid discharges is a point of considerable interest. It must be remembered that an offensive odour does not necessarily indicate caries of the osseous walls, as was formerly supposed. In some cases the discharge acts as an irritant to the meatus, and causes circumscribed or diffuse inflammation, or even leads to ulceration; the floor of the meatus is the part most liable to be thus affected. In long-standing cases, the canal may be considerably reduced in size, owing to the swelling of the soft parts, and to chronic periostitis. Eczema of the auricle is another

* *Zur Morphologie der Bakterien des Ohres und des Nasen-Rachenraumes*, Zurich, 1889.

somewhat frequent accompaniment of middle-ear suppuration. The eczematous secretion contains various forms of bacilli and micrococci.

The **Condition of the Membrana Tympani** is the next subject for investigation. As a preliminary step it is often necessary to cleanse the meatus, either by means of the syringe or with cotton-wool. Dark crusts sometimes adhere to the tympanic membrane and adjacent parts of the canal, and are difficult to remove. When the discharge is scanty, little, if any, may escape into the meatus; it adheres to the edges of the perforation, and a small opening may be thus entirely occluded.

The appearances presented by the tympanic membrane exhibit great variations. In all but exceptional cases, an aperture exists in this structure, so that the meatus communicates with the middle ear. The opening may be situated in almost any portion of the membrane, but the anterior inferior quadrant is the most common site. Next to this comes the posterior inferior quadrant, and in many cases both these quadrants are involved. In 53 per cent. of all cases, the perforation is either confined to or involves the anterior inferior quadrant. When both sides are affected, the perforation is often found in the same part of each membrane, and its shape is often similar on each side. Perforation of Shrapnell's membrane takes place in about $3\frac{1}{2}$ per cent. of all cases.

The **Size of a Perforation** is also liable to great variations. In some cases, the aperture is no larger than a small pin-hole; in others, the gap involves almost the whole of the membrane, and any degree of size may exist between these extremes. As already stated, the greatest destruction results from scarlatina and diphtheria, and from the effects of tubercular ulceration of the lining membrane of the tympanum. A narrow border generally remains at the circumference, and a like strip is usually connected with the handle of the malleus. In very severe cases, Shrapnell's membrane is also involved, and the upper border of the tympanic ring, with the adjacent portion of the osseous meatus, is the seat of caries. A small opening is sometimes noticed to increase in size during the continuance of inflammation; and variations in measurement, due to increase or diminution of swelling, are not infrequent. Illustrations of various forms of perforation will be found in the next chapter.

The **Form of a Perforation** is in most cases roundish—that is,

comparatively circular, oval, or elliptical. When the opening is large and involves the lower half of the membrane, the projection of the handle of the malleus may give it a reniform shape. In large perforations, with almost total destruction of the membrane, only a wedge-like piece may remain over the same process of bone, causing the opening to appear somewhat V-shaped above. In rare instances, the opening is funnel-shaped, with the wider end directed towards the tympanum. Another form of opening is a canal running obliquely through the layers of the membrane; and sometimes the coats are unequally destroyed, so that for some distance round the opening the membrane has an uneven appearance. Angular and slit-like perforations are somewhat rare; but when the membrane is the seat of chalky deposits, a cleft is sometimes noticed at the margin of the calcified portion. Occasionally a minute orifice is found at the apex of a prominent part of the membrane, and when this peculiarity occurs, the suppurative process is apt to be of a very obstinate character.

In most cases, only one opening exists in the tympanic membrane; but there are sometimes two or even more, and when this is the case, the openings vary in size. Perforations sufficiently numerous to give the membrane a sieve-like appearance are sometimes found in cases of tuberculosis, scarlatina, diphtheria, and pyæmia.

The **Appearances presented by the remains** of the membrane vary considerably in different cases and in different stages of the same case. While the discharge continues, the membrane is more or less swollen and reddish, or decidedly greyish in tint, owing to accumulation of epithelium on its surface. After removal of these shreds, the appearance of the membrane may be either comparatively normal or changed in various ways, *e.g.*, opaque, yellowish-red or deep-red in colour. Calcareous deposits cause greyish or whitish spots, between which a reddish hue may predominate. The surface may be either smooth or uneven, and covered in places with granulations. These latter frequently encircle the perforation and occupy its margin; they are likewise apt to occur near the periphery of the membrane. The margin of the perforation varies in appearance, and is notably influenced by the condition of the discharge. It is often covered up by secretion, and appears as a red line when this is removed. It is sometimes free and sometimes in contact with the inner wall of the tym-

panum, being either closely adherent or connected by membranous bands. In later stages, the margin may be covered with calcareous deposit; the occurrence of granulations has been already referred to.

Some portion of the handle of the malleus is often connected with the remains of the membrane, and its position is considerably modified when the perforation is large. In such cases, the tensor tympani, no longer opposed by the tympanic membrane, draws inwards the remains of that structure, together with the handle of the malleus, which may indeed be placed above the upper portion of the periphery, so as not to be visible from the meatus. If, on the other hand, in a case of almost total destruction of the membrane, the handle of the malleus be in a comparatively normal position, there is either a pathological change in the tensor tympani or some abnormal obstacle to the action of the muscle. Obstacles of this character are caused by ankylosis or rigidity of the malleo-incudal articulation, by immobility of the remains of the membrane with calcification or hypertrophy of its tissue, and by tension of the anterior ligament of the malleus which antagonises the tensor tympani muscle. Partial destruction of the handle of the malleus, extending up to the short process, is not uncommon, and sometimes the long leg of the incus and its articulation with the stapes are exposed to view.

The **Mucous Membrane of the Tympanum**, as seen through a large opening, varies in appearance with the stage of the disease. At first it is red and swollen, and more or less covered with exudation. If the swelling be inconsiderable, various parts of the inner wall may be more or less clearly distinguished; under opposite conditions, all that can be seen is a reddish mass, either smooth or covered with granulations or polypoid growths. Such excrescences sometimes project through the opening in the membrane. After the inflammation has subsided, the lining of the tympanum becomes either yellowish-red or yellowish-white; it may undergo atrophy and resemble cicatricial tissue. Calcareous deposits are not uncommon appearances. Masses of inspissated secretion and detached epithelium often project below the upper border of a large perforation.

Various Portions of the Inner Wall of the tympanum and of the structures contained in the cavity can sometimes be distinguished through the opening in the membrane. In cases of

large and central perforations, the promontory, with numerous vessels on its surface, the vertical limb of the incus and the depression of the fenestra rotunda, are more or less distinctly seen. When the opening involves the posterior superior quadrant, in addition to the limb of the incus, portions of the stapes, and sometimes the tendon of the stapedius muscle, may come into view. When the lower half of the membrane is absent, the cells in the floor of the tympanic cavity may become exposed, while anteriorly, the opening into the osseous portion of the Eustachian tube will appear as a dark depression.

Perforations of Shrapnell's Membrane have been already noticed (*see* page 393); some of their peculiarities require a more minute description. They are usually indicative of chronic suppuration, and the process is sometimes confined to the upper part of the tympanic cavity. In some cases in which the perforation is in the lower part of the membrane, the morbid process has begun in the spaces near the roof of the cavity; the opening is caused by the secretion which passes downwards. These spaces may, however, be subsequently cut off from the rest of the tympanum by membranous adhesions, in which case a second perforation is likely to be formed in Shrapnell's membrane, while the lower opening becomes closed. The anatomical conditions of the "attic" impede the escape of secretion; the fluid portion trickles away, but inspissated matters remain behind, and the morbid processes are thereby prolonged. Caries of the adjacent portions of the ossicles and bony wall is often superadded; granulations then form and sometimes project through the perforation into the meatus. In severe cases, the greater part of the malleus and incus is destroyed, a large gap is made in the bone above, and the process may likewise extend to the remainder of the membrane.

Masses of epithelial cells and débris and of inspissated secretion are apt to accumulate in these cases, and cholesteatomatous deposits are thus formed. The epithelial cells are derived from the epidermis of the external meatus, which often prolongs itself, through a perforation, into the tympanum.* It may, indeed, extend into the mastoid cells. The epithelial cells form closely packed layers around a central mass of inspissated secretion, and these deposits, as they gradually enlarge, exercise

* *Zeitschrift für Ohrenheilkunde*, vol. xx, p. 15.

considerable pressure upon the osseous walls. Other effects of such accumulations will be described in a subsequent chapter.

The occurrence of suppuration confined to the "attic" and Prussak's space, with perforation of Shrapnell's membrane, has been explained in various ways. The view that the process is of a primary character is opposed by some on the ground that the action of micro-organisms passing through the Eustachian tube could scarcely be confined to these spaces without affecting the lower portion of the tympanum. Prof. Walb* thinks that there are two ways of accounting for suppuration in these spaces. In the first place, during middle-ear suppuration, with the tympanic membrane strongly indrawn and the Eustachian tube closed, the exudation may force its way through Shrapnell's membrane. Secondly, suppuration may be confined to these spaces, as a result of infection propagated from the external meatus through a minute opening in Shrapnell's membrane. Such an opening (the foramen of Rivinus) is sometimes congenital; but is by no means invariably present. Schwartze thinks that middle-ear inflammation is sometimes due to the passage of water through this opening while bathing. Be this as it may, there is no doubt that inflammatory processes in the external ear may lead to partial destruction of Shrapnell's membrane. At the commencement, the morbid processes in the "attic" may be confined to the immediate neighbourhood of the perforation; granulations may form, or the upper margin of the bone may be already carious, while the ossicles remain intact.

In cases of chronic suppuration, confined to these spaces, which are completely separated by adhesions from the remainder of the tympanum, no perforation-sound is heard when air is injected through the Eustachian tube, inasmuch as the current is prevented from reaching the opening. Caries of the ossicles is often superadded, and the head of the malleus is most liable to be affected, but the process tends to spread to other portions of the bone, and to the incus. Closure of a perforation in Shrapnell's membrane is somewhat uncommon; more or less of the "attic" is exposed to view, and in course of time is seen to be covered by a smooth, shining, pale yellow membrane, almost dry, and coated with epidermis. It very rarely happens that this portion of the membrane is entirely destroyed, but when such is

* Schwartze's *Handbuch der Ohrenheilkunde*, Bd. II. S. 268

the case, the neck and head of the malleus, the articulation with the incus, and a portion of the latter bone come into view. The roof of the tympanum, and posteriorly the beginning of the mastoid antrum are also visible.

Perforations in Shrapnell's membrane may occur in the anterior, posterior, or central portion. When in front they are generally connected with disease of the naso-pharynx; when posteriorly, they are usually associated with suppuration in the mastoid cells, and are far less amenable to treatment. Central perforations are said by Dr. Burnett to be most frequently due to affections of the external auditory meatus; they are less serious, inasmuch as they improve under treatment, and are not attended with much impairment of hearing.

The importance of chronic suppuration in the upper tympanic spaces is largely due to the dangers attendant upon the continuance of the process, which may extend not only to the mastoid cells but also to the membranes and brain. A very thin layer of bone separates these spaces from the latter structures, and cerebral abscess is a not infrequent complication of suppurative processes in the "attic" and Prussak's space.

The **Course and Results** of chronic middle-ear suppuration exhibit many and great varieties in different cases. Not infrequently the suppuration ceases, the appearances of inflammation pass away, and the perforation either remains open or is closed by a cicatrix. Such closure may take place soon after suppuration has ceased, or not until many months have elapsed. The hearing-power may be either completely restored, or remain impaired in various degrees. When the opening is persistent, exacerbations of the process in the tympanum are very prone to occur, as a result of exposure to cold, recurrent catarrh of the naso-pharynx, the passage of foreign matters and even of cold water through the perforation, etc.

The course of the complaint is influenced by the general condition of the patient, the existence of complications in the meatus, mastoid process, and osseous walls of the tympanum, and the state of the nose and naso-pharynx. The course is also decidedly affected by the nature of the constitutional disorders (*e.g.*, tuberculosis, scarlet fever, and diphtheria) with which middle-ear suppuration is often associated.

The course of the complaint is generally tedious when the

tympanic cavity is occupied by granulations or polypoid growths, when the walls or ossicles are the seat of caries or necrosis, and when abscesses form in the neighbourhood of the ear.—Purulent exudation may find its way through the petro-mastoid and squamo-mastoid sutures, and pass between the cartilaginous and osseous portions of the meatus and through the fissures of Santorini towards the parotid gland. Pharyngeal abscesses are rare complications; they result from suppuration in the Eustachian tube. The cartilaginous portion is loosened from its connection with the osseous part, and the pus either burrows between the structures at the back of the naso-pharynx, or passes into the tissues of the soft palate. In very severe cases, the two portions of the tube are completely separated, and the pus is infiltrated into the side of the neck as well as between the structures of the pharynx. In children, pus from the tympanum may find its way through the Glaserian fissure to the parotid gland and adjacent structures.

Another serious cause of complications, tending to lengthen the duration of the disease, consists in the formation of adhesions between the membrane and various structures of the tympanic cavity. The parts may be closely applied to each other, or may be connected by bands or fibrils of false membrane. More or less impairment of hearing is the necessary result, and the cavity is liable to be divided into separate spaces, difficult of access, and in which suppuration may be prolonged for indefinite periods.

Complications threatening the life of the patient may arise in the course of chronic middle-ear suppuration. They result either from extension of morbid processes to the contents of the cranium, or from the constitutional effects of the local disease. Extensive caries of the walls of the tympanum is by no means necessary for their development; they may rapidly supervene upon conditions regarded as comparatively mild and unimportant. They will be fully described in a subsequent chapter.

Diagnosis.—The existence of chronic suppurative inflammation of the tympanum can generally be ascertained without any difficulty. There is, in the first place, a chronic purulent discharge from the ear; and secondly, a perforation in the membrane. The discharge may, however, have ceased, in which case a perforation or a cicatrix may be the only sign of the previous condition.

The diagnosis of a perforation is effected (1) by direct in-

spection; (2) indirectly, by inflation of the middle ear; by injection of fluids through the Eustachian tube; by the passage of water into the naso-pharynx after injection into the meatus.

(1) The appearance of a perforation, as seen from the meatus, has been fully described (*see* page 393). If the membrane be drawn inwards and in contact with the wall of the tympanum, it may be necessary to force it outwards in order to detect the opening. To effect this purpose, air may be injected into the tympanum through the Eustachian catheter, or Siegle's speculum may be used to rarefy the air in the meatus. Inflation of the cavity serves also to distinguish cases of total destruction of the membrane from instances in which relaxation of its tissue allows it to be drawn inwards and closely applied to the inner wall, so that the mucous lining becomes clearly visible. Very small, slit-like perforations are apt to be overlooked on inspection; they will, however, be detected on inflating the tympanum. Inspection alone may also be insufficient to detect a perforation situated near the periphery, in the anterior and inferior portion, as there is often a bulging out of the external auditory canal in this position. It is just necessary to mention that minute deposits of blackish cerumen or of epithelial débris on the membrane, and dark atrophic spots and cicatrices, may present appearances somewhat like those of a perforation. A careful examination after syringing, and, if necessary, inflation of the middle ear, will determine the real nature of the case. Greater difficulty will arise when the field of view is occupied by an uneven granulating surface, which may belong either to the tympanum or to the membrane. One of the methods about to be described should then be practised.

(2) Inflation of the middle ear, either by the aid of the Eustachian catheter or by Politzer's method, causes a whistling or hissing sound as the air passes through the perforation. The sound is most distinct when the opening is small, and may often be heard even without the use of the auscultation tube. It is much less distinct when the perforation is large and the air escapes freely. When the tympanic cavity contains fluid, bubbles will be formed by the injected air and a corresponding sound will be audible; on inspection, the fluid mingled with air will be seen to come through the opening. If the fluid be removed, and inflation be again practised, the reappearance of secretion will indicate a perforation. Minute air-bubbles sometimes appear as

dark globules in the deep part of the canal when the tympanum is inflated; these are certain signs that an opening exists in the membrane. Also, if the meatus be filled with warm water before inflation, the existence of a perforation will be demonstrated by the bubbles caused by the air escaping through the fluid. In some patients evidence of a perforation is yielded by the passage of tobacco-smoke from the throat into the meatus, and fluids injected into the latter canal sometimes pass into the pharynx, and even into the nose when the head is thrown forwards.

Another sign of a perforation is a pulsating movement in the secretion collected in the ear; it is most often noticed when the opening is small. The pulsating spots strongly reflect the light, and the movements consist in a rhythmical rising and falling or in lateral vibrations. They are due to the pulsations of the small arteries of the middle ear; the mucous membrane and the secretion which covers it rise and fall alternately. In very exceptional cases, similar movements are witnessed with an imperforate membrane, and it must be remembered that pulsation is sometimes observable in a deeply-seated abscess of the external meatus. It is possible that the pulsations of the carotid artery may be communicated to fluid accumulations within the tympanum.

Another method of detecting a perforation is to introduce a manometer into the meatus and then to inflate the tympanum; the fluid suddenly rises in the instrument. For this experiment to be successful, the Eustachian tube must be pervious to air, and the tympanum must be free from adhesions which would obstruct the passage of the current.

Prognosis.—This must always be guarded in cases of chronic middle-ear suppuration; the questions to be considered refer to the danger to life, the cessation of the discharge, and the improvement of the function of hearing. With regard to the first point, the risk of cranial complications must always be borne in mind, in spite of the fact that the vast majority of patients suffering from this disease never present any serious symptoms. A fatal result, however, may supervene when quite unexpected, and in an apparently simple case, with a history of otorrhœa of long duration. Under the influence of some external cause—*e.g.*, exposure to cold, a blow on the head, or an attack of naso-

pharyngeal catarrh—the process may suddenly become acute, and severe pain in the head, rigors, fever, delirium, convulsions, and coma indicate the course the disease has taken.

With regard to the cessation of the discharge, the prospect is generally favourable in persons otherwise healthy, when the perforation is small and situated in the lower part of the membrane, when the naso-pharynx is not seriously diseased, and the Eustachian tube is patent. On the other hand, the prognosis is unfavourable when the discharge has continued for a long time, and when such local changes exist in the tympanum as granulations, polypoid growths, caries, or necrosis of the osseous walls. Abscesses in adjacent parts are serious complications. An obstinate form of the disease and a chronic course may be expected when a small perforation exists in Shrapnell's membrane, and when the upper part of the tympanum is mainly involved in the suppuration. The prognosis is decidedly unfavourable in cases resulting from scarlet fever, diphtheria, tuberculosis, and syphilis. Stricture of the Eustachian tube impairs the prospect of recovery, and thickenings or exostoses in the external meatus not only prevent the escape of secretion, but constitute serious obstacles to proper treatment.

The prognosis as to improvement in the hearing-power depends upon various considerations. It is favourable when the impairment of function is comparatively slight, when adhesions are absent, and improvement is noticed after cleansing the part and using the air-douche, and when the tympanic mucous membrane gradually regains its normal appearance. In some cases hearing-power is lessened with the cessation of the discharge; in others, a favourable result is witnessed, and even when the perforation is extensive. Improvement is likely to follow the removal of polypi and granulations, blocking up an opening in the membrane. The closure of a perforation by a cicatrix is not necessarily accompanied by improvement of hearing-power; if the newly-formed tissue be either very elastic or very rigid, the hearing-power may be less than before. The prognosis is unfavourable when the loss of function is considerable, when bone-conduction is lessened, and subjective symptoms continue troublesome. Under these circumstances, disorder of the labyrinth may be inferred to exist. Rigidity of the fenestræ and of the joints of the ossicles is another probable condition, tending

still further to impede the conduction of sound and to increase the pressure upon the labyrinth.

Treatment.—Various measures are required for the satisfactory treatment of chronic middle-ear suppuration, the choice being determined by the nature of the symptoms and appearances. The first point to be attended to is the thorough removal of accumulated secretion and débris, which tend to promote suppuration and prevent the direct application of remedies to the diseased tissues. The middle ear may be cleansed in several ways. (1) Syringing through the external meatus in the ordinary way, or by the aid of a tube introduced through the perforation. (2) Inflation of the middle ear either by Politzer's method or by means of the Eustachian catheter, and in some cases by the injection of fluid remedies through the latter instrument. (3) Aspiration, with Siegle's pneumatic speculum. (4) Condensation of the air in the meatus. (5) Dry cleansing, by means of absorbent cotton-wool.

(1) The **Syringe** is used in the ordinary way, but especial care is necessary in making the first few injections. Very slight force must be employed, and if giddiness or pain be caused, the injections must be discontinued. When the discharge is free from odour, pure warm water will suffice, from eight to twelve ounces being used at each sitting, and the injections being repeated according to the amount of secretion. If the latter be very abundant, the ear should be thus cleansed three or four times daily. A little common salt or sodium sulphate (5 per cent.) may be dissolved in the water with advantage. Whenever the secretion is offensive, disinfectants or deodorants should be added to the fluid, and of these the most generally efficacious is carbolic acid (1—2 per cent.). Other disinfectants useful in the same class of cases are: permanganate of potassium (a 5 per cent. solution); boric acid (4 per cent.); salicylic acid (5j. of a 10 per cent. alcoholic solution to ℥xij. Aq.), and perchloride of mercury (1—2: 1,000). This last must be used with care, owing to the risk attendant upon its passage into the pharynx. Politzer states that when the discharge is profuse, obstinate, and blennorrhœic in character, very good results may be obtained by adding four or five drops of oil of turpentine to the eight ounces of water used for injection. Dr. Rohrer* strongly recommends a 10 per cent. solu-

* *Lehrbuch der Ohrenheilkunde*, S. 141. See also a paper by Dr. Dayton, of New York, *Archives of Otology*, vol. xiv. p. 6.

tion of peroxide of hydrogen as an antiseptic. Before using it, the meatus is to be thoroughly cleansed and dried with absorbent wool. The patient's head, with the affected side uppermost, is then made to rest on a pillow, and the solution is poured into the ear and allowed to remain for a few minutes. It is then removed and more fluid is poured in; this process is repeated until the solution when withdrawn appears clear. The meatus is then dried and plugged with cotton-wool.

Removal of accumulated secretion from the mastoid cells is attended with great difficulty. If there be reason to suspect that these parts are filled with inspissated matter, warm water should be poured into the ear while the patient is lying on his side, with his head on a pillow, and his face directed upwards. When the head is in this position the fluid tends to pass towards the mastoid cells and to soften the inspissated contents. After this method has been practised several times, foetid caseous masses will sometimes come away with the water used for syringing; and in all cases, after the ear has been cleansed by means of fluid applications, the head should be inclined to that side, and the meatus thoroughly dried with pieces of absorbent cotton-wool attached to a cotton holder, or introduced with suitable forceps.

If the perforation be very small, syringing in the ordinary way will produce little, if any, effect upon accumulated masses of secretion, especially if these be situated in the upper part of the tympanic cavity, or in the mastoid cells. For such cases it is necessary to employ a tympanic tube which directs the stream at a right angle to the meatus. Before using the irrigator, the meatus should be thoroughly cleansed by syringing, and it is well afterwards to render the *membrana tympani* and neighbouring parts less sensitive by the instillation of a few drops of a warm 10—20 per cent. solution of cocaine. The instrument* which I use (Fig. 98) consists of a tapering silver tube seven and a-half inches long, with a small aperture in its side close to the extremity of its lesser end. The larger end is connected by a piece of india-rubber tubing with a pipe which passes through a hole in the cork, almost to the bottom of the bottle which holds the solution to be injected. Through another hole in the cork passes a pipe, one end of which is above the fluid in the bottle, and connected to its other

* The instrument may be obtained from Messrs. Mayer & Meltzer, 71, Great Portland Street, London, W.

end is a piece of india-rubber tubing fitted with a mouth-piece. With this apparatus, the attic and entire cavity of the tympanum can be irrigated, and the force of the stream regulated by the expiratory effort employed. Most of the tympanic syringes hitherto in use are too large to pass through a small perforation, and they require an assistant to work them, as the surgeon's hands are occupied in holding the syringe and keeping the speculum in its proper position.

In order to introduce the irrigator, the ear is illuminated with the forehead-mirror, and a speculum is passed into the meatus and

FIG. 98.

THE AUTHOR'S TYMPANIC IRRIGATOR.

kept in position with the left hand. The tube, taken in the right hand, is passed carefully through the perforation, and kept in position by resting the hand against the patient's head. Whilst the water or solution is being injected the tube is turned from time to time, so as to direct the current towards various parts of the cavity. If no uncomfortable sensations be produced, the irrigation is to be continued as long as any fragments of inspissated secretion come away. As a matter of course, the greatest care and gentleness are requisite in carrying out this treatment. The fluid should be injected very gently at first, and the force should then be gradually increased. Plain water may be employed in this manner; but the addition of bicarbonate of sodium (gr. iv. to ʒj.) will increase its efficacy.

(2) **Inflation of the Middle Ear**, by Politzer's method, has the

effect of forcing out fluid secretion from the tympanum into the external meatus, and is of much value as a means of treatment in conjunction with syringing. The meatus should first be syringed, and then a Politzer's inflation given, after which some of the pus which was in the tympanum will be found forced out of that cavity. The ear should then be again syringed and another Politzer's inflation given, and these processes repeated alternately until the water which flows from the meatus is free from pus or mucus. The Eustachian catheter must be substituted for Politzer's method when the tube is blocked up by swelling and secretion, and when the cavity is filled with granulations and exudation products. Under such circumstances, the direct current of air is more efficacious than Politzer's method.

The Eustachian catheter may also be used for the injection of fluids into the middle ear. A large catheter should be selected, and its beak should be inserted as far as possible into the pharyngeal orifice. The fluid is injected by means of a syringe, the nozzle of which fits into the outer extremity of the catheter. Weak solutions of common salt ($\frac{3}{4}$ per cent.) or of boric acid (3 per cent.) are suitable for this purpose. The air-douche should be employed both before and after the injection of fluids. Air passing through the Eustachian tube acts especially upon the anterior part of the tympanic cavity; but has little influence upon secretion contained in the posterior recesses and in the mastoid cells. To cleanse these latter parts, Politzer's method requires to be supplemented by the use of the tympanic irrigator as above described.

When the perforation is very small, thorough cleansing of the cavity by any of these methods may be found impossible, and it will then be necessary to enlarge the perforation or to make a second opening. An incision is likewise indicated when the perforation becomes prematurely closed, in which case symptoms due to the retention of the discharge are apt to supervene. A slight enlargement of the opening will enable a tube to be introduced and facilitate the escape of secretion.

The operation is easily performed with the paracentesis needle. The incision should not exceed an eighth of an inch in length, and should be carried through any projecting portion of the membrane. A few drops of a warm 20 per cent. solution of cocaine should be previously instilled into the meatus, and allowed to remain there for several minutes. (*See page 139.*)

It is sometimes desirable to make a second opening in the tympanic membrane; the indications for this operation are as follows:—

(i.) In cases of perforation of Shrapnell's membrane, when there are signs of accumulation of secretion on the floor of the tympanum, the lower part of the membrane being yellowish, and bulged out.

(ii.) When the same appearances are noticed in any other portion of the membrane, at a distance from the perforation, and are accompanied by oft-recurring severe pain, and symptoms of constitutional disturbance. A second opening not only facilitates the escape of secretion, but it permits the introduction of tubes through which fluids can be injected into the cavity. Warm alcoholic solutions of boric acid and perchloride of mercury may be used in this manner, and Politzer states that very good effects may be obtained from a watery solution of the latter drug (1 : 1000) in cases in which the alcohol sets up irritation.

A much more severe kind of operation is recommended for cases in which the tympanum is broken up into several irregular spaces by polypous growths, and remedies fail to influence the course of the suppuration. The best plan to be pursued is to remove the remains of the membrane, together with the malleus and incus, thus converting the tympanum into a cavity with smooth walls, when the suppuration can be more easily dealt with. Repeated removals of portions of the membrane are necessary, in consequence of the tendency to new growth. Politzer recommends this operation in cases in which the remains of the perforated membrane are covered with polypous excrescences, and separated above, while the malleus is partly detached and very movable, rough and separated from the incus. Besides taking away the remains of the membrane, it is necessary to divide the tensor tendon, and to cut through the long process of the incus.

When obstinate suppuration is connected with caries of the head of the malleus, Schwartze recommends excision of the remains of the membrane and bone. The effect upon the suppuration is generally favourable; but the hearing-power is not much improved. Removal of the remainder of the membrane has been proposed in cases of perforation of Shrapnell's membrane, attended with very obstinate suppuration; but such cases can generally be cured by antiseptic injections introduced

through a suitable tube, as before described, with, if necessary, enlargement of the opening in an upward direction, and the removal of granulations and masses of epidermis. For both these latter operations a general anæsthetic is required.

(3) **Siegle's Pneumatic Speculum** may be used to withdraw purulent secretion from the tympanum in cases in which the Eustachian tube is impermeable, and when the recesses of the cavity are filled with fluids which are not removed by any of the means above described.

(4) **Condensation of Air in the Meatus.**—This is effected by means of Lucae's apparatus, which consists of an india-rubber bag, furnished with an olive-shaped nozzle, which is inserted into the meatus. When the bag is compressed, the air is driven through the perforation into the tympanum and thence into the Eustachian tube, carrying with it more or less fluid secretion. The current acts upon the anterior portion of the cavity and the tube. This plan of removing the secretion has been principally used for children, but it sometimes causes giddiness, and may be followed by more serious consequences.

Although this method has been often employed it cannot be recommended, as, even with the greatest care, mischief is liable to result from its use. Moreover, not only does it possess no advantage over other means of removing discharge from the tympanum, but it entails the positive disadvantage of forcing pus into the patient's throat instead of effecting its complete removal. Unless the perforation in the membrana tympani is small, the inlet to the tympanum is obviously greater than the outlet, and, as the meatus is plugged by the nozzle of the syringe, the fluid which cannot escape by the Eustachian tube is forced into the mastoid cells and attic, and by this means the mischief which already exists may be increased.

(5) **Cotton-Wool.**—Cleansing may to some extent be performed by means of absorbent cotton-wool, introduced on a holder or probe, or by means of suitable forceps (Fig. 99). This method is applicable to cases in which unpleasant symptoms are produced by syringing, and when the discharge is scanty and not offensive. It is insufficient for a thorough cleansing of the middle ear, and fails of course to effect the removal of inspissated matter from the recesses of the cavity. Cleansing with cotton-wool is especially useful as a supplement to fluid injections.

Antiseptic and Astringent Applications.—The methods above described are seldom sufficient to check the suppuration, and to induce a healthy condition of the tympanic mucous membrane. In most cases it is necessary to have recourse to remedies possessing antiseptic and astringent properties. Dr. Rohrer has shown that the fœtid character of the discharges in middle-ear suppuration is probably due to the presence of certain forms of bacteria, and there is therefore a rational basis for the use of antiseptics. Owing, however, to the position and the peculiarly complicated structure of the middle ear, it is impossible to apply antiseptics to every portion of it. Still, experience shows that the best results are obtained from the use of remedies of that character, and especially from boric acid, which was first recom-

FIG. 99.
WOOL FORCEPS.

mended by Dr. Bezold,* of Munich, in 1879. It may be employed either in solution, or as a fine powder, the latter being the more efficacious. It is applied in the following manner:—The meatus and tympanum are cleansed from secretion by syringing with warm water, and inflating by Politzer's method alternately as previously described (page 406), and then carefully dried by means of absorbent cotton-wool. The boric acid, reduced to a very fine powder, is then blown into the meatus, by means of an insufflator (Fig. 79, p. 254), or with a glass tube or portion of a quill, and a plug of cotton-wool is finally introduced into the meatus. I have long discarded the wool-holders in general use, which are roughened in order to allow the wool to be more firmly attached. This roughening is unnecessary, and, moreover,

* For an account of Bezold's more recent experience of this treatment, see *Archives of Otology*, vol. xvii. p. 77.

possesses the disadvantage of preventing the wool, when done with, from being easily removed. I employ a plain straight piece of silver wire about five inches long, and attach the wool in the following manner after it has been teased out. First place the end of the probe about the longitudinal centre of the piece of wool, then hold the proximal end of the wool to the probe with the right hand, whilst the probe is being twisted, and the wool pressed against the probe between the finger and thumb of the left hand. It will then be found to be firmly attached to the probe, and yet can be readily slipped off. The object of placing the end of the probe in the longitudinal centre of the wool is to ensure the distal half of the wool being soft by not being supported by the probe in its centre.

The frequency with which the powder should be used depends upon the amount of the discharge. If the latter be copious, the application must be repeated four or five times daily. Improvement is indicated by the lessening of the secretion, and when this is the case, a repetition of the treatment every second, third, or fourth day may be all that is necessary. In favourable cases, the discharge ceases after a few applications; but as a general rule the treatment has to be continued for several weeks, or even for some months. The deodorant and antiseptic effects of the powder are increased by the addition of carbolic acid (one drop to 15 grains), and when the discharge consists of stringy mucus, the addition of a few drops of oil of turpentine will prove advantageous (Politzer). Powdered boric acid occasionally causes irritation, in which case a warm saturated solution should be poured into the ear several times a day, and allowed to remain there for several minutes.

While this treatment is being carried out, the secretion should be frequently examined by the microscope, in order to discover whether any effect is being produced upon the development of micro-organisms. There is reason to believe that the presence of bacteria is the cause of the extension of the morbid process to the osseous walls and intracranial structures, and that antiseptic treatment is the best means of preventing such complications. If no decided improvement take place after the boric acid powder has been used for some weeks, a solution of the same drug in alcohol and water (Acid. Boric. \mathfrak{z} iiss.; Sp. Vin. Rect., Aq. Destill. aa. \mathfrak{z} j.), as recommended by Löwenberg, will sometimes produce

a good effect. Löwenberg's opinion* is to the effect that this solution often proves more efficacious than the powder, inasmuch as it comes into contact with the whole expanse of the mucous membrane, whereas the powder fails to reach the many recesses of the cavity. If granulations or polypi exist in the tympanum or meatus, they must first be attended to in the manner to be shortly described. There are some cases in which the application of boric acid seems to have little, if any effect, in checking the suppuration. (1) In tubercular disease, in which it may be presumed that the boric acid fails to prevent the development of the bacilli. (2) When the perforation is very minute: in such a case it is desirable slightly to enlarge the opening. (3) When the perforation is situated in Shrapnell's membrane, a saturated solution, introduced through the intra-tympanic tube, is likely to prove more efficacious than the powder. (4) The existence of carious or necrotic fragments of bone will maintain the suppuration, and neutralise the effects of the boric acid.

Other antiseptic remedies may be substituted if the treatment by boric acid prove unsuccessful. *Carbolic acid* may be used in various forms, *e.g.*, 1 : 10 of glycerine or olive oil, of which a few drops may be placed in the ear. If pain be caused, a weaker solution should be tried, *e.g.*, 1 : 15 of rectified spirit, and a like quantity of water: 15—20 drops to be warmed and instilled into the ear. Much irritation is, however, sometimes caused by carbolic acid. *Iodoform* is much employed by some surgeons, and is very highly spoken of by Dr. Barr, of Glasgow. He recommends that half a drachm be added to an ounce of spirit of wine, in which it is partly dissolved and partly suspended. After the mixture has been well shaken, fifteen drops are poured into the ear, and allowed to remain for fifteen minutes, after which the ear is dried with cotton-wool. Some of the spirit evaporates, and leaves a coating of iodoform on the diseased surface. Dr. Barr states that a few applications of this remedy have cured cases in which other treatment, persevered with for a whole year, had proved useless. It is especially suitable for cases of perforation of Shrapnell's membrane, and is most thoroughly applied by means of the tympanic tube. The disagreeable odour of the drug may be masked by the addition of a little tincture of Tonquin beans to the spirituous solution.

* Quoted by Knapp, *Archives of Otolaryngology*, vol. xi. p. 223.

or of one grain of coumarin to fifty of the powdered iodoform. The objection to this treatment, if long continued, is that the iodoform is liable to collect in the recesses of the tympanum, and remain there, as it is only sparingly soluble in water, and therefore does not become dissolved and absorbed. *Iodol* is another remedy of the same class; Politzer states that he has obtained very good results from an alcoholic solution (1 : 20). *Salicylic acid* is recommended by Burckhardt-Merian; it may be used either in an alcoholic (2—5 per cent.) or an aqueous solution (1 : 200). More or less irritation is apt to ensue when a strong solution is employed. A combination of salicylic and boric acids (1 to 10—15) is sometimes more efficacious than either used separately. *Perchloride of mercury* is another valuable antiseptic remedy and powerful germicide. It may be used in an aqueous solution (1 : 1000), of which 15—20 drops are to be instilled into the ear. A solution of similar strength, but made with equal parts of water and rectified spirit, is generally more efficacious, but it is apt to cause irritation. If no improvement be noticed after a fortnight's use of the perchloride, some other form of treatment should be adopted, and the same rule holds good with regard to the other remedies previously mentioned. It is necessary to be provided with a somewhat long list of remedial measures, inasmuch as the treatment which has proved successful in one case may be found almost useless in another. Rohrer strongly recommends a 10 per cent. solution of *peroxide of hydrogen* to be poured into the ear, and allowed to remain for some minutes. Dr. Brandeis,* of New York, states that he has found instillations of *boroglyceride* (a 10—50 per cent. solution) very useful in cases of otorrhœa. While the fluid is still in the meatus, he inflates the tympanum through the catheter, so that the air passes through the column of fluid. To complete the list of antiseptics used and recommended for the treatment of chronic middle-ear suppuration, it is necessary to mention *resorcin* (a 4 per cent. spirituous or aqueous solution); *thymol* (1 : 100); finely powdered (doubly sublimed) calomel by insufflation;† borax in solution, either alone or combined with 5 per cent. of salicylic acid; and permanganate of potassium (4 : 1000).

If treatment by boric acid and other antiseptics prove

* *Archives of Otology*, vol. xiii. p. 16.

† See a paper by Dr. Gottstein, of Breslau, *Archives of Otology*, vol. xiii. p. 284.

unavailing, other remedies must be tried. Caustics are often useful in obstinate cases, with extensive destruction of the tympanic membrane, muco-purulent secretion, and relaxation and swelling of the mucous lining. Chromic acid in solution (5 to 15 grains to the ounce) is very useful; or a strong solution of nitrate of silver (20 to 60 grains to the ounce) may be employed instead; but the latter must be used with certain precautions. The meatus in both cases must first be cleansed, and thoroughly dried. When nitrate of silver is used it is well to have a warm weak solution of common salt at hand. From 5 to 10 drops of the caustic solution, warmed, are dropped into the ear from a glass pipette, the patient lying down and with the affected ear directed upwards. The caustic may be allowed to remain for three or four minutes, after which water or the saline solution should be injected; but recourse must be had to this treatment immediately, if severe burning pain be experienced. The relief is generally immediate, but should the pain continue after the application of nitrate of silver, the ear should be syringed out with a weak solution of iodide of potassium. The meatus should then be carefully dried and plugged with cotton-wool.

The immediate result of the application of nitrate of silver is the formation of a white pellicle, which is sooner or later thrown off, exposing the red mucous membrane. In most cases, it will suffice to repeat the treatment every second day until seven or eight applications have been made. In cases in which the granulations are large and soft, and bleed freely when touched with a probe and when water is injected into the meatus, it is best to apply a saturated solution of chromic acid on a carrier (Fig. 82, page 257). When solid nitrate of silver is used, the caustic is fused in a porcelain crucible and the probe dipped into it. In touching the granulations, care must be taken to obtain a good view of the wall of the tympanum and of the remains of the membrana tympani. It will sometimes be found that a small ulcer exists in the deep part of the cavity, and that a few applications of the solid caustic will produce cicatrisation. To prevent excessive action, water or the saline solution should be injected, as before.

For cases similar to those just described, the application of rectified spirit of wine sometimes proves very advantageous. It is said to act by withdrawing water from the granulations. The

undiluted spirit is apt to cause severe pain and irritation, and therefore it should at first be diluted with an equal quantity of water. About 15 to 20 drops of this mixture are warmed and poured into the meatus, and allowed to remain for about a quarter of an hour. The fluid is then removed and the ear carefully dried. The application may be made daily, or every other day, the strength of the mixture being gradually increased, if little or no pain be experienced. Lessening of secretion and a paler tinge of the mucous membrane are indications that the alcohol is producing a beneficial effect. As holds good with regard to all other applications to the tympanic cavity, if the alcohol cause pain, headache, giddiness, or other uncomfortable sensations, its use must be discontinued. It often acts very satisfactorily, and has this advantage, that under proper precautions the patient or his friends may be intrusted with its use.

Astringents constitute a class of remedies which at one time were very generally used in the treatment of otorrhœa; their efficacy is far inferior to that of boric acid and other antiseptics. Those still occasionally employed are sulphate of zinc, sulphocarbonate of zinc, acetate of lead, acetate of zinc, alum, and sulphate of copper; they are applied either in solution or in the form of fine powders. Pain in the ear, or any other symptom indicative of an acute process, contra-indicates their employment, and all of them are liable to the objection that they form insoluble albuminates with the secretions in the tympanum. Alum is, perhaps, the most efficacious; but it should be reserved for cases of large perforation, and should not be tried until boric acid has been used without avail. Its use must not be intrusted to the patient, for the powder is apt to form a solid plug in the deep part of the meatus and thus to prevent the escape of secretion. It is also liable to irritate the integument of the auditory canal, and to cause much pain and even inflammation, which cannot fail to aggravate the original disease. When used, only a small quantity must be insufflated, and any of the powder which adheres to the skin of the meatus should be removed with a camel-hair brush. The application may be repeated when the coating formed by the alum appears moist: careful syringing and drying with cotton-wool should precede each insufflation. If no satisfactory result be obtained after six or eight applications, some other method of treatment must be adopted. Acetate of lead

(gr. iv.— ℥j.) is occasionally serviceable, and is the least irritating of this class of remedies. From 15 to 20 drops of this solution are made warm and instilled into the meatus, the patient's head being kept in a horizontal position. The solution is allowed to remain for about ten minutes, and then removed, and the application is to be repeated daily or every other day. Preparations of lead thus applied cause the mucous membrane of the tympanum to assume a dark-grey colour, and thus mask its real condition. In some cases the discharge becomes decidedly black or blackish, the change being due to the formation of the sulphide of lead, and indicating decomposition of the secretion. Under such circumstances, treatment by means of antiseptic remedies should at once be adopted. The preparations of zinc and copper are of comparatively little value in the treatment of chronic middle-ear suppuration. If used, they are applied in the form of solutions of the sulphate (gr. ii.—iv. to ℥j.) in the same manner as the acetate of lead. Dr. Knapp* recommends the sulpho-carbolate of zinc, 1 or 2 parts to 50 parts of alcohol and 50 parts of water.

When a large perforation exists and also in cases of otorrhœa with only a scanty discharge, Urbantschitsch† recommends the employment of gelatin bougies, containing such astringents as acetate of lead, tannin, sulphate of copper, sulphate of zinc, etc. He prefers these to solutions, but restricts their employment to the classes of cases above mentioned. Whenever the secretion is profuse, it is undesirable to create any obstacles to its free escape. Urbantschitsch reports very good results from mercurial preparations thus applied. He uses thin tablets, which can be cut into fine strips, and then passed through small perforations in the tympanic membrane.

Of all the methods of treatment which have just been described, that by boric acid will be found to be more generally suitable and successful than any other. If, however, after a thorough trial, continued for five or six weeks, little or no improvement result, another remedy should be tried, and the choice will usually lie between occasional applications of a solution of chromic acid or nitrate of silver (either in substance or solution), and daily treatment by rectified spirit of wine (either alone or

* *Archives of Otology*, vol. xi. p. 222.

† *Lehrbuch der Ohrenheilkunde*, III. Aufl. S. 323.

combined with boric acid). It is often necessary to try several remedies in succession until a satisfactory result is obtained; and in some cases success is achieved only by a combination of remedies. Thus after boric acid and caustics have failed when separately employed, a cure will result from insufflations of the former drug after application of the nitrate of silver.

In all cases of chronic middle-ear suppuration, the greatest importance must be attached to constitutional treatment and attention to hygienic measures of all kinds; and the condition of the naso-pharynx must be carefully and repeatedly examined, and means adopted to remove any abnormal condition. It is useless to apply remedies to the tympanic cavity, if a chronic nasopharyngeal catarrh, the source of the aural complaint, remains unchecked. So likewise in cases of constitutional disease, *e.g.*, syphilis or scrofula, unless general treatment be superadded to the local measures, a good result can scarcely be expected. Conditions of general debility and of anæmia will also require attention; iron, quinine, nourishing food, cod-liver oil, fresh air, change of air to the sea-side, baths, and hygienic measures of all kinds are often indispensable adjuncts to any method of local treatment.

In order to complete this description of the treatment of chronic otorrhœa, it is necessary to refer to certain measures whereby the hearing-power may often be improved. These are: (1) Inflation of the middle ear; (2) rarefaction of air in the meatus; (3) the adaptation of an artificial tympanic membrane; (4) operations of various kinds. Of these only the two first will now be referred to; the others will be more appropriately discussed in the next chapter.

1. Politzer's method is best adapted for the inflation of the middle ear in these cases; it should be employed twice or three times a week, and continued during four or five weeks after the discharge has ceased, unless its employment is likely to break down a cicatrix which is forming or one which has formed across the perforation which previously existed. In this case, an Eustachian catheter should be used, the injecting force being merely sufficient to enable the air to enter the tympanum. If the discharge is more than slight, or even then does not quickly disappear, the combination of Politzer's inflation with syringing for the purpose of thoroughly cleansing the middle ear, as before described, should not be neglected.

2. Rarefaction of the air in the meatus is not only useful in the secretory stage, when the tube is impervious, and in cases of circumscribed suppuration in the tympanum, but it likewise tends to improve the hearing-power, after all discharge has ceased. Improvement, though only of a temporary character, has been observed even in cases of adhesion of the tympanic membrane with the joint between the incus and stapes, when inflation through the tube was without effect (Politzer). Rarefaction of the air in the meatus, with either Siegle's or Delstanche's (Fig. 100) instrument, is always worthy of trial.

It would appear, from certain facts that have come under the author's notice, that persons suffering from chronic suppurative

FIG. 100.

DELSTANCHE'S MASSEUR.

inflammation of the middle ear may be a source of danger to others. A medical practitioner, thus affected, attended several women during their confinements. Intervals of several weeks elapsed between the attendances; but all the women were attacked by puerperal fever. No cause could be discovered, and the medical man was led to suspect that the discharge from his own ear had produced the mischief, and he ceased to attend cases of midwifery. Granted that his suspicions were well founded, it is probable that the poison was conveyed by his fingers, and the question must arise as to whether a practitioner or nurse suffering from chronic suppuration of the middle ear is justified in attending cases of midwifery, and likewise surgical cases requiring the application of dressings, etc.

CHAPTER XXIX.

CHANGES IN THE MEMBRANA TYMPANI IN VARIOUS
AFFECTIONS OF THE EAR.

Cicatrization—Persistent Perforation of the Tympanic Membrane—Appearances and Consequences—Artificial Substitutes—Method of Determining Effect of Closing a Perforation—Treatment of Perforations—Attempts to Produce Cicatrization—Myringo-Plastic Operations—Artificial Tympanic Membrane—Appliances devised by Yearsley, Toynbee, Gruber, Hartmann, and others—Rules to be Adopted—*Modus Operandi* of such Appliances—Indications for Employment of Artificial Membranes—Calcareous Deposits in the Membrana Tympani—Appearances—Symptoms and Treatment—Thickening of the Tympanic Membrane—Atrophic Processes in the Membrane—Adhesions between the Membrane and the Wall of the Tympanum.

It seems desirable to give a connected account of those various abnormal conditions of the tympanic membrane which result from affections of the middle ear, and most frequently from suppurative inflammation. These conditions may be considered under the following heads: (1) cicatrization; (2) persistent perforation; (3) calcareous formations; and (4) adhesions between the membrane and other structures of the tympanum.

(1) **Cicatrization.**—Solutions of continuity of the membrana tympani, in the form of small slits and attended only by slight and transient inflammation, may unite directly by simple union. But under different circumstances, when the opening is large, and retraction or destruction of the membrana propria has taken place, healing becomes possible only with the formation of a cicatrix. In this latter process, the membrana propria takes no share; the new tissue is formed by proliferation of the epithelial and connective tissue cells of the cutaneous and mucous layers. The cicatrix,

therefore, consists of a delicate layer of connective tissue, coated externally by a thin epidermis, and internally by a single stratum of the flat epithelium-cells of the membrana tympani. The cicatrix is therefore thinner than the normal membrane; when illuminated with the mirror it is seen to be more transparent than the adjacent part, and is bright or dark according as it approaches the inner wall of the tympanum or is withdrawn from it. As a general rule, its lessened thickness causes it to be somewhat below the level of the rest of the membrane. The fibres of the membrana propria frequently terminate at the margin of the cicatrix, as if cut off abruptly; but sometimes they are bent upon themselves and run for some little distance in an opposite direction. Occasionally it is possible to detect in the middle of a cicatrix an oval pearl-like mass of epithelium, covered with a layer of epidermis.

With regard to the *colour* of cicatrices of the tympanic membrane, when small and situated opposite the promontory they are clearer than those which are found in the anterior inferior quadrant. A depressed cicatrix, which is near to the wall of the tympanum, may be of a light-brown colour. Cicatrices are always more highly tinted than the adjacent parts of the membrane, and the difference is often increased by the whitish colouration of the latter portions.

Cicatrices in the membrana tympani are for the most part well defined; sometimes there is a decided reflex of light, of varying form and dimensions. A sharply-defined border is, however, sometimes noticed as bounding small atrophic spots on the membrane; but when a history of otorrhœa is forthcoming, there can be little doubt as to the nature of the case.

Cicatrices of the membrana tympani vary in *size*, for large perforations are as capable of closure as small ones. They are most often seen in the lower half of the membrane; their form varies according to that of the original orifice. In many cases they appear as sac-like depressions and involutions of the membrane; in other cases their inner surface is connected, either directly or by strands of connective tissue, with the wall of the tympanum or the ossicles, and especially with the long process of the incus and the head of the stapes. Large cicatrices, owing to their transparency, often allow the inner wall of the tympanum to be clearly seen, and, in many cases, are so closely applied to this part, that the appearance is that of total loss of

the membrane. As the result of atrophy and diminished resistance, the entire membrane, or certain parts of it, become much relaxed, and move freely under the influence of variations of pressure. These movements are visible if the ear be examined during expiration and inspiration, during swallowing movements, and especially when air is forced into the tympanum by Valsalva's method, or with the aid of the catheter. As a general rule, during inspiration the membrane moves towards the tympanic cavity, and in the opposite direction during expiration.

During inspiration, the air in the naso-pharynx becomes momentarily rarefied, and this action is reinforced by the effect of the air-current upon the pharyngeal opening of the tube. The air is thus drawn towards the throat, and the diminution of pressure in the tympanum causes the membrane to be drawn inwards. When expiration follows, the air in the naso-pharynx is condensed, and this effect is transmitted through the Eustachian tube, so that the membrane is again forced outwards.

During the act of swallowing, the relaxed portion of the membrane moves slightly but rapidly inwards, then more decidedly outwards towards the meatus and then again inwards. As the tube is opened by the act of swallowing, the air passes from the middle ear to the throat, and hence the short movement occurs in an inward direction. The movements outwards and then inwards are consequent upon the condensation and rarefaction respectively of the air in the middle ear caused by the elevation and depression of the pharynx and base of the tongue.

When air is artificially forced into the tympanum, the relaxed portions of the membrane either become slightly convex or bulge out like little sacs or bladders; if the relaxed portion or cicatrix involve the greater part or the whole of the membrane, it becomes distended, like the belly of a sail. If the pressure be sufficient, the relaxed part may give way, when a loud noise is heard and the patient complains of pain. On examining with the speculum an opening is seen, varying in size, but with retracted border, marked with recent extravasation of blood.

When Siegle's speculum is used, the cicatrix or atrophied portion of the membrane, unless adherent to the inner wall of the tympanum, moves to and fro, in accordance with the alternations of pressure in the meatus.

Pulsating movements are sometimes observed ; these arise in the arteries of the inner wall of the tympanum, and are communicated either directly to the closely applied and relaxed portion of the tympanic membrane, or through serous exudation in the cavity.

It must be remembered that a perforation sometimes undergoes only partial cicatrisation. When the opening is large, membranous formation may be confined to one part, so that perforation and cicatrisation coexist. In large perforations in the neighbourhood of the umbo, the end of the handle of the malleus is not always included in the cicatrix, but projects behind it into the tympanic cavity, attached, if at all, to the membrane, only by strands of connective tissue. When this is the case, the condition of the parts can usually be made out by the aid of Siegle's speculum.

It seldom happens that cicatrices in the tympanic membrane give rise to any symptoms appreciable by the patient. When, however, they are large and much relaxed, and when they are drawn inwards and adherent, the patient may complain of noises in the ears and more or less deafness. Less frequently there is a sensation of fluttering or undue movement in the ears, noticed especially during inspiration and expiration.

Cicatrices in the membrana tympani rarely demand any kind of treatment. Something may be done, however, for the relief of deafness associated with relaxed and indrawn cicatrices. For such a condition Politzer recommends multiple incisions, either parallel or crossing each other. These, on healing, sometimes produce thickening with increased resistance, and consequent diminution of the symptoms. As a temporary measure, for the relief of symptoms dependent upon an indrawn cicatrix of the membrane, the air-douche may be tried with advantage ; but the frequent employment of this method, and still more, of Valsalva's plan, is likely to cause undue relaxation and mobility of the cicatrix.

(2) **Persistent Perforation of the Membrana Tympani.**—As a result of long-continued or repeated attacks of suppuration in the middle ear, a large perforation of a permanent character sometimes ensues. A certain amount of contraction may take place, but an aperture remains, the margin of which is usually thickened, owing to increase of connective tissue and

calcareous deposit, which often gives it a whitish tint. The epidermis of the membrana tympani is continued over the margin of the opening to its inner border, and sometimes covers the greater portion of the internal surface, and may extend even to the walls of the cavity.

The *shape* of the opening varies in different cases; its most common seat is the lower half of the membrane. Sometimes two perforations co-exist, one in the anterior and the other in the

posterior inferior segment; these are separated from each other by the handle of the malleus and by a narrow strip of the original tissue extending from the extremity of the bone towards the periphery. Sometimes the loss of substance involves the larger part of the membrane, only a narrow border being left at the circumference (Fig. 102). The portion that remains is often more or less dull, either thickened or atrophied, and coated with calcareous deposit (Fig. 104). It seldom happens that the membrane is totally wanting. According to the position and size of the

perforation, various structures contained in the middle ear are more or less freely exposed to view (*see* Figs. 101, 102, 103, 104, and 106).

Other appearances and consequences depend upon the size and position of the opening. Cases are often met with in which, notwithstanding very considerable loss of substance, the hearing-power is relatively good. It may, therefore, be inferred that marked loss of function, when present, is largely due to impediments to conduction connected with the ossicles, or to obstruction of the fenestræ. Pathological changes of this kind are due to the disease which caused the perforation, and those most often met with are: retraction of the handle of the malleus,

FIG. 104.

FIG. 105.

THE RIGHT EAR of a girl, aged 24 years, who had chronic suppurative inflammation. There is a perforation in the posterior segment, through which can be seen the tip of the long process of the incus and the head of the stapes. A patch of calcareous deposit occupies the greater portion of the anterior segment.

Fig. 105. THE LEFT EAR of the same patient, showing a large patch of calcareous deposit.

FIG. 106.

THE RIGHT EAR of a woman, aged 31 years, showing a perforation in the posterior segment, through which can be seen the stapes, which has become disarticulated from the incus, and its head in consequence has dropped downwards. There has been also a perforation in front of the short process of the malleus, but adhesions have formed between its edge and the deeper parts.

sometimes to such an extent as to cause the bone to become adherent to the inner wall; adhesive processes between the latter part and the margin of the perforation; ankylosis, displacements and exfoliation of the ossicles. More important as regards their influence on the hearing-power are formations of connective tissue and calcareous deposits in the fenestræ. The existence of a perforation in the membrana tympani favours the access of micro-organisms and other sources of mischief, and hence increases the liability to recurrences of attacks of inflammation.

It sometimes happens that even large perforations, after remaining quiescent for several years, suddenly begin to diminish

in size, and eventually are covered in by cicatrices. This process has been observed to take place under the influence of a slight attack of inflammation, and its occurrence has stimulated the desire to produce a similar result by artificial means.

Before proceeding to describe the various methods of forming an artificial membrana tympani, it is well to consider the difficulties that have to be overcome and the prospects of success. As already stated, the question whether the hearing-power will be improved by the closure of a perforation and the production of a cicatrix must depend upon the condition of the other portions of the sound-conducting apparatus. If the condition of the malleus or incus constituted a permanent obstacle to the conduction of sound, the formation of a cicatrix would tend only to impair the hearing-power. Sonorous undulations which passed through the perforation direct to the foot-plate of the stapes, would, after the development of a cicatrix, be communicated to the malleus and incus, and their intensity would be diminished by the obstacle therein existing. Politzer has suggested a method of determining whether the closure of a perforation would have any effect upon the hearing-power. The amount existing in an ear in which the membrane is perforated is determined by careful examination: the opening is then closed by a drop of glycerine or a small piece of paper, and the hearing is again tested. If the sounds be less distinctly heard, an obstacle to conduction, connected with the malleus or incus, may be inferred to exist.

As a general rule, perforations of the tympanic membrane with relatively good hearing-power are best left alone. When, however, the defect is bilateral and a marked degree of deafness co-exists, it becomes desirable to take steps to close the opening. The good effects of such an alteration are sometimes very evident; their discovery was first made by patients themselves, the subjects of perforation, who found their hearing-power improved when a roll of paper was passed deeply into the meatus for the purpose of removing secretion. Politzer states that the use of an artificial membrana tympani was known as far back as 1640.* It was, however, only about the middle of the present century that the plan became used by a few aural surgeons, and notably by Yearsley, Erhard, and Toynbee. Before describing the various

* Marcus Banzer, *Disputatio de Auditione Læsa*, 1640 (cited by Politzer, S. 346).

appliances used by them and their successors, reference will be made to the plans adopted with the view of causing the openings to close.

One simple plan is that of stimulating the edges of a perforation by applying nitrate of silver. The caustic is fused, and a small portion is then taken up on the head of a probe, or a piece of cotton-wool twisted tightly on to a probe and moistened with a strong solution of the same drug, may be applied to the edges of the opening. With small perforations this plan sometimes proves successful, but it involves the risk of setting up too much irritation, with suppuration and enlargement of the opening as probable results. The same drawbacks are associated with the use of the galvano-cautery, or the knife, for the removal of tissue at the edge of the perforation. This plan is spoken well of by Gruber,* who also recommends for small perforations numerous incisions $\frac{1}{2}$ —1mm. in length, made quite close to one another, and at right angles to the margin of the perforation. The operation causes only slight pain and hæmorrhage. Gruber states that small perforations, even of long standing, treated in this way, often close up, and larger ones diminish in size. The experience of other surgeons is, however, less favourable. In some cases of dry perforation, division of the tensor tympani tendon is followed by partial or complete closure of the opening; and removal of the malleus, when the handle seems foreshortened, reinforces the effect of the operation on the tendon.

Many attempts have been made to utilise portions of skin and various membranes in order to cover up the perforation, but hitherto without any decided amount of success. The first surgeon to perform this myringoplastic operation was Prof. Berthold,† of Königsberg. He first applied a piece of court plaster (which was allowed to remain for three days) in order to remove the epidermis. He then detached a portion of skin from the patient's forearm and applied it to the opening, the edges of which it overlapped. The external meatus was afterwards plugged with cotton-wool. Subsequently Berthold used a portion of egg-membrane for the same purpose. A very fine glass-pipette, bent at an angle of 125° , and fitted with an ordinary piece of india-rubber tubing, closed at the further end, was used for the introduction. The mouth of the

* *Lehrbuch der Ohrenheilkunde*, II. Aufl. S. 362.

† *Tagebl. d. 51. Versammlung Deutscher Naturforscher und Aerzte*, Cassel, 1878.

pipette was dipped in white of egg, and a small piece of the egg-membrane aspirated on to it with the moist inner surface outermost. The membrane adheres to the mouth of the pipette, and can thus be conveniently trimmed into shape. It is then conveyed to the required position on the tympanic membrane, to which it is made to adhere by compressing the india-rubber tube. It soon becomes closely united with the edge of the perforation, and it may remain for weeks or months, but the effect is never permanent.

Since 1888 Berthold* has returned to his first plan of utilising the integument, but he applies it not to the remains of the tympanic membrane, but to the mucous membrane. After suppuration has ceased, and he has loosened any adhesions between the edge of the perforation and the opposite wall of the tympanum, he places on the granulating mucous surface of the promontory a piece of skin precisely the size of the perforation, and of a thickness equal to the distance between the margin of the latter and the inner tympanic wall. The piece of skin fits into the margin of the perforation, as a watch glass into the groove of the rim. The granulating mucous membrane affords the material for the nourishment of the transplanted skin, whilst the latter is tied down to the edges of the perforation by the secretion which oozes out. Transplantation with human skin proved successful, in Berthold's hands, in closing over the largest perforations, and even in cases in which the tympanic membrane had been completely destroyed. One drawback connected with this method is due to the uncertainty as to whether union will take place, and the difficulty of selecting the proper time for the operation. If the mucous membrane were still secreting, the continuance of the suppuration would almost certainly prevent adhesion. If, on the other hand, suppuration had ceased, the mucous membrane would have a coating of epithelium, which would prove an obstacle to union. Moreover, in the hands of some surgeons, this method, although successful so far as regarded closure of the perforation, resulted in more or less diminution of hearing-power.

The Artificial Tympanic Membrane.—As already stated, an English surgeon, Mr. Yearsley, was the first to call attention to the improvement in hearing, which can sometimes be produced by applying a little plug of cotton-wool over a perforation in the

* *Archives of Otology*, vol. xx, p. 371.

tympanic membrane (Figs. 107, 108). Since his time many attempts have been made to discover more efficacious contrivances, and a considerable amount of success has been attained. The objects aimed at and the modes in which the various appliances act differ to some extent in character. By some the vibrating surface of the membrane is increased, if not restored to its original amount, while at the same time pressure is exercised on the remains of the membrane and the ossicles connected therewith. If also the handle of the malleus be much drawn inwards,

pressure upon the short process overcomes this condition and causes a movement of the ossicles in an outward direction.

Not long after Yearsley advocated the cotton plug, Toynbee devised an artificial drum, consisting of a disk of vulcanite india-rubber, 6—7mm. in diameter. Attached to its middle is a piece of silver wire, about $1\frac{1}{4}$ inches in length (Fig. 109). The disk is cut to fit the meatus, and, when moistened, is easily introduced by taking the free end of the wire between the fingers, drawing the auricle

backwards and upwards, and then pushing the disk along the meatus until it meets with resistance. In some patients, however, the wire handle causes uncomfortable sensations or irritation in the meatus, and it may become detached, hence a thread has been used instead of the wire (Fig. 110), and various modifications of Toynbee's appliance have been suggested. In place of the wire, Lucae has a fine india-rubber tube connected with the disk, and insertion is effected by the aid of a probe filling the tube. Gruber* has designed a somewhat elaborate but effective apparatus, by means of which the patient can construct the artificial membrane. The apparatus consists of a vulcanite case containing needles, silk thread, and a suitable sheet of gutta-percha tissue. The end of the case contains a punch, corresponding to the size and shape of the normal tympanic membrane. By this instrument a disk is punched out of the gutta-percha and threaded with silk through the centre. A simple instrument is employed for the introduction of the artificial membrane. It is a piece of wire curved round to form a small ring, which is bent at a right angle to the shank. The other end is bent to form a larger ring. To insert the disk, the thread is passed through the small ring and along the wire, being kept in contact with this by the finger. When the disk has been properly adjusted in its place, the thread is released and the wire is withdrawn. A pair of bent forceps may also be used for the introduction of the artificial membrane. Linen, silk, or paper may be used in place of the gutta-percha. Dr. Katz† recommends a thin pellicle of celloidin (celloid 10, alcohol and ether aa. 50); this is applied by means of a plug of wool dipped in the solution.

Another convenient contrivance is that devised by Dr. Hartmann.‡ It consists of a small portion of cotton-wool, twisted into a round ball and continued into a thin process, around which a thread is carried: the whole is impregnated with a solution of wax. Delstanche has devised an equally simple contrivance. He takes a small piece of soft wire, which he bends at one end. Around this wire the cotton-wool is wrapped in such a way as to form a little ball at the end, while the rest of the wire is covered only with a thin layer of wadding. Politzer has suggested

* *Lehrbuch der Ohrenheilkunde*, S. 364.

† *Deutsche Med. Woch.*, 1889, Nr. 28.

‡ *Diseases of the Ear*, English Translation of 3rd Edit. p. 118.

a more durable contrivance. This consists of a piece, half a centimetre long, cut from the side of an india-rubber tube 2—3mm. thick, the lower end is perforated and fixed to a moderately strong wire. Good results can also be obtained from the introduction of a piece of india-rubber tubing, adapted to the length of the meatus, and having its inner extremity either rounded off or cut obliquely. The same authority recommends another contrivance, viz., a combination of Toynbee's membrane with a stapes bone, taken from a dead body, for cases in which the crura have been destroyed by erosion, and only the base of the bone is present in the fenestra ovalis. The ossicle is fastened by thread to the india-rubber plate, and, when introduced, is directed towards the niche of the fenestra ovalis. The waves of sound are conveyed from the disk to the foot-plate of the stapes, and thence to the labyrinth.

It would seem that on the whole the best substitute for the natural tympanic membrane is a cotton-ball or pellet impregnated with boric acid, salicylic acid, or thymol, and then moistened with diluted glycerine (1 : 4 Aq.). It is well to attach a piece of thread to the pellet, so that it may be easily removed. Cotton-wool causes little, if any, irritation, and has the further advantage of absorbing secretions. In some cases two or three layers of lint, cut to the requisite size and shape, answer better than the pellet of cotton-wool. It must be remembered that different appliances are suitable for different patients, and it is therefore well to be provided with several forms.

Any form of artificial substitute for the membrana tympani requires renewal, and should generally be removed at night; it is, therefore, well to teach the patient the method of application. After a little instruction, the task will be found very simple; the patients soon find out the best position for the pellet and the exact amount of pressure which renders it effective. During the introduction, the external meatus must be straightened by drawing the auricle outwards and backwards. The pellet is grasped by a pair of forceps, and pushed to the bottom of the meatus with an inclination slightly forwards.

As a general rule, it is necessary that the parts should become gradually accustomed to the presence of any artificial substitute for the tympanic membrane. More or less irritation may be caused not only to the remains of the membrane and the tym-

panum, but to the structures of the labyrinth, and this result must be as far as possible avoided. For this purpose, the pellet should at first be worn only for an hour or two and then removed, and this practice must be pursued for several days, increasing the time until the pellet can be worn during the daytime. The pellet should be removed on the appearance of any sign of irritation. In some cases, the best plan is to let the patient wear it only when conversation becomes necessary.

With regard to the *modus operandi* of these appliances, Toynbee thought that the resonance of the tympanic cavity was restored by the rubber disk; but, against this view, it must be remembered that the perforation is not always closed by the disk, and certainly not occluded by a cotton-wool pellet, the effect of which is often considerable. Erhard considered that the effect was due to the pressure upon the remains of the membrane and the handle of the malleus, or upon the stapes if separated from the incus. His idea was that the bones, whose articulations had been loosened, were thus held closely together, with improvement of sound-conduction as the result. Alteration in the intra-labyrinthine pressure has also been suggested as an explanation. According to another view, pressure upon the short process of the malleus acts upon the ossicular chain, which, previously drawn inwards, is restored to a more natural position. In all probability these causes frequently co-operate, their influence varying in degree in different cases.

The employment of an artificial membrane is indicated when the perforation is accompanied by marked deafness on both sides, and when the inflammatory swelling of the remains of the membrane and of the mucous lining of the cavity and the suppuration have been reduced to a minimum. The appliance sometimes proves beneficial in cases in which the membrane is intact; the deafness, which is the prominent symptom, is momentarily improved by pressure upon the short process. When perforation exists only on one side, and the hearing-function is good on the other, an artificial membrane may be worn as a protection against the ingress of foreign bodies, though its good effects may be outweighed by the irritation it causes. The size of the perforation does not influence the results of the appliance, which, however, often acts remarkably well when the opening is large and the stapes exposed and freely movable.

The question whether the artificial appliance will prove useful in any given case, even if the external conditions appear favourable, can be determined only by repeated experiments. These should be conducted in the following manner: any exudation should be removed either by means of cotton-wool or by syringing. When the parts have been thoroughly dried, the hearing-power for speech should be tested. The artificial membrane is then introduced as previously directed, and the test is again applied. If the rubber disk be used, it should be of such a size and form as to overlap the margin of the opening; and before introduction it should be moistened with warm water, glycerine, or some antiseptic solution.

In some cases, the introduction of the appliance is followed by no alteration of hearing-power, but by pain and noises in the ear. Under such circumstances, it is well to alter the position of the artificial membrane or to try other appliances, until a different result is obtained. It sometimes happens that the patient is able, after a little instruction, to adjust the appliance and to make it act satisfactorily. When this result has been achieved, the improvement in the hearing-power is often very considerable; *e.g.*, a patient who previously could hear spoken words perhaps at no greater distance than 15 or 20 inches, can now hear a whisper uttered 6—10 yards off. Such an improvement is, however, impossible if the ossicles, and especially the stapes, have been rendered all but immovable by adhesions. Apparent improvement in bone-conduction sometimes results from the use of one of these appliances.

After having tried several forms of artificial membrane, that one which causes the most improvement should be selected for use. If there still be any discharge from the ear, a pellet of cotton-wool, which can be impregnated with some antiseptic fluid, will be found the most suitable appliance. In all cases, should any signs of inflammation appear, the appliance must be disused for a few days, during which boric acid should be employed by insufflation. In some cases the application of an artificial tympanic membrane, though not materially improving the hearing-power, decidedly alleviates the subjective sensations, and is a source of great comfort to the patient.

(3) **Calcareous Deposits in the Tympanic Membrane.**

—Calcareous deposits are frequent results of various affections of

the tympanic membrane, *e.g.*, of inflammation, with or without the formation of abscesses, of middle-ear catarrh, and of chronic purulent inflammation. When resulting from this last complaint, they are usually associated with cicatrices or persistent perforations (Figs. 104, 111). Their presence indicates previous infiltration, the result of inflammatory processes. The deposited matters have not been absorbed, but have undergone calcareous metamorphosis, in which amorphous calcium phosphate has been formed with more or less pigment. In some deposits the calcium phosphate takes the form of crystals.

These calcareous deposits occur as patches varying in size, either isolated or collected together, so as to form more or less crescentic masses in the substance of the tympanic membrane; they are greyish-white, like chalk, or perhaps somewhat yellowish in colour. The margin towards the periphery is usually smooth, whereas the concavity, towards the umbo, is often

FIG. 111.

THE RIGHT TYMPANIC MEMBRANE of a man, aged 21 years, the subject of chronic middle-ear catarrh, with a large patch of calcareous deposit in the anterior and lower part of the membrane.

irregularly serrate or dentate. When thick they cause the internal surface of the membrane to become uneven, as if some fluid plaster had been poured over it and had set irregularly. If, on the other hand, the calcareous masses are nearer the external surface, they form little elevations thereon, like those on a map in relief. Between the calcareous portions and the handle of the malleus, and likewise between the former and the circumference, the membrane is generally normal in character, and capable of executing vibrations. It very rarely happens that the entire structure is infiltrated, stiffened, and unyielding, as a result of calcareous deposit. Sometimes small calcareous patches are found scattered about in cicatrices; they are probably developed from infiltration resulting from recurrence of inflammation in the part. In very rare instances osseous deposits are found in the membrane.

Once formed, these calcareous deposits remain permanent;

if inflammation of the membrane takes place, and the external layer becomes relaxed and injected, the patches appear larger, yellowish-red in colour, and more deeply imbedded in the surrounding parts. After the process has subsided, the deposits resume their former appearance.

There are no special subjective symptoms connected with these calcareous patches on the tympanic membrane. The deafness and noises in the ears, not infrequently present, are probably due to changes in the deeper parts. When, however, the greater portion of the membrane is occupied by calcareous deposits, its elasticity and capacity for vibration will be much impaired, with diminution of hearing-power as a direct result.

It seldom happens that any treatment is required for calcareous deposits in the tympanic membrane. The removal of such patches may cause inflammation, and can only be followed by cicatricial formation, by which the hearing-power will be still more impaired. Operative interference is, however, justifiable when the entire membrane is affected by the deposit, provided that the stapes be movable, and bone-conduction be little, if at all, impaired. Under such circumstances, improvement may be effected by excising the tympanic membrane and the malleus. Medical treatment, whether local or general, has no effect on such deposits.

Thickening of the Tympanic Membrane.—This condition, which is by no means infrequent, is distinguished from calcareous deposit by the fact that the diseased portions are not so clearly circumscribed, and are less white in tint. The thickening is due to increased volume of tissue, either epithelial or connective, or to deposit of molecular detritus; it may affect any layer of the membrane, or all of them to the same extent; it is apt to be most marked in the membrana propria, and it may be either diffused or limited to certain spots or zones.

The thickening more or less modifies the transparency of the membrane, and causes it to become cloudy; the affected spots have a whitish, milky, or tendinous appearance. This change sometimes causes a whitish semi-circle to be distinguishable; it begins at the short process, and passes downwards and backwards, and thence into the anterior inferior quadrant. In other cases, it forms a complete circle. In old persons, the lower half of the membrane is sometimes thus marked.

Opacity of the tympanic membrane is not infrequently caused by new formations of connective tissue within the cavity. These take the form of bands or false membranes, extending from the tympanic walls or ossicles to the internal surface of the membrana tympani, and the opacities they cause vary in size according to their form and the extent of surface to which they are attached. In all such conditions, the lustre of the membrane and the reflection of light may remain unchanged; it is only when the epidermis of the cutis is insufficiently illuminated (as in young children) or much increased (as in old persons) that the external surface of the membrane has a dull, lustreless appearance.

Permanent opacities of the tympanic membrane have to be distinguished from similar appearances due to the presence of morbid products within the cavity, such as accompany the various catarrhal and inflammatory affections already described. The history of the case, and the fact that the opacity is confined to or most marked in the lower part of the tympanic membrane, and undergoes various alterations when the tympanum is inflated, will serve to distinguish the two conditions.

It remains to add a few words on an opposite condition of the membrana tympani, viz., loss of substance, which sometimes occurs in patches, either alone, or while thickenings exist in other portions of the membrane. The change principally affects the membrana propria, the fibres of which, once destroyed, are not renewed. The nutritive disorder which produces this result may be of a subacute inflammatory character, with infiltration as a consequence; or it may be attendant upon abnormal conditions of pressure and tension, the effects upon the membrane being the degeneration of its fibres, molecular disintegration, fatty changes, and absorption. Atrophy is the ultimate result, and the affected portions of the membrane are therefore thinner and less resistant. If the wasting process be of a more rapid character, and attended with exudation into the tissue of the membrane and softening, the process is apt to involve all the layers, and perforation is the necessary consequence.

In atrophic processes, such as those just described, only small islets of the membrane may be affected, or the greater portion thereof may be involved, and between the two extremes there are many intermediate degrees. The atrophied portions are more

transparent, have a darker look, and are below the level of the adjacent parts. They are darker, because when light impinges upon them only a smaller portion is reflected, the greater part being transmitted. The inner wall of the tympanum is not, however, a good reflecting surface, and therefore less light reaches the eye; this diminished reflection causes the atrophied spots to appear darker, as compared with the parts immediately surrounding them. The alteration in the level of the affected spots and their depressed position are due to the absence of the *membrana propria*. Hence they offer less resistance to the pressure of the atmosphere and become concave. Such circumscribed, dark, and depressed spots may be mistaken for perforations. A similar mistake may also be made when the whole membrane is in a marked state of atrophy, so that the inner wall of the tympanum becomes clearly visible.

The movements of these atrophied spots during the respiratory acts and under the influence of the air-douche are the same with those that take place in relaxed cicatrices under similar circumstances (*see* page 420).

(4) **Adhesions between the Membrane and the Inner Wall of the Tympanum.**—These are a frequent result of chronic middle-ear suppuration: the remains of the membrane, the margin of the perforation or the cicatrix itself become adherent to the wall or to the contents of the cavity. In the majority of cases union takes place between the central portion of the membrane and the promontory, or between the posterior superior quadrant and the long process of the incus. Small cicatrices rarely become thus adherent; but in exceptional cases, the upper and posterior part of the membrane is found attached to the articulation between the incus and stapes. Adhesions of any kind are generally formed during the continuance of the secretion. When they are complete, the discharge sometimes ceases altogether; but suppuration may continue in certain portions of the tympanum and come to a standstill in others.

Adhesions between the membrane and the inner wall of the tympanum, or the long process of the incus, are for the most part easily diagnosed. When either the air-douche is used or the air in the meatus is rarefied by means of Siegle's speculum, the adherent portions appear to be still more depressed. Before the air-douche is employed, the membrane, as seen from the meatus,

is decidedly drawn inwards, while the handle of the malleus is displaced in the same direction, and drawn more or less forwards or backwards in different cases. Sometimes it lies horizontally across the upper part of the cavity. When the membrane is adherent to the promontory, the attached portion appears as a yellowish disk with an indistinct margin. The attachment may be either direct, or by means of connective tissue; in the latter case the depression is less marked, and the spot is opaque and whitish, rather than yellowish in colour. Adhesion between the long process of the incus and the membrane appears as a yellowish-white streak, and when the malleus is connected by bands with the lower extremity of the incus, a patch of the same tint can sometimes be recognised.

The appearances as just described alter considerably after air has been injected into the tympanum. If the adhesion be sufficiently close effectually to resist the force of the air, no change will be noticed in the appearance of the spot itself, but the membrane at the circumference will be forced more or less outwards, and will reflect the light differently. If the result of the injection be to separate the membrane from its attachment and to break up adhesions, the abnormal concavity will to a great extent disappear, and a reddish tint may be noticeable, due to escape of blood from ruptured vessels.

Politzer recommends that a probe should be used to assist in the diagnosis of adhesions. If any portions of the membrane fail to move when air is injected or when Siegle's speculum is used, and a firm osseous basis can be felt with the probe, it may be inferred that the cicatrix is directly connected with the bony wall. It must, however, be remembered that thickened and calcified portions of the membrane will appear, when touched, as hard as bone.

The manner in which light is reflected also serves to guide the diagnosis. When the lower portion of the membrane is adherent to the inner wall of the tympanum, the normal cone of light is decidedly enlarged. When the posterior segment of the membrane is adherent, the light is reflected from a triangular spot, the apex of which corresponds with the extremity of the handle of the malleus, while the base is towards the promontory. If this cone of light remain unaltered when the membrane is forced outwards by the air-douche, there can be no doubt as to the existence of adhesions.

When the membrane is attached by connective tissue to the inner wall, and is, therefore, somewhat movable, the diagnosis becomes more difficult. Inflation of the tympanum may, in such a case, cause the membrane to bulge outwards and produce a decided change in the reflection of the light, but, unless the movement be somewhat considerable, there will be no marked depression corresponding with the adherent spot. Appearances similar to those caused by adhesions may also be due to increased tension of portions of the membrane. When air is forced into the tympanum, such portions, being more resistant to pressure, remain below the surface of the membrane generally, as is the case with adhesions. When this condition is noticed and the depressed spot is at the same time opaque, the question whether adhesions exist will be very difficult to determine.

The adhesions which are formed between various portions of the tympanum are liable to produce great alterations in the condition of the cavity. The latter is often divided into irregular spaces, either communicating with or shut off from each other; and the opening into the Eustachian tube and into the mastoid antrum may be completely occluded by false membrane. Spaces of this kind, formed in the tympanum and shut off from the air, become filled with epithelial debris and particles of cholestearin. As a matter of course, the size of the cavity is much reduced by the connective-tissue formations, which not only extend across it, but sometimes fill up the depressions so as completely to obliterate them. As a further result, the bands and layers of connective tissue sometimes become ossified or indurated from calcareous deposits, and produce ankylosis of the ossicles and rigidity of the fenestra rotunda, with serious impairment of hearing-power as a necessary result.

In these cases of adherent cicatrices of the membrana tympani, the degree in which the hearing-power is affected varies with the condition of the ossicles and fenestræ. The impairment is least in those cases in which only that part of the membrane which is below the handle of the malleus is adherent to the inner wall. When, however, the upper portion is affected and the handle of the malleus is drawn inwards and united with the promontory, and the incus and stapes are adherent to the membrane, the obstacles to the conduction of sound will necessarily be very great. Some compensation occurs in those cases in which the stapes,

though separated from the incus, becomes adherent to the membrane; sound is then conducted from the latter to the bone in contact with it.

Treatment of Adhesions.—When the hearing-power is decidedly impaired, and no improvement results from inflation and other methods already described, division of the adherent tissues may prove successful. Obstinate subjective sensations are also sometimes relieved by operations of this kind, which are, however, contra-indicated when bone-conduction is lost or considerably diminished.

The indications for operative treatment are by no means clearly defined; they are summed up as follows by Politzer, who has operated repeatedly with a fair amount of success:—

(1) When adhesions exist between the membrana tympani and the inner wall; when the surface of the former is marked by irregular depressions and bar-like ridges, while the ossicles are immovable and the hearing-power is much impaired. The condition of the membrane remains unchanged when the air is rarefied in the meatus. Under such circumstances, the operation consists in dividing the ridges at right angles to their course; one or two incisions are made with a small knife rounded off at its extremity, and are carried down to the promontory. Politzer states that he obtained favourable results in cases in which band-like ridges extended between the handle of the malleus and the articulation between the incus and stapes. The edges of the incisions are apt to unite soon after the operation, the result of which is sometimes permanent, but sometimes temporary.

(2) When the lower end of the handle of the malleus is united with the wall of the promontory, so that the incus and stapes are drawn inwards, there is serious impairment of hearing, which may, however, be relieved by several incisions, made at right angles, into the cicatricial tissue, near the extremity of the handle of the malleus. The operation will prove useless, if the latter bone and the incus be imbedded in connective tissue. If, in such cases, the articulation between the stapes and incus be exposed, and the condition be improved when pressure is made with a probe, the inference may be drawn that the adherence of the malleus to the promontory keeps the remaining ossicles in a tense condition. To remedy this, and to release the stapes, Politzer divides the long

process of the incus by means of a pair of small scissors, having blades 4mm. long and $1\frac{1}{2}$ mm. wide. One blade is fixed, while the other moves with a lever action. The scissors, fitted into an appropriately curved handle, with the blades closed, are passed in a horizontal direction towards the long process of the incus, and then opened, pushed forward, and closed. After the operation, in order to prevent union, a probe is used to push the upper end of the bone backwards and upwards; some amount of force is necessary for this purpose. The position of the bone cannot be altered when there is much connective tissue in the upper tympanic spaces, or when there is ankylosis of the incus.

(3) When the movements of the stapes are interfered with by fibrous connective tissue in the posterior superior quadrant of the promontory, and in the pelvis ovalis. In these cases, a horizontal incision is carried below the head of the stapes, dividing the cicatricial tissue and releasing the bone to some extent. If little or no improvement result, another incision should be made, parallel to the former, but above the head of the stapes. If the tendon of the stapedius muscle be imbedded in the cicatricial tissue in the niche of the fenestra ovalis, and is visible on the surface of the cicatrix as a whitish band, extending backwards from the head of the stapes, an incision through the new tissue will include the tendon, and it should be carried at right angles to its course. Other methods are required for cases in which no opening exists in the tympanic membrane, but its tissue is so changed as to allow bands of false membrane to be visible through it, and no alteration is produced either by the air-douche or by aspiration. If an operation be decided upon, the first step is to make an opening in the membrane with a paracentesis needle close to the spot, where the band appears to be attached. A tenotome, suitably curved near its apex, is passed through this opening, and the band is then divided. Wreden's instrument consists of a lancet-headed needle, bent close to its apex nearly to a right angle, and having a very sharp edge all round. The needle is attached to a handle, and can be fixed in any position by means of a screw-arrangement.

Separation is usually attended with great difficulties when portions of the membrane are closely applied to the inner wall and firmly adherent. The method of operating is to make an

incision just outside the margin of the adherent spot, and then to introduce a curved needle terminating in a flattened extremity, resembling a very small sharp spoon. An American surgeon, Dr. Prout,* divides adhesions between the membrane and the promontory with a very small iridectomy knife, having a long handle. He allows the adherent portion to remain, and thus establishes a permanent opening in the membrane. In a case thus treated, hearing-power for the voice was much improved by the operation. "A year afterwards, the opening in the membrane remained of the original size; the cavity of the tympanum was dry; the watch was heard when pressed upon the auricle—before the operation it was not heard at all—ordinary conversation was readily heard at the distance of twenty feet." Chronic suppurative inflammation was the result in another case.

Dr. H. Schwartze† maintains that in the large majority of cases, the operations above referred to have proved unsuccessful. Antiseptic precautions render them almost, if not altogether, free from danger; but the improved hearing-power obtained in the most favourable cases is, for the most part, transient. Adhesion again takes place, and the deafness and subjective sensations exhibit no change. The best results are witnessed after the division of tight cord-like bands, whose insertion into the membrane or handle of the malleus is distinctly visible through the former structure. Adhesions between the promontory and the malleus are especially suitable for operation. Should reunion take place, complete excision of the malleus is the only method of treatment likely to prove successful.

CHAPTER XXX.

CONSEQUENCES AND SEQUELÆ OF CHRONIC MIDDLE-EAR SUPPURATION.

Formation of Cholesteatomatous Masses in the Tympanic Cavities—The Growth of Polypi—Caries and Necrosis of the Temporal Bone—Extension of Inflammation to the Mastoid Process and Cells—Cholesteatoma of the Tympanum, Nature and Pathology—Virchow's Views—Theories Advanced by Tröltsch, Habermann, and Politzer—Symptoms and Consequences—Diagnosis—Prognosis—Treatment.

IN the account, given in a previous chapter, of chronic middle-ear suppuration, reference was made to the fact that the disease is very prone to lead to further consequences and changes, some of which affect particularly the structures of the organ of hearing, while others involve various parts more or less closely connected therewith. In this and in three succeeding chapters, a description will be given of those consequences which may be included in the first category; in subsequent pages, those which belong to the second will be duly considered.

The principal consequences and sequelæ which implicate the organ of hearing are four in number, and will be described in the following order: (1) The formation of cholesteatomatous masses in the tympanic cavities. (2) The growth of polypi. (3) Caries and necrosis of the osseous walls of the ear and other parts of the temporal bone. (4) Extension of inflammation to the mastoid process and cells.

CHOLESTEATOMA OF THE EAR.

Nature and Pathology.—As a result of chronic purulent inflammation of the middle ear, soft masses are sometimes found to occupy the tympanum and the mastoid cells. Owing to the fact that such masses contain cholesterine and fatty materials, the term *cholesteatoma* has been generally applied to them. This name was introduced by J. Müller more than fifty years ago: he regarded the masses as tumours, without blood-vessels, encapsulated by a thin membrane, and composed of cellular elements, arranged in layers. The cholesterine found between the layers of these pearly-white tumours was considered as essential and characteristic, and as distinguishing them from other fatty growths.

Virchow's view of the nature of these masses is altogether different. He regards them as epithelial neoplasms, made up of polygonal, flat, non-nucleated epidermoid cells, with cholesterine crystals lying between them. Whether occurring in the temporal bone or elsewhere, they are *heteroplastic* formations, and in this respect differ from atheroma. They are most common in the temporal bone, and especially in the upper and outer portion of the tympanic cavity towards the cells of the mastoid process, the *recessus epitympanicus* (or the *aditus ad antrum*). At first the growth is entirely inclosed in the bone, and it may continue thus limited; but it often distends the bony cavity, causes absorption, and finally perforates the bone into the tympanum, or the external auditory canal, or reaches the surface of the mastoid process, or breaks into the middle or posterior cranial fossa. The absorption of the bone may cause no symptoms, but inflammatory processes are apt to arise, the bone becoming carious and the neoplasm undergoing more or less disintegration. As results of extension of inflammation, the membrane or canal may be perforated and otorrhœa may set in. If the growth extend towards the cranium, it may induce phlebitis of the lateral sinus, with thrombosis, meningitis, or cerebritis.

An entirely different view of the origin of these masses has been put forth by v. Tröltsch* and others. They are regarded as epithelial accumulations, in which the cells have been transformed from the cylindrical to the flattened kind, the change being the result of pressure exercised by the inspissated and degenerated

* *Archiv f. Ohrenheilkunde*, vol. iv. p. 97.

pus cells, or of injurious influences acting through the perforated membrane.

According to Prof. Habermann,* whose views have been adopted by Politzer, the formation of cholesteatoma is due to the growth and development of the epidermis of the external meatus or of the membrana tympani, and the occupation by such growth of the spaces of the middle ear. During chronic inflammation of the lining membrane of the tympanum, there is active proliferation of the epidermis of the membrana tympani and of the adjacent portion of the meatus. This process not infrequently extends over the margin of a perforation to the ulcerated mucous membrane of the middle ear, and thus not only the tympanum, but the mastoid antrum becomes coated with epidermis, and then, if the inflammation ceases, healing takes place. If, however, the process continue, and be accompanied by more active proliferation of the cells of the Malpighian layer, these latter will enormously increase, and the horny layers will become detached and removed through the meatus. Should removal not take place, the cells (accumulating in layers for the most part concentric) will form masses corresponding in size and shape to the spaces they occupy, and such masses constitute a cholesteatoma.

According to this view, a cholesteatoma represents a sac-like growth of the epidermis of the membrane or of the meatus into the middle ear, and it is to be observed that from a mass of this kind, sac-like prolongations may branch off and occupy spaces near at hand. Habermann† gives a drawing of a cholesteatoma of the mastoid antrum, formed by the growth of epidermis in the vicinity of the *membrana flaccida*. From the primary formation, a branch extended and filled the space between the malleus and the incus on the one side, and the inner wall of the cavity on the other. A large strip of its external surface is covered by cylindrical epithelium. These lateral prolongations are probably due to the development of plug-shaped portions from the Malpighian layer, which then become hardened in their centres—a process similar to that which sometimes occurs in polypoid growths. The so-called “epithelial pearls,” sometimes formed on the membrana tympani, and on cicatrices after perforation, have a similar origin.

* *Archiv f. Ohrenheilkunde*, vol. xxvii. p. 42.

† Dr. H. Schwartz's *Handbuch der Ohrenheilkunde*, S. 257.

There are, therefore, two principal theories as to the origin of cholesteatomata in the middle ear. Virchow believes them to be always true *heteroplastic* formations. Other authorities believe that they become developed in the course of chronic suppuration in the middle ear from epidermis, which has extended therein from the perforated membrane or the external auditory canal, and which has slowly and continually kept shedding its horny layer, thus forming a stratified mass.

Cholesteatomata, made up of concentric lamellæ, appear to be destitute of a membranous capsule, differing in this respect from true pearly tumours. The spaces, however, which they occupy, are usually lined by a delicate, shining membrane.

Symptoms and Consequences.—The presence of these masses in the cavities of the middle ear may be attended with very serious results. Owing to their peculiar structure, they are especially liable to be acted upon and increased in size by the infiltration of fluid matters, and they are, moreover, constantly growing by additions from without. The slight but continuous pressure on the walls of the cavities tends to cause atrophy and even loss of substance and the formation of gaps. Openings may thus be formed into the large vascular channels, and into the cavity of the skull. When the mastoid cells are occupied by cholesteatoma, openings may form in the posterior wall of the meatus, or prolongation of the growth may take place into the "attic," and thence through Shrapnell's membrane. In some cases, the masses undergo decomposition, with pyæmia or suppuration within the cranium as results. Micro-organisms are invariably present, and all the conditions are favourable to their growth and development. The formation of cholesteatoma is most often observed in scrofulous and tuberculous subjects, who are especially prone to suffer from chronic suppurative disorders of the middle ear.

Cholesteatomatous formations may continue for some time in a quiescent state, without causing any very marked symptoms. Sooner or later, however, they will produce more or less deafness, tinnitus, and discomfort in the ear. Febrile symptoms, due to retention of purulent discharge, giddiness, and vomiting are not infrequently superadded. The severity of the symptoms is increased from time to time, owing doubtless to swelling of the masses. This result is sometimes witnessed after syringing the ear.

Diagnosis.—The nature of the case can be positively deter-

mined only when cholesteatomatous masses are visible in the meatus or tympanum, or when fragments of the same are removed by syringing. Characteristic portions can occasionally be removed with a probe or scoop. It sometimes happens in these cases that the examination is rendered very difficult by swelling of the posterior and upper wall of the meatus, to such a degree as to occlude a large portion of the canal. A good light and the greatest care are necessary during the examination. When the growth occupies the mastoid antrum and cells, there are often signs of inflammatory irritation and swelling of the adjacent parts.

The **Prognosis** is always more or less grave, by reason of the danger that exists of the growth breaking through the bony walls and setting up mischief in important structures. The formation of cholesteatoma may go on for some time without causing any decided symptoms. Retention of purulent matters is indicated by pain in the head, great tenderness of the parts about the ear, rigors, giddiness, fever, and vomiting. Openings may form in various directions, *e.g.*, into the external meatus, through the posterior wall; externally, through the mastoid portion; into the labyrinth, the lateral sinus, or into the middle or posterior fossa. Of these possibilities, an external opening is the only favourable course. Pyæmia, meningitis, or cerebral abscess may be set up in the event of implication of other portions of the temporal bone. The prognosis is decidedly influenced by the degree of facility with which the removal of fragments and disinfection of the cavity can be effected. So long as any portion remains there is danger of infection, which is reinforced by the tendency to fresh formations.

Treatment.—This consists in the removal of the mass and the application of antiseptic and other remedies to the cavities it occupied. When the tympanic membrane has been completely destroyed, it may be possible to remove the entire growth with the aid of a blunt hook. Fragments and detached portions are difficult to deal with, but sometimes they can be drawn out by means of the forceps. If they cannot be reached from the meatus, careful syringing or irrigation should be practised, with the aid, if necessary, of the tympanic irrigator (Fig. 98, page 405). After these attempts the parts should be thoroughly dried, and subsequently dusted over with iodoform. Any existing granulations or polypoid growths should be carefully removed or otherwise

treated. So long as these remain reaccumulation is certain to take place. If the opening in the membrane be so small as to prevent the escape of débris, it should be carefully enlarged with the paracentesis knife. If an opening has formed in the wall of the meatus or of the mastoid process, removal of portions of the mass may be thence effected. Should head-symptoms supervene, the proper treatment is to open the mastoid process and to scrape away the contents of the mastoid antrum. The same operation is indicated* whenever there are signs of inflammation in the mastoid region, and when there is persistent and foetid otorrhœa. It may, indeed, as Dr. Bezold points out, be necessary to repeat the operation. Excision of the malleus and incus, both of which are often more or less carious, has been performed with success in cases of cholesteatoma. Bezold recommends the subsequent insufflation of boric acid. He considers that an etiological relation probably exists between catarrh of the tubes, perforation of Shrapnell's membrane, and cholesteatomatous formations. The development of these latter may therefore be prevented by the adoption of Politzer's method of inflating the middle ear, and by the removal of adenoid growths from the naso-pharynx.

There is another way of acting upon these accumulated masses, viz., by injecting fluids through the Eustachian tube into the tympanum, and this plan is especially useful in cases in which any obstructions exist in the meatus. Rapid injection is to be avoided, inasmuch as it is liable to cause giddiness, pain, and various other symptoms. When carefully performed great quantities of accumulations can sometimes thus be removed from the tympanum, and the immediate results of their removal are often very satisfactory. Not only is relief obtained from such symptoms as pain, headache, feelings of pressure, fulness, etc., but far more serious manifestations—*e.g.*, giddiness, vomiting, rigors, and facial paralysis—may completely subside. After thorough cleansing and drying the ear, it is well to instil a few drops of alcohol from time to time, as little diluted as can be borne, with the view of checking epithelial desquamation. Such patients should, however, be frequently seen by the surgeon, so that proper steps may be taken to prevent recurrence of accumulations.

CHAPTER XXXI.

POLYPI OF THE EAR.

Classification of Polypoid Growths—Mucous Polypi or Granulation Tumours—Fibrous Polypi—Angio-Fibromata—Myxomata—Relative Frequency of Various Forms—Etiology—Chronic Middle-Ear Suppuration—Sex and Age—Seat of Origin—Number of Polypi—The Pedicle—Size and General Conformation of Aural Polypi—Symptoms, Subjective and Objective—Consequences which may Result—Development and Progress of the Growths—Diagnosis—Polypi of the Tympanum, with the Membrane Intact—Treatment—Operative and by Application of Remedies—Removal by the Snare—Politzer's Knife—The Use of Scoops and Crushing Forceps—The Galvano-Cautery—Caustic and Astringent Applications—Acids—Alcohol, Cases for which Adapted—Acetate of Lead.

POLYPI and polypoid growths are frequently found in the tympanic cavity and external meatus. Considered with regard to their structure, these growths may be divided into three, or perhaps four, classes, and designated as *mucous polypi*, also termed round-celled polypi or granulation tumours, *fibromata* and *myxomata*. Some of the fibromatous growths are extremely vascular, and hence have been named *angio-fibromata*.

The **Mucous Polypi** or **Granulation Tumours** are those which most often occur. They consist of a delicate fundamental tissue, between the fibrils of which are imbedded many cells, mostly round, but some oval and spindle-shaped (Fig. 112). These growths are freely supplied with vessels, and they sometimes contain cysts and gland-like formations. The depressions and fissures on the surface are due to the inward proliferation and disintegration of epithelial cells, and to the same cause may be attributed some of the gland-like formations which often extend more or less deeply into the growths. In other instances

these formations are due to hyperplasia of glands normally occurring in the meatus; the mucous membrane of the tympanum does not contain glands. The small cysts, also common, are the result of retention of glandular secretion. In rare cases the polypus is made up of a single cyst containing fluid.

The surface of the polypi is often stained with blood owing to their vascularity and the size of their capillary vessels. These form loops under the surface; the largest vessels are to be found in the stalk of the polypus, whence they give off many branches.

The **Fibrous Polypi** which usually grow from the periosteum are firm and resistant to pressure; on section they are paler and less vascular than those just described. According to

FIG. 112.

GRANULATION POLYPUS. $\times 200$.

Moos and Steinbrügge,* blood-vessels are only indirectly connected with the development of the fibromata, whereas they take a direct part in that of the angio-fibromata. Formative cells which have wandered from the blood-vessels are the source of fibromata; these give rise to spindle-cells, and these again to connective tissue fibres, which predominate in the stroma of the tumour and give it its peculiar appearance (Figs. 113 and 114).

Angio-Fibromata begin as granulation tumours, and are the result of proliferation of the elements of the vascular walls. The cells of the *tunica adventitia* also proliferate, and thus produce a network of cellular strands. The same process takes place in the endothelium, and the vascular walls increase in thickness, sometimes to such an extent that many of the vessels become

* *Archives of Otology*, vol. xi. No. 4.

obliterated. The elements of the cellular strands become transformed into spindle-shaped cells, and these again into connective

tissue fibres (Fig. 115). The structure of such a tumour resembles that of a cylindroma, or angio-sarcoma, but the latter is distinguished by the facts that the neighbouring tissues are prone to be invaded, and that secondary growths are often seen.

Myxomata.—Aural polypi belonging to this class are very rare. They consist of gelatinous connective tissue, having its cells and fibrils separated and inter-penetrated by a transparent fluid (Fig. 116). It is supposed that they are developed from some remains of those mucous tissues which had outlasted foetal life.

FIG. 115.

ANGIO-FIBROMATOUS POLYPUS. $\times 25$.
(From a Patient, aged 20.)

With regard to the relative frequency of these four classes of polypi, Moos and Steinbrügge's tables show the following proportions:—

Granulation tumours	55
Angio-fibromata	27
Fibromata	14
Myxomata	4
						—
						100

Aural polypi often present certain peculiarities of structure.

Thus, small cholesteatomatous masses may be found in the centre of the growths, and likewise extravasations of blood, blood-corpuscles, and blood-pigment, with hæmin crystals. Minute bony formations are sometimes noticeable.

Etiology.—The formation of aural polypi is in many cases traceable to *chronic suppurative inflammation of the tympanum*, which is often associated with hypertrophy of connective tissue. They occur in about 11 per cent. of these cases. Purulent secre-

FIG. 116.

MYXOMATOUS, FIBRO-MYXOMATOUS OR MUCOUS POLYPUS. $\times 300$.
(From a Patient, aged 25.)

tion acts as an irritant; its influence is shown by the fact that polypi in cases of suppuration diminish in size, and often disappear, as the latter subsides under treatment. In Moos and Steinbrügge's series of 100 cases, otorrhœa was absent in only one instance. Polypi are often associated with external indications of scrofula, and in such cases are prone to re-appear after removal. *Local affections* in the ear, such as circumscribed *caries* or *necrosis* of the walls of the tympanum, are apt to give rise to polypoid growths,

which subside when the osseous disease is cured. Polypi of the meatus, besides being caused by local affections, are sometimes due to irritative processes in the middle ear, without perforation of the tympanum.

In some cases of aural polypi the etiology is obscure, and no history of suppuration or previous mischief can be obtained. It is probable that the real cause is often forgotten, owing to the interval that has elapsed between its occurrence and the manifestation of the growth, and to the inattention of the patient. In 10 per cent. of Moos and Steinbrügge's cases the formation of aural polypi could be ascribed to scarlatina; and in 6 to other infectious diseases.

With regard to the *sex of the patients*, these polypi are more common in males than in females, perhaps because the former are more often exposed to sources of irritation. Out of 100 cases noticed by the above-named authors, there were sixty-six males and twenty-seven females, and seven not noted.

Aural polypi are *most frequent during the second decade of life*. The ages of the patients just referred to may be tabulated thus:—

Between 1 and 10 years	12 cases
„ 10 „ 20 „	36 „
„ 20 „ 30 „	23 „
„ 30 „ 40 „	9 „
„ 40 „ 50 „	9 „
„ 50 „ 60 „	1 „
„ 60 „ 70 „	4 „
Unknown	6 „

A few cases of congenital aural polypus have been placed on record.

In the majority of cases (68 per cent.) aural polypi originate in the tympanic cavity, and from its internal and superior walls and the tissue covering the ossicles; in 25 per cent. the tumours are attached to the walls of the meatus. The pedicle is connected with the superficial layer either of the cutis or of the mucous membrane, or may be more deeply attached, and even to the bone itself. Polypi are sometimes, though rarely, connected with the membrana tympani, and they have been found on both sides of that structure. In cases of perforation of the membrane, minute polypoid growths are sometimes seen to spring from the margins

of the aperture. The tympanic orifice of the Eustachian tube is the occasional seat of polypous formations.

Polypi are usually single, but multiple growths are found in about 19 per cent. of all cases. In those already alluded to the multiple polypi occurred sometimes in the meatus alone, in a few cases in the tympanum alone, and six times in both places simultaneously.

The *pedicles* or *stalks* of aural polypi vary in length and thickness; in some cases the growths are sessile, and consist of minute lobules attached to a common base. The pedicle is sometimes branched, each branch supporting a head, and it may contain one or more cavities resembling cysts. Nerve-filaments are found in the pedicles, but not in the heads of the polypi. Sometimes a polypus is attached to its base by several roots, and it not infrequently happens that a growth becomes attached at various points to the surrounding parts, and thus additional pedicles are formed. Small excrescences not infrequently surround the point to which the root is fixed. In some cases polypi spring from the mastoid cells, and appear in the external meatus after the posterior and superior walls of the canal have been destroyed.

Aural polypi vary considerably in *size*; sometimes they are very minute, and only just perceptible; sometimes they fill up both tympanum and meatus, and protrude from the latter (*see* Fig. 117). In the majority of cases which come before the surgeon the growths are as large as, or larger than, a pea. In some cases of suppurative inflammation of the tympanum, the growth of polypi is exceedingly rapid, and may be watched from day to day.

The *surface* of the granulation tumours or mucous polypi is generally much indented and lobulated, like that of a raspberry. In the case of large growths, the depressions are apt to be obliterated as a result of pressure, and the surface becomes smooth and glistening. In fibrous polypi, depressions are generally absent, and the surface is rounded and smooth. In most cases there is a Malpighian investing membrane, with its horny layer; the epithelium towards the root is either cylindrical or ciliated, but over the body of the polypus is generally tessellated and composed of several layers. The mechanical conditions of the growths have an important influence upon the amount and character of the epithelial covering.

Symptoms.—These may be classified as subjective and objective. With regard to subjective symptoms, they may be altogether absent in the case of small polypi, or masked by those of some previous affection. Otorrhœa is always present, and in cases of large polypi not a few serious symptoms may result from the obstacles thus opposed to the free escape of the discharge. Besides deafness and subjective auditory sensations, the patients may complain of headache, vertigo, vomiting, supra-orbital neuralgia, and clonic spasms in the extremities of the affected side. Ptosis and hemianæsthesia have also been observed, and in a few

FIG. 117.

A FIBROUS POLYPUS removed by the Author from a boy, aged 14 years. The triple appearance before removal was due to the lobulated shape of the outer extremity of the growth.

cases epileptiform attacks accompanied the disorder in the ear. In all these instances the cerebral symptoms disappeared when the hindrance to the escape of pus was removed.

The **Objective Symptoms** depend upon the situation, progress, and size of the growth. Besides purulent discharge hæmorrhage is almost always present, and when the polypus is a large one, a red growth, either smooth or more or less lobulated, may be seen to occupy the external meatus. In the large majority of cases, viz., in about 80 per cent., the membrana tympani is found to be either perforated or destroyed. This fact "shows that the

prime cause of the formation of polypi is to be sought for in suppurative inflammation of the tympanum; it also explains the extremely frequent origin of the tumour from the mucous membrane of the drum, especially from the labyrinthine wall." In cases of polypi growing from the meatus, the membrana tympani is generally found to be intact, at least in the earlier stages.

The retention within the tympanum of the products of supuration is the most serious cause of danger in connection with aural polypi. Such retention may cause caries and necrosis of the bone, and the irritation is very liable to extend to the membranes of the brain. Sometimes the purulent secretion becomes condensed into cheesy masses, the decomposition of which leads to necrosis and its results.

As a general rule, the *development* of aural polypi is a lengthy process, and when a certain size has been attained, the growth is apt to remain stationary. There are, however, many exceptions to this rule, and in some cases the meatus becomes blocked up in a few weeks. Spontaneous discharge is a not infrequent ending, and this process is most common in large polypi with long and thin pedicles, which are liable to be lacerated and torn through. Twisting of the pedicle may also cause detachment, inasmuch as the blood-vessels are liable to be occluded. Fatty degeneration of the pedicle has occasionally been noticed, and in some cases the part becomes so fragile as to give way during syringing. Disappearance of a polypus is sometimes due to ulceration and atrophy. The occurrence of cholesteatomatous masses has been already noticed; and chalky and osseous deposits are sometimes found. It must be remembered that polypi are occasionally connected with the malleus, which is apt to be detached with the growth.

The **Diagnosis** of aural polypi is for the most part easily made; purulent discharge from the ear, and especially hæmorrhage, are the two symptoms which attract the patient's attention. It is of special importance to determine the place of origin of the polypus, whether it springs from the neighbourhood of the membrana tympani, or from this structure itself. Any special sensitiveness of the tumour when touched with a probe is generally indicative of some growth other than polypus, the tissue of which is destitute of nerves. When the membrane itself is in a state of polypoid degeneration, some resistance will be offered to a probe by the handle of the malleus; but a mucous polypus is

soft and unresisting, unless it is the seat of calcareous or osseous deposit.

When the polypus is small or elongated, a probe generally enables its root and place of attachment to be detected; but in the case of a large polypus filling the meatus these parts may be very difficult to ascertain. It is well to adopt Politzer's plan, and to use a blunt probe bent at a right angle near its extremity, and with its anterior end marked by divisions of five millimetres each. The bent portion of the probe is pushed between the polypus and the wall of the canal, and after passing round the larger circumference of the growth, is carefully directed into the deeper parts. When the circular movement of the point of the probe is arrested at a distance less than that of the external orifice from the membrane, it may be concluded that the obstacle is due to the root of the polypus. If the root be met with at 15mm. from the orifice, it is almost certain that the growth originates in the external meatus; when the distance is greater, the growth probably springs from the tympanic cavity. If the polypus be easily movable, the stalk will be narrow and thin; but if the movements be restricted, the pedicle will probably be of an opposite character, and any operation upon it will therefore prove more difficult.

The external appearance of polypi is, to some extent, a guide to their origin. The soft, red, vascular growths, with elevations and depressions like those of a raspberry, generally spring from the tympanum; while the paler and smoother polypi mostly originate in the meatus. It must be remembered that the appearance of polypi changes as time goes on, and with their enlargement. Pressure obliterates the inequalities, and in the course of time even mucous polypi are apt to become paler owing to the development of layers of epithelium. Swollen and enlarged portions of the mucous membrane of the tympanum, especially over the promontory, may resemble polypous growths, but a probe will serve to detect their true nature. Malignant growths of the tympanum and meatus can scarcely be mistaken for polypi; their surface is rough and ulcerated, and their development is apt to be attended by considerable swelling of the parts around the ear. Such tumours, moreover, rapidly increase in size, and manifestations of cachexia sooner or later set in. A circumscribed abscess of the meatus may in some respects resemble a polypus, inasmuch

as it forms a smooth, tense, reddish tumour. It is, however, always attended with pain, which is much increased on pressure, and its development takes place rapidly. The history of the case, examination with a probe, and, if necessary, puncture of the swelling, will prevent any mistake from being made.

The diagnosis is, of course, difficult in those rare cases in which there is a polypus growing from the walls of the tympanum, with the membrane intact. If such a case is seen in an early stage, when the growth is impinging upon the membrane, the latter presents a reddened spot at the point of contact, and becomes gradually bulged out. Perforation then takes place, and the growth protrudes through the opening and into the meatus. Such a tumour might easily be supposed to be growing from the membrane itself, unless its progress had been watched. As its size increases, it consists of two parts, connected by a narrow neck at the aperture in the membrane. The size of the projecting portion is no indication of that which is contained in the tympanum, and which may be so large as to require incision of the membrane for its removal. It must not be forgotten that a polypus springing from the mastoid cells may break through the posterior wall of the meatus and appear in that canal. Examination with a probe will show that the pedicle of the growth passes through the bone. Finally, in rare cases, a portion of a cerebral tumour projects into the meatus, but such a growth, with its attendant symptoms, is not likely to be mistaken for a polypus.

Treatment.—In the treatment of aural polypi the objects to be attained are: 1st, the removal of the cause, whether local or constitutional; and 2nd, the removal of the polypus and the destruction of its root and of granulation tissue around the point of attachment. To fulfil the first indication the ear must be carefully cleansed, and the treatment recommended for chronic suppurative inflammation must be adopted. Any obvious source of irritation, such as sequestra in the meatus or tympanum, and adenoid growths in the pharynx, should be properly dealt with; while any scrofulous indications will require cod-liver oil, iodide of iron, good diet, and hygienic measures of all kinds.

The *local treatment* of aural polypi consists in various operations for their removal, and in the application of remedies which have an astringent or destructive effect on their tissue. The removal of aural polypi by operation must be at once undertaken

whenever symptoms are present indicative of accumulation of pus. These generally appear in the form of convulsive attacks, vertigo, and vomiting. It is also indicated whenever the growth has attained such a size as to fill up the cavity which it occupies. In such a case head-symptoms are very prone to occur. When the conditions just noted are absent, astringent remedies may be first tried. In attempting to remove a polypus, its situation and attachment will guide the operator in selecting the most suitable method. Before any operation, however, the meatus should be carefully cleansed, and then ten to twenty drops of a 10—20 per cent. solution of cocaine warmed by having been previously placed in hot water (*see* page 139), should be dropped into it. This will greatly diminish the pain in the subsequent manipulations. When the pedicle is attached to the external meatus, the growth may be

FIG. 118.

WILDE'S SNARE.

extracted by means of *forceps* or Wilde's *snare* (Fig. 118). The latter is generally the more convenient instrument. The loop is pushed over the polypus as far as possible, and then tightened until it grasps the pedicle; the polypus should then be detached by a slight jerk, so as to tear it from its detachment. By this method the growth is often removed almost entirely, whereas, if the loop is tightened too much, it cuts off the polypus at the place at which it has been encircled, and a stump remains. In many cases silk covered with wire, such as is used for the bass string of musical instruments, is better than wire alone, as it does not cut so readily into the polypus. If the root be very firm and resistant, the wire, after being tightened, should be twisted by turning the instrument on its long axis, and then cut off. In a few days

the polypus will become detached, and will fall out of the ear, or may easily be removed with a pair of forceps.

In dealing with polypi connected with the tympanum, it is sometimes best to use a thin wire loop, and to cut through the pedicle as near as possible to its attachment. Various modifications of Wilde's instrument have been devised. One of the best is Blake's *polypus-snare*, which is provided with a movable metal cannula into which the wire loop can be completely withdrawn. Thin platinum wire is the best for the purpose, and an oval loop can be more readily slipped over a polypus than a round one. The polypus either comes away with the instrument, or may be removed by forceps or syringing. If there be anything more than slight hæmorrhage, it may be checked by injecting hot water, or by inserting a plug of cotton-wool dipped in powdered alum.

One drawback connected with the snare is the uncertainty of being able to remove the polypus close to or at its attachment. It is seldom possible so to adjust the wire that constriction takes

FIG. 119.

BARKER'S AURAL CURETTES.

place at the farther extremity of the pedicle; the tendency is for this structure to be cut through near the polypus, or for the latter itself to be divided, even when care has been taken to tear it away at its origin. Under these circumstances portions of the growth remain, and unless dealt with may be the starting-points of new tumours. After removal the ear should be carefully examined, in order to ascertain the condition of the parts at the base of the growth. If any remains of the pedicle are apparent, or if small masses of granulation tissue surround the point of attachment, a small circular knife or a strong solution of chromic acid, and in exceptional cases the galvano-cautery, may be employed for their removal. A curette (Fig. 119) is also suitable in many cases. Politzer recommends a *knife* in the form of a concavo-convex ring, with a very sharp inner margin, and attached to a steel handle.

The *same instrument* is suitable for the removal of small polypi and granulations in the meatus. When introduced its convex

surface is to be pressed against the growth, until a firm base is felt. The tumour which protrudes through the ring is cut through as the instrument is withdrawn, and comes away on the concavity of the knife. Larger polypi may also be removed by the same instrument, used so as to divide the root.

In some cases, the growth can be removed by the aid of a small *round sharp scoop*; this is pushed down to the root of the polypus, and the division of its attachment is effected from behind. This method is suitable only for the removal of polypi of the meatus with soft stalks and loosely attached to their base. Polypi of this character are sometimes capable of being removed by forcible syringing.

Crushing by means of *forceps* is another mechanical method of removing polypi. It has been tried for dealing with large growths, which cannot be entirely removed by any of the methods already described, and for portions of growths remaining after operations. A pair of dressing-forceps, suitably curved, is used to crush the tissue of the growths, and several portions may be dealt with in succession, provided that the hæmorrhage does not obstruct the view. After the operation upon tympanic growths, it is well to introduce plugs of cotton-wool, covered with finely powdered alum. The pressure, coupled with the astringent effects of the alum, will tend to cause atrophy of any remaining portions.

The *galvano-cautery* is indicated for the removal of those polypi, which, owing to the firmness of their pedicles, cannot be dealt with by means of the snare. For ordinary polypi, removable by the snare, curette, or the ring-knife, the cautery is not to be recommended, owing to the risk of cicatricial contraction which attends its use. It is, however, adapted for the destruction of multiple deeply-seated polypi, and small granulations and the remains of polypi, after their removal by other means. I prefer, however, a saturated solution of chromic acid for most cases, the application of this drug being usually successful, and, moreover, less painful; and unattended, as in the case of the cautery, with the risk of injury to other parts. The cautery affords the best means of destroying cholesteatomatous masses, which are often difficult to remove, and of obtaining a satisfactory channel for the escape of pus in cases of caries with formation of polypi.

The shape of the cautery should be adapted to the form of the growth. A simple pointed instrument is generally sufficient, but

for large growths a small flat surface is desirable. Great care should be taken to avoid burning healthy parts, and especially the walls of the tympanum. The circuit should not be closed until the cautery is in contact with the growth. The number of applications at each sitting and their duration must be regulated by the size and position of the polypus. The vapour evolved should be removed by blowing into the ear as soon as it obstructs the view. Before each successive cauterisation the cautery should be heated so as to destroy any tissue which may adhere to it.

If properly applied, the galvano-cautery causes no bad after-effects; but cases are on record in which facial erysipelas and marked constriction of the meatus, due to cicatrisation, were the results of the application. In another case in which the polypus was situated near the membrana tympani, periostitis, accompanied by severe pain, was caused by the operation.

Caustic and Astringent Applications.—A concentrated solution of *chromic acid* is very efficacious, if applied with proper precautions. Before using it, the surface of the growths should be thoroughly dried, and the acid then applied by means of a chromic acid carrier (Fig. 82, page 257), or a camel-hair brush, or a small piece of cotton-wool twisted tightly on to a probe. After the application, the ear should be syringed, and again dried. Chromic acid has also been found efficacious in dealing with large polypi; the application, which is not attended with much pain, should be made about twice a week until the growth has disappeared. *Nitrate of silver* is sometimes used as an application to granulations and to the root of a polypus after removal. Its application is wont to cause somewhat severe and persistent pain, and the slough produced is only superficial. Politzer recommends in preference the *chloride of iron*, as rarely causing severe pain, while it penetrates much more deeply into the tissue even of firm fibrous growths, and more rapidly leads to mortification and detachment. It is applied by dipping the point of a chromic acid carrier or a probe into the liquid, or by means of a small brush, or a piece of cotton-wool, twisted tightly on to a probe, and the cauterisation is to be repeated when the slough is detached by syringing. For hard growths it is well to use the crystallised chloride, a small fragment of which is taken up with the forceps and pushed against the growth, being retained in position by means of a plug of cotton-wool. The salt soon becomes liquefied,

and penetrates into the growth, forming a slough of some size. Politzer recommends the crystals of the sesquichloride of iron for hard growths, occupying the entire circumference of the osseous meatus and coming into contact with it all round, so that a probe cannot be passed between the tumour and the wall of the meatus; but in my opinion the galvano-cautery is more suitable for such cases, as its action can be better regulated.

Various other caustics have been recommended for the destruction of granulations and the remains of polypi; but such as *potassa fusa* and *nitric acid* are open to the objection that it is impossible to limit their action to the affected part, and that healthy portions of the meatus are liable to be destroyed.

The treatment of polypi by the application of *alcohol*, first recommended more than fifty years ago, has recently been fully tried by Politzer and others both for polypi and granulations. Before using it the ear must be carefully cleansed and dried with cotton-wool. A little warmed alcohol is then poured into the meatus, and allowed to remain from fifteen to thirty minutes. The application is to be thus made twice daily, and the treatment regularly continued until the polypus has completely shrivelled up and disappeared; the length of time generally required is from three to six weeks. The treatment is adapted not only for remains of polypi and granulations, but even for large fibrous growths filling up the meatus.

The action of alcohol upon aural growths is not followed by any bad consequences. The treatment may be carried out by any practitioner, and in not a few cases will be found to be an effective substitute for removal by operation. Inasmuch, however, as the method requires time, it is generally best to remove by operation all polypi which can be thus dealt with, and afterwards to employ the alcohol to produce atrophy of any fragments that remain, if they cannot be reached by chromic acid or the other safe remedies mentioned previously, which are quicker in effecting a cure.

Politzer* thus sums up the cases for which the alcohol treatment is especially adapted.

(1) For the removal of the remains of polypi in the external meatus and on the membrana tympani.

* *Lehrbuch der Ohrenheilkunde*, S. 419. See also English Translation of 3rd Edit. p. 541.

(2) For the treatment of intra-tympanic polypi, and their remains, which can seldom be entirely removed by operation, are often beyond the reach of instruments and very often recur.

(3) For multiple granulations of the external meatus and on the membrana tympani.

(4) For diffuse excessive proliferation of the mucous membrane of the tympanum.

(5) For cases in which on account of mechanical obstacles in the external meatus (exostosis, stricture), the removal of polypi cannot be accomplished with instruments.

(6) In order to avoid operations in persons afraid of them, and in children in whom surgical treatment presents great difficulties, and very often necessitates the aid of anæsthetics.

There is another remedy, viz., *acetate of lead*, which when applied to aural polypi produces very satisfactory results. Moos and Steinbrügge recommend a supersaturated solution, containing from ten to twenty-five per cent. of lead, with the addition of from five to ten drops of acetic acid. This solution is transparent; it is dropped into the ear from a glass pipette, the patient's head being held over the opposite shoulder, and the ear is afterwards plugged with salicylic cotton-wool, in order to keep the solution as long as possible in contact with the affected surface. The application should be made twice daily, after the ear has been thoroughly cleansed. There is sometimes pain, of a stinging or burning character, which, however, soon subsides. The length of time required for the treatment varies; but six weeks is generally sufficient. With regard to the manner in which the lead acts upon the polypus, it appears to cause wasting of the cellular elements and constriction of the blood-vessels. It may be that the lead-solution reaches the interior of the vessels, and causes coagulation and thrombosis, and consequent death of the growth. Comparing the effects of the lead with those of alcohol, Moos and Steinbrügge suggest that the latter is probably more suitable for cases of granulation polypi, and lead for the coarser fibromatous growths. "It is also possible, that in cases of tympanic polypi with minute perforations in the membrane, alcohol may act more favourably on account of its greater power of penetration."

CHAPTER XXXII.

CARIES AND NECROSIS OF THE TEMPORAL BONE.

Causes—Cases Due to Injuries—Middle-Ear Suppuration—Constitutional Disorders—Parts most often Involved—Varying Extent of the Disease—Caries of the Ossicles—Necrosis of Tympanic Walls—Subjective Symptoms—Objective Symptoms—Symptoms of Lesion of the Facial Nerve—Paralysis—Perversions of Taste—Character of the Discharge—Examination with a Probe—Course—Diagnosis and Prognosis—Bezold's Statistics—Occasional Multiplicity of Complications—Treatment—Special Measures for Dealing with Caries and Necrosis of the Ossicles—Treatment of Necrosis of Temporal Bone.

Caries and Necrosis of the temporal bone result, in the majority of cases, from acute and chronic suppurative inflammation of the middle ear, and such processes are most often seen in children. In adult cases, it is often reported that discharge from the ear has existed for many years before any evidence of necrosis appeared. Other causes are rare; but severe injuries to the temporal bone—*e.g.*, from blows or projectiles—may eventually lead to caries and necrosis. Dr. Bezold records a case of necrosis of the cochlea in a man aged forty-eight. When seven years old he had been kicked by a horse on the side of the head, and the effects of the injury had been permanent.

It is in those cases of chronic suppuration of the middle ear in which the secretions are retained and decomposed that the bony walls of the cavity are most likely to become involved. Similar complications are prone to occur when the ear affection is associated with some infectious disorders, as diphtheria, scarlet fever, tuberculosis, or syphilis. Those cases in which the mastoid process and cells are the seats of primary disease would appear

to owe their origin to micro-organisms which have passed along the tube from the throat, or have been conveyed by the blood. The pneumatic spaces and the spongy substance of the mastoid portion of the bone are especially favourable spots for the development of micro-organisms, which in most of these instances are those of tubercle. In very rare cases, necrosis of the temporal bone is due to suppurative inflammation of the dura mater, which constitutes the periosteum on the internal surface.

The parts of the temporal bone most prone to be attacked by caries and necrosis are: the mastoid process, the posterior superior wall of the external meatus, the roof of the tympanum, and the ossicles, especially the malleus. Less frequently the processes involve the floor of the cavity and the walls of the carotid canal. Occasionally the promontory is the seat of caries. Various portions may be implicated at the same time, and the process may even extend to adjacent bones, *e.g.*, the occipital and parietal. Caries and necrosis of the mastoid portion will be described in the next chapter. Caries occurring in other parts of the bone may be limited to small circumscribed portions of the walls or of the ossicles, or may cause extensive destruction and exfoliation. Between these extremes there are many intermediate degrees. As a result of diphtheria, partial exfoliation of the tympanic ring, with portions of the external meatus and of the mastoid process, is by no means rare in children. Necrosis of the osseous meatus may affect only a portion of the canal, or involve the whole of the tympanic bone and adjacent parts. Destruction of this character is generally the result of chronic suppuration of the middle ear, such as occurs in children, the subjects of hereditary syphilis. In such cases extensive necrosis is not unusual, even during the first few months of life.

In exceptional cases of caries and necrosis of the temporal bone, the membrana tympani is found to be intact; as a general rule it exhibits one or more perforations. The affected portions of bone are either ulcerated and honeycombed, or necrosis takes place with the formation of a sequestrum. The presence of this latter is liable to cause prolonged suppuration, the development of fistulæ and abscesses (from the burrowing of pus), with, in some cases, lesions of the brain and membranes, or of the large vascular channels.

Caries of the Ossicles results in their destruction and

detachment. In some cases the bones come away spontaneously, or after syringing, during the course of severe suppurative inflammation of the middle ear, in which the soft parts perish and the ossicles become free. This result most often occurs in cases of scarlatina. When the malleus is affected with caries, the handle is especially implicated, and the process likewise attacks the upper and outer wall of the so-called "attic," in which granulations sprout up, while Shrapnell's membrane becomes perforated. In less frequent cases the head of the malleus and the incus are involved, and the upper half of the membrana tympani is destroyed; sometimes again the processes of the incus are attacked. The stapes is the least liable to be attacked; but it loses sometimes one and sometimes both crura, while the foot-plate is very seldom involved. While the osseous walls of the tympanum are the seat of caries, fungous granulations always sprout up from the mucous membrane or its remains. The secretion, which is foul-smelling, and irritates the skin of the meatus, often contains the bacilli of tubercle.

Necrosis is the result of destruction of a circumscribed portion of bone, which constitutes a sequestrum. The part involved may be small and quite superficial; or the process may attack large portions of the temporal bone—*e.g.*, the squamous, mastoid, or pyramidal part—and cause their detachment. The labyrinth, being composed of compact bone, is less frequently implicated; but cases sometimes occur of extensive necrosis of this part, with detachment of the entire cochlea as a result. Most cases of necrosis occur in connection with scarlatina, and children constitute the majority of sufferers. This tendency, as compared with adults, is explained by their proneness to be attacked by acute infective diseases, and also by the comparatively very large size of the labyrinth in early life. It must also be borne in mind that the necrosis may show itself years after the fever.* The sequestrum may remain for some time in the cavity; but as time goes on, it generally moves towards the external meatus, and either escapes or is removed. So long as it remains in the tympanum, it acts as a foreign body, and excites suppuration and fungous granulations. After its removal, the healing process sets in, and assumes various forms. The newly developed connective tissue may become ossified, and a bony cicatrix

* See cases reported by Bezold, *Archives of Otology*, vol. xvi. p. 312.

results; in other cases, the surface is covered with a membrane, within which cholesteatomatous growths may be developed; while in a third class bony formations are the prevailing feature, and the process sometimes goes on to such an extent as to obliterate the cavity of the tympanum, and to obstruct the external meatus.

Subjective Symptoms.—In the majority of cases, caries and necrosis of the temporal bone fail to produce characteristic symptoms. Pain in and about the ear is almost always complained of, and is due to inflammation of the periosteum and retention of secretions. It is generally continuous and violent, but sometimes intermittent. In cases of tuberculosis, the processes may become very advanced without causing any very decided pain. Comparative or even absolute painlessness is a common feature of tuberculous inflammation of the middle ear. When detachment of a sequestrum is in progress, the pain is described as deep down in the ear; it is generally of a boring, tearing character, and very severe, and if a large portion of the bony wall of the tympanum be involved, this symptom may last for many weeks or months. Retention of secretions will cause the pain to become even more severe, and especially if the cerebral meninges are implicated. The pain is accompanied by more or less diminution of hearing-power, giddiness, and noises in the ears of various kinds. These symptoms are, of course, in no way characteristic of caries; they are commonly met with in middle-ear suppuration confined to the soft parts. Neuralgia of branches of the fifth pair is a not uncommon complication. If the labyrinth be specially involved, vertigo and disturbance of equilibrium will be prominent symptoms.

Objective Symptoms.—These are likewise of a more or less indefinite character. In the early stages there will be the signs of purulent inflammation of the middle ear, *e.g.*, perforation of the tympanic membrane and more or less discharge, hypertrophy and ulceration of the mucous membrane of the cavity, with granulations and polypoid growths, thickening, swelling, inflammation or ulceration of the floor of the external meatus, enlargement and induration of the lymphatic glands in the neighbourhood of the ear. These symptoms are, however, often present when the osseous walls of the tympanum are not implicated. More definite signs of affection of bones are furnished by

abscesses which form in various directions, and result from the burrowing of pus towards the front and back of the ear, neck, and throat. The parotid gland and the articulation of the lower jaw are often involved in the suppuration; and when the abscesses communicate directly with the carious bone, fistulous passages are apt to remain long after the pus has been discharged. Such passages originating in the temporal bone, sometimes pass for long distances under the skin, and open on the side of the neck or even towards the shoulder.

Symptoms indicating *lesions of the facial nerve* are of frequent occurrence in cases of caries and necrosis of the temporal bone. The nerve may be directly involved in the destruction of the osseous canal in which it runs, or it may be compressed by serous exudation in the absence of any bony lesion. Even when caries of the bone is known to exist, it is by no means certain that the co-existing facial paralysis is due to direct implication of the nerve. If its canal be imperfect (and such a condition is sometimes congenital), the pressure of exudation within the tympanum may give rise to symptoms of paralysis. Still, in connection with other symptoms, facial paralysis is highly suggestive of carious or necrotic processes involving portions of the temporal bone. On the other hand, the absence of any such symptoms referable to the nerve does not show that the canal in which it runs has remained unaffected. There are several cases on record of partial or complete destruction of the walls of the aquæductus Fallopii, with exposure of the facial nerve, but without any symptoms of paralysis.

If, after lasting for some time, the paralysis should subside, exudation into the canal may be assumed to have been its cause; but if the paralysis continue, there is probably some osseous lesion. In necrosis of the labyrinth, the facial nerve rarely escapes;* it is seldom involved when the cochlea alone is the seat of disease. Inasmuch as the aural affection is generally unilateral, the facial paralysis is usually limited to one side. Its degree varies, according to whether the entire nerve or only some of its fasciculi are affected. In the latter case, the paralysis will involve different muscles, *e.g.*, those of the forehead, or those of the side of the face and nose. Sometimes all the muscles supplied by the nerve are slightly affected; in other cases, the paralysis is com-

* Bezold, *Archives of Otology*, vol. xvi. p. 297.

plete. In some cases the muscles of the soft palate on the affected side are likewise paralysed.

Various perversions of the sense of taste are wont to accompany these lesions of the facial nerve. The glosso-pharyngeal is the nerve of taste for the posterior part of the tongue; the lingual branch of the fifth for the anterior part of the organ. The latter receives its gustatory fibres from the chorda tympani nerve, which runs with the facial trunk, until just above the stylo-mastoid foramen. When the latter nerve is implicated before the chorda leaves it, the gustatory function is lessened or even abolished in the anterior two-thirds of the tongue on that side; and, in addition to this symptom, though only in rare cases, there is dryness of the mouth, due to implication of those fibres of the chorda which regulate the secretion of saliva.

In cases of slight paralysis, the electrical reaction of the muscles and branches of the nerve is little changed. In severe forms the faradic reaction is often increased at first; but it is soon reduced to a minimum, while the irritability of the muscles, as tested by the galvanic current, is more or less increased. In advanced cases, the latter current fails to evoke any response.

In addition to the paralysis, secondary contractions and spasmodic twitchings of the muscles sometimes occur; the former being due to the development and induration of connective tissue in the muscles. The course of the complaint depends upon the nature and progress of the aural lesion, and the extent to which the nerve is involved. In some cases recovery is complete; in others, there is permanent paralysis of all or some of the muscles supplied by the nerve. Secondary atrophy is then apt to supervene, and the conjunctiva is subject to attacks of inflammation, owing to the want of power to close the eye.

The **Discharge** from the ear in cases of caries and necrosis is sometimes peculiar. It is muco-purulent and somewhat tenacious; it often contains decided traces of blood, or assumes a brownish-red colour; its odour is intensely disagreeable, and, in the absence of antiseptic measures, poisons the room occupied by the patient. Sometimes it is quite putrid, quickly discolouring silver instruments brought into contact with it. Fragments of bone, some large enough to be seen with the naked eye, are occasionally discoverable. In all cases, the discharge should be examined from time to time with the microscope; if small osseous particles are

detected there can be no doubt as to the nature of the lesion. A negative result of the examination does not disprove the existence of caries.

As in other cases of destruction of bone, the best evidence of the actual condition is afforded by the use of a probe, which should be handled with the greatest care and gentleness, and under the guidance of the eye. Serious consequences might ensue from using the instrument with any degree of force. It is easy to detect carious or necrosed bone when the disease is situated in the meatus, the inner wall of the tympanum, or in the upper part, under the roof, when Shrapnell's membrane is perforated. Failure to detect caries must not be held to imply that the bone is not affected, for the diseased part may be inaccessible to the most careful examination. Indeed, in not a few cases in which the symptoms point to caries, the diseased spot cannot be reached by a probe. The instrument should be bent in various ways according to circumstances, and should have a well-rounded head. Sometimes the meatus is occupied by polypoid excrescences, which spring from the mastoid antrum, and project through openings in the posterior wall of the canal. Caries and necrosis in the mastoid process may involve the external layer of bone, and in that case masses of granulation tissue will be seen to sprout through the integument. These surround and cover up fistulous openings, through which, if a probe be introduced, softened or necrosed bone, or a loose sequestrum, may be more or less easily felt. If water be injected into the meatus a few drops, or even a thin stream, will be seen to issue from the external fistulous opening, bringing with them inspissated or caseous masses of pus.

The **Course** pursued by caries and necrosis of the temporal bone, following middle-ear suppuration, varies greatly in different cases; but it is only in a minority that favourable results can be anticipated. The progress of the osseous disease is, however, sometimes very slow; there may be long intervals during which some little improvement may seem to be going on. In young subjects the process is usually more rapid than in adults; sequestra are speedily formed and detached, large portions of the mastoid process often become exfoliated, and in severe cases nearly the whole of the temporal bone is destroyed. In not a few cases, symptoms of cerebral or meningeal disease suddenly become developed, while in others a fatal issue is due to phlebitis and

thrombosis of the lateral sinus. Pyæmia is another accident liable to occur in these cases. If, as sometimes happens, the carotid canal be invaded, fatal hæmorrhage is likely to ensue. Such an accident would be a more frequent complication of caries, were it not for the fact that during chronic suppuration, progressive development of connective tissue usually takes place. This process is succeeded by partial ossification, and the diseased portions of tissue are thus to some extent isolated.

Diagnosis.—This is sometimes very difficult, and in many instances it is necessary to keep the patient under observation for a long time before a definite opinion can be given. If, when a probe is introduced, roughened bone can be felt, or a portion of bone which is clearly movable and denuded of its periosteum, the nature of the case will be of course evident. But the affected part may be inaccessible, and the negative result of probing is, therefore, of no great value. In the absence of the positive evidence which a probe often yields, caries or necrosis may be suspected to exist when the following symptoms are present:—

1. A long-continued purulent discharge from the meatus, offensive in character and not yielding to ordinary treatment carefully conducted.

2. The constant re-appearance of granulations in the same place in which they have been destroyed.

3. The previous escape of small sequestra or particles of bone.

4. The existence of fistulous openings behind the ear, with an intermittently copious and offensive discharge therefrom.

5. The formation of abscesses in the neighbourhood of the ear and in the side of the neck and swelling of the lymphatic glands.

6. Perforation of the tympanic membrane at its upper part, the opening having a crater-like appearance, and giving exit to very offensive secretion.

7. Severe lancinating pain in the deeper part of the ear, and extending over the side of the head.

Prognosis.—Any opinion as to the probable results in cases of caries of the temporal bone must be given with great caution. As a general rule, when the lesion is due to injury, the prognosis is more favourable than when it has supervened upon suppurative inflammation. In all cases, if the general health be good, the process slight and confined to the mastoid portion, if there be free vent for all discharges and if exfoliation take place, there is reason

to anticipate a favourable issue. While, however, caries is in progress, there is always the possibility of extension to some important part, with serious results, as already described. There is also the risk of pyæmia, general exhaustion, or pulmonary tuberculosis. In some instances, patients with caries of the temporal bone attain a ripe age, and die from disease unconnected with the local affection. The degree to which the hearing-power is affected depends upon the seat and extent of the caries. If the latter be confined to the mastoid portion, the hearing may be almost or quite normal: on the other hand, necrosis of the labyrinth will involve total deafness.

Dr. Bezold's* list contains forty-six cases of necrosis of the labyrinth. Of these, nine died, all but two from "implication of the neighbouring meningeal and cerebral regions, extension of the suppurative process taking place from the posterior surface of the pyramid, corresponding to the position of the *porus acusticus internus*. The cerebellum was most frequently involved." Septic phlebitis was demonstrated in two cases. Of the thirty-seven cases in which the issue was favourable, in twenty-nine the sequestrum was removed through the auditory canal, in seven it was extracted through fistulæ in the mastoid portion; in the remaining case, it was said to have passed through the tube. With regard to the prognosis in cases in which the Fallopian canal is implicated, Bezold thinks there is great probability of restoration of the function of the divided facial nerve even after extensive loss of substance.

It must be borne in mind that caries, as a result of suppurative inflammation of the middle ear, may spread so as to involve several important parts at the same time. Thus in a fatal case, reported by Dr. Hedinger,† there was a sub-dural abscess, thrombi and ulceration of the superior petrosal sinus, and ulceration leading into the lateral sinus. The external auditory canal was narrowed to a mere slit, and the bony portion was carious. In this case, pus had been discharged into both the lateral and the superior petrosal sinuses. A case of caries of the tympanum, with fatal hæmorrhage from the carotid, is recorded by Drs. Moos and Steinbrügge.‡ There was an opening 15mm. in breadth and 7mm. in

* *Archives of Otology*, vol. xvi. p. 346.

† *Ibid.*, vol. xiii. p. 42.

‡ *Ibid.*, vol. xiii. p. 160.

height in the external bony wall of the carotid canal. The artery was bare to the whole extent of this opening, and corroded and perforated near the promontory. The case was remarkable not only for the lesion of the artery, but because of the rapidity with which the entire series of processes had become developed. The time occupied was only four months.

Treatment.—This must at first be directed towards the improvement of the condition of the middle ear, and this object may be attained by the use of antiseptic remedies and great cleanliness. Supposing that caries is known or strongly suspected to exist, the treatment should be still more energetically carried out, and every effort should be made to remove secretion and prevent its accumulation. It is all-important to remove luxuriant granulations so as to provide for the escape not only of secretion but of dead particles of bone. If there be only one or two small perforations in the membrane, it is desirable that these should be enlarged by incision, so as to afford a free passage. Polypoid growths should be removed by Wilde's snare, or by applications of a concentrated solution of chromic acid, after which alcohol should be introduced into the ear, as recommended by Politzer.

When the granulations have been thus dealt with, antiseptics and astringents of various kinds will come into use. Powdered boric acid, introduced by means of an insufflator, is one of the best remedies. The objections sometimes raised against it, on the ground that it causes the secretions to be retained, are without real foundation. If fluids be preferred, they should be injected through a small tympanic tube, which can be passed into the tympanum or into the mastoid antrum. Fluids may also be introduced by the aid of the Eustachian catheter; a considerable amount of secretion may sometimes thus be driven out through the meatus. The air-douche likewise fulfils a similar purpose. Carbolic acid (gr. xv. to ℥j.), salicylic acid (gr. v. to ℥j.), iodoform (gr. xx. to Sp. Vin. Rect. ℥j.), (*see* page 411), creolin (1 to 200), resorcin (1 to 200), and hydrogen peroxide are the best antiseptic remedies.

When carious spots are visible and accessible—*e.g.*, in the meatus—improvement may be effected by touching them with a concentrated solution of chromic acid, a fine point of nitrate of silver, or with the galvano-cautery. The local application of a

solution of lactic acid (15—20 per cent.) sometimes proves serviceable in cases of circumscribed ulceration of the inner wall of the tympanum. The applications cause the detachment of small sequestra, but are apt to produce more or less severe pain. Dr. Ole Bull,* of Christiania, recommended the application of the mineral acids, hydrochloric and nitric, for the removal of diseased bone. The acids act by rendering the bone capable of absorption. As the result of many trials, Dr. Bull found that hydrochloric acid was the best solvent for the earthy particles of bone, and that sulphuric, and still more, sulphurous acid were rather unserviceable for the same purpose. His method was to soak small pieces of cotton in a solution of hydrochloric acid (2—4 per cent.), and lay them on visible portions of diseased bone. The cotton was allowed to remain for twenty-four hours, and then removed. The applications were continued at intervals until discharge ceased, and the vacant place in the bone was then found to be occupied by a soft mass, presumably cartilage, proceeding from the bone bordering the dead part. The treatment was sometimes continued for three or four months.

There are, however, obvious dangers connected with the application of acids within the tympanum, and the object aimed at can often be attained more rapidly and with less risk by the use of a sharp curette or spoon. This latter is well adapted for the removal of small, circumscribed patches of diseased bone from the inner wall of the tympanum. There is, of course, less difficulty in dealing with caries of the mastoid portion or external meatus. Special care is necessary when removal of diseased bone from any part of the tympanum is the object in view. The treatment of caries and necrosis of the mastoid process will be described in a subsequent chapter.

It remains to consider the treatment of those cases in which the ossicles are especially involved. Caries of the malleus is often associated with disease affecting neighbouring portions of the roof of the tympanum and with perforation of Shrapnell's membrane. Granulations are apt to protrude through such an opening, and to be formed upon its borders. When these conditions coexist, the case is always chronic, and the ordinary therapeutical measures are generally unsuccessful. Removal of the malleus and a portion of the membrane would appear to be the best plan of treatment

* *Archives of Otolaryngology*, vol. xviii. p. 123.

in these cases, and to yield good results after other methods have failed. Before, however, resorting to such an operation, it is well to try the effect of removing the granulations and of astringent remedies introduced by means of a small tympanic tube passed through the perforation.

In the cases under consideration when the opening in the membrane is large, the handle of the malleus is often drawn inwards, and so placed as to be reached with difficulty. The patient must of course be under the influence of an anæsthetic, and the steps of the operation consist in detaching the membrane at its circumference, dividing the tendon of the tensor tympani, cutting through the articulation between the incus and malleus, and extracting the latter with forceps or a wire loop. If the incus be likewise carious, it must be removed with a hook adapted for the purpose. It is probable that the caries of the roof of the tympanum, near to Shrapnell's membrane, will then be within reach, and if so, an attempt may be made to remove the diseased bone with a small curette, bent at a suitable angle. A much more formidable operation has been proposed by Stacke.* He detaches the auricle and draws it down with the cartilaginous meatus; he then separates the periosteum from the bony meatus, and, after removing the malleus, chisels away the layer of bone above the membrana tympani, thus opening the so-called "attic" from the outside, and making it one with the tympanum. The seat of the disease is thus freely exposed, and it may be treated either by scraping or the application of strong solutions of nitrate of silver.

As a general rule, removal of the ossicles can be effected without injury to other parts, but the chorda tympani nerve is sometimes torn through. The ends of the nerve, however, soon become united, and its function is restored. The Fallopian canal is occasionally opened, especially when the incus is being removed. Another and a somewhat common result of the operation is the setting up of purulent inflammation of the middle ear; this, however, is easily dealt with, inasmuch as there is free vent for the secretions.

There is a considerable mass of evidence to the effect that this operation proves, on the whole, very successful. In many cases the suppuration ceases completely with the removal of the cause. It is not to be expected that even so serious an operation will

* *Archiv f. Ohrenheilkunde*, vol. xxxi. p. 201.

cure all cases of caries of the ossicles and roof of the tympanum, for the ulcerative processes localised in these parts of the middle ear often constitute only a portion of the disease which affects the temporal bone. In those cases in which excision of the ossicles and treatment directed to the upper part of the tympanum fail to check the symptoms, it is reasonable to assume that disease exists in other portions of the cavity, not accessible to operation. With regard to effect upon the hearing-power, those who advocate this method of dealing with caries assert that the operation seldom or never causes any decided diminution of function. Even if such a result were sometimes produced, it would be worth while to run the risk, keeping in view the grave dangers attendant on caries, if left to itself.

The treatment after the operation consists in the adoption of antiseptic measures of all kinds. The best applications are perchloride of mercury (1 to 1000), carbolic acid (2 per cent.), and boric acid in powder. The instillation of rectified spirit is the best method of dealing with any granulations that may remain.

The treatment of necrosis resolves itself into the use of antiseptics and the removal of sequestra, when these are in process of detachment. They can usually be withdrawn through the meatus. Small fragments sometimes come away during syringing; larger pieces may be broken up with the forceps, and removed with the wire-loop or sharp hook. If the dead portions of bone be imbedded in the tissues and firmly held, and attempts to divide them prove unavailing, it may be necessary to detach the auricle from the side of the head above, with the cartilaginous meatus, so as to obtain more room. Disturbances of the function of the facial nerve usually subside as the process in the bones comes to an end. The constant current, iodide of potassium, and tonics of various kinds will prove more or less efficacious in expediting recovery. If, however, the canal be extensively involved, and a large portion of the nerve quite destroyed, no result can be expected from any kind of treatment.

CHAPTER XXXIII.

AFFECTIONS OF THE MASTOID PROCESS.

Alterations in Size of Cells—Inflammation of the Mastoid Process—Mastoid Periostitis—Inflammation of the Mastoid Cells—Causes of the Disease and Circumstances under which it Occurs—Morbid Appearances—Symptoms and Course—Caries and Necrosis of the Mastoid Process—Course and Consequences—Prognosis—Treatment—Indications for Opening the Mastoid Process—Various Methods of Operating—Difficulties and Objects of the Operation—Appearances Seen on Opening the Mastoid Process—After-Treatment—General Results and Prognosis of the Operation—Statistics—Cholesteatoma—Effects on Hearing-Function—Gravitation-Abscesses—Significance of Attacks of Fever after Operation.

Variations in the Mastoid Cells.—The cellular spaces of the mastoid process are sometimes increased in size; and in rare specimens, owing to atrophy of the septa, the process may be found to contain a single large cavity. In another class of cases, the cells are smaller than usual in consequence of thickening of the mucous membrane, or of abnormal growth of the osseous tissue. In the latter case, the cellular structure may be altogether obliterated, and the mastoid process converted into a solid bony mass. This change is not infrequent in advanced life. Sometimes abnormal communications exist between the mastoid cells and the cellular structure of adjacent bones; thus, the cells of the mastoid portion may open into those of the basilar process of the occipital. Owing to defective ossification, a fissure occasionally separates the mastoid from the squamous portion, and by this channel pus may escape from the cells into the subcutaneous tissue. Atrophy of the internal lamina of the mastoid process is sometimes associated with dilatation of the lateral sinus. Other

peculiarities of the mastoid process and cells have been fully described in the chapter dealing with the anatomy of these parts (*see* page 57).

Inflammation of the Mastoid Process seldom occurs alone, except as the result of injury confined to this spot; it is far more often caused by extension of the process from the tympanum or external parts, and it may involve the integument, periosteum, the outer layer of bone or the cells, or all these parts at the same time. When the integument is mainly affected, the inflammation is generally of the phlegmonous type, and both ears are occasionally involved without participation of the tympanum. The symptoms are redness and swelling of the skin over the lower part of the mastoid process and the speedy formation of pus. The swelling causes the auricle to project considerably from the head. The development and course of the local symptoms are accompanied by severe pain and more or less decided febrile movement. The pus is apt to infiltrate the tissues, and to cause fistulous passages, which open either on the skin or into the auditory meatus.

The **Treatment** consists in the local application of cold, which may be most conveniently effected by means of Leiter's apparatus (Fig. 58, page 138). This consists of a series of tubes through which cold water circulates. One or two tubes surround the ear, while six or eight are applied to the surface of the mastoid process. The action of the cold is aided by the application of a few leeches, and the latter may be first employed. If the inflammation has extended so far that the skin is raised and boggy, a free incision should be made down to the bone, parallel to the line of attachment of the auricle, and about a quarter of an inch behind it. The wound should then be treated in the ordinary way, with warm applications, etc. Purgatives are generally indicated, and the diet should be of a non-stimulating character. The pain is usually sufficient to necessitate rest and quiet.

Periostitis of the Mastoid Process is very rare as an independent affection,* and is usually the result of extension from adjacent parts. It may of course be set up by direct injuries to the process. It is a not infrequent consequence of extension of cutaneous or periosteal inflammation from the external auditory

* A case, presumably of primary origin, is reported in the *Archives of Otolaryngology*, vol. xiii, p. 22. See also other cases in same journal, vol. xix, p. 95.

meatus, and of suppurative inflammation of the middle ear, involving the mastoid cells. In the latter case, the morbid process may also affect the osseous lamina, or may leave it intact. Whenever fissures or cracks exist in the bone, a deeply-seated inflammation may easily spread to the superficial parts. Suppurative processes in the middle ear are very liable to extend to the mastoid cells when free escape of the discharge is impeded. Small perforations in the upper part of the membrane and constrictions of the meatus are common obstacles of this nature.

The **Objective Symptoms** of mastoid periostitis vary in degree according to the extent of tissue involved. The inflammation may spread over the whole mastoid region, and even upwards and forwards towards the temple. The parts behind the ear are red and swollen, and the auricle stands out from the head. The swelling is somewhat defined in the early stages, but afterwards becomes diffused; sometimes the upper part of the sterno-cleido-mastoid is stiff and swollen; the head is turned towards the opposite side and kept in that position. There may be more or less marked symptoms in the meatus; *e.g.*, redness, swelling, and perhaps discharge of pus. Even when pus has formed, the swelling behind the ear is generally boggy to the touch, without giving any distinct sensation of fluctuation. The development of the inflammation is not infrequently accompanied by rigors, which are succeeded by high fever; pain is always severe, and is apt to radiate in various directions. The entire surface of the part is excessively tender. Hearing is not interfered with unless the meatus be at the same time affected. In rare cases, mastoid periostitis runs its course without pain, and with local symptoms of an apparently slight nature* until an abscess forms, which, on being opened, is found to communicate with a portion of exposed bone. Sometimes, even after pus has formed, the osseous surface is merely roughened and slightly eroded.

Mastoid periostitis may terminate in resolution without supuration; and even after pus has formed the abscess may burst externally, or the pus may be discharged from an opening artificially made, with no further ill consequences. Caries of the subjacent bone is, however, likely to occur in children, and

* See a case recorded by Dr. F. M. Wilson in *Archives of Otolaryngology*, vol. xiv. p 25.

portions of the external layer sometimes become necrotic. The pus sometimes finds its way into the external meatus, through a fissure in the cartilage.

The **Diagnosis** is, for the most part, easily made, as the local symptoms are generally distinct. After the abscess has burst or been opened artificially, a probe should be used to determine whether the bone is exposed. Furuncular inflammation and enlargement of a gland close to the mastoid process may cause redness and swelling behind the ear; but such cases can always be discriminated by careful examination. Chronic periosteal inflammation and a succession of abscesses are indicative of caries or necrosis of the mastoid process.

The **Treatment** resembles that of phlegmonous inflammation, and should be energetically carried out. The application of leeches should be followed by that of cold (by means of Leiter's apparatus). If the inflammatory symptoms do not subside within two or three days, an incision should be made down to the bone. This latter step should be taken at once if fluctuation be detected when the case is first seen. After incision, the condition of the bone can be determined. Any existing sinuses should be slit up, and granulations should be scraped away with a sharp spoon. If the abscess point in the external meatus, the incision should, of course, be made there.

Inflammation of the Mastoid Cells.—This is very rare as a primary affection, but it may occur as a consequence of cold and of direct injury; it is most frequently the result of extension of inflammation from the tympanum, and it sometimes follows inflammation of the external meatus. Foreign bodies in the external meatus not infrequently injure the membrana tympani; the mischief may extend to the middle ear, causing suppurative inflammation, and this in turn may spread to the mastoid cells. The mucous lining of the mastoid cells is continuous with that of the tympanic cavity, and morbid secretion easily finds its way from the latter to the former, and is especially apt to be retained in those cells which have a vertical direction. Politzer thinks that in cases of supposed primary inflammation of the mastoid cells, the attack is really due to bacterial infection from the nasopharynx. He suggests that the microbes in the tympanic cavity may perish, while those in the mastoid process may increase in virulence owing to favourable conditions for development.

It is probable that the mastoid cells are more frequently affected in middle-ear suppuration than is generally supposed. In fatal cases of the latter disease, the walls of the cells are almost invariably reddened and swollen, while the spaces are occupied by sero-mucous or bloody secretion, or by fluid or inspissated pus. Even in such cases there may have been no symptoms connected with the mastoid process, and hence the absence of pain and of external swelling over that part of the bone is no indication that the mastoid cells are free from disease.

The mastoid cells are especially liable to be implicated in cases in which any obstacle exists to the free escape of secretion. Such impediments, in the form of granulations, polypi, and membranous bands, are by no means infrequent. Retention of secretions is also likely to occur when the perforation is small and situated in the upper portion of the membrane, and when the external meatus is constricted. In cases of scarlatina, tuberculosis, syphilis, and influenza, there would seem to be a special tendency towards the implication of the mastoid cells. Recent investigations have shown that the spread of the process is mainly due to the action of micro-organisms (streptococci and diplococci), which are often found in the secretion in complicated cases of middle-ear inflammation.

Morbid Appearances.—These, as mentioned above, consist of swelling and hyperæmia of the lining membrane, and accumulation of secretion in the mastoid cells, sometimes to such an extent as to fill them up completely. These appearances are generally most prominent in the antrum; but in severe cases the entire system of cells is occupied by fluids, which take the place of air, while the spaces and their communications are much reduced in size owing to the swelling of the mucous membrane. The inflammation may be limited to the muco-periosteal membrane, or may extend to the osseous walls of the cells.

When the secretion occupying the cells is largely purulent, the condition resembles that of an abscess which may either communicate with the tympanic cavity or be separated therefrom by membranous formations. Caries and necrosis are the usual results; these processes are more common in the mastoid portion than in any other part of the temporal bone, and children constitute the majority of the patients. The anatomical structure of

the part facilitates the development of the morbid processes. The inflammation of the mucous membrane lining the cells tends to involve the osseous tissue, and retention of exudation is favoured by the arrangement of the cells and the minuteness of the orifices by which they communicate with each other. Necrosis may affect portions in the interior of the process, or of the internal or external surface. Periostitis, with purulent effusion separating the membrane from the bone, generally precedes necrosis of the external layer. In severe cases the greater part of the mastoid process is eventually detached as a sequestrum, and sometimes the bony wall of the lateral sinus is similarly affected. During its progress, the disease of the bone causes abscesses and fistulous openings to be formed in the soft parts. Such openings are most often found on the surface of the process and in the posterior wall of the meatus. But the pus may burrow inwards and downwards in the connective tissue of the neck, and openings may form as low down as the scapula and even in the axilla. A more serious condition of things occurs when the pus makes its way towards the cranial cavity, where it may set up sub-dural abscess, meningitis, cerebral abscess, or thrombosis of the lateral sinus. Owing to the free communication with the sinus by means of the mastoid veins, extension of inflammation to the former part may easily take place. In yet another class of cases the suppuration involves the external semi-circular canal and the internal ear, and purulent secretion may also find its way into the cranium along the connective tissue occupying the loop formed by the superior canal. Under this latter part in the young subject an irregular opening often exists (the *hiatus subarcuatus*), having an external aperture on the posterior surface of the petrous portion below the groove for the superior petrosal sinus, and on a plane behind the meatus.

When a large portion of the mastoid process has been destroyed, the brain-substance itself may be exposed, as in a case recorded by Kuhn.* The patient was a girl, aged eight, the subject of middle-ear suppuration associated with scarlatina.

Inflammation of the mastoid cells does not always result in caries or necrosis. In some cases of a chronic type, the process induces a hyperplasia of the walls of the cells, and finally a complete sclerosis of this portion of the bone. The cells, whether diploetic or pneumatic, are gradually filled up by bony growth.

* *Ueber Prolapsus Cerebelli Durch Cariöse Lücken*, A.f.O. xxvi. S. 56.

Sometimes the periosteum is likewise implicated, and the surface of the bone becomes roughened or studded over with many prominences. In such cases, the walls of the tympanum itself are not infrequently thickened by osseous deposits.

Symptoms.—These vary with the cause and degree of the inflammation. When resulting from the extension of suppurative processes from the tympanum, they may for some time be masked by those of the original affection. They may either precede or follow perforation of the tympanic membrane. The patient complains perhaps of a feeling of fulness or uneasiness in the mastoid process, or the part may be swollen and hot, and excessively painful and tender. More or less fever and headache are generally present; the pain is aggravated by movements of the head, and exacerbations are apt to occur at night. In some cases, however, in which the mastoid cells contain a considerable amount of pus, there is a remarkable absence of symptoms (tenderness, heat, and swelling) in the process itself, though there may be severe pain in other parts of the head.* If, as generally happens, the external parts are simultaneously involved, the symptoms already described (*see* page 479) will be more or less conspicuous. The meatus is usually swollen; its upper and posterior walls are often tense and prominent. A diminution of the discharge is a common symptom, and is generally indicative of some obstruction in the meatus or tympanum. The perforation is most often situated in the posterior superior quadrant of the membrane. Inflammation in the interior of the mastoid process has been observed to occur several weeks after the apparent termination of acute inflammation and suppuration in the tympanum; but so long an interval is quite an exception to the rule. In another class of cases, the mastoid affection coincides with some exacerbation of the original disease.

The course of the affection varies considerably in different cases. When due to injury, or to the presence of a foreign body in the meatus, the inflammation may rapidly assume a serious form and extend to the membranes of the brain, with a fatal result within a few days. On the other hand, under proper treatment, the inflammation may subside in a week or ten days; but in cases due to extension the course is apt to be long and tedious, and disease of the bones (caries or necrosis, or both) is

* Roosa's *Diseases of the Ear*, 7th Edition, p. 525.

liable to set in. The process may continue in the mastoid cells for some time after the original affection has subsided, and without causing any observable symptoms. The periosteum, in chronic cases, often becomes thick and rough.

In severe cases the most common course is the formation of an abscess in the bone, and this again is followed by necrosis and caries, affecting either the deep or superficial layers. These consequences (which are not uncommon in otitis due to influenza) are sometimes averted by the escape of the pus into the tympanum and auditory meatus; but the mastoid cells are often cut off from the former cavity by caseous or granulation masses which block up the antrum. In the absence of treatment, the pus usually finds its way to the surface of the process, and one or more openings take place externally. Less commonly, an opening is formed through the posterior wall of the meatus; in rare cases the pus breaks through the process on its internal aspect. Very serious complications are developed when the wall of the lateral sinus or the roof of the mastoid antrum gives way.

Caries and Necrosis of the Mastoid Process as a result of inflammation of the mastoid cells are most common in children. The two processes are often united, the cellular tissue of the bone being the seat of caries, while the compact substance becomes necrotic. The formation of abscesses and fistulous openings has been already alluded to. In scrofulous children, as a result of periostitis, patches on the surface of the mastoid process are apt to become carious, without participation of the deeper portions.

It is remarkable that caries and necrosis of the mastoid process may go on for some time and result in considerable destruction, without causing any marked subjective or objective symptoms.* Instances of this kind are not infrequent in tuberculous subjects. There is, however, usually more or less pain or uneasiness in the part and tenderness on pressure, and the periosteum is apt to become swollen and inflamed. If an incision be made, the finger or probe will detect dead bone or fistulous openings. The latter are apt to be occluded by granulation tissue, which is sometimes so abundant as to cause a sensation of fluctuation before the skin has been perforated or the parts laid bare by an incision.

* See a report, by Dr. H. Ferrer, of a case in which external symptoms were absent, *Archives of Otology*, vol. xvii. p. 314.

It sometimes happens that the pus of an abscess in the mastoid process finds its way to the surface through the posterior wall of the external meatus. In such a case the discharge is preceded by inflammation of the periosteum and bulging of the wall of the meatus, perhaps to such an extent as completely to occlude the passage. After discharge of the pus, a fistulous opening remains, more or less covered up by sprouting granulation tissue.

In those cases in which the disease of the bones is due to extension of suppurative inflammation from the tympanum, perforation of the membrane is almost invariably present. The membrane has, however, been found normal in such cases.

The **Course** of the morbid process when the bone is affected varies in different cases. Extension of the inflammation in an

FIG. 120.

Natural Size.

A SEQUESTRUM FROM THE MASTOID PROCESS, with a portion of the groove (*a*) for the lateral sinus. It was removed by the author from a child, aged five years, who was brought to the London Hospital on account of a purulent discharge from the right ear following scarlet fever.

outward direction, with periostitis and abscess as results, is the most common course. Several such abscesses, in more or less rapid succession, over the mastoid process are indicative of disease of the bone. Sometimes the pus finds its way down the side of the neck and forms a swelling of considerable size; it may pass forwards to the side of the pharynx and downwards even as far as the pleura. The inflammation may likewise extend towards the cranial cavity, and set up phlebitis of the lateral sinus, or involve the Fallopian aqueduct and the membranes of the brain. This latter result is not infrequent in children; in adults the cerebellum is most often affected. In favourable cases the carious and necrotic portions are detached, the granulation tissue is absorbed, and healing takes place (*see* Fig. 120). Sometimes a good result is obtained after exfoliation of the whole of the

mastoid process. On the other hand, only small portions of bone may be detached, and fistulous openings may remain for some years, or until properly dealt with. Polypous growths are apt to form in cavities left after the discharge of an abscess, and may assume a large size.

The **Prognosis** in these cases of mastoid disease varies with the cause, extent, and severity of the affection, and with the general health of the patient. It is favourable when the lesion is not deeply seated, and when all secretions can escape from the meatus and the patient exhibits no signs of any marked dyscrasia. It is unfavourable in tuberculous cases, and when there is extensive and deep-seated caries and pent-up secretions, with intermittent febrile attacks, and when the tympanum is the seat of severe and chronic changes. The prognosis is always serious whenever there are symptoms of extension of the inflammation to the membranes of the brain. Attacks of partial or complete unconsciousness, restlessness, and feverishness are always of grave import when occurring in a person suffering from disease of the mastoid process.

Treatment.—In treating a case of inflammation of the mastoid cells, the cause of the mischief is the first point to be ascertained. If, as often happens, there be chronic suppurative inflammation of the tympanum, this must be treated in the manner already laid down. When there are evidences of accumulation of pus in the mastoid cells, and the membrana tympani is found to be destroyed or perforated, the best plan to adopt is to wash out the cells with the aid of a bent catheter introduced into the tympanic cavity. The point of the catheter should be directed upwards and backwards, so that the fluid may pass towards the antrum. The subsequent injection of air or fluids through the Eustachian tube to ensure thorough cleansing of the tympanum is also likely to be serviceable. Another method worthy of trial is to exhaust the air in the tympanum, in order to withdraw secretion. Such measures as enlargement of a small perforation, the formation of a second opening in the lower half of the membrane, and the removal of granulations preventing the escape of secretion, are often requisite in these cases.

Whenever there are indications that these methods of treatment will prove unavailing, the question of opening the mastoid antrum will suggest itself for consideration. The object aimed at

is to provide a channel for the escape of purulent matter. In most of these cases, evidences of purulent accumulation between the integument and bone will have necessitated an incision down to the latter structure; but this operation, though often followed by considerable relief to the local symptoms, will not be sufficient unless the osseous shell has already given way, in which case the pus may be reached. As a general rule, the incision should be made from below upwards, about a quarter of an inch behind the attachment of the auricle; it can then, if necessary, be utilised for the operation of opening the mastoid process. If the symptoms be only temporarily improved by the incision, the more serious operation must not be delayed.

According to Prof. H. Schwartz, the following indications for opening the mastoid process are in accordance with the teachings of accumulated experience.

1. In acute inflammation, either primary or secondary, of the mastoid process, when antiphlogistic remedies (especially the application of ice) fail to relieve the pain, œdema and fever within eight days, at the farthest.

2. In chronic inflammation of the mastoid process, attended with recurrent swelling of the part, or with the formation of abscesses or cutaneous fistulæ, with gravitation abscesses in the lateral or posterior parts of the neck, in the meatus or pharynx, even in the absence of any obvious symptoms of a directly threatening character.

3. In chronic suppuration of the middle ear, without external signs of inflammation of the mastoid process, whenever symptoms occur suggestive of the advent of dangerous complications resulting from retention of secretion or the formation of cholesteatoma.

4. In neuralgia of the mastoid process, unrelieved by other methods of treatment.

5. As a prophylactic measure against the fatal results of incurable fœtid middle-ear suppuration, without signs of mastoid inflammation or of retention of secretion (pain and fever); the operation should be performed as soon as careful otoscopic examination has demonstrated the fact that the suppuration is not confined to the tympanic cavity.

These indications require some additional explanations and illustrations. Considerable experience is requisite to enable the surgeon to decide as to the necessity of an operation in a case

of purulent inflammation of the mastoid cells. Severe uncontrollable pain is generally regarded as a special indication; but as a matter of fact, this symptom is by no means pathognomonic of the condition in question. It may indeed be due to inflammation strictly limited to the periosteum. A more trustworthy indication is to be found in the presence of inflammatory swelling of the meatus, involving especially the posterior superior wall of the osseous portion, and a similar appearance below the apex of the process. Pus may break through into the meatus by one or more openings, from which granulations are apt to sprout, so as to block up the passage. Swelling of this character, involving the posterior superior wall of the osseous meatus, must be distinguished from a similar condition of the roof of the meatus, close to the tympanic membrane, and due to extension of inflammation from the upper tympanic spaces. Ordinary furuncular inflammation may cause somewhat similar appearances; but the history of the case will suffice to distinguish it from suppuration of the mastoid cells.

When openings already exist in the bone, the operation will certainly tend to lessen the duration of the disease, and to prevent further consequences. Spontaneous recovery under ordinary treatment is, however, not infrequent in children; and in these subjects, if the general health be fair, and the discharge can freely escape, operative interference may often be dispensed with.

The conditions described under the third heading require to be carefully considered. In cases of middle-ear suppuration, with no external symptoms referable to the mastoid process, the setting-in of pain and fever, accompanied by the sudden cessation of previously copious discharge, indicates retention of secretion, which is liable to cause dangerous complications. If the symptoms be not relieved by ordinary measures (*e.g.*, syringing by the meatus, and injections through the Eustachian tube), opening of the mastoid antrum, either from the external surface or from the meatus, should be undertaken without delay. The operation is even more decidedly indicated when the presence of cholesteatomatous masses in the middle ear is associated with symptoms of cerebral irritation. In such cases palliative measures are always useless, and are certain to prove mischievous, inasmuch as they cause the postponement of the operation, which alone

is likely to be attended with good results. In these cases the opening should be large, so that the morbid material is rendered freely accessible.

Dr. Schwartze has applied the term "neuralgia" to cases in which the mastoid process is the seat and starting-point of severe and persistent pain, in the absence of any external signs of inflammation, and without retention of discharges. Examination of the meatus reveals either a normal condition or such indications of previous middle-ear suppuration as cicatrices or calcareous deposits in the membrane. The hearing-power is either normal or more or less diminished. The pain, which is often very severe, is liable to remissions or intermissions, and is never accompanied by fever; the complaint is most common in young and anæmic persons. According to Schwartze it is by no means rare, and always yields to partial removal of the outer layer of the mastoid process. It is but little affected by ordinary anti-neuralgic treatment and counter-irritation. Complete exposure of the antrum is unnecessary; all that is requisite is to remove a funnel-shaped portion of bone from the surface of the process, and thereby to open a number of terminal pneumatic cells. In the subsequent treatment drainage is unnecessary; the edges of the wound should be brought together by sutures.

The operation is sometimes desirable as a prophylactic measure, but great care is necessary in recommending its performance in any given case. The symptoms may subside under ordinary medicinal treatment, or after less formidable operations, such as the removal of carious ossicles or the opening of the tympanic attic. Incurable fœtid otorrhœa is not a sufficient indication, unless the symptoms point to the mastoid process as the principal seat of disease. If the suppuration be limited to the tympanum proper, opening the mastoid antrum will prove useless though it may not do any harm.

An abscess may exist in the mastoid process, and may even be accompanied by extensive caries and necrosis without causing any external symptoms; in such cases the outer layer of bone is sometimes much thickened and indurated, while in other instances the process is converted into an almost solid mass of bone, with perhaps a little caseous pus or mass of cholesteatoma occupying the cavity of the antrum. In most cases, however, there is a fistulous opening in the osseous meatus, or a perforation in the

posterior and upper part of the tympanic membrane, and sometimes a large carious opening, through which a suitably bent probe may be passed into the mastoid process.

The indications mentioned under the first three headings can often be reinforced by the results of an ophthalmoscopic examination. The earliest appearances of pathological hyperæmia of the optic papilla in an eye previously normal, must give rise to the suspicion of intracranial complications, and would be an additional indication for opening the mastoid process. The absence of any other cause which would account for the hyperæmia in the fundus oculi must, of course, be determined. If there be decided optic neuritis, which may be the earliest sign of an intracranial complication, the operation is still indicated, though it is likely to be too late to be of any service. If the eye-symptoms continue unchanged after the operation, the prognosis is very unfavourable. The appearances in the eye are due to inflammatory increase of the sub-arachnoid fluid, and its mechanical accumulation in the sheath of the optic nerve. It is possible that the lymph-canals around the central vessels may be irritated and plugged up by micro-organisms, but the extent to which the symptoms are due to this cause has not been clearly ascertained.

Exclusive of those general morbid conditions which interfere with the success of all operations, purulent meningitis is held by Prof. Schwartze to be the only counter-indication to the operation under discussion. In the early stage, the exclusion of meningeal suppuration cannot always be depended upon; the use of the ophthalmoscope should never be neglected. According to the same authority, coma is a very unfavourable symptom, and contra-indicates the operation; on the other hand, delirium, vertigo, difference in the size of the pupils, double vision from paralysis of the ocular muscles, sopor, and even unilateral motor paralysis of the extremities, may prove to be transient, and do not prevent the success of the operation.

The anatomical relations of the mastoid process are such as to render great care necessary in performing the operation. The internal surface is in close contact with the lateral sinus and with the floor of the posterior fossa of the base of the skull. The spot at which the sinus is nearest to the surface is situated about three-fifths of an inch behind the process of bone which is just above

the meatus. The line of the posterior attachment of the auricle corresponds with the deepest portion of the fossa of the sinus.

The instruments especially requisite for the operation are: two or more strong scalpels, a director and probe-pointed bistoury, hooks for separating the edges of the wound, probes of various sizes, several small chisels and gouges for removing the layers of bone, a surgical hammer, and sharp spoons of various sizes for scraping out cavities. Instruments for checking hæmorrhage, needles, scissors, cotton-wool, iodoform gauze, bandages, sterilised sponges must, of course, be at hand. It is well to be provided also with an ear-syringe, a tympanic irrigator, and Eustachian catheters.

The safest spot for perforating the bone is situated about one-fifth of an inch below the *linea temporalis* (which is the continuation backwards of the upper border of the zygoma), and at about the same distance behind the posterior wall of the meatus, and nearly on a level with the upper wall. Perhaps the best directions that can be given are:—Draw a horizontal line across the upper margin of the meatus, and a vertical line a quarter of an inch behind the opening; the meeting point of these two lines will indicate the proper spot for perforating the bone. In 66 per cent. of the skulls examined by Dr. Hartmann, the floor of the middle fossa of the base was above the *linea temporalis*, at a distance of two-fifths of an inch behind the external meatus. A similar investigation, undertaken by Dr. Schülzke, yielded a proportion of 82·5 per cent.

Mr. Barker's rules for opening the mastoid antrum and cells are as follows:—The patient is placed in a supine position, with the head turned towards the sound side; the operator stands beside the patient's head, on the affected side. The instruments required are a strong scalpel, a narrow chisel, a narrow gouge, artery forceps, probes, and sharp spoons. The point to be aimed at is the antrum; opening this will drain the mastoid cells and the lymphatics. An incision is made to the bone, a quarter of an inch behind the auricular insertion, and vertically downwards, its centre being at the level of the meatus. The bone is to be examined at the junction of this line with another running horizontally at the level of the roof of the canal. If the bone be soft and spongy, it should be cut with the chisel or gouge, so as to open up the cavity of the middle ear at the posterior and upper part. Very

often the bone is so soft that the knife only is required. If no pus escape, the bone should be gouged below and behind this point for the mastoid cells, taking care to avoid the lateral sinus. The outer part of the mastoid process may be freely removed, and even the groove in the bone for the lateral sinus may be opened without injury to the latter. When the pus has been evacuated, the opening should be scraped carefully with a sharp spoon, well washed out, and then dusted over with iodoform. Afterwards, boric acid forms the best application; a drainage tube is often desirable.

In operating upon children, the opening should never be below a line level with the roof of the meatus, and just behind a line perpendicular to its posterior wall. In adults, the opening should be a little below and behind this spot; the gouge should be directed forwards as well as inwards.

The following are Prof. Schwartz's* directions for performing the operation:—The patient is placed under the complete influence of an anæsthetic, and after shaving the part and applying an antiseptic solution, an incision is made two-fifths of an inch behind the insertion of the auricle and parallel to it. It should begin about two-fifths of an inch above the *linea temporalis*, and be carried downwards as far as the apex of the mastoid process. Any carious opening that exists should be followed up and enlarged; but should the outer layer appear to be sound, after checking hæmorrhage in the usual way, the periosteum is to be removed from the bone for about half an inch. The chisel is then applied below the temporal line, at an angle of about 45° , and directed inwards, downwards, and forwards. The bone should be opened at about the level of the upper wall of the meatus, a little behind the insertion of the auricle. If the opening be made too far backwards, there is risk of injuring the lateral sinus. Its depth should never be more than four-fifths of an inch, in order to avoid injuring the aqueduct of Fallopius and the horizontal semi-circular canal.

When the bone is soft, the only instrument required for opening the mastoid process is a stout scalpel or cartilage knife; but for other cases a gouge is required. The advantages connected with the gouge, as compared with the drill or trephine, are that the part to be operated upon remains fully exposed to view,

* *Archiv f. Ohr.*, vol. xiv. p. 215.

and injury to the soft parts can be avoided. Moreover, the perforation is not liable to be blocked up by splinters of bone.

In the last edition of his work on "Diseases of the Ear" Politzer has considerably expanded his account of mastoid inflammation, and has given a separate description of the acute and chronic forms of the diseases to which this part of the bone is liable. He states that when the inflammation of the cells occurs during the course of acute suppuration of the middle ear, the most common site of the abscess is the middle and lower part of the vertical portion of the mastoid process, lying next to the cortical layer. As a general rule, there is only one abscess-cavity, and this is almost invariably isolated, and has no communication with the mastoid antrum. The symptoms are: pain; increase of temperature over the affected process; perforation of the membrana tympani, with a nipple-like projection in the posterior superior quadrant of the membrane; depression of the posterior superior wall of the meatus, with narrowing of the canal; profuse discharge of pus from the ear.

Antiphlogistic treatment, and especially the application of cold, often proves successful; but in the event of failure, operative interference becomes absolutely necessary. The continuance of pain and fever, vomiting, rigors, and symptoms of meningeal irritation necessitate the immediate opening of the process. The operative procedures for mastoid abscesses in these acute cases are quite different from those required for opening the mastoid antrum in chronic middle-ear suppuration.

Politzer's directions for opening the mastoid process are as follows:—Before the operation, the external meatus is washed out with an antiseptic solution, then dried, and subsequently plugged with cotton-wool. The hair is then shaved from the mastoid region, and the skin cleansed with soap, sublimate solution (1 in 1,000), and finally with sublimate ether. An anæsthetic is next administered.

An assistant bends the auricle forwards, and the operator makes a vertical incision one-fifth of an inch behind its insertion, slightly curved forward, and about two inches long, through the skin in the region of the point of the mastoid process, and continued through the fascia and periosteum down to the bone. The periosteum is pushed away from the line of incision on both sides, until an area of about three-quarters of an inch of the middle

portion of the mastoid surface is laid bare. Hæmorrhage is checked by gauze, torsion or ligature, as may be required. The next step is to chisel out with a large gouge a piece of the cortex, about two-fifths of an inch wide and half an inch vertically. The abscess is frequently reached after the first blow of the chisel, but it may be requisite to enlarge the opening in various directions. When the abscess-cavity has been exposed, all diseased tissue must be freely but carefully removed with the sharp spoon or gouge. The application of iodoform gauze is usually sufficient to check the hæmorrhage. Politzer states that he has very rarely seen any communication between the abscess and the mastoid antrum, and that the establishment of such an opening is not to be desired.

After it has been well scraped, the abscess-cavity is irrigated with weak sublimate solution, and lightly packed with iodoform gauze. This dressing, retained by a bandage, may be suffered to remain for several days, if the discharge of pus be only moderate. In favourable cases, cicatrization is completed in from two to five weeks. As a general rule, the operation has a very favourable effect upon the condition of the tympanum; the discharge gradually decreases and comes to a standstill within a fortnight, and the opening in the membrane becomes closed.

In secondary chronic diseases of the mastoid process, associated with chronic middle-ear suppuration, the most important processes are caries and necrosis of the osseous tissue and the formation of cholesteatomatous masses. Obstacles to the discharge of secretion are the most frequent cause of implication of the mastoid process. The symptoms and course have been already described; it seems desirable to give some account of Politzer's views with regard to the indications for opening the process and the methods of performing the operation.

When the disease of the bone is confined to the mastoid process, it is usually sufficient to open it, to remove the diseased portions, and to lay the antrum free. But if the disease in the mastoid process be combined with caries of the meatus, tympanic walls and ossicula, and with septic inflammation and cholesteatomatous formations in the attic, not only the mastoid antrum, but the posterior and upper part of the meatus and the tympanic cavity must be laid bare.

According to Politzer, opening the mastoid process in chronic

middle-ear inflammation is indicated under the following circumstances :—

1. Painful inflammatory infiltration of the covering of the mastoid process, especially if an accompanying narrowing of the meatus, or obstruction of the tympanum by granulations renders it probable that stagnation of pus exists in the mastoid process. The operation becomes urgent when there is high fever and signs of meningeal irritation, and when the symptoms in the mastoid process have repeatedly occurred.

2. Spontaneous pain in the mastoid process, increased by pressure, and accompanied by bulging and sinking of the posterior superior wall of the meatus.

3. Persistent or occasionally remittent pain in the mastoid process, with marked tenderness, even if there be no swelling of the external integument, and no visible hindrance to the escape of discharge from the tympanic cavity.

4. The existence of cholesteatoma in the tympanic cavity, if removal of the mass and extraction of the malleus and incus with subsequent washing-out of the cavity fail to check the condition.

5. Fistulæ in the mastoid region and gravitation abscesses below it.

6. Extensive caries and necrosis of the posterior osseous wall of the meatus.

7. In all cases of middle-ear suppuration, during which symptoms of meningeal irritation or of incipient sinus-phlebitis make their appearance.

8. Protracted septic suppuration in the attic, the symptoms remaining unchanged after removal of the malleus and incus and several months' energetic treatment.

9. Pain in the mastoid process developing in certain rare cases of connective-tissue hypertrophy, in osteo-sclerosis, and in osseous scars after the healing of a mastoid operation.

The operative treatment of chronic mastoid disease is quite different from that of an abscess in acute mastoid otitis. The antrum must always be opened, and under certain conditions the tympanic cavity must also be laid bare. With regard to the position of the lateral sinus, Politzer states that abnormalities in this respect (the sinus being situated more externally and anteriorly), occur more frequently in diploetic and compact pro-

cesses than in those which may be classified as pneumatic. For opening the process, the chisel is greatly to be preferred to the drill-trephine.

With regard to the operation and its extent, Politzer states that the *modus operandi* will often be determined by the changes which the operation brings into view in the mastoid process, and on the posterior wall of the meatus. It is usually sufficient to open the vertical portion of the process and the mastoid antrum; but in diploetic and compact mastoid processes, the operation must be principally limited to opening the antrum.

To open the mastoid process and expose the antrum, a vertical incision, slightly curved forwards, is made one-fifth of an inch behind the line of insertion of the auricle, and parallel with it. It should be from one and a-half to two inches in length, and should extend nearly to the tip of the mastoid process. After the hæmorrhage is checked, the periosteum is divided and pushed backwards and forwards, so as to expose the middle and upper portions of the mastoid. If, at any particular spot, the bone should be found to be inflamed, discoloured, or rough, the gouge or chisel should be used so as to make an opening in the cortex sufficiently large to expose the diseased portion. Evidences of disease in the bone are most often found in the middle portion of the surface, behind the external meatus. The cavity exposed by the chisel may contain pus, or crumbling masses, or portions of dead bone. It should be thoroughly cleared with the spoon and forceps, special care being necessary in scraping the inner and upper walls of the cavity on account of the proximity of the lateral sinus and dura mater. After thorough removal of débris, the wound-cavity must be irrigated with carbolic solution (2 to 3 per cent.), or sublimate solution (1 in 2000—4000).

It sometimes happens that no communication can be detected between the abscess-cavity and the antrum, and it then becomes necessary to scrape away the anterior and upper portion of the cavity, until the antrum is reached. Care should be taken to establish a free communication between the cavity, the antrum and the tympanum, thoroughly to scrape away all diseased portions and to wash out the middle ear. Politzer emphasises the necessity of making the irrigation from the wound, and not from the meatus, as in the latter case, the wound might become infected from septic secretion washed from the tympanic cavity. Iodoform

and gauze are now applied, and the latter secured in position by means of a bandage.

In cases in which, after the incision is made, the exposed surface of the mastoid appears to be normal, the bone must be opened at that point from which the antrum can be most readily laid bare. This spot is below the *linea temporalis*, at the level of the upper wall of the meatus, and about one-third of an inch behind the *spina supra meatum*. When this latter process cannot be detected, Politzer's advice is to use the place where the mastoid plane bends into the posterior wall of the meatus as the anterior border of the opening to be made, and the upper edge of the osseous meatus as the superior limit. The position of the antrum is frequently marked by a depression behind the upper portion of the external opening of the meatus.

After determining upon the site of the opening, a small piece of bone (about the sixteenth of an inch across) is removed with the gouge, and the opening is deepened and enlarged with the aid of smaller instruments. The direction of the passage, forwards and inwards, must always be kept in mind. According to Politzer, the external opening should be large, even three-fifths of an inch in size, so as to obtain a good view of the field of operation. The same measurement may be given for the depth of the opening; the structures to be avoided are the lateral sinus, the tegmen of the antrum and tympanum, the horizontal semi-circular canal, and the facial nerve. The operation is most easily effected in those mastoid processes which are cellular in structure.

Exposure or even a wound of the lateral sinus is not so serious an accident as was at one time considered. If, as sometimes happens, a very prominent sinus is separated from the meatus only by a thin wall of bone, its exposure can hardly be avoided. It can be recognised by its bluish-grey colour. Exposure of the dura mater, in the middle cranial fossa, is not necessarily dangerous; but injuries to the membrane are more serious, owing to the possibility of meningitis.

The good effects of opening the mastoid antrum are often witnessed a few hours after an operation. The pain and temperature are both diminished; alarming symptoms subside, while the state of the middle ear rapidly improves. On the other hand, if the septic suppuration continue after a few weeks of careful treat-

ment, there is probably caries in the tympanum. The appearance in the discharge of small lumps of inspissated matter points to the presence of cholesteatomatous formations in the attic.

In the subsequent treatment, if the symptoms remain favourable, the dressings may be changed every five or six days. Iodoform gauze, with a rubber drainage tube, constitutes the best application. When the dressing is changed, the wound should be carefully irrigated with sublimate solution, 1 in 10,000. In favourable cases, the wound fills up in two or three weeks. As a matter of course, increase of pain after the operation, rigors, feverish attacks, and profuse suppuration would necessitate frequent dressing and investigation of the wound. It is sometimes requisite to remove carious bone, to scrape fistulous passages, and to chisel away the posterior wall of the meatus and to open the attic. Burrowing of pus down the neck will require appropriate treatment.

In some cases, disease of the mastoid process is accompanied by caries of the osseous meatus and of the walls of the tympanum. It then becomes necessary to remove a portion of the posterior superior wall of the meatus and the external wall of the attic. According to Politzer, the indications for chiselling away the posterior superior wall of the meatus are:—(1) The formation of fistulæ in the posterior wall of the meatus, with caries or necrosis of the mastoid process, or with suppuration in the antrum or in the external attic. (2) Abnormal sinking of the posterior superior wall of the meatus, if caries of the osseous wall can be detected after incision. (3) Cholesteatoma on the posterior superior wall of the meatus, with granulations sprouting from the abscess-cavity. (4) Hyperostosis of the external meatus, with dangerous symptoms of the retention of pus. (5) Continuance of severe symptoms after opening the mastoid antrum. (6) The formation of fistulæ on the mastoid process and in the external meatus.

According to the same authority, in addition to the antrum, the upper tympanic cavity should be opened under the following circumstances:—(1) Caries of the walls of the tympanum and of the ossicula. (2) Excessive formation of granulations in the tympanum, and of cholesteatoma in the attic. (3) The continuance of suppuration or the setting-in of dangerous symptoms after the antrum has been opened.

Various methods of opening the mastoid process from the external meatus have been proposed during the last few years; the plan suggested by Küster is recommended by Politzer. It consists in the partial or complete removal of the posterior superior wall of the meatus, and also of the external wall of the attic, when necessitated by changes in the tympanic cavity. The first step is to loosen the auricle from its insertion, and for this purpose a nearly semi-circular incision is made one-fifth of an inch behind the line of its attachment, and extending from near the tip of the mastoid process to the anterior point of the insertion of the helix. The soft tissues are divided down to the periosteum, and the latter is pushed backwards and forwards, so as to expose the posterior superior edge of the meatus. The membranous meatus is then separated from its posterior superior insertion, and drawn downwards and forwards, with the loosened auricle. After the hæmorrhage has been checked, the exposed surface of the mastoid process and of the wall of the osseous meatus should be carefully examined for fistulous openings and carious spots.

The next steps depend upon the condition of the exposed bone. Discoloured portions are removed with the chisel; fistulæ are enlarged, and all softened tissue, granulations and cholesteatomata, are scraped away with the spoon. If the surface of the mastoid or the upper part of the posterior wall of the meatus be affected, the posterior and external portion of the antrum is to be laid bare so as to obtain access to the tympanic cavity. If the bone does not appear changed externally, the antrum is opened in the manner above described, and the posterior superior wall of the meatus is removed as far as the tympanic cavity. The condition of the external wall of the attic is next examined. This is often carious and in contact with granulations or cholesteatomatous masses. Removal of more or less of the posterior superior wall of the meatus is effected by chiselling away the external wall of the attic with a small gouge, until no process of bone remains between the upper tympanic cavity and the upper wall of the meatus. The malleus and incus or any fragments of them should be withdrawn with the small forceps, and sharp spoons may be used to remove granulations and débris. It is well, if possible, to avoid dislocating the stapes, in view of possible complications in the labyrinth. It is generally necessary, however, to make a free communication between the tympanum, external meatus, and mastoid process.

After the operation, the wound is irrigated with weak sublimate solution and packed with iodoform gauze. The auricle is replaced and a large drainage tube is introduced into the meatus. If the defect in the bone be small, a suture may be introduced into the soft tissues; but in any case it is better to leave open a portion of the wound corresponding to the cavity in the bone.

Several difficulties may be encountered in opening the mastoid process. The bony cellular tissue may be in a condition of sclerosis; and in some cases there is considerable depth of diploetic tissue. Under such circumstances great care is necessary to avoid injury to the labyrinth or the aqueduct of Fallopius. The sinus may also be injured, unless the gouge is directed forwards, close to the posterior wall of the meatus. Injury to this sinus is not necessarily fatal; several cases are on record in which this accident happened when opening the mastoid process for purulent inflammation, and yet recovery took place.* The operation should not be persisted in, if indurated osseous tissue is still found three-fifths of an inch from the surface. The antrum may occupy an abnormal position; in the case of a lady, aged twenty-seven, upon whom I operated about eighteen months ago, it was situated over the posterior superior margin of the meatus. The objects of the operation are the evacuation of a purulent collection, and the restoration of a passage between the mastoid antrum and the tympanic cavity. The first-named object may be achieved at once; the second may be either impracticable, or may be only gradually accomplished. In the most favourable cases the discharge of the pus and restoration of the communication are the immediate results of the operation. The channel is apt to be interrupted by growth of connective tissue, and by osseous growths and sclerosis of the mastoid process. Connective and granulation tissue can be removed with a small chisel or scoop, but in cases of sclerosis communication is not likely to be restored. A satisfactory result may, however, be obtained even if no communication be established.†

The treatment of cases in which the purulent collection is situated nearer to the apex of the mastoid process differs, of course, from that just described, inasmuch as the opening must be made over the lower section of the process. If the operation

* *Archiv für Ohrenheilkunde*, Bd. xxvi. p. 171.

† *Archives of Otolaryngology*, vol. xvii. p. 311.

be delayed, the pus is apt to find its way downwards from the inner side of the process, and abscesses may form in the side of the neck, with considerable infiltration around them. If the muscular insertions on the mastoid process are raised, or the swelling is still more extensive in this region,* Bezold points out that the most natural route for a collection of pus on the inner side of the mastoid process is an opening right through the bone, and reaching the digastric fossa. He therefore recommends that the chisel should be applied further down upon the process, and made to perforate its entire thickness.

The appearances seen on opening the mastoid process vary in different cases. Sometimes the abscess-cavity comes into view at once, and is found to contain, mingled with the pus, fragments of dead bone, or one large sequestrum, either movable or attached to the walls of the abscess. In some cases the cells are found to be filled up with granulation-tissue and polypoid formations; in others, there are cheesy or steatomatous masses, mingled with osseous débris and inspissated secretion. In yet another class of cases, the process is found to be hard, like ivory (sclerosing mastoiditis).

For some days or weeks after any operation upon the mastoid process, the patient must be confined to bed and placed on low diet; the wound must, of course, be protected from all injurious influences. As secretion becomes normal, the diet should be improved, and the patient can be allowed to leave his room and go into the open air, with proper precautions. When the mastoid process has been opened, but without meeting with an abscess, the wound should be dressed with sublimate or iodoform gauze, and the dressings renewed every three or four days.

After the mastoid process has been opened, any existing affections of the external meatus and tympanum generally improve, but these parts should be carefully examined with the speculum from time to time, and any sequestra or masses of secretion that present themselves should be removed.

Results and Prognosis of the Operation.—These have become much more favourable during the last ten or fifteen years; and when due consideration is paid to the serious character of the disease which the operation is intended to remedy, the danger attendant upon opening the mastoid process may be regarded

* *Archives of Otology*, vol. xvii. p. 177.

as comparatively small. Among Professor Schwartz's earliest cases (the list beginning in 1860), the operation proved fatal in 20 per cent. In 578 cases, accounts of which were published in the eight years commencing April 1, 1884, only forty-five died, the causes of death in the majority of cases being meningitis, cerebral abscess, and sinus-thrombosis. Among 406 cases collected from the reports of ten surgeons, forty-seven proved fatal. In the total number of cases, the average mortality was 10.69 per cent.

In addition to the results of the operation as regards the life of the patient, its effects upon the condition of the organ and the hearing-power require to be considered. These latter are more marked in acute than in chronic cases, in which suppuration, though it may cease for a time, not infrequently recurs. Cases must be kept under observation for long periods and subjected to careful treatment before any definite conclusion can be arrived at. In favourable cases, the subsidence of suppuration is accompanied by the disappearance of the subjective symptoms (headache, giddiness, and neuralgia), and the patient's general health more or less rapidly improves. In tuberculous cases the good effects of the operation are sometimes very marked. Cessation of epileptiform attacks and restored function of the facial nerve have been observed in several cases belonging to another category. With regard to effects upon the function of the organ, it is, of course, supposed that the performance of the operation involves no injury to the sound-conducting apparatus. In most cases cessation of discharge is followed by closure of the perforation in the tympanic membrane. No change in the hearing-power can be expected when the labyrinth is seriously affected. When the operation is undertaken for chronic caries or necrosis, the prognosis depends upon the extent to which the bone is involved. If the mastoid process alone be affected, the prognosis is more favourable than when the walls of the tympanum and portions of the osseous labyrinth are likewise diseased. But when the labyrinth is involved in caries or necrosis, a cure is by no means impossible. A sequestrum may be detached and escape by the meatus, and carious excavations may gradually be filled up by granulations which undergo conversion into ossifying connective tissue.

The existence of cholesteatoma renders the prognosis more

serious, and necessitates greater care on the part of the surgeon. The destruction of the osseous tissue is often greater than could have been anticipated. The morbid material may extend into the neighbouring bones and even into the cavity of the skull, and the difficulties of removal may be almost or quite insuperable. After apparently complete removal, new growth is very apt to occur in the cavities of the middle ear.

Fistulous openings in the outer surface of the mastoid process tend to facilitate the operation, and are not in themselves dangerous; but they are often associated with extensive pathological changes in the deeper parts. The lateral sinus may be completely laid bare by carious processes involving the groove, and may be surrounded by purulent fluid; openings may be formed at other spots into the cranial cavity, and there may be an epidural or a cerebral abscess, communicating with the suppurating cavity in the mastoid process and with the external opening. In other cases the fistulous aperture leads into a long canal, traversing indurated bone, and not capable of being followed to its extremity.

The existence of gravitation abscesses in the side or towards the back of the neck may render the operation somewhat more difficult, but does not necessarily affect the prognosis. As a rule, such cases are less dangerous than those which present no external signs of suppuration. Fatal results may, however, follow when the matter finds its way beneath the clavicle and passes into the thorax and pleural cavity. Compression of the trachea and formation of an opening into the larynx have been known to occur; but such results are very uncommon. Less rarely, the pus passes down between the structures of the pharynx, into which it may eventually escape.

The information to be obtained from an examination of the eyes has been already mentioned. It is scarcely necessary to add that the urine should be carefully examined for sugar and albumen before undertaking the operation. The discovery of either of these substances renders the prognosis unfavourable; in diabetic cases, the healing process is likely to be incomplete, and the risk of septic poisoning is considerable. The presence of albuminuria is a grave symptom as regards prognosis.

Sharp attacks of fever are not uncommon for a few days after the operation, and may be of serious import. In favourable cases

the temperature falls after the opening has been made, provided that antiseptic precautions have been observed, and no marked febrile movement is again appreciable. Sometimes, however, the temperature rises on the fifth day, and indicates the setting-in of cranial complications. According to Dr. Schwartze, it is not until the eighth day has passed without any rise, that the risk of complications may be disregarded. If a previous temperature of 102° — 104° be maintained without change after the operation, there is no hope of a favourable issue. The same authority states that if the temperature rises for the first time after the operation and within twenty-four hours thereof, there is no need for alarm, as the symptoms are those of the so-called aseptic wound-fever. If, however, the rise in temperature does not occur till the second or third day, it is probably due to infection proceeding from some purulent accumulation which has not been removed. The height to which the temperature rises is not a positive indication of the severity of the infection, the other signs of which are pain and swelling of the lymphatic glands of the neck and throat. The wound may at first appear normal, but it soon becomes dry, bleeds on the slightest touch, and has a dull grey look. The occurrence of remissions is more favourable as regards prognosis than a continuously high temperature. When the thermometer in the axilla indicates 105° or more, the prospect of recovery is but slight, though exceptional cases have been noticed.

Even in cases in which the operation is classed as unsuccessful, because no pus or dead bone is reached, the results are often very satisfactory, showing themselves in cessation of pain and discharge from the ear. Politzer attributes the good effects to diminution of hyperæmia in the temporal bone and in the veins of the skull.

CHAPTER XXXIV.

CRANIAL AND OTHER COMPLICATIONS OF MIDDLE-EAR
SUPPURATION.

Extension of Morbid Processes to Intra-Cranial Structures—Cerebral Meningitis—Two Forms—Spots at which Perforation of the Bone is likely to Occur—Course Taken by the Pus—Symptoms—Diagnosis—Treatment—Cerebral Abscess, Development and Symptoms—Influence of Micro-Organisms—Seats of Abscesses—Stages of the Morbid Process, and Appearances Presented by the Abscess—Sinus Thrombosis as a Complication—Diagnosis—Terminations—Trephining the Skull—Abscess in the Cerebellum—Phlebitis and Thrombosis of the Lateral Sinus and Jugular Vein—Symptoms—Course—Diagnosis—Treatment—Ulceration of the Carotid Artery—Conditions under which it Occurs—Symptoms—Diagnosis—Treatment—General Tuberculosis as a Result of Ear Disease.

IN the present chapter a description will be given of those complications of middle-ear suppuration which occur in other parts, and mostly within the cranium. They are all of a serious character, and are often the immediate causes of fatal results in connection with middle-ear disease. The cerebral meninges, the cerebrum, the cerebellum, the arteries and the venous sinuses in the neighbourhood of the temporal bone, may all become implicated as a result of the extension of carious and suppurative processes.

(1) **Cerebral Meningitis.**—There are at least two forms of this affection which have been noticed in connection with middle-ear disease. In one, the irritation proceeding from the temporal bone causes circumscribed inflammation and thickening of the dura mater; the process is slowly developed, and the newly-formed tissue prevents the inflammation from spreading towards

the brain. By pressing, however, upon the latter organ, it gives rise to symptoms of direct or reflex irritation, and more or less active congestion. The lesions in the petrous portion do not react directly on the cranial contents, as is the case when the dura mater is affected in a different manner. On the other hand, parts of the bone itself are apt to become thickened and indurated, thus forming an additional barrier to the spread of the disease. Portions of the dura mater sometimes become calcified.

Such a process as that just described is the exception to the general rule. It was noticed only in seven out of two hundred cases cited by Robin.* In the large majority, the dura mater covering the diseased portions of the bone, after resisting for a time, becomes discoloured, softened, and perforated (sometimes like a sieve), and the purulent matter finds its way into the cavity of the arachnoid and along the pia mater to the brain, anterior part of the cerebellum, or medulla oblongata. In severe cases of this character, the dura mater becomes gangrenous, and large openings exist, through which the brain, bathed in pus, projects into the gaps caused by the caries and necrosis in the base of the skull. Adherence of the membranes sometimes prevents extension of the process; in the absence of any such hindrance the surface of the brain over a large extent becomes coated with pus.

In these cases of purulent meningitis due to middle-ear suppuration, there are certain spots in the base of the skull, at which perforation, with escape of pus, is likely to occur. The first of these is the osseous roof of the tympanum and of the mastoid antrum. The former is often very thin, and the perforation may involve a large portion of it; sometimes there are several smaller openings, and sometimes the bone is riddled like a sieve. In some instances, such openings are in great measure plugged up by cholesteatomatous masses and inspissated pus. The gaps or dehiscences, which not infrequently exist in the bone forming the roof of the tympanum, obviously favour the escape of purulent matter; and sometimes an opening in the bone directly communicates with an abscess in the brain.

Purulent matter sometimes passes from the tympanum, or the mastoid antrum, through the pneumatic and diploetic cells of the

* *Des Affections Cérébrales consécutives aux Lésions nontraumatiques du Rocher et de l'Appareil Auditif*, p. 31.

petrous portion to the posterior surface of the bone, the extension of the disease sometimes involving the osseous labyrinth and sometimes leaving it intact.

In a third class, the course taken by the pus is somewhat more circuitous. It passes into and destroys a semi-circular canal, the vestibule and cochlea, and finds its way through the lamina cribrosa in the internal meatus, and thence to the base of the brain. In other cases, it destroys the aquæductus Fallopii, and passes with the facial nerve to the same destination. In a case recorded by Sir W. Gull, the suppuration advanced from the labyrinth through the aquæductus vestibuli to the base of the cranium.

The appearances presented by the dura mater vary in different cases; the formation of adhesions between the membrane and the bone has been already mentioned. In a case observed by Urbantschitsch, there was chronic purulent tympanitis, with extension through the roof of the cavity to the basal meninges, and through the labyrinth and internal auditory canal to the surface of the cerebellum. In another case, recorded by the same writer, there was suppuration of the labyrinth, with extension to the convexity.

The **Symptoms** of cerebral meningitis, due to middle-ear disease, vary in different cases; they may be divided into two stages, but these are not always clearly distinct. The first symptoms are indicative of cerebral irritation, but sooner or later give place to those of depression. The supervention of the cranial lesion is indicated by rigors, fever, and severe headache; the last being most acute in the neighbourhood of the ear, and at first remittent, but soon becoming continuous and extending over the head. The local pain is soon accompanied by general hyperæsthesia, sleeplessness, giddiness, excitement, nausea, and vomiting. If the patient attempts to stand or walk, he finds it impossible to keep in an erect position. Ere long, unconsciousness sets in and gradually becomes more and more profound. Spasmodic contractions of the muscles of the face and of the limbs on the affected side are soon superadded; sometimes the convulsions are general, and there is rigidity of the neck and trismus. The pupils are contracted; the pulse very frequent, but becoming slower as pressure on the brain increases. The temperature is persistently high and steady, especially when the convexity is

affected; the abdomen is retracted and hard. Symptoms of paralysis are generally present; sometimes the facial, the hypoglossal and the glosso-pharyngeal are thus involved; in other cases there is hemiplegia, and sometimes single limbs are affected. Towards the close the pupils become unequal, the bladder and rectum are paralysed, the pulse is small and frequent, the respiration is accelerated, convulsions occur from time to time, and death is ushered in by coma. The duration of the symptoms varies considerably in different cases: sometimes months elapse before the fatal issue, the symptoms subsiding or altogether disappearing for weeks at a time. In some instances, the symptoms are very insidious, and consist only of occasional headache and spasm of a few of the facial muscles, appearing and disappearing at uncertain intervals. In other cases the symptoms, having once shown themselves, speedily become severe; headache, vomiting, and convulsions are followed in a few days by loss of consciousness and death. This latter is the usual result; though recovery is not impossible if the process affect only the external surface of the dura mater, with consequent thickening, which may prevent the extension of the mischief. Free escape of secretion externally is a favourable symptom.

Diagnosis.—It is extremely difficult to distinguish meningitis from cerebritis, as the two affections frequently co-exist, the process extending from the one part to the other. Moreover, in middle-ear inflammation, symptoms of meningeal mischief, of a transient character, not infrequently set in as a result of the retention of purulent secretion, and pass off when the discharge becomes re-established. Meningitis may, however, be inferred to exist when headache and vomiting are succeeded by paralysis of one or more limbs, and convulsions, delirium, and loss of consciousness. Other evidences of meningitis are detected by the ophthalmoscope, and consist of optic neuritis, and symptoms of hyperæmia of the retinal vessels.

Treatment.—When symptoms of meningitis manifest themselves in a case of ear-disease, the part should be thoroughly examined, and steps taken to remove any obstruction which may exist to the escape of purulent matter. It may be that a perforation in the tympanic membrane has become occluded, or a polypus blocks up the meatus. In the former case an incision is required; in the latter the tumour must be removed, and in both

cases the tympanum must be carefully cleansed and disinfected after the operations. If there be evidences of suppuration, or of old deposits in the mastoid cells, or of caries or necrosis, the mastoid process must be opened, and the part thoroughly disinfected.

To combat the meningitis purgatives must be given and ice-bags applied locally, the patient being kept at absolute rest. In most cases a few leeches or a blister applied near the ear will afford relief to the pain. If there be evidences of a sub-dural abscess, opening the skull, to be described under Cerebral Abscess, will constitute the proper treatment.

(2) **Cerebral Abscess.**—Chronic middle-ear suppuration is one of the most frequent causes of cerebral abscess, which is apt to become developed in a very insidious manner. The course of events is generally as follows:—The patient has had a discharge from the ear for a considerable time, *i.e.*, for months or even for years. The discharge is more or less offensive; the patient's hearing is impaired on that side, and there are occasional attacks of pain. In a large proportion of the cases the ear-affection dates from childhood, and has commenced after scarlatina, measles, or some other febrile complaint. The setting-in of acute symptoms may follow exposure to cold, injury to the head, or the development of some inflammatory condition in the throat, the application of caustics to the latter part, or operations on the ear; but, in some cases, no such immediate cause is discoverable.

The first symptom to attract notice is usually severe pain in the ear and adjoining parts; this generally occurs in paroxysms, and is apt to be very intense, but not of so sharp a character as in meningitis. Rigors, nausea, and vomiting are more or less frequent accompaniments of the pain, and the latter is increased by the slightest pressure. In some cases there is pain or aching in the back and limbs; in others diarrhœa. Giddiness is experienced if the patient attempts to walk, and delirium is sometimes an early symptom. When the abscess is seated in the cerebellum, the pain extends from the side to the back of the head. Aphasia is sometimes present, indicating the left frontal convolution as the seat of disease. The pupils are generally contracted, and there is intolerance of light; the skin often becomes hot, the pulse quick, and the tongue dry and parched; the patient becomes heavy and drowsy, and the symptoms generally may closely resemble those

of continued fever. In other cases attacks resembling coma supervene and pass off; on the other hand, there may be no loss of consciousness, but only some impairment of sensation. In some patients it is noticed that all cerebral functions are very slowly performed. Convulsive attacks frequently occur, and are accompanied by paralysis of various parts. When the face is thus affected, the loss of power is usually on the same side as the aural disease. When the acute symptoms have set in, and while they last, the discharge from the ear often lessens, and sometimes ceases altogether. The odour of the discharge is not of prognostic value; the symptoms of cerebral mischief may set in in cases characterised by non-fœtid discharges. The hearing-power may remain unaltered, but if the abscess involve the auditory nerve, complete deafness will result. As the disease progresses, the pulse becomes very slow: it may be only fifteen per minute.

In some cases of cerebral abscess there are no prominent symptoms till a few days before death, when paralysis or convulsions supervene; in others, the disease remains latent until the pus finds its way into the lateral ventricle, when symptoms immediately set in. Evidences of optic neuritis are sometimes noticed in cases of cerebral abscess.

The temperature of patients suffering from cerebral abscess, due to aural disease, presents several points of interest. According to Wreden,* there are three forms or stages characterised by marked differences of temperature. In the first, or pyrogenetic stage, the temperature quickly rises to 102° — 104° , and rigors are uncommon. In simple inflammation of the brain, and in diffuse meningitis, it is not till the second or third evening that the temperature reaches 104° , and the rise is preceded by severe rigors. When a cerebral abscess results from purulent middle-ear inflammation, the process is completed by the evening of the first day; and during the next four days the temperature varies but little, remaining at 102° — 104° both morning and evening. It thus differs from that recorded in pyæmia, in which the fever reaches its height about the end of the first or beginning of the second week, and undergoes considerable daily variations. In meningitis the temperature is persistently high, and its course is more regular. On the fifth day, in cases of abscess, fluctuations begin, and the morning temperature is reduced, the daily readings

* *Archiv für Aug. u. Ohr.*, vol. iv. p. 2, S. 311.

during the next seven days being between 100.4° and 101.5° . At the same time the subjective symptoms are lessened in intensity, and gradually subside as the temperature falls. This process may continue until a period of comparative health sets in, when the symptoms are in abeyance, and no abnormal temperature can be detected. In some cases the temperature becomes sub-normal;* but in any stages the range may be modified by the existence of various complications.

The part played by bacteria in chronic middle-ear suppuration has been already alluded to (*see* page 392), and the question arises as to whether different symptoms are due to different organisms, and whether different parts are liable to be affected by special microphytes. Inspissated pus in the middle ear and cholesteatomatous deposits are especially dangerous, because they are often infected with peculiar microphytes. In not a few of these cases of chronic ear-affections, grave symptoms are set up by some other inflammatory affection, their sudden onset resulting from the ingraft of a fresh inoculation. Death sometimes results after the disturbance of old deposits in the ear, and hence caution should be observed in operating in carious affections. Small veins may easily be opened up, and septic matter thus readily introduced into the blood. The ear, of course, may be invaded from without, the secretion forming a favourable nidus for the reception of pathogenic microphytes.

Seats of Abscesses.—The abscess may form in any part of the brain; the white substance is more commonly affected than the grey, and the middle lobes are the most frequent seat of the disease. In Lebert's cases, eighty in number, one-fourth of which were due to middle-ear suppuration and caries of the temporal bone, there were fifty-three men, twenty-four women, and three children. In one-seventh of the cases the disease occurred before puberty; the majority of the remaining patients were between sixteen and thirty. This difference is probably due to the greater development of the mastoid cells after puberty. Men are more frequently affected than women; and some authorities state that the right side of the brain is more often attacked than the left. There is, however, no great difference in this respect: both ears are equally liable to be affected with otitis media.

* See Mr. A. E. Barker's statements on this point in his Hunterian lectures on "Intra-Cranial Inflammations starting in the Temporal Bone," p. 43.

The formation of the abscess may take place in a part of the brain which is close to the roof of the tympanum, or at a spot some distance therefrom; and sometimes the abscess is situated in the cerebellum and in the corpus striatum. Multiple formations are not uncommon; they were found in twenty-two of Lebert's cases. Less frequently the abscess is formed on the side opposite to the diseased ear; but it is not unusual for the abscess-cavity to be separated from the diseased bone by a layer of healthy brain-substance. In such cases, the inflammatory process must have extended along the connective tissue and vessels, without implicating the more superficial parts of the brain. Hence, in a fatal case of middle-ear suppuration, whenever an abscess is found at some distance from the temporal bone, it must not be assumed to be of independent origin: a closer examination may reveal signs of a connection between the abscess and the bone. It must be remembered that even when the former is obviously dependent upon the disease in the ear, there may be no caries of the bone, and the membranes may appear to be healthy. When the abscess is situated at some distance from the diseased bone, and is separated therefrom by healthy brain-tissue, it may be assumed that micro-organisms have passed into the circulation, or into the connective tissue accompanying the vessels. In one case of middle-ear inflammation, swarms of bacteria were found in the temporal bone, both surrounding the vessels and in the diploetic spaces and in the sheath of the facial nerve. The labyrinth was disorganised, whereas its walls were intact, the mischief having extended by way of the sheaths of the vessels. The cerebellum was the seat of an abscess containing hosts of bacteria and micrococci.

The **Stages of the Morbid Processes** can sometimes be traced on post-mortem examination. The tympanic cavity is filled with pus and débris; its mucous membrane is destroyed, and its walls are carious or necrotic. The dura mater above the roof of the tympanum may be separated from the bone by pus, or softened and sloughing, and the middle lobe of the cerebrum is found to contain an abscess which comes close to the under surface. In other cases, the inner wall of the mastoid cells, or the posterior surface of the petrous portion, is carious, and the abscess is found in that half of the cerebellum. Among eighteen cases of cerebral abscess at Guy's Hospital, recorded by Drs. Hilton Fagge and Pye-Smith, "there were twelve in which the temporal lobe was

the seat of the abscess, three in which it lay in the cerebellum, two in the centrum ovale, and one in the pons."

The **Appearance of the Abscess** varies according to its duration. If recently formed, the cavity is generally ill-defined and surrounded by softened cerebral substance, without any appearance of a lining membrane. On the other hand, abscesses which have been formed some time are generally circumscribed by a thick vascular capsule, formed of fibro-cellular elements. The pus is commonly greenish, viscid, and acid in reaction, and sometimes horribly foetid; in old-standing cases it is mucoid, green, and alkaline, and on microscopical examination the pus-corpuscles are found to be very few in number, having been converted into fatty and granular débris. The abscess becomes encysted about six weeks after its formation; when solitary, it may become as large as a hen's egg, or even larger. The pus tends to make its way towards the surface or towards a lateral ventricle. When the abscess communicates directly with diseased bone, and local adhesions have been formed, its contents may pass into the tympanum, and escape into the meatus: such cases have been described as "cerebral otorrhœa."

Other parts besides the brain are apt to be involved in cases of caries of the temporal bone. Thus when the mastoid cells are diseased, the lateral sinus is often the seat of thrombosis, and its external surface is coated with pus and lymph. The process may extend along the internal jugular vein, and cause suppurative pleuritis and pulmonary abscess.

In cases of cerebral abscess, the fatal issue most commonly takes place before the end of the first month; but life is sometimes prolonged for six and even eight months. During this period such symptoms as headache, vomiting, and a dull mental condition are more or less prominent. Death is usually ushered in by delirium followed by stupor and coma, or severe epileptiform convulsions.

The **Diagnosis** of cerebral abscess is by no means easy, but a careful consideration of the history of any given case will aid in the interpretation of the symptoms. When rigors, headache, vomiting, etc., supervene in a patient who has for some time suffered from otorrhœa, the decision will rest between *abscess* and *meningitis*, and possibly a *cerebral tumour*. In abscess, the headache is more continuously felt; it comes on suddenly and remains

very severe; in tumour there are more frequent intermissions, and the pain follows the course of certain nerves. Moreover, the patient at times appears to be free from symptoms; whereas in abscess, after their first appearance, evidences of cerebral disorder are never wanting. It must be remembered that middle-ear suppuration may be complicated by a cerebral tumour; in such a case the symptoms are very likely to be misinterpreted.

The diagnosis between *cerebral abscess* and *meningitis* may be quite impossible; the two conditions not infrequently co-exist, and such symptoms as headache, fever, delirium, convulsions, and stupor are common to both. Meningitis is indicated by very marked initial symptoms of fever and cerebral excitement, and by cutaneous hyperæsthesia affecting both sides of the body: cerebral abscess may be expected when the initial symptoms affect one side only, when the convulsions and paralysis are likewise unilateral, and when the patient appears to be stupid and lethargic, and, if able to answer questions, replies very slowly and deliberately.

Intracranial abscess nearly always ends in death unless the pus escape through the mastoid portion or the external meatus, or is removed by an operation. When the symptoms of abscess become developed, trephining the skull affords the only prospect of relief. The operation is of course a formidable one on account of the risks which it involves, such as, irreparable injury to the brain, septic inflammation of the meninges, and hæmorrhage from injury of a vessel. The diagnosis must be established as clearly as possible, and it must be remembered that the symptoms may indicate, with more or less probability, not only abscess, but meningitis (limited or diffuse) and thrombosis.

The symptoms of abscess have been already discussed. The purulent collection may be situated either in the temporo-sphenoidal lobe or in the cerebellum: such symptoms as hemiplegia and hemispasm indicate its position to be above the tentorium cerebelli. In order to explore the temporo-sphenoidal lobe of the brain, the trephine is applied one and a quarter inches behind the centre of the bony meatus, and the same distance above the base line of the skull, which runs from the lower border of the orbit backwards through the centre of the meatus (Barker). This will open the posterior inferior angle of the parietal bone, close to the squamosal suture. Having exposed the dura mater, the mem-

brane should be carefully examined, and then incised across the opening in the bone. If there be a subdural abscess, the pus is generally found along the squamoso-petrosal suture, and will thus be reached. If no pus be found under the dura mater, an exploratory needle, the size of a No. 4 catheter, is then passed inwards, forwards, and downwards, when pus will escape if the abscess be in the supposed position. After the pus has ceased to flow, a rubber drainage tube should be inserted, and the wound washed with carbolic lotion (1 : 20), and subsequently dusted over with finely powdered iodoform ; it is then to be covered with sublimate or iodoform gauze.

Before opening the parietal bone, as above described, Mr. Barker* recommends that the foramen for the mastoid vein should be exposed and carefully examined. If pus escape, mischief may be inferred to exist in the cerebellum, and another spot must be selected for opening the cranium, viz., in the occipital bone, two centimetres (four-fifths of an inch) behind and inwards from the mastoid process. A horse-shoe incision is made through the skin, with its ends above the level of the external occipital tuberosity, and its curve slightly below the level of a line joining the apices of the mastoid processes. After reflecting the skin, the muscles are to be divided by an incision parallel to the superior curved line of the bone. The inferior curved line is a good guide for the opening ; the trephine should just encroach upon it. After the circle of bone has been removed, the dura mater is opened as before, and the cerebellum examined. Should no pus escape, an exploratory needle is passed inwards in various directions for half-an-inch, or rather more, in the hope of finding the abscess. Should the search prove successful, the wound is to be treated as described in the previous paragraph.

(3) Phlebitis and Thrombosis of the Lateral Sinus and Jugular Vein.—The floor of the tympanum forms the roof of the jugular fossa, and through this layer of bone, often very thin, inflammation may extend from the cavity to the commencement of the internal jugular vein, the process being facilitated by the apertures which not infrequently exist in the bony septum. The result of such extension may be either inflam-

* *British Medical Journal*, vol. ii. 1886, p. 1154. The case here referred to is the first in which a cerebral abscess, due to tympanic suppuration, was correctly diagnosed, localised, and successfully treated by operation.

mation of the vein and thrombosis, or destruction of its wall and consequent fatal hæmorrhage.

The lateral sinus is liable to be similarly implicated as a result of the extension of the inflammation from the tympanum to the mastoid antrum. The intervening osseous septum is often very thin, and its continuity is generally interrupted by foramina, some of which give passage to veins. Septic infection of the lateral sinus is preceded by and associated with the presence of a subdural abscess, or, more accurately, of an extra-dural abscess. Less frequently the superior petrosal sinus becomes inflamed and contains thrombi, as a result of extensive disease of the petrous portion. According to Wreden, inflammatory thrombosis of the jugular vein and cerebral sinuses is a somewhat frequent complication of suppurative middle-ear disease: he met with it five times in thirty-six cases.

Symptoms.—These resemble those of typhoid fever, but are apt to be intermittent, the patients appearing to be tolerably well in the intervals. Rigors and pain in the head (increased on pressure) are the first symptoms, and are followed by pains in the limbs, delirium, restlessness, hyperæsthesia, and finally by evidences of cerebral depression. Consciousness may remain unaffected, but paralysis of the opposite side, sometimes of an intermittent character, is not infrequent. The skin is dry, and becomes yellowish as the case goes on; the tongue likewise is dry and blackish; the pulse is frequent and corresponds with the temperature, which exhibits irregular and rapid fluctuations, "very often amounting to a well-marked rigor."*

When the internal jugular vein is the seat of thrombosis, a swelling becomes developed on the side of the neck, extending downwards from the articulation of the lower jaw along the inner border of the sterno-cleido-mastoid muscle. The adjoining parts of the neck are œdematous, but not reddened, and the swelling is very painful on pressure. The superficial veins of the face and neck, and especially the external jugular vein, are much swollen, and pulsations may be observed in some of them; whereas the internal jugular vein, below the thrombus, may be quite empty, or, as in some cases noticed by Schwartze, more distended than the vein on the other side. When the internal jugular vein

* See a recent paper by Mr. Arbuthnot Lane, *British Medical Journal*, Sept. 9, 1893.

alone is affected, the neighbouring vessels carry off the blood from the face, and no great change is apparent; but when the thrombosis extends to the facial veins, the cheeks and eyelids become swollen and erysipelatous, and large vesicles are sometimes formed on these parts. The thrombi may also extend through a branch of the facial vein in the orbit to the cavernous sinus.

The swelling of the vein in the jugular fossa may encroach upon the eighth pair of nerves, and cause symptoms either of irritation or paralysis. The most common symptom thus caused is tonic or clonic spasm of the sterno-mastoid or trapezius muscles, supplied by the spinal accessory, the head being drawn downwards, and either backwards or forwards. When the pneumogastric is affected there is inability to swallow, loss of voice, cough, and paralysis of the laryngeal muscles.

When the superior and inferior petrosal and the cavernous sinuses are the seat of thrombi, the symptoms are apt to be more complicated. Those which have been noticed are: epistaxis, swelling of the frontal and temporal veins, and epileptiform convulsions. When the cavernous sinus is especially affected, there will be congestion of the orbital vessels, impairment of vision, intolerance of light, paralysis of the third and sixth nerves, exophthalmus, ptosis, œdema and erysipelas of the eyelids. The latter symptoms are especially suggestive of thrombosis of the cavernous sinus. When the thrombus extends into the lateral sinus there is swelling in the neck, extending from the mastoid process to the foramen magnum, and due to the impeded escape of venous blood through the emissary veins of Santorini, which connect the sinus with the veins at the back of the head and neck. From this sinus the thrombotic process may extend forwards to the superficial petrosal and cavernous sinuses, and to the superior longitudinal sinus.

When the last-named sinus is the seat of thrombosis, the most prominent symptom is swelling and tortuosity of those veins which are found between the anterior fontanelle and the temporal and auricular regions. In some cases of children, the enlargement has been very considerable; it is sometimes associated with cyanosis in the anterior part of the face, and hæmorrhage from the nose. Copious perspiration on the head and thorax has been occasionally observed. Attacks of an epileptiform character are

not infrequent, and are caused presumably by minute hæmorrhages in the cortex, consequent upon the impeded escape of blood from the convexity of the brain.

The symptoms, as above described, of thrombosis of the cerebral sinuses, resulting from ear-disease, are by no means always present in a uniform manner; several may be absent in any given case, and the diagnosis will become very difficult or even impossible. The course of the symptoms varies greatly; it is sometimes very rapid, death taking place within a few days from collapse or from implication, by metastasis, of some important organs. In other cases, the symptoms run a chronic course, and there are several remissions or intermissions, death at last taking place from pyæmia or exhaustion. As a result of softening of a thrombus, secondary deposits are liable to occur in various organs, *e.g.*, the lungs, liver, spleen, kidneys, etc., where they cause special symptoms, such as hæmoptysis, pneumonia, hepatitis, enlargement of the spleen, and hæmaturia. Sometimes metastasis takes place to the joints, pleura, and pericardium. Recovery from thrombosis of the cerebral sinuses is very rare, though a few recorded cases show that its occurrence is not impossible. There is some evidence to the effect that patients presenting typical symptoms may recover for a time, but only to succumb to the secondary effects after intervals varying from two to twelve months.*

The **Diagnosis** of thrombosis of the cerebral sinuses, consequent upon ear-disease, is sometimes difficult, and sometimes clear. Optic neuritis is very suggestive of its existence. In twenty-two cases recorded by Dr. Pitt, the optic discs were stated to be normal only in one instance; neuritis is far less common as a symptom of cerebral abscess. The otorrhœa in cases of thrombosis has generally lasted for months or years; only in rare cases has the affection of the vein or sinuses been noticed to supervene a few weeks after the appearance of the ear-symptoms, and in very acute cases life has lasted only a week or ten days after the development of the vascular lesions. Pyrexia, rigors, and headache are the most constant symptoms; and if the two former continue after the mastoid cells are opened and the tympanum thoroughly drained, there are strong reasons for sus-

* See Dr. Newton Pitt's Goulstonian Lectures on "Some Cerebral Lesions," *British Med. Journal*, March 22, 1890.

pecting thrombosis. Extreme and rapid oscillations of the temperature, taken in connection with the other symptoms will tend to establish the diagnosis.* Earache, vomiting, coma, delirium, and convulsions are more or less frequently present. Should the case become chronic, the symptoms will more and more resemble those of typhoid fever or septicæmia. There will be considerable emaciation, with a very dry tongue and rapid pulse. The local symptoms will remain as described in a former paragraph; sometimes abscesses form along the course of the internal jugular vein. Symptoms are very apt to occur in other organs, and especially the lungs, liver, and spleen. Acute pulmonary mischief is seldom absent: in three-fourths of the cases, death occurs from pulmonary pyæmia.

Treatment.—The condition being so dangerous, it is justifiable to incur serious risk in the hope of saving a patient. The mastoid antrum should first be opened, and if the state of that cavity does not account for the symptoms, the more dangerous operation should be undertaken. Only very heroic treatment can be of any avail. It consists in applying a ligature to the internal jugular vein in the neck, opening the lateral sinus, and scraping out the clot. The operation should, of course, be performed under strict antiseptic precautions, and if there be much purulent matter in the vein or sinus, irrigation should be practised. Dr. Pitt points out that in some instances it may be desirable to apply a ligature to the jugular vein low down in the neck and to seal the wound; then higher up the vein may be again tied and divided, and the upper end brought out, so that any septic matters which may pass down may escape externally. In the case of a boy, aged ten years, under the care of Mr. Lane,† for symptoms of thrombosis of the lateral sinus, after the mastoid cells had been opened and examined without result, the sinus was explored, a mass of foul clot removed, and the jugular vein tied. The boy made an uninterrupted recovery and remained quite well eighteen months after the operation. Optic neuritis had been a prominent symptom, and the fact that rigors and pyrexia continued after the mastoid cells had been explored, pointed to the existence of a thrombus.

* See paper by Mr. Ballance, *British Med. Journal*, April 5, 1890, p. 783.

† See reports of other cases operated upon by the same surgeon, *British Med. Journal*, Sept. 9, 1893, p. 561.

(4) **Ulceration of the Coats of the Carotid Artery.**—

Caries and necrosis of the petrous part of the temporal bone sometimes affect that portion which forms the canal for the carotid artery, causing destruction of the coats of the vessel and fatal hæmorrhage. Such cases are fortunately very rare; the researches of Hessler,* Moos, and Steinbrügge† have brought to light some fourteen instances, and another has been recorded by Politzer.

The anterior wall of the tympanum is in close contact with the carotid artery; any gap or deficiencies in the bony septum are of serious import, as they render the artery liable to be involved in inflammatory processes. The vessel, likewise, while passing through the canal gives off minute branches to the cavity, and along these, inflammation may extend to the main trunk, producing thickening of its walls, thrombosis, and ulceration. Gruber alludes to cases of this character, in which the connective tissue forming the sheath of the vessel was much relaxed and infiltrated with pus-corpuscles and fluid exudation.

When the arterial wall gives way, the opening is usually found at the junction of the vertical with the horizontal portion, and the corresponding part of the canal is carious or necrotic. Less commonly there are two openings in the vessel; in all cases direct communication could be traced between its interior and the tympanum. The blood, of course, pours into the latter cavity, and thence into the meatus; but in one case in which the membrane was intact, hæmorrhage took place through an opening in the floor of the auditory canal, leading to an abscess in the anterior part of the petrous bone. Some constitutional disorder could be traced in the majority of the recorded cases; thus, in eight, there was a history of tuberculosis; in one, of scrofula, and in another, of syphilis. In one case the necrosis was due to the application of a concentrated acid. In several of the cases the arterial lesion was accompanied by meningitis and cerebral abscess, the result of the caries and necrosis of the temporal bone.

The **Symptoms** of ulceration and rupture of the carotid artery are sufficiently distinct. Blood streams forth from the ear in more or less distinct jets, or trickles away continuously. It also

* *Archiv für Ohrenheilkunde*, Bd. xviii.

† *Zeitschrift für Ohrenheilkunde*, Bd. xiii.

finds its way through the Eustachian tube into the throat, whence it passes into the stomach or is ejected from the mouth. The ordinary symptoms of loss of blood are soon exhibited; the patient becomes pale, faint, and collapsed. In some cases death ensued from the first hæmorrhage; in others, the flow ceased and the patients rallied for a while, and the hæmorrhage was repeated at intervals from ten to twenty times until the fatal result ensued. The time between the latter and the first appearance of the symptoms varied, in the cases alluded to, from five minutes to thirteen days. In several instances the carotid artery was tied; but all of them terminated fatally.

The **Diagnosis** can seldom be difficult. There is the previous history and symptoms of severe middle-ear suppuration, the sudden discharge of arterial blood from the meatus, and the possibility of arresting the bleeding, at least temporarily, by compressing the carotid artery on that side. In hæmorrhage from the ear from ulceration opening into the lateral sinus, the blood is dark-coloured, and the flow is not influenced by compression of the carotid artery.

Treatment.—Compression may first be tried, but after a time it is apt to become too painful to be borne, and its effects are only temporary. Ligature of the carotid will of course arrest the hæmorrhage which, however, is likely to recur. The operation was performed in one of the cases alluded to above; the hæmorrhage ceased during nine days, and then reappeared, the carotid artery on the other side was then tied, but death took place three days later from a recurrence of the hæmorrhage. As a matter of course no permanent result can be expected from injecting styptics into the middle ear, though the hæmorrhage may be thereby checked to some extent for a time. The chlorides of iron and zinc have been employed for this purpose.

(5) **General Tuberculosis.**—There remains one more consequence of middle-ear suppuration to which reference must be made, viz., general tuberculosis. In not a few cases of otorrhœa, the complaint exercises an unfavourable influence upon the general condition of the body, and the majority of such patients die without reaching old age. Perhaps there may not be decided symptoms of phthisis, but emaciation, weakness, and cachexia gradually become more and more evident, and the general results are attributable to the absorption of morbid matters from the

cavity of the tympanum or mastoid cells. More than thirty years ago, Buhl* pointed out that when pus was collected in an osseous cavity, the walls facilitated the absorption of the morbid materials, and the consequent supervention of miliary tuberculosis. The tympanic cavity is for the most part bounded by osseous walls, and when it is the seat of suppurative inflammation it closely resembles an abscess situated in a bone.

Referring to the occasional difficulty of discovering caseous sources of infection in the bodies of persons who have succumbed to miliary tuberculosis, Dr. Barr† alludes to the fact that the mastoid process is almost always neglected by pathological anatomists, and yet the conditions for the development of caseous masses exist there more frequently than in any other place. The mastoid cells are especially liable to be invaded by micro-organisms, which readily gain access either through the throat or directly through the meatus. Among these, the bacilli of tubercle must often find their way into the cells; and in favourable cases, general tuberculosis is sooner or later set up. All conditions which tend to depress vitality, such as improper food, cold, damp dwellings, insufficient ventilation, etc., will increase the liability to constitutional infection from these *foci*.

Tubercular meningitis, in all probability, frequently owes its origin to caseous deposits in the ear. The pia mater is closely connected with the middle ear by means of lymphatic channels. Dr. Barr points out that the internal auditory artery, which is distributed to the pia mater, close to the favourite seat of the tubercular deposits, anastomoses freely with the stylo-mastoid artery which supplies the greater part of the blood to the mucous membrane of the middle ear. These vessels are accompanied by plexuses of lymphatics, which presumably act as the carriers of the infective materials; and the preference of tubercle for the base of the cerebrum may thus be explained on anatomical grounds.

CHAPTER XXXV.

LOCAL AND GENERAL AFFECTIONS LIABLE TO CAUSE
DISORDERS OF HEARING.

Two Principal Classes—Extension of Morbid Processes and Localisation of Specific Micro-Organisms in Ear—Cerebral Anæmia and Hyperæmia—Cerebro-Spinal Meningitis—Lesions of Cerebral Blood-Vessels—Lesions of the Psycho-Acoustic Centre—Acute Hydrocephalus—Tumours of the Brain—Spinal Diseases—Croup, Diphtheria, and Scarlatina—Measles—Mumps—Influenza—Typhus, Typhoid, and Small-Pox—Tuberculosis—Syphilis.

MANY diseases, of a more or less grave character, are liable to be accompanied by disorders of hearing and lesions of the auditory apparatus; in some instances, as a direct consequence of the extension of morbid processes, and in others as the result of the constitutional disturbance and of the localisation of specific micro-organisms in portions of the ear.

Almost any morbid process in the brain may cause disorder of hearing, either by directly involving the auditory nerves or nervous centres, or by setting up irritation which is transmitted to those parts. The diseases of the brain and its membranes which most often cause aural complications are hyperæmia and anæmia, encephalitis and meningitis, lesions of the blood-vessels (as in apoplexy), hydrocephalus, and new formations. Any of these conditions may, however, exist without producing auditory disturbance; the occurrence of the latter is for the most part the direct result of pressure upon, or irritation of, the auditory nerve, and if these conditions be absent, there will probably be no functional derangement of the sense-organ.

In another class of cases, the aural complications are pro-

duced in a different manner. The diseases with which they are associated are due to the presence in the blood of specific micro-organisms, and these latter are conveyed to the organ of hearing in which they exert their deleterious influences. In some of these diseases, of which scarlatina may be taken as the type, the morbid processes in the ear would appear to result from extension of disease from the throat through the Eustachian tube. In others—*e.g.*, influenza and tuberculosis—the excitants of the aural disease would seem to be conveyed by the vascular or lymphatic channels, for there is no necessary throat-disease as a starting-point and source of the mischief.

The present chapter will be devoted to a consideration, firstly of those local diseases which may affect the ear, and secondly of those general disorders which are more or less frequently attended by aural complications.

Cerebral Anæmia and Hyperæmia, unless associated with organic lesions, seldom cause any serious change in the hearing-power. They may, however, give rise to subjective sensations in the ears, such as noises of various kinds, and to giddiness; and anæmia, as in persons convalescing from severe diseases, is an occasional cause of deafness, which subsides as the general condition improves.

In ordinary meningitis, the auditory nerve and the structures of the labyrinth are seldom affected. Politzer alludes to a few cases in which purulent inflammation of the ependyma, softening of the floor of the fourth ventricle, purulent infiltration and atrophy of the auditory nerves were found after death. In children who recover, deafness from this cause is usually complete, and for some months afterwards symptoms of loss of co-ordination are generally present. In adults, the deafness is apt to be less marked, but noises in the ears may continue for indefinite periods. In hæmorrhagic pachymeningitis, deafness has been found to be due to extravasation of blood between the fibres of the auditory nerve.*

Cerebro-Spinal Meningitis is often accompanied by symptoms of auditory disturbance, and followed by serious lesions of the internal and middle ear. At an early stage of the complaint, noises in the ears and more or less deafness are frequently noticed,

* See report of a case examined by Drs. Moos and Steinbrügge, *Archives of Otology*, vol. xi. p. 322.

and may continue until the patient becomes insensible. In fatal cases, the following appearances have been observed: swelling and hyperæmia of the trunk of the auditory nerve, and purulent matter deposited around it; suppurative inflammation of the tympanum, and a similar condition, accompanied by hæmorrhagic effusion, in the membranous labyrinth. The changes in the latter structure may be developed independently of the other aural lesions, and either as a result of the neuritis or by propagation of the mischief along the aquæductus vestibuli and cochleæ. Facial palsy is absent in the majority of cases.

Children are more liable than adults to be thus affected, and the loss or impairment of function generally extends to both ears. Should the meningitis terminate favourably, marked unsteadiness of gait is often associated with the deafness, and is a prominent feature during convalescence. This, however, passes off after a time, but the deafness remains. It is a somewhat remarkable fact that the liability to aural disease is not in proportion to the severity of the meningeal disorder, and different epidemics vary as to the frequency of the complication referred to. Thus, cases have been observed in which the febrile symptoms were of a very acute type, but the aural complications were absent. On the other hand, the latter are sometimes severe and frequent among what may be termed abortive forms of cerebro-spinal meningitis. Politzer thinks that impairment of hearing and disturbance of equilibrium, as complications of cerebro-spinal meningitis and likewise of simple inflammation of the meninges, are sometimes due to pathological changes in the brain without any lesions in the organ of hearing itself. In some cases the deafness is accompanied by impairment of vision in one or both eyes, by disorders of speech, and symptoms indicating that other nerves are involved.

Cerebro-spinal meningitis is the most common cause of acquired deaf-mutism, and in this connection a special interest is attached to the former disease, inasmuch as a controversy has arisen with regard to the etiology of certain cerebral symptoms of a more or less mild character, but liable to be attended by loss of hearing. In 1882, Dr. Voltolini,* of Breslau, published an account of 187 deaf-mutes, whose malady was due, in his opinion,

* *Die Acute Entzündung des hautigen Labyrinthes der Ohres Irrthümlich für Meningitis Cerebro-Spinalis Gehalten*, Breslau, 1882.

to otitis labyrinthica, and in whose history he failed to recognise any indication of cerebro-spinal meningitis. On the other hand, Drs. Hartmann* and Gottstein† have shown that Voltolini's views are erroneous, and that at least in the majority of his cases, the aural affection was the result of epidemic cerebro-spinal meningitis. This conclusion has been also adopted by Professor Moos, of Heidelberg, in his monograph on the disease in question.‡ According to the same authority, when the deafness comes on between the third and tenth day of the disease, the labyrinth is involved by becoming in itself the seat of inflammatory changes; but when the deafness begins on or after the fourteenth day, the internal ear has become affected by extension of inflammation along the auditory nerve.

Dr. H. Knapp,§ of New York, considers that in cerebro-spinal meningitis, the eye as well as the ear may be affected in two ways, viz., by propagation of the inflammation along the optic and auditory nerves—which for the eye at least is the rarer of the two—or secondly, by metastatic inflammation of the interior of the eye and ear. In cases belonging to the second category, the functions of the visual and auditory organs are not always destroyed. Voltolini's theory of an independent otitis intima fails to explain the simultaneous occurrence of disease in the two organs.

The **Prognosis** in the cases under discussion is very unfavourable; improvement is quite the exception when the hearing is much impaired, and any change for the better is seldom permanent. According to Prof. Moos, those who are able to hear high notes have a better chance of recovering hearing than those who cannot; and in cases of absolute deafness without tinnitus, the occurrence of the latter symptom is favourable, as showing a tendency in the auditory nerve to resume its function.

Treatment.—As soon as aural complications are discovered in a case of cerebro-spinal meningitis, cold should be continuously applied to the ear and mastoid process, while the ordinary remedies are used to subdue the fever and other symptoms.

After a time the preparations of iodine may be given with the view of promoting absorption. Politzer also recommends the internal use of pilocarpine, four to six drops of a two per cent. solution, or about three drops subcutaneously injected. An ointment containing iodine or iodoform may at the same time be applied to the mastoid process. Neither strychnine nor electricity would seem to be of any use in these cases.

Lesions of the Cerebral Blood-Vessels, including embolism, aneurism, and rupture, may disturb the function of hearing in various ways; the result, in such cases, depending upon the site of the lesion. When the latter, though small in extent, is situated so as to involve the auditory centres, or any portion of the auditory nerve, the hearing is likely to be very seriously affected. Degenerative changes in the labyrinth, with loss of hearing, are sometimes due to embolism; thus, in a case of endocarditis, the sudden deafness which supervened was found after death to be due to embolism of the internal auditory artery. The same process in vessels at some distance from the ear may likewise cause deafness as a result of secondary processes in the brain. Aneurism of the basilar artery is liable to cause deafness; in some recorded cases of this kind, the loss of function was for a time intermittent. Hæmorrhage from the cerebral vessels does not frequently produce disorders of hearing; in most of the cases in which this symptom was present, either the pons Varolii or the cerebellum was the part affected.

The frequent occurrence of deafness in connection with lesions of certain parts of the brain has helped to indicate the spots in which the acoustic centres are localised. In several cases in which, after death, the left temporal convolution was found to be the seat of various lesions, such as embolism, softening, tubercle, etc., it had been noticed that the patients had not been able to understand what was said to them, although they evidently heard the sounds of the words. It was therefore assumed that the psycho-acoustic centre was placed in the cortex of the left temporal convolution, and that excitement of the auditory nerve led to the formation in this part of an acoustic representation of words. Destruction or removal of this centre is followed by a condition in which sounds are heard, but the sense of words is not understood; this is termed sensory aphasia or word-deafness. It would therefore seem that the first left temporal convolution is the

psycho-acoustic centre. Munk's experiments, however, show that adjacent ganglia must possess the same function, for, after injury to the greater part of the centre, the disorder of hearing subsides in the course of a few weeks.

There would appear to be an analogy between disorders of hearing, due to central lesions, and those of vision, produced by a similar cause; and three forms may be distinguished. The first is simple cortical deafness; the second is psychical deafness, in which the patient is unable to interpret any impressions made upon his auditory nerves; he does not understand what is said to him, and fails to recognise any difference between the barking of a dog and the ringing of a bell, etc. In the third form, or word-deafness, the patient hears the words, and can repeat them, but cannot affix any significance to them. He resembles one who in early youth has learned a foreign tongue, and at a later period has completely forgotten it. This condition of word-deafness is said to be not infrequent in syphilitic disease of the brain, such as gummata of the cortex, and is generally combined with hemiplegia.

Acute Hydrocephalus is sometimes accompanied by deafness, which, should the patient survive, may either subside or remain permanent. In a small proportion of deaf-mutes, the loss of function is attributable to an attack of hydrocephalus in early childhood. The lesions produced by the disease are stated to be inflammatory changes in the floor of the fourth ventricle, and softening and atrophy of the auditory nerve-nuclei. In chronic hydrocephalus, the nerve becomes atrophied from pressure.

In cases of **Tumour of the Brain** sight is far more frequently affected than hearing, and complete deafness is comparatively rare. More or less impairment of function is noticed in about one-thirteenth of all cases. Ladame's statistics show that the hearing was affected in seven out of seventy-seven cases of tumour of the cerebellum; in three out of fourteen of tumour of the middle lobe; while in forty-five other instances, the parts involved being the anterior lobe (twenty-seven), the posterior lobe (fourteen), and the floor of the fourth ventricle (four), there was no disorder of the hearing-function. The affection of the auditory nerve was caused in various ways, the principal changes being atrophy of the trunk or nuclei from pressure; embolism of the internal

auditory or basilar artery; extravasation of blood at the base of the brain or in the labyrinth.

The symptoms pointing to implication of the auditory nerve are deafness of various degrees, subjective sensations and giddiness: the deafness is generally unilateral, but sometimes both sides are affected. Evidences of disorder of vision are very commonly superadded; and in some cases these latter precede the deafness.

Syphilitic Growths in the Brain may involve the auditory nerve with disorder of function as a result. In a case of this kind, recorded by Wernicke and Friedlander,* a lesion existed in the temporal lobe on both sides. The patient, a woman aged forty-three, had suffered from epilepsy in her youth, and about a year before her death, the attacks returned, and were accompanied by deafness, to which aphasia and right-sided hemiplegia were afterwards superadded. She was under treatment for some weeks, with the result that the speech was somewhat improved when she was discharged from the hospital. A month later she returned with her left arm decidedly paretic, but restoration of power in the right arm. There was no further improvement in the speech, and the deafness on both sides was complete. She died a few days afterwards with symptoms of leukæmia. Post-mortem examination showed gummatous softening in both temporal lobes and lesions indicative of syphilis in many other organs. In the left temporal lobe, the whole of the first and second convolutions and a portion adjoining were occupied by the deposit. In the right temporal lobe, the superior and posterior portions were involved, while anteriorly the deposit extended almost to the parietal lobe.

Disorders of the spinal cord are sometimes attended by disorders of hearing. Thus in locomotor ataxy, noises in the ears, deafness, and auditory hallucinations are not very infrequent. Giddiness is much more common, and may be attributable to lesions of the nerve-fibres supplying the semi-circular canals. Atrophy of the auditory nerve has also been discovered in several cases of ataxy.

It now remains to consider the aural complications which more or less frequently attend certain general disorders, for the most part febrile in character. Chief among these are diphtheria,

* Cited by Gruber, *Op. cit.*, p. 623.

scarlet fever, measles, mumps, and influenza. Aural diseases are also not infrequently due to tuberculosis and syphilis.

CROUPOUS AND DIPHTHERITIC INFLAMMATION OF THE MIDDLE EAR.

Both these forms of inflammation occur in the middle ear; the diphtheritic form is rarely an independent affection. It sometimes happens that when diphtheria attacks the throat and causes death, the Eustachian tubes and tympanic cavities are found to be occupied by secretions and membranous formations, which latter belong rather to croup than to the original affection, inasmuch as they affect the surface only, and can be more or less easily detached. Croupous deposits sometimes accompany chronic middle-ear suppuration and perforation of the membrane; they take the form of greyish-white patches, and are presumably due to infection from without.

During the last few years, evidence in some cases has been obtained of positive diphtherial invasion of the tympanum by the special bacillus, discovered by Klebs and Löffler. The patients were children who had succumbed to pharyngeal diphtheria, and whose tympanic cavities were filled with secretion. Cases of diphtheria of the tympanum, associated with a similar affection of the pharynx, have been recorded by Wendt,* Kupper,† Loring,‡ Stocquart,§ and Hirsch.|| In one of Dr. Hirsch's cases, that of a child twenty-one months old, who had died from diphtheria of the pharynx and larynx, the mucous membrane of the tympanum was greatly thickened, almost obliterating the entire cavity, and was covered with a tenacious membranous deposit. This exudation was found, under the microscope, to consist of a fibrinous network, with many red and white blood-corpuscles and other cellular elements. After the use of Weigert's method for staining, vast numbers of micrococci were discoverable. It is worthy of note that in this, as in similar cases, very slight evidences of inflammation were found in the Eustachian tube, as compared with the pronounced affection

* Wagner's *Archiv f. Heilk.*, vol. xi. p. 257.

† *Archiv für Ohrenheilk.*, vol. xi.

‡ *Ibid.*, vol. xviii. p. 102.

§ *Ibid.*, vol. xxii. p. 45.

|| *Archives of Otology*, vol. xix. p. 34.

of the pharynx and tympanum, and it seemed probable that the morbid agents reached the tympanic cavity by way of the blood-vessels or lymph-channels, and not through the tube. Two cases of diphtheria of the tympanic cavity without marked implication of the Eustachian tubes have been recorded by Burckhardt-Merian.*

There is no doubt as to the important part played by micro-organisms in the causation of this disease, though inoculations have failed to prove with certainty that diphtheria is due to the presence of any one organism. In three fatal cases of diphtheria, in which the middle ear was invaded, Dr. Moos† was unable to discover any micro-organisms in the diseased parts; but in six other cases micrococci and streptococci were found in abundance. Many of the histological observations of croupous or diphtheritic inflammation of the middle ear were made in cases of nasopharyngeal diphtheria which had spread through the Eustachian tubes. The Vienna specialists maintain that primary pharyngeal diphtheria is not very often accompanied by a similar affection of the ear; but that if the pharyngeal disease be associated with scarlatina, croupous inflammation of the middle ear is very liable to occur. In Dr. Moos's opinion,‡ all we can say is that the primary pharyngeal diphtheria is *more rarely* complicated with diseases of the middle ear than scarlatinal diphtheria. In many of the recorded cases, it is impossible to state definitely whether the changes should be described as croupous (*i.e.*, superficial fibrinous) or diphtheritic (S. Hirsch).

In severe cases of diphtheria of the middle ear the destructive changes are apt to be very considerable. Thus the greater part or the whole of the membrana tympani may be destroyed; the ossicles and osseous walls may be the seats of extensive caries or necrosis; the carotid and facial canals may be opened or broken up; and the mischief may spread to the labyrinth and to the jugular fossa. The process has been known to extend to the external meatus and the auricle. Dr. Bezold§ has collected the statistics of 185 cases of aural disease associated with scarlatina. Among these there were thirty in which the tympanic mem-

§ *Archiv für Ohrenheilkunde*, vol. xxi.

brane was entirely destroyed and one or more ossicles lost; in fifty-nine, there was destruction of at least two-thirds of the membrane.

Symptoms.—Diphtheritic inflammation of the tympanum generally affects both sides at the same time and extends to the cavity from the throat. The first symptoms are more or less severe pain, and high fever. Deafness is likewise present; but the patient soon becomes dull and apathetic, and the state of partial unconsciousness is interrupted only by short periods of restlessness and excitement. If it be possible to examine the ear, the tympanic membrane is found to be of a dusky bluish-red colour and much swollen, so that not even the short process of the malleus can be distinguished. This condition of the membrane probably explains the frequent absence of perforation. On the other hand, the structures within the tympanum rapidly become disorganised; the ossicles and the structures connecting them together are rapidly involved. In diphtheria associated with scarlatina, the tympanic membrane soon gives way, and is often completely destroyed; the secretion, at first scanty and sero-purulent, becomes copious and thicker, and contains epithelial shreds and portions of diphtheritic membrane. Facial paralysis is not uncommon, and may affect both sides; it is generally due to destruction of the walls of the aqueduct of Fallopius. The process is very apt to extend to the labyrinth, with total deafness as a result of the destruction of the nervous tissue. A similar condition more often follows the disintegration of the sound-conducting apparatus; and young subjects, if life be preserved, are very liable to become deaf-mutes. Extension to the external meatus has been already referred to. The auricular, submaxillary, and cervical glands are always more or less swollen.

In non-fatal cases, the suppuration and purulent discharge may continue for several months. Even if the secretion should cease, the perforation in the tympanic membrane very rarely heals. Cranial complications—*e.g.*, meningitis, cerebral abscess, and thrombosis of the sinuses—may set in during the suppurative stage, and end rapidly in death.

Prognosis.—This is always bad, for even in comparatively mild cases, more or less structural damage is certain to remain in the tympanum. The prospect is worse in all respects among children; the risk of deaf-mutism has been already alluded to, and if this

be avoided the dangers attendant upon chronic suppuration are always present. The treatment will be subsequently described.

OTITIS MEDIA DUE TO SCARLATINA.

Very severe forms of acute middle-ear inflammation are not infrequently developed in the course of scarlatina; statistics show that about 5 per cent. of all diseases of the ear owe their origin to the latter complaint. The frequency of the complication is due to the association of pharyngeal diphtheria with the scarlatina, the diphtheritic process extending along the Eustachian tube to the tympanum. On the other hand, scarlatina running its course without any trace of diphtheria in the throat may be complicated by severe purulent inflammation of the middle ear.

The frequency with which ear-affections occur during scarlatina varies in different epidemics. In two small outbreaks recorded by Burckhardt-Merian,* there were thirteen cases of middle-ear disease among fifty-one patients. The aural symptoms are usually developed when the throat affection is at its worst; but in some patients, they do not set in until the desquamative stage has been reached. They consist of violent pain in the ears, increase of temperature (which may rise as high as 104°), deafness, and swelling of the auricular, submaxillary, and cervical glands. The mastoid process is sometimes painful and tender on percussion. In children delirium and convulsions are very apt to occur. Rapid and extensive destruction of the membrana tympani is the characteristic feature of middle-ear inflammation complicating scarlatina. When the affection occurs in the desquamative stage, its onset is accompanied by distinct elevation of temperature, sometimes preceded by rigors. The fever comes on in the evening, and remits during the morning; the pain is apt to extend to the face, along the second and third divisions of the fifth pair. After perforation has taken place, the fever and the local symptoms usually subside; on examining the ear, shreds of diphtheritic membrane can sometimes be detected in the deep part of the meatus, and hæmorrhage is apt to occur when attempts are made to remove them. The discharge is at first slight; but it soon becomes copious, dark-coloured, and offensive. The perforation

* *Ueber den Scharlach in seinen Beziehungen zum Gehörorgan*, Volkmann's "Sammlung," No. 182.

is always large; sometimes the membrane is wholly destroyed, and after separation of the shreds, the inner wall of the tympanum and portions of the ossicles come into view. Months may elapse before the discharge ceases; granulations are apt to form in the tympanum, on the remains of the membrane, and even in the external meatus.

Serious impairment of hearing is the almost invariable result of this form of middle-ear suppuration. In eighty-five cases, observed by Burckhardt-Merian, eighteen were totally deaf on one or both sides, while three others became deaf-mutes. Statistics collected from various institutions show that 10 per cent. of all cases of deaf-mutism originate in scarlet fever. The loss of hearing-power is not always due to suppurative processes in the middle ear; it may also be caused by adhesions and indurations of the fenestral structures, and by lesions of the auditory nerve. The risk of extension to the cranial contents is another element of danger. Such complications as meningitis, cerebral abscess, phlebitis of the sinus, and facial paralysis, are not infrequent results of middle-ear inflammation due to scarlatina.

Treatment of Middle-ear Inflammation caused by Diphtheria or Scarlatina.—The complaint is of a very serious character, and requires very careful treatment. When the throat is the seat of diphtheritic patches, the application to the diseased spots of a 10 per cent. alcoholic solution of salicylic acid is the treatment which Burckhardt-Merian found to be the most efficacious. The application is made by means of a cotton-wool holder, the little ball of cotton being thoroughly saturated with the solution. A suitably curved holder is used to apply the same remedy to the naso-pharynx and posterior nares, the object being to prevent the extension of the process to the Eustachian tubes, and to disinfect the parts as far as possible.

In adults suffering from pharyngeal diphtheria, an antiseptic lotion should always be applied through the nostrils by means of a spray-producer (*see* page 249, and also note on page 250 the objection to the employment of a douche). It is absolutely necessary whenever scarlatina is accompanied by swelling and obstruction to respiration in the nasal passages, and by symptoms of nasal catarrh. The object of the lotion is to cleanse and disinfect the nose and naso-pharynx; a syringe is sometimes employed for the same purpose, but if any amount of force be

used, the fluid injected is apt to be driven into the Eustachian tubes.

The spray-producer should be used several times daily, its frequency being determined by the severity of the case. At the same time the throat should be frequently painted with an antiseptic lotion. The following formula is suitable:—*R* Ac. Sulphuros. $\mathfrak{z}\text{vj}$., Ac. Carbolic. $\mathfrak{z}\text{ss}$., Aq. Destil. ad $\mathfrak{z}\text{ij}$. *M*.

As a matter of course the spray-producer cannot always be used for young children, and for such patients an attempt must be made to apply an antiseptic solution to the naso-pharynx and anterior nares by means of a cotton-wool holder. In treating infants, sulphur, in the form of a fine powder, may be applied to the nose and naso-pharynx by means of an insufflator.

In addition to applying local remedies to the mouth and naso-pharynx, bags of ice, of a suitable form, should be kept in contact with the anterior part of the throat, from one mastoid region to the other. Great relief is often soon experienced, and doubtless results from the diminution of the congestion in the naso-pharynx, and a corresponding influence upon the mucous membrane of the tympanum. At first, continuous application of the ice is desirable; but afterwards, when the fever shows morning remissions, the ice should be reserved for exacerbations, and withdrawn when these are at an end. Ice may be freely given to the patient to suck; it will aid in relieving the throat-symptoms.

If, in spite of treatment, the ear has become seriously affected, and on examination it is found that the membrane has been destroyed, and the meatus is filled with diphtheritic shreds, Burckhardt-Merian's practice was to remove as much as possible of the latter by the aid of a polypus-snare or curette, and then to apply a 10 per cent. solution of salicylic acid, or the same remedy in very fine powder. These applications are apt to cause pain; but in the course of a week the diphtheritic process will cease, and the parts will speedily assume a healthy appearance. Closure of a perforation is a not infrequent result of this treatment, properly carried out. In cases in which the diphtheritic membrane is already in process of detachment, and suppuration is profuse, boric acid (1 to 2 teaspoonfuls to half a pint) should be used, as an injection, three times daily. Another and a more powerful remedy in these cases is carbolic acid, a drachm of which may be mixed with ten ounces of water. Other anti-

septic remedies, advocated by some authorities, are resorcin (2 per cent. solution); ozonic ether and papain as a pigment or spray (5—10 per cent.). Several German authorities recommend the solution of acetate of aluminium of the German Pharmacopœia ($2\frac{1}{2}$ per cent. with water). As a matter of course, constitutional treatment must be adopted throughout the progress of the case. The treatment should be continued until suppuration has entirely ceased; it is only by constant attention that the risk of serious complications can be averted. It must never be forgotten that otorrhœa due to scarlatina is a very dangerous complaint, by reason of the consequences only too likely to follow.

After suppuration has ceased, the ear must be protected from injurious influences of all kinds, and especially from draughts of cold air, moisture, and dust. The danger of a relapse is, of course, greater in cases of permanent perforation; such patients should always keep a plug of absorbent cotton-wool in the meatus, and when washing the part should be careful not to allow any water to reach the tympanum. Should any discharge reappear, recourse must be at once had to the insufflation of powdered boric acid, and if this should fail, rectified spirit, at first more or less diluted, should be instilled into the meatus every second or third day. This last remedy is especially indicated when there is a tendency to moist desquamation.

DISEASES OF THE EAR OCCURRING DURING THE COURSE OF MEASLES.

Recent observations have proved that the ear is more often affected in cases of measles than had generally been supposed. It would appear that all forms of the disease, whether mild or severe, are liable to be accompanied by aural complications which may occur at any stage and may affect any part of the organ of hearing.

Statistics show that the aural complications occur in about 4 per cent. of all cases of measles; but there are great variations during different epidemics. Among forty cases of measles attended by complications, Tobeitz* found disease of the ears in sixteen patients, and in nineteen among twenty-two fatal cases.

* *Archiv f. Kinderheilkunde*, vol. viii. p. 321.

The symptoms occurring in the ears are for the most part as follows:—

At the beginning of, or during the desquamation stage, the patients, usually children, complain of a sudden and violent pricking and deep-seated pain in the ear, generally on one side. There may be no febrile symptoms, but in some cases there are signs of throat-catarrh. On examination, the tympanic membrane appears either reddish-grey and shining, or flattened or perhaps bulged out, dull, pale, greyish-red, or decidedly reddish, unless exudation has taken place into its structure; the radiating vessels are branched and injected. The general appearances are those of tubal and tympanic catarrh, and acute catarrhal inflammation of the middle ear. The function of the part is but little affected. Under suitable treatment with gargles and inhalations, the process often comes to a standstill, without the formation of secretion. Sneezing should be avoided as much as possible. In some cases, there is a decided tendency to relapses, during which symptoms of a more acute type are prone to set in. Very severe pain is then experienced; the tympanic membrane is covered with swollen, whitish shreds of epithelium, and, when visible, is seen to be dull red or greyish in colour. Febrile symptoms are more or less prominent, and the hearing-power is decidedly lessened.

Perforation of the membrane occurs on the third or fourth day, when the pain usually subsides. In a small proportion of cases, less frequently than in scarlatina, the aural complication is unattended by any marked symptoms.

The opening is generally situated in the anterior inferior quadrant of the membrane, and is often indicated by a pulsating reflection of light over a small area. If the somewhat abundant secretion be removed with cotton-wool, a minute opening, perhaps as large as a pin's head, appears as a black spot. In most cases the aperture does not increase in size, but occasionally rapid destruction takes place in the membrane, and sometimes a second or even a third perforation, with a similar tendency to increase in size, is speedily developed. In exceptional cases, the membrane is almost entirely destroyed; but in the majority the progress is favourable, and cicatrization takes place in from two to five weeks.

The development and course of the aural disease present occasional variations. Sometimes the local affection precedes the outbreak of the general disorder, and tends to make the real

nature of the case somewhat obscure. If there be no previously existing throat-complication, the aural disease must be regarded as due to the general infection, and analogous to those evidences of disorder of the respiratory and intestinal tracts which often precede the cutaneous manifestations. In another, but less numerous class of cases, the ear-affection comes on when the eruption is at its height.

As in cases due to other causes, local complications are occasionally superadded. Thus, the inflammatory process may spread to the mastoid cells and to the periosteum. The antrum is sometimes filled with pus, and acute caries, with or without necrosis, may affect the walls of the tympanic cavity, the ossicles, and parts of the mastoid portion, and cause rapid destruction. Symptoms of meningeal irritation and epidural abscesses are occasional results. The osseous lesions are for the most part of a secondary character; they are most liable to occur when the perforation is small and unfavourably situated for the escape of discharge. Their advent is likewise favoured by the presence of constitutional disorders—*e.g.*, scrofula and tuberculosis.

Chronic suppurative disorder may follow an acute stage, and be attended by the complications already discussed. The development of polypous growths is not infrequent.

Croupous and desquamative processes may occur in the ear during the course of measles. The general symptoms are then always serious, and one or both external auditory canals are filled up with tough white membrane, which can be more easily detached than that of diphtheria, and soon re-appears. In such cases the discovery of a small perforation may prove very difficult.

Mention must be made of those cases in which the results of measles are confined to the auricle and meatus, and take the form either of circumscribed or of diffused inflammation. These are mostly seen when the eruption is very marked, and papules are somewhat prominent. The latter form largish, bluish-red elevations in the meatus, and if they become confluent may cause a severe sensation of tension, which passes off as desquamation sets in. Gangrene of the auricle has been observed in two cases of this kind.

Localisation of the morbid process in the labyrinth occurs in another series of cases. This complication is of serious import;

the tympanum may be very slightly affected, transient hyperæmia of the membrane may be all that is noticed. There is, however, more or less pain, marked disorder of equilibrium, and very troublesome tinnitus. After these symptoms have lasted for a few days or even hours, hearing-power is found to be much impaired on one or both sides, or even altogether lost. So serious a complication seldom occurs in cases of measles; the prognosis is extremely unfavourable. Among 147 cases of deaf-mutism examined by Dr. Roosa,* in seven instances measles was assigned as the cause.

The pathology of these cases has been carefully studied by Dr. S. Moos,† of Heidelberg, who discovered various histological changes in the labyrinth. In one class, these were due to a purely mechanical condition—*e.g.*, coagulation of lymph, aggregation of lymphoid cells, either isolated or in numerous groups occupying the semi-circular canals and ampullæ, the inner cavities of the utriculus and sacculus, the vestibule, etc. Tortuosity and engorgement of the blood-vessels in the petrous bone were other marked changes, and this “globular stasis” resulted in a general thrombosis which extended through the entire labyrinth. The stapedius muscle was in a state of partial degeneration. The coagulation of lymph and the other changes were connected with the presence of micro-organisms, in the forms of monococci, diplococci, and tetracocci.

The following statements seem justifiable with regard to the origin of ear-complications in connection with measles:—

The middle-ear inflammation may be the result of exanthematous eruption, or may be produced by irritants brought thither by the current of blood. In another series of cases, the aural disease is propagated from the nose or naso-pharynx.

Assuming that the changes in the labyrinth are due to micro-organisms, it may be supposed that the necrosis of tissue is either the indirect or the direct result of their presence. They cause fatty degeneration of the endothelium of the vessels and consequent thrombosis, which, in its turn, leads to grave disorder of nutrition, and even death of the affected part. The microbes likewise directly destroy the tissues which they invade, and this

* *Archives of Otolaryngology*, vol. xiii. p. 70, and *Treatise on Diseases of the Ear*, 7th Edit. p. 707.

† *Ibid.*, vol. xviii. p. 49.

effect is particularly manifested in the nervous structures. The trunk of the auditory nerve is still further destroyed as a result of hæmorrhage caused by necrosis of the vessels, and the process may be so extensive as to account for the total deafness. In only a very few cases is the loss of function temporary in its character. In such instances, when hearing is restored after two or three weeks, it may be inferred that central changes were the cause of the deafness.

MUMPS AND DISEASES OF THE EAR.

Disorder of hearing has been occasionally noticed in connection with parotitis; but the manner in which the ear is attacked remains doubtful; in some of the cases, the tympanum was the part involved in the lesion. Toynbee* pointed out the connection between mumps and deafness, and supposed that the latter was due to some affection of the auditory nerve. "As a general rule, no appearance of disease can be detected in the meatus, membrana tympani, or tympanic cavity." Hinton regarded the sequela as a somewhat common one; but the experience of most surgeons is probably to the contrary effect. Hinton's words are, "Next, or perhaps equal in frequency to scarlatina, in this respect, stands mumps, which has an effect on the nervous apparatus of the ear which has as yet received no explanation, and affords no clue to the use of remedies, every part of the ear being normal, so far as examination can extend, but the function is almost abolished." Sir W. Dalby says that mumps must be included among the causes that induce deaf-mutism, and that on many occasions he has known partial or total deafness to take place during an attack of mumps. On the other hand, Politzer makes no reference to this disease as a cause of deafness. It would appear that disease of the middle ear is not infrequently associated with the labyrinthine disorder. When, apparently, the labyrinth alone is affected, the deafness may be on one or both sides, and is generally complete and incurable. Gruber records a case in which the swelling of the gland was relatively very slight; but on the third day, the patient, a boy ten years of age, became totally deaf on both sides, and was not relieved by any treatment. The case was a

* *Diseases of the Ear*, p. 361.

sporadic one, and all the symptoms were of the mildest description. Such cases are explained by assuming a process of metastasis, and are compared with those in which inflammation occurs in the testes and breasts. Various substances may enter the circulation, and cause obstructions and secondary disturbances in organs, such as the labyrinth, with complicated circulatory apparatus, particularly when the escape of blood is in any way hindered. In typical cases, the complete deafness, its rapid occurrence, the absence of marked symptoms of middle-ear disease, and the disturbances of equilibrium which may continue for weeks or months afterwards, tend to prove that the lesion is situated in the labyrinth.

Dr. Brunner,* of Zurich, arrives at the following conclusions with regard to deafness after mumps: (1) The nervous deafness after mumps may be unilateral or bilateral, the former being more frequent. (2) It is complete, and, according to past experience, incurable. (3) It develops rapidly (that is, in a few days) with vertigo and subjective noises, the latter symptoms lasting a long time. (4) There is little or no fever, and pain is very seldom complained of, and consciousness is not lost. (5) The complication is noticed in children and in adults, and would seem to be more frequent in the latter. Cases of bilateral deafness from mumps have been recorded by Drs. Moos† and Knapp‡.

According to Dr. Haug the deafness and other aural symptoms occasionally precede the local pain and swelling, and may then be regarded as the evidences of general infection. In most cases, however, the aural symptoms are developed either between the third and eighth day of the complaint, or as the latter subsides. The deafness comes on suddenly and rapidly increases; it is usually accompanied or closely followed by tinnitus, giddiness, pain in the forehead or occiput, and nausea. The patient staggers on attempting to walk; but there is no loss of consciousness. Pain may be altogether absent, and when present, it may last only a few hours.

The degree of febrile movement varies; the temperature is likely to be high if the otitis occur at an early period. Both ears may be simultaneously or successively affected; but the symptoms

* *Archives of Otology*, vol. xi. p. 102.

† *Ibid.*, vol. xi. p. 12.

‡ *Ibid.*, vol. xi. p. 385.

are not infrequently confined to one ear, and the right is more prone to suffer than the left. The same difference is observed in the case of the testicles.

On examination, the tympanic membrane and cavity are found normal; but there is absolute deafness for sounds and notes of all kinds. Bone-conduction also is totally lost. The deafness is often permanent, though the other symptoms may gradually disappear. Deaf-mutism is sometimes, though rarely, attributable to mumps. Among 147 cases, two were said to have been caused by the latter affection (Roosa).

Besides this purely nervous lesion, exudative and suppurative middle-ear disorders may occur during the course of mumps. In these cases, the infectious material may be supposed to travel from the gland to the mouth, and thence through the Eustachian tube to the ear, where it gives rise to acute inflammation. The labyrinth is seldom affected.

According to Gruber,* the inflammation may take another course, and reach the ear through the Glaserian fissure; in those rare cases in which abscess forms in the gland the matter may, of course, pass direct into the ear.

The aural complications in these latter cases are easily explained; but the case is different with regard to the purely labyrinthine disorders connected with mumps, and at least two different views are held as to their origination. The first regards the inflammation of the parotid gland as a local disease, and the development of the processes in other organs as the results of extension or of metastasis. According to the second view mumps is a general disorder, which may localise itself in various parts of the body. The affection of the internal ear, possibly amounting in its final stage to atrophy of the auditory nerve, may be regarded as the direct local effect of the general infection, just as occurs in the testicles, ovaries, breasts, kidneys, and prostate gland. These parts, however, differ from the ear in being glandular organs.

We must suppose that the blood contains a specific virus, perhaps like the monadina of malaria, connected with the blood-corpuscles, or some other micro-organism, and that this passes into the internal ear and sets up a plastic or exudative inflammation. The products thus formed do not become absorbed, but are converted into connective tissue extending between the end-organs

* *Wiener Med. Zeitschrift*, 1884, pp. 4—6.

of the nerves and the parts around, and inducing atrophy of the sentient structures.

Another explanation, suggested by Urbantschitsch,* is to the effect that the changes in the labyrinth are due to reflex action. The irritation of the fibrils of the fifth nerve contained in the gland is conveyed to the labyrinth. This author has seen two cases of deafness consequent upon inflammation of the sub-maxillary gland. In one of these the deafness, after lasting four years, subsided for a few weeks, and then recurred and remained unaffected by treatment.

Prof. Schwartz's† view is that all the local disorders, including those of the labyrinth, which occur in mumps are due to the migration of a specific micro-organism, the exact nature of which has not as yet been definitely ascertained.

INFLUENZA AND DISEASES OF THE EAR.

During the recent epidemics of influenza various forms of aural diseases have been noticed as complications of the general affection in a small proportion of cases. These forms may be classified under four heads :—

1. Cases characterised by swelling and hyperæmia of the mucous membrane of the middle ear, with scarcely any or very little loss of function.

2. Cases in which the symptoms are pain in the ear, fever, diffused redness and exudation in the tympanum and redness of the membrane, with more or less secretion, at first sero-mucous and afterwards sero-purulent in character.

3. The purely hæmorrhagic form, and the one most typical of its origin. Either the tympanic cavity or the surface of the membrane may be the source of the hæmorrhage, which may continue at intervals during several weeks. The bleeding in some cases is preceded by the formation of hæmorrhagic vesicles. Politzer‡ observed several cases in which such vesicles were developed on the tympanic membrane. They have also appeared in the external meatus.§ (See page 184.)

* *Lehrbuch der Ohrenheilkunde*, III. Aufl. S. 436

† *Handbuch der Ohrenheilkunde*, I. Band. S. 585.

‡ *Wiener Klin. Woch.*, 1890, No. 10.

§ *Archives of Otology*, vol. xx. p. 197.

4. The fourth form is characterised by severe purulent inflammation of the middle ear, and the process is very apt to extend to the mastoid cells; this portion of the bone is often painful on the first or second day of the disease.* Politzer noticed mastoid symptoms in eighteen out of 134 cases.

In some cases of influenza the symptoms point to disorder of the labyrinth, as in two instances recorded by Dr. Moos.† In one of these the symptoms were those of Ménière's disease; in the other, that of a man twenty-five years of age, there was sudden rupture of the tympanic membrane, with escape of blood, but without giddiness. Hearing was, however, totally lost, and it was inferred that hæmorrhage had likewise taken place into the cochlea.

It must be observed that these disorders of the tympanum may either be preceded by affections of the naso-pharynx or may be developed spontaneously, *i.e.*, through the blood as the channel of infection. That this latter is the source of origin in many cases is made probable by the fact that the marked aural symptoms may occur at a very early period, either simultaneously with the fever or very soon after its development.

The hæmorrhages are certainly peculiar, though some authorities refuse to admit their special significance. In cases of influenza, hæmorrhage has been observed to take place from mucous membranes in various parts of the body—*e.g.*, the nose, the bowels, and the female genital organs. That changes take place in the blood is shown by the frequent appearance of a yellowish or jaundiced hue of the sclerotic or of the integument, the diminution of hæmoglobin, the destruction of many red blood-corpuscles, and the swelling of the spleen. Other changes in the vascular system are due to the effects of the disease on the vasomotor apparatus; the most noticeable being the alterations in the blood-pressure and the increased permeability of the capillary walls, a predisposing cause both of inflammatory processes and of capillary thromboses. It is also possible that the toxines secreted by the bacillus of influenza may cause necrosis of blood-vessels, and thus play a considerable part in the production of hæmorrhages.

With regard to the bacteria present in the ear in cases of

* *Deutsche Med. Woch.*, 1890, No. 12.

† Schwartz's *Handbuch der Ohrenheilkunde*, S. 582.

inflammation of the tympanum occurring in the course of influenza, recent investigations have shown that no one species is exclusively found, but that several may exist together or may occur consecutively. These observations are similar to those made in lung-affections connected with the same disease. In these latter, pneumo-cocci and streptococci are first discoverable; but in a later stage the former are far less in number or altogether absent. They return, however, with each exacerbation of the pneumonic symptoms. In the ear the micro-organisms most abundantly present are the pneumo-diplococci, next the streptococcus pyogenes, and lastly the staphylococcus albus and aureus. Several of these are not infrequently present at the same time. All of them have been demonstrated to exist in the secretions escaping after paracentesis, in the discharges from the ear, and in pure cultivations. It is no longer possible to assume that any one organism is the cause of the organic disorders which so frequently occur in the course of influenza.* Those organisms which have been discovered would appear to play a secondary part in the causation of the diseases in question.

In connection with the recent epidemic of 1890-91, various observers have published accounts of micro-organisms which they regarded as peculiar to influenza. Klebs† reports the discovery, in the blood, in almost every case, of a flagellate monadina, a one-celled organism executing marked zig-zag movements. It more or less closely resembled the hæmatozoon found by the same authority in cases of progressive anæmia, and was obviously analogous to the monad which Klebs regards as the true cause of malarious disorders. This protozoon is not present in healthy blood, and Klebs obtained positive results by inoculating dogs with the secretions of influenza.

The presence of such an organism appears to explain many of the symptoms of the protean complaint, and especially the nervous phenomena which often last for months, the evidences of muscular exhaustion, the profuse sweating, and the tedious stage of convalescence. It will also furnish a clue to the development of hæmorrhagic inflammation in the tympanum, the disorders of equilibrium, and the loss of function.

* *Monatsschrift für Ohrenheilkunde*, vol. xi. 1890, and *Zeitschrift für Ohrenheilkunde*, vol. xxii. p. 146.

† *Centralblatt für Bacteriol. u. Parasitenkunde*, No. 5, 1890.

It may be assumed that the micro-organism acts by causing disintegration of blood-corpuscles, and that the resulting caseous masses produce temporary or even permanent capillary thrombosis. Hæmorrhages into the tympanic cavity and membrane are the consequences of the local obstruction in the vessels. Local necrosis becomes developed, and other pathogenic organisms, notably pneumo-diplococci and streptococci, pass into the ear. The protracted character of the stage of convalescence is accounted for by supposing that a long period is necessary for the total removal of the micro-organisms from the blood.

Still more recent researches by Pfeiffer and Kitisato,* in Berlin, have brought to light another micro-organism, which they regard as the source of the influenza virus. This is an extremely minute bacillus, even smaller than the bacillus of mouse septicæmia; it is found in the sputum when the disease is at its height, and also in the blood, and positive results have been obtained from inoculation experiments on monkeys.

According to Dr. Haug, in the influenza epidemic at Munich, 1890-91, aural complications were recorded in about 12 per cent. of all cases, and were confined to the catarrhal and nervous forms of the disease. They were not noticed in the cases marked by gastro-enteric symptoms. According to this authority, the cases with aural complications might be divided into two classes: the first containing those cases in which the disease spread from the throat; and the second, those in which the aural infection was the direct result of the influenza-poison. The first class contained two sub-divisions, characterised respectively by the mildness and severity of the symptoms; while the presence of hæmorrhagic inflammation and of nervous affections served, in like manner, to sub-divide the second class.

The symptoms belonging to the first sub-division usually appear between the third and the eighth days of the complaint, and consist in more or less marked swelling and hyperæmia of the Eustachian tube, tympanum, and tympanic membrane. The subjective symptoms are comparatively slight; there is more or less pain, sometimes of a pricking character, in the deeper part of the ear and along the tube, but there is little, if any, change in the hearing-function. As a general rule, the symptoms subside in from one to three weeks.

* *Deutsche Med. Woch.*, No. 2, 1892.

In the more severe form symptoms of acute middle-ear inflammation become rapidly developed. They consist in pain in the ear and adjacent parts, impairment of hearing and tinnitus, pulsation in the deep part of the organ, redness of the membrane and osseous meatus, appearances of mastoid inflammation, and effusion, first sero-mucous and then muco-purulent, into the tympanum. Perforation of the membrane marks the next stage in the process; the opening usually takes place in the anterior inferior segment, but it is not infrequent in other portions, and sometimes occurs in Shrapnell's membrane. The complaint is generally unilateral, but both sides may be attacked, either together or in succession.

In most cases the occurrence of perforation is soon followed by amelioration of all the symptoms; the fever subsides and the pain abates, the patient is conscious of a feeling of pressure and pulsating sounds in the ear, and of more or less impairment of function. Under ordinary circumstances and proper treatment recovery is completed in from three to six weeks.

It remains to consider the second class of cases, in which the symptoms are much more serious. The inflammation is of the hæmorrhagic type, and its features are almost peculiar to influenza. The ear-symptoms* come on while the patients are suffering from catarrh of the air-passages or from the phenomena of the nervous form of the disorder; the throat is free from any catarrhal changes. The patients are usually adults; young children appear to escape this complication. The attack comes on in the evening or during the night with severe boring pain deep down in the ear; this is sometimes preceded by epistaxis. The pain rapidly increases in intensity, and spreads not only to the forehead, temples, and neck, but likewise to the thorax and upper extremity of the affected side. Sounds greatly aggravate the suffering, the evidences of which are very marked.

With the pain the fever also increases, and the loss of function on the affected side soon becomes complete. The membrane is found to be of a dull bluish-red, or even bluish-black colour, convex externally, and marked with dots. In other cases the membrane is either dark-red or scarlet in colour, and its surface is covered with tense hæmorrhagic vesicles,† some as large as a

* See an exhaustive paper by Dr. R. Haug, "Die Häufigsten Erkrankungen des Gehörorganes bei Influenza," *Münchener Med. Woch.*, 1890, No. 8.

† *Zeitschrift für Ohrenheilkunde*, vol. xxii. p. 145.

pin's head and others larger, varying in colour from bluish- to blackish-red : sometimes there is one large vesicle, and the appearances are apt to be most marked on the posterior part of the membrane.

Hæmorrhagic infiltration of the tympanic membrane, without affection of the cavity, is a less common appearance. Sometimes reddish or blackish ecchymosed spots appear on a reddened or almost normal membrane.

In all the varieties above described rupture of the membrane soon occurs, sometimes within a few hours, and is followed by the escape of dark-coloured blood, either fluid or more or less coagulated. In a small proportion of cases the hæmorrhage is so profuse that styptic remedies are required. All the former symptoms, with the exception of the deafness, now rapidly subside ; and if this course be not observed, some complication—*e.g.*, the development of acute suppuration—may be looked for. More or less purulent discharge, however, usually succeeds the escape of blood, and the symptoms then take the ordinary course. It is a somewhat remarkable fact that in the later stages of a given epidemic of influenza, the ear-complications are apt to be much more severe than at the commencement. The virulence of the organism is supposed to increase as time goes on.

The situation and size of the perforation exercise a decided influence upon the progress of the case ; an opening in the posterior superior segment, or in Shrapnell's membrane, and a very small orifice in any situation, will render the progress more tedious and increase the liability to complications. Such obstacles to the escape of secretion tend to the development of mastoid inflammation and suppuration with their attendant dangers ; and, unless proper treatment be adopted, the mischief may spread to the bones, and set up caries and necrosis, with sinus-thrombosis or pyæmia as subsequent results. Enlargement of the aperture in the membrane, a free incision behind the ear down to the bone, and opening of the mastoid antrum,* are the operative measures likely to be required in such cases. In some instances symptoms of pyæmia† are very rapidly developed, and terminate in death. Inflammation of the external meatus is another, but less frequent, complication. It may, however, prove to be severe,

* *Archiv f. Ohrenheilkunde*, vol. xxxii. p. 29.

† *Ibid.*, vol. xxx. p. 204.

and lead to troublesome abscesses in the parotid or cervical regions.

In a very small proportion of cases the aural complication is of a nervous type. The patients are usually free from all catarrhal symptoms, and the troubles in the ear are referable to the sound-perceiving apparatus. In the mildest forms there is simply more or less hyperæsthesia, for notes of all kinds and sounds in general. Vertigo and subjective sensations are usually superadded; but the hearing-power is unimpaired. These symptoms almost invariably subside.

It very rarely happens that evidences of marked disorder of equilibrium make their appearance; but cases have occurred in which this symptom became prominent, and was attended by vomiting and decided impairment of hearing. Even total deafness has been observed, and without any change in the middle ear. This complication is presumably due to the action of specific micro-organisms, conveyed to the labyrinth by the blood-current or by the lymphatics.

DISEASES OF THE EAR ASSOCIATED WITH TYPHUS AND TYPHOID FEVERS AND WITH SMALL-POX.

Typhus.—According to the late Dr. Murchison,* disorders of hearing, and especially deafness, occur in 50 per cent. of all cases of typhus fever. Both the internal and the middle portions of the organ are liable to be affected. The symptoms connected with the former part may appear at the commencement of the disease or not until the period of convalescence. In 130 cases of patients recovering from typhus, Dr. Hartmann found that thirty-six had aural lesions, and of these thirteen were suffering from acute otitis media. In many cases, about the fourth or fifth day of the disease the patients complain of noises in the ears, and especially of ringing sounds, and a few days afterwards the attendants find that there is more or less deafness, and sometimes complete loss of function. In other cases there is intolerance of sound, which is a more unfavourable symptom (Murchison). Nothing abnormal can be detected in the tympanum or middle ear. Both sides are most commonly affected; the symptoms pass off during convalescence, and the function is quite restored.

* *Treatise on the Continued Fevers of Great Britain*, 3rd Editt. p. 177.

The deafness is possibly due to softening of the internal muscles of the ear.

In another class of cases the middle ear is specially affected, and the symptoms usually begin when the fever is at its height ; but, owing to the state of the patient, they may attract little, if any, attention. The symptoms are those of naso-pharyngeal catarrh, extending to the Eustachian tube and tympanum. The patient complains of uncomfortable sensations in the throat, of more or less deafness, and sometimes of autophony. If the ear be examined, the membrane is seen to be indrawn, and its lustre is increased, while the handle of the malleus is shortened ; the cavity of the tympanum is decidedly hyperæmic. Sooner or later the subsidence of the throat-symptoms is followed by that of the ear-troubles.

There is yet another class of cases in which the symptoms are those of acute middle-ear inflammation ; there is very severe pain and marked diminution of hearing-power. Perforation of the membrane sometimes takes place ; occasionally, indeed, a copious discharge from the ear is the first symptom connected with the organ. In some cases rigors, high fever, intense headache, delirium, and even convulsions occur during convalescence, and cease at once on the appearance of the discharge. Other instances* have been recorded, in which the otorrhœa was preceded by profound coma, dilated pupils, etc. The opening is always small, and shows no tendency to enlarge ; it is generally in the lower half of the membrane. Speedy closure and restoration of function are the general rule ; complications in the labyrinth and extension of the process to the mastoid cells are very seldom noticed.

Typhoid Fever.—Aural complications connected with typhoid fever were noticed in the early part of this century. The additional fact that meningitis may be thus induced was observed and recorded by Louis† in 1841, and by Dr. Peacock‡ some years later. The frequency with which aural complications occur in this complaint would appear to vary in different epidemics ; but sometimes the proportion is as high as 4 per

* See a paper by Drs. G. A. Kennedy and W. T. Gairdner, *Glasgow Medical Journal*, 1865.

† *Récherches sur la Fièvre Typhoïde*, vol. ii.

‡ *Medical Times and Gazette*, 1856.

cent. All parts of the ear are liable to be affected; the auricle may be the seat of gangrenous ulceration, of furuncles, and of abscesses. Moreover, in severe forms of typhoid, the parotid gland on one side is sometimes the seat of abscess, and the pus may find its way through the fissures of Santorini into the meatus.

In the middle ear, the symptoms vary in character, but assume for the most part two principal forms. In the first of these, the condition is mainly catarrhal, and the Eustachian tube is especially affected. In the second, inflammatory symptoms predominate, and the exudation is manifestly purulent. The former condition is rare; but the second is decidedly common, and may be attended by serious consequences.

In most cases the aural symptoms appear during the later stages of the fever—that is, during the fourth week. The patient complains of pain (not particularly severe) and deafness; the tympanic membrane is hyperæmic, and more or less swollen and opaque. These symptoms continue for two or three weeks, and then subside. The complaint, however, not infrequently assumes a more serious type. There is severe and increasing pain, marked deafness, tinnitus, and evidences of decided inflammation of the membrane; bone-conduction is not interfered with. The temperature, which may previously have approached the normal, again rises in proportion to the inflammation.

After a few days perforation occurs, and most commonly in the posterior superior quadrant. This exceptional position is said to be due to the fact that the patient almost constantly lies on his back; multiple perforations are not very rare. The discharge, at first sanious, soon becomes purulent, and contains numerous shreds of epidermis. In a later stage, granulations and polypoid growths are somewhat common. The proliferation and detachment of epithelial cells gradually cease, and the membrane assumes a more normal condition; the perforation appears as a black opening in a red surface.

The subjective symptoms do not subside with the establishment of the perforation, and febrile attacks are apt to recur, especially when the opening becomes blocked up, and the secretion is prevented from escaping. As a general rule the opening shows no tendency to enlarge.

A marked feature in these cases of middle-ear inflammation

connected with typhoid fever is the tendency of the process to extend to the mastoid portion. Such extension occurs very soon after the development of the disease in the tympanum; in some cases indeed it would appear to be contemporaneous with or even antecedent to it. At a very early period there is often tenderness on pressure over the mastoid, and pus may form under the periosteum; and the bone may become either carious or necrotic. Caries of the ossicles is another complication which will greatly prolong the duration of the case. As a general rule, however, inflammation of the middle ear, connected with typhoid fever, gradually subsides, and the parts are restored to their normal condition. If, however, the mastoid complication be severe, and an operation be required, the course is certain to prove tedious. Symptoms of meningeal irritation sometimes appear, and may prove serious, but they are usually transient, and are due only to hyperæmia extending from the labyrinth. In one case, recorded by Dr. Murchison,* the head-symptoms appeared at intervals during more than two years. The patient, a girl aged sixteen, had suffered from typhoid fever, and on the thirty-fourth day pain in the ear and deafness were complained of. Five days later there was purulent discharge. Three months afterwards there were marked head-symptoms, and the attacks continued for more than two years. During this period there were frequent signs of mastoiditis, and detachment of portions of the bone.

There is yet another class of cases in which the aural complication of typhoid fever affects the nervous structures. The symptoms appear in the early stage of the disease, and consist of very severe tinnitus, the sounds being of a ringing or buzzing character. They are accompanied by a greater or less degree of deafness, affecting generally both sides. Disorder of equilibrium has not been noticed, and no objective changes can be detected on examination.

The course of the aural complication is for the most part favourable, but there is this remarkable feature connected with it, viz., that the local symptoms are apt to be redeveloped during recurrences of fever. Subsidence is, however, the rule, and only in a very small proportion of cases is there any permanent deterioration of hearing-power.

With regard to the cause of these aural complications of

* *Treatise on Continued Fevers*, 3rd Edition, Case No. 59, p. 564.

typhoid fever, the gangrene of the auricle must be set down as evidence of a trophoneurosis, and not as the result of pressure. The affections of the middle ear are in part due to extension from the pharynx, but in still greater measure to the direct action of the micro-organisms contained in the blood. Not only the bacilli of typhoid, but staphylococci, streptococci, and diplococci take part in the causation of the local disease.

The cause of the nervous form of the complication is very obscure. Changes in the blood-current may be assumed to exist, or it may be supposed that the specific virus gains access to the labyrinth and affects the organ of hearing, or causes changes in the nervous elements. In fatal cases, deposits of lymphoid cells, infiltrations of small cells, connective-tissue formations, and fatty degeneration of various parts have been occasionally observed.

Small-pox.—This disease is rarely attended by aural complications; the proportion in which these appear varies from 0·2 to 1·6 per cent. Moreover, they are seen only in the severe forms (confluent and hæmorrhagic), and not in the ordinary type of the disease.

In many cases of severe small-pox the eruption is very marked on the auricle, and shows itself at a very early period. The pustules follow the usual course, and cause great swelling of the part and alteration of shape. Owing to their confluence large accumulations of pus are sometimes formed. The osseous meatus remains unaffected; but the cartilaginous portion may be quite occluded by the pustules, which cause not only severe pain, but also deafness and noises in the ear. In later stages some amount of ulceration may take place, and the resulting cicatrization may produce more or less of deformity.

In some cases, however, the aural affection is of a different kind, and is due to extension from the throat. The symptoms are pain, moderate deafness, and a hyperæmic and indrawn condition of the membrane; but these may remain unnoticed when the constitutional symptoms are in any way severe. Occasionally the aural complication is much more serious; the membrane soon becomes perforated, and the symptoms are those of diphtheritic inflammation. In exceptional cases suppurative inflammation of the labyrinth is superadded. In another class of cases the Eustachian tubes are the parts most affected; ulceration

occurs, and the healing process results in obliteration of the tube.

In the severest or hæmorrhagic form of small-pox, symptoms referable to the ear are usually masked by those of the general condition. On post-mortem examination the labyrinth has been found in a condition of marked hyperæmia, or presenting circumscribed or diffuse patches of infiltration. Hæmorrhage into the sheath of the nerve is another appearance, and is presumably due to embolism and rupture of vessels.

TUBERCULOUS DISEASE OF THE MIDDLE EAR.

Tuberculosis of the middle ear is not uncommon; the complaint is, however, generally secondary to tubercular deposits in other organs, and especially in the lungs. A few cases of primary tuberculosis of the temporal bone have been placed on record. Zaufal* reports a case in which a mass of tubercles was imbedded in the compact tissue of the petrous bone, and did not communicate with any of the adjacent cavities. In another instance,† the internal auditory meatus was blocked up by a mass of tubercles as large as a pigeon's egg.

The Eustachian tube is the ordinary channel through which bacilli pass into the tympanum, but they may also escape from the vessels of the periosteum of the middle ear. In the propagation of tuberculosis, the Eustachian tube acts in one of two ways: it either remains normal, and serves merely as a channel for infective materials, the movements of which depend upon variations of air-pressure, or its mucous membrane is the seat of disease, which is continued into the middle ear. When perforation exists in the tympanic membrane, bacilli can easily pass into the cavity from the outer air.

Anatomical Appearances.—The first trustworthy accounts of tuberculosis of the middle ear were given by Schwartz,‡ who described small grey, miliary nodules on the inflamed and proliferated mucous membrane on the inner wall of the cavity. The patients were children, the subjects of tubercle, suffering from purulent otitis. He likewise described caseous inflammation of

* *Archiv f. Ohrenheilkunde*, II. 174.

† *Ibid.*, vol. v. p. 292.

‡ *Pathol. Anatomie des Ohres*, S. 99.

the tympanic mucous membrane, occurring almost exclusively in tuberculous subjects. Similar cases were described by v. Tröltsch, who considered that the appearances were due to specific tuberculous processes in the tissues of the tympanum and membrane. In recent times the diagnosis has been established by the discovery of the tubercle-bacilli.

Tuberculosis of the tympanum occurs in two forms, acute and chronic; these are marked by differences in the anatomical appearances. In the first form, diffuse cellular infiltration of the mucous membrane and proliferation of the cellular elements are the prevailing features. There are few, if any, giant cells, but large numbers of tubercle-bacilli. The result is extensive necrosis of the diseased mucous membrane, the tissues of which become caseous and disintegrated. Great loss of substance necessarily ensues; but this form usually occurs in much debilitated subjects, and death puts a stop to the progress of the local disease. In the second, or chronic form, circumscribed masses of tubercle are first seen in the superficial layers of the mucous membrane; their centres become caseous, and giant cells are developed, but bacilli are not very abundant. Caseous disintegration results in superficial ulcers, and fresh deposits of tubercle take place in the deeper layers. In consequence of inflammatory proliferation of cells and infiltration with leucocytes, the mucous membrane becomes much thickened; healthy granulations may then spring up on the surface, and the deeper deposits may be isolated and rendered harmless by connective tissue formation. Under favourable circumstances, the process may come to an end with healing as the ultimate result.

In most cases, however, the disease extends, for the caseous masses, detached from the surface, infect other portions of the mucous membrane, and a similar process readily takes place between parts already in contact. Thus the inner surface of the membrana tympani and the whole outer wall of the cavity, the mucous covering of the ossicles and fenestræ are all liable to be invaded. As deeper layers of the mucous membrane are attacked the bones become involved, and the carious process extends to the ossicles. Destruction of the foot-plate of the stapes or of the promontory lays open the labyrinth, and the tuberculous process extends to the perilymphatic space. Unless the tube be already affected, the process extends thither from the cavity; and the

mastoid antrum and cells are likewise apt to be invaded. Portions of the mastoid process are often detached as sequestra, after the formation of abscesses. Caries of the roof of the tympanum is likely to lead to inflammation of the dura mater, which either becomes perforated or much thickened. Carious destruction of the floor of the tympanum may expose the jugular vein or the carotid artery, with fatal hæmorrhage as an almost certain result. The canal of the facial nerve may become involved, and the process may extend along the nerve towards the periphery, or in the opposite direction to the internal meatus. Extension to the cochlea is another possible result. Lastly, when the process has become very severe and chronic, the access and development of other micro-organisms may set up profuse suppuration, or gangrene and fatal septicæmia.

Symptoms.—In the majority of cases, unless perforation had already existed in the membrane, the first symptom noticed by the patient is the sudden discharge of a somewhat large quantity of purulent matter. This is sometimes preceded by sensations of fulness or pressure and impaired hearing; but severe pain, so marked in acute suppurative inflammation of the ordinary type, is always absent. This sudden, painless discharge of pus from the ear is characteristic of the complaint. In all other processes accompanied by exudation into the cavity and rupture of the membrane, acute pain is a constant and early symptom. Its absence should at once excite the suspicion of tuberculosis. Deafness is marked only when deeper parts are involved; it is then often accompanied by noises in the ears. The local affection tends to aggravate the general condition of the patient. It is always of serious import, notwithstanding the comparative mildness of the symptoms.

Diagnosis.—The nature of the case can seldom be ascertained until the membrane has given way and the secretion has escaped. But before these symptoms have appeared, certain changes may sometimes be discovered in the tympanic membrane. This latter becomes dull and yellowish-grey in colour, and minute reddish-yellow patches are seen on its surface and mark the spots at which perforation takes place. The openings, at first very small, rapidly become larger, owing to suppurative disintegration of their margins. As this latter process extends several openings coalesce, and in this way the greater portion of the membrane

may be destroyed. The rapid enlargement of the openings and their confluence are characteristic symptoms of the disease. With regard to the diagnostic value of bacilli in the discharges, Dr. Gottstein* states that the micro-organisms of tuberculosis are by no means always discoverable. He cites several instances in which bacilli were abundant in the sputum, but could not be found in the pus discharged from the ear. In other instances there was positive evidence of the presence of bacilli.

Perforation usually exists in the lower half of the membrane, the remainder being pale and greyish-yellow. The mucous membrane, as seen through the opening, is either reddish or yellowish; it is sometimes dotted over with caseous masses, and sometimes ulcerated. When the perforation is larger it may be seen that both malleus and incus are either displaced or wanting; in some cases they are quite covered up by greyish-red masses of granulation. In a subsequent stage, but sometimes, even at an early period, the bone is found to be involved; there may be caries of the mastoid process or of the petrous bone, or of the osseous wall of the labyrinth.

Prognosis.—This is very unfavourable, and especially when the aural affection is obviously secondary to tuberculous disease elsewhere. In such cases, the process runs an extremely rapid course, and life is rarely prolonged for more than a few months after the development of the disease in the tympanum. In non-phthisical cases the process sometimes comes to a standstill and suppuration ceases, but the perforation remains, and shows no tendency to close. The risk of meningeal and cerebral complications is always present. There may be no acute stage in the aural affection, and but little elevation of temperature. The otorrhœa may set in only a few days before death, while the symptoms of meningeal or cerebral mischief are of still shorter duration.

Treatment.—This is that of chronic suppurative otitis. Antiseptic remedies are especially indicated; boric acid and finely powdered iodoform introduced by insufflation are the most suitable. Some authorities recommend that little plugs of gauze, saturated with antiseptic solutions, should be introduced into the tympanum. Besides those in common use, iodol may be thus employed (Iodol gr. ij.; Sp. Vin. Rect. ℥xx.; Glycerin. ℥xl.). As a matter of course, the ordinary treatment of tuber-

* *Archives of Otology*, vol. xiii. p. 226.

culosis should be carried out. The patients are generally improved by fresh air, good food, and a warm climate. Injections of tuberculin have, of course, been tried; but the results were by no means satisfactory.

SYPHILIS AS AFFECTING THE MIDDLE EAR.

Syphilis affects the structures of the middle ear in a variety of ways. It is certainly a cause of catarrhal processes in the mucous membrane, acting usually by extension from the naso-pharynx. Less frequently, it appears to be associated with acute purulent inflammation of the middle ear. Its effects upon the osseous walls and the periosteum are more definite and serious. They consist of hyperæmia, thickening of the mucous membrane, bony outgrowths from the walls and ossicles, ankylosis, etc. In a case recorded by Kirchner,* the patient, a man aged twenty-nine, had contracted syphilis four years previously, and had been treated during two years for deafness, exudation into the tympanum, and occasional pricking pain. After death, the cavity was found to contain sanious exudation, and the mucous membrane of the promontory was decidedly injected. Examination with the microscope showed thickening of the mucous membrane, small-celled infiltration surrounding the blood-vessels, and penetrating their walls. The larger arteries on the promontory were much narrowed, owing to endarteritis syphilitica. This latter process, together with thickening of the adventitia, had led in many places to complete obliteration of the vascular canals, and it appeared probable that the oft-repeated accumulation of serous fluid in the tympanum was due to the changes in the vessels. Corresponding to those parts of the mucous membrane which were most seriously affected, were small bony outgrowths, the result of periostitis, and resembling those found on other bones. The Haversian canals contained similar deposits, together with small-celled infiltration and accumulation of pigment. In the bone itself were many cavities of various sizes and filled with detritus; these resulted from disorder of nutrition consequent upon the obliteration of the vessels.

It would appear, from Bürkner's statistics, that about 5 per cent. of all cases of middle-ear suppuration and 7 per cent. of cases

* *Archiv für Ohrenheilk.*, vol. xxviii. p. 172.

of nervous deafness are due to syphilis. But little is known with regard to syphilitic disease affecting the auditory nerve. A few cases of gummata at the base of the skull, pressing upon the nerve and causing total deafness, have been placed on record.

Syphilitic affections of the labyrinth begin with hyperæmia and infiltration with small cells; at a later stage, such processes as new formation of connective tissue, calcareous deposits, periostitis, and bony formations about the base of the stapes, would appear to be the results of the disease. Primary suppurative inflammation of the labyrinth has also been seen in a case of fatal meningitis occurring in a syphilitic subject. The middle ear and the trunk of the auditory nerve were not involved.

In the cases above referred to very severe symptoms may appear during the stage of small cell-infiltration. In unilateral disease intense vertigo may supervene, and when both sides are affected the patient may not be able to make a few steps without staggering. The hearing-power will be much diminished or even quite lost; while the patient is much distressed by severe tinnitus, nausea, and vomiting. Coincidentally with the advent of these symptoms bone-conduction is greatly lessened, particularly for high notes, or even altogether lost. Dr. Roosa thinks that the cochlea is especially affected in these cases. Syphilitic affections of the internal ear will be more fully described in a subsequent chapter.

Lesions of the ear are somewhat common in cases of hereditary syphilis. In the labyrinth they take the form of hyperæmia, infiltration with round cells, and extravasation of blood into the perilymph and endolymph, periostitis and changes in the nervous structures. Periostitis would appear to be a common appearance; it may lead to bony growths, ankylosis of the base of the stapes, osseous closure of the fenestra rotunda, and ossification of portions of the labyrinth. Retrogressive changes are also noticed, such as the formation of cavities in the bony walls of the labyrinth, sometimes filled with caseous matter, and chronic suppurative inflammation of the middle ear.

Some thirty years ago Mr. Hutchinson called attention to the fact that in cases of hereditary syphilis, affections of the ears are often associated with diseases of the eyes and a peculiar condition of the teeth. Choroido-iritis and interstitial keratitis are the

principal affections of the eye, and may appear at any time from a few weeks after birth up to the fortieth year. The appearances in the teeth are manifested in the incisors, which are more or less pointed and narrow at their edges, and furrowed with a crescentic notch. The central incisors are especially affected, the deformity being nearly always symmetrical.

The aural affection may be localised either in the middle ear or in the labyrinth, or in both these parts at the same time. In all probability, the disease in the labyrinth is primary in its origin. It shows itself generally between the tenth and the eighteenth years; but sometimes much earlier. Females are more liable to be affected than males.

In exceptional cases the deafness suddenly supervenes, but in most instances its development is gradual, though rapid. Both sides are usually affected, and the condition may eventually amount to absolute deafness. It is generally associated with marked subjective sensations, and sometimes with vertigo and staggering. The appearance of the deafness is generally coincident with that of the keratitis, but it may precede or follow the development of the lesions in the eye. In the early stage very high notes are lost much sooner than ordinary sounds, such as the voice; the cochlea is the most probable seat of the disease. In early life deaf-mutism is an occasional result of this affection. Bone-conduction is lessened or altogether lost at a very early stage. The prognosis in all these cases is decidedly unfavourable.

CHAPTER XXXVI.

INJURIES OF THE TYMPANUM—HÆMORRHAGE IN THE
TYMPANUM.

Direct and Indirect Injuries—Causes and Symptoms in both Classes—
Escape of Cerebro-Spinal Fluid; its Significance—Other Sources of
Watery Discharge from the Ear—Openings in Walls of Tympanum
and their Possible Consequences—Hæmorrhage in the Tympanum
—Causes—Symptoms—Treatment—Hæmorrhage with Perforation
or Rupture of Membrane—Treatment.

THE tympanum may be injured either by direct or indirect violence. The first category includes cases in which foreign bodies and corrosive fluids pass through the meatus and tympanic membrane and gain access to the cavity, and likewise those in which the Eustachian tube is the channel. The second class includes such examples of indirect injury as those which sometimes occur in connection with fractures and fissures at the base of the skull, resulting from falls or blows. Defects in the osseous walls of the tympanum may also be caused by disease and by arrest of ossification in early life.

When the tympanum is injured by a foreign body, the consequences vary with the nature and form of the substance and the degree of force with which it acts. Rupture of the tympanic membrane, injury or dislocation of the ossicles, and laceration of the mucous membrane are the immediate effects. If the capsule of the labyrinth or the roof of the tympanum be broken through, escape of cerebro-spinal fluid is likely to follow. Sometimes the facial canal is opened and the nerve injured. In one recorded case,

during attempts to remove a foreign body from the tympanum, the floor of the cavity was perforated, with hæmorrhage from the jugular vein as the result.

Direct injury to the structures of the tympanum is sometimes caused by projectiles, and wounds of this nature usually involve adjacent parts. In addition to the ossicles and the walls of the cavity, the injury may affect the chorda tympani nerve.

Symptoms.—When a foreign body, of such a shape as to pass readily through the meatus, is driven into the tympanum, it gives rise to more or less severe pain, hæmorrhage, subjective noises and deafness. The blood which escapes from the meatus varies in quantity; but the hæmorrhage is generally moderate and ceases spontaneously. In the absence of antiseptic remedies, promptly applied, purulent inflammation of the tympanum with its consequences is very apt to result. Division of the chorda tympani will cause loss of taste in the corresponding half of the tongue, with sensations of pricking, cold, etc. Injuries which involve the inner wall or the roof of the tympanum are to be regarded as especially serious. The former portion of the cavity is in relation with the labyrinth; while the roof, often very thin, is in close contact with the dura mater. Attempts to remove foreign bodies from the tympanum have occasionally resulted in serious injury to these portions of the tympanum.

Injuries to the tympanum by heated or corrosive fluids are extremely rare. They are always attended by extensive destruction of the neighbouring soft parts, and are likely to be followed by purulent inflammation, sloughing, etc. Symptoms of a like nature, though less severe, may be excited by the injection of stimulating remedies, for curative purposes, through the Eustachian tube.

Injuries belonging to the second class—viz., those caused by blows or falls on the head, and involving fracture or fissures of the base of the skull—generally cause more or less profuse hæmorrhage, the source of the blood being either the lateral or petrosal sinuses, and in some cases, the middle meningeal artery. Escape of cerebro-spinal fluid is another symptom which may continue for several days. The fluid may be either purely serous in appearance or more or less deeply tinged with blood. It must be borne in mind that a serous discharge, coming on some days after an injury, and when hæmorrhage has ceased, is not neces-

sarily indicative of escape of cerebro-spinal fluid; it may be secreted by the tympanic mucous membrane. Moreover, the discharge, by the meatus, of cerebro-spinal fluid may occur in the absence of fracture of the base of the skull, inasmuch as this fluid passes into the labyrinth, and may escape therefrom when the inner wall of the tympanum is the seat of fracture. Cases in which serous fluid escapes from the ears after injury are by no means rare, and the quantity may be very considerable; thus three or four ounces and even more have been discharged within an hour. The symptom may continue for several days, and then gradually cease. Fissures involving the base of the skull are by no means necessarily fatal.

The various questions connected with watery discharges from the ear after severe injuries to the head are fully discussed in Sir P. Hewett's Article in Holmes's *System of Surgery*.^{*} It is there laid down that the escape of cerebro-spinal fluid "implies a fracture cutting across the meatus internus and communicating with the tympanum, a laceration of the tubular sheath of the cerebral membranes surrounding the seventh pair of nerves within this meatus, and a laceration of the membrana tympani." Those cases, however, in which the fracture does not involve the internal meatus, though passing across the internal and middle ear, require a different explanation. The watery discharge has then been thought to be derived from the perilymph of the labyrinth; but its quantity in some cases would seem too great to be furnished from this source. Profuse watery discharge has also been noticed after a severe injury of the head, in cases in which it was proved that there was no fracture involving either the internal or the middle ear, and no communication whatsoever between these cavities. In such cases, the inflamed lining membrane of the middle ear is regarded as the source of the fluid discharge, which makes its appearance some hours after the occurrence of the injury.

According to Sir P. Hewett, cases of watery discharge from the ear after injury may be divided into three classes.

In the first, the fluid is plentiful, and of a decidedly watery character immediately after the injury—the discharge is due to escape of cerebro-spinal fluid, which can only take place through a fracture of the petrous bone, implicating the internal auditory canal and its membranes.

* Vol. i. p. 593.

In the second class, there is copious and prolonged bleeding from the ear, followed by a watery discharge. This sequence of events indicates fracture of the petrous bone; but it cannot be said that the fracture follows any particular course.

In the third class of cases the discharge at first consists of blood alone; this is followed by a watery discharge, varying in quantity, and as to the time of its appearance. "It may be present within a very few hours after the accident; it may be profuse within a very few hours of its appearance." In such cases the diagnosis is doubtful. The discharge of blood is not of such a character as positively to indicate a fracture of the petrous bone, and it is well known that a watery discharge may occur within a few hours after the accident, that its quantity may even be profuse, and yet there may be no fracture.

Urbantschitsch points out that cerebro-spinal fluid is distinguishable from serous exudation by the fact that it contains some reducing constituent (pyrocatechin, according to Halliburton), and very little albumen. It does not spontaneously coagulate.

In connection with fissures caused by injury, it would seem desirable to refer to those openings in the bony walls of the tympanum which are the result of defective ossification or of absorption due to pressure. The openings referred to are most commonly found in the roof and the floor of the cavity, and in the layer of bone between it and the carotid canal.

The plate of bone forming the roof of the tympanum, and particularly that portion of it which is above the malleo-incudal joint, and covers the recessus epitympanicus, is often so thin as to be transparent, and it is here that openings or dehiscences are most often met with. Through such minute gaps the lining membrane of the cavity comes into contact with the dura mater, and diseased processes in the middle ear may be easily propagated to the brain. In children, the condition of the petrosquamous suture facilitates communication between the two cavities. The fissure between these two portions of the bone is occupied by a prolongation of the dura mater containing vessels and connective tissue, and closely connected with the mucous membrane of the tympanum. Inflammation may thus easily spread from the one cavity to the other.

The openings in the tympanic roof in adult life are in most cases the evidences of atrophy due to pressure by the

convolutions of the brain. Bürkner,* who has investigated this subject, states that in the macerated skull they are often found associated with deep digital impressions and tenuity of the orbital plates. He points out that besides the spots already mentioned, dehiscences are sometimes present in the walls of the aqueduct of Fallopius, in the jugular fossa, in the mastoid process and in the squamous portion. The formation of dehiscences in the roof of the tympanum is favoured by excessive development of the cavity and thinness of the osseous boundaries. Other investigations† show that dehiscences occur in about 7 per cent. of all cases, and exclusively in brachycephalic skulls.

Openings or dehiscences in the floor of the cavity may result either from defective development or from pressure. This portion is membranous until the fifth month of embryonic life, and in some cases this condition persists for several years after birth. Dehiscences, the result of atrophy, are sometimes associated with unusual size of the jugular fossa, which encroaches upon the cavity of the tympanum.

The osseous lamella separating the carotid canal from the tympanum is sometimes very thin, and openings occasionally exist. These are for the most part the result of defective development, but they may be due to caries. In one recorded case, a groove existed in place of a canal.

Hæmorrhage in the Tympanum most often results from injuries; but it may occur in connection with various morbid conditions. When the membrane is intact, the injury is almost always of an indirect kind, *e.g.*, a fall or blow on the chin, violent coughing (as in whooping-cough), sneezing, straining efforts at vomiting, or forcible injection of air through the Eustachian tube. After death by strangulation, blood is often found effused in the tympanum. The diseases with which a similar condition is sometimes associated are—Bright's disease, diphtheria, leucocythæmia, scurvy, and hæmophilia. During menstruation and in advanced stages of pregnancy effusion of blood has been known to take place into the tympanum.

Embolism of the tympanic arteries is another condition which may cause hæmorrhage within the tympanum, and this symptom has been known to arise in the course of endocarditis. The

* *Archiv für Ohrenheilkunde*, vol. xiii. p. 185.

† *Ibid.*, vol. xxviii. p. 169.

blood is effused both within the substance of the mucous membrane and on the surface.* The emboli occupy the spots at which lateral branches are given off, and consist of finely granular masses, probably composed of micro-organisms, which are found in abundance in the effused blood. In cases of sudden deafness occurring during pyæmia, minute sharply-defined patches of effused blood, purple or black in colour, have been found in the mucous membrane. Other local processes—*e.g.*, ulceration, caries, and necrosis of the walls of the cavity—may give rise to varying degrees of hæmorrhage.

When the membrane is intact, hæmorrhage within the tympanum will cause more or less marked subjective symptoms, as deafness, noises in the ear, a sensation of fulness, and sometimes pain and vertigo. The objective symptoms vary with the amount effused and the previous condition of the membrane. When the part was previously normal and the hæmorrhage has been somewhat copious, the membrane appears bluish-red or even black, devoid of lustre, and projecting, especially at its posterior and upper part, into the meatus. The handle of the malleus appears more distinct than usual against the darkened membrane. Such appearances are, of course, absent when the membrane is opaque and thickened. Râles are heard when air is forced into the tympanum; bone-conduction is increased on the affected side, while Rinne's test gives a negative result. In favourable cases, absorption gradually takes place; the membrane becomes yellowish-red, and in the course of three or four weeks assumes its normal tint. Suppuration, followed by perforation of the membrane, very rarely occurs.

Treatment.—This consists in protecting the affected ear and keeping the patient at rest. A low non-stimulating diet should be prescribed, and purgatives are generally useful. After several days have elapsed, the air-douche may be employed to hasten absorption. It is very seldom necessary to make an opening in the membrane, and unless there be great tension and violent pain, it is better to refrain from any such operation. If, however, the latter be deemed necessary, it should be performed under strict antiseptic precautions, otherwise there is great risk of setting up purulent inflammation.

Hæmorrhage into the Tympanum with perforation or

* *Archiv für Ohrenheilkunde*, vol. xiv. p. 73.

rupture of the membrane.—When an injury which causes rupture of the membrane gives rise at the same time to hæmorrhage within the cavity, more or less blood will escape from the meatus. A discharge of blood from the external meatus is also a symptom of hæmorrhagic tympanitis, of new formations in the canal or in the middle ear, of polypoid growths, of ulceration within the cavity, and of caries of its walls. Foreign bodies thrust through the membrane, attempts at their removal, and operations upon polypoid growths are other causes of hæmorrhage from the tympanum. Except in cases of hæmophilia, the discharge is seldom profuse. Hæmorrhage from the ear after injury is regarded as one of the most valuable diagnostic signs of a fracture of the base of the skull (*see* page 562). As a positive symptom, however, of this injury, the bleeding must be copious and must continue for some time. Hæmorrhage of this character is indicative of fracture of the base running through the petrous bone, and creating a communication between the cavity of the tympanum and some of the large vascular channels which surround the bone, or with extravasated blood within the cranium itself.

It must, however, be noticed that fractures of the temporal bone frequently occur without causing hæmorrhage from the ear. In such cases, either the fracture does not involve the tympanum, or the membrane remains intact, so that the blood cannot escape. Sir P. Hewett has recorded seventeen cases of fractured base, without bleeding from the ear; in twelve of these, the tympanum was not involved; in the remaining five, the tympanum was fractured, but the membrana tympani was not ruptured.

In cases of fractured base, with ruptured tympanic membrane, when the fracture communicates with one of the venous cerebral sinuses and the walls of the tympanum, the hæmorrhage may be very profuse. In a case of injury to the occiput, recorded by Mr. Holden, the escape of venous blood from the meatus was like the flow from the spout of a tea-pot. The fracture was considered to involve the lateral sinus. In another case, an incision through the lower part of the membrana tympani penetrated the floor of the cavity (through a dehiscence) and injured the jugular vein. Injuries involving the carotid canal and the middle meningeal artery may likewise cause hæmorrhage from the meatus.

If hæmorrhage take place into the tympanum, without rupture

of the membrane, the blood will find its way through the Eustachian tube, so that there may be bleeding from the nose or from the mouth, or subsequent vomiting of blood. And even when a rupture of the membrane exists, escape of blood through the Eustachian tube may also take place; so that in some cases of fractured petrous bone, bleeding occurs from the ear, nose, and mouth at the same time, the blood thus discharged from several openings being derived from the same source.

As already mentioned, in cases of injury, in which escape of blood from the ear is an early symptom, the bleeding, after a few days, is often replaced by a pale, straw-coloured fluid. A case in which both membranæ tympani were ruptured, and the hæmorrhage was followed by discharge of a yellow fluid, is recorded by Dr. Ray,* of Louisville, U.S.

Destruction of the tympanic walls by caries or necrosis may implicate one or other of the large vascular channels contained in the petrous bone, viz., the carotid artery, the jugular vein, and the lateral sinus. In a case reported by Drs. Moos and Steinbrügge,† there was caries of the petrous portion of the temporal bone, with facial paralysis and fatal hæmorrhage from the carotid artery. On examining the bone after death there was a deficiency in the external wall of the carotid canal, measuring 15mm. ($\frac{3}{8}$ inch) in breadth and 7mm. (about $\frac{3}{16}$ inch) in height. The artery was bare to the whole extent of this opening, and corroded and perforated near the promontory. Hessler‡ has collected fourteen cases in which fatal hæmorrhage was the result of a similar lesion in the walls of the carotid artery. The latter may, however, be exposed after carious destruction of the carotid canal without being involved in the disease. Cases in which fatal hæmorrhage has been caused by destruction of the walls of the jugular vein or of the sinuses connected with the temporal bone are less common.

Treatment.—When the hæmorrhage is slight in amount and is caused by polypoid or other growths, or by injury not involving the large vessels, it often ceases spontaneously. Should it continue, a plug of cotton-wool, impregnated with powdered alum or perchloride of iron, should be introduced into the meatus.

* *Archives of Otology*, vol. xv. p. 192.

† *Ibid.*, vol. xiii. p. 162.

‡ *Archiv für Ohrenheilkunde*, vol. xviii. p. 1.

When large vessels are affected, more active measures will be required, though for venous hæmorrhage—*e.g.*, from the lateral sinus—plugging the meatus is the only available means of arresting the flow of blood. The sinus readily becomes occluded by the formation of a thrombus. When the blood comes from the internal carotid, ligature in the neck may not prove successful, inasmuch as the collateral circulation is readily established. In one case, Prof. Billroth tied the common carotid artery, but ten days afterwards the hæmorrhage recurred and became so profuse as to induce the surgeon to tie the corresponding artery on the other side. Two days later the hæmorrhage recurred, and the patient died. Urbantschitsch points out that ligature of the carotid should be performed only if it be found that well-directed pressure upon the artery arrests the bleeding. Such pressure will, of course, have no effect upon hæmorrhage the result of lesions of the sinuses. The artery has been tied when the lateral sinus was the real source of the hæmorrhage.

CHAPTER XXXVII.

OTALGIA.

Causes—Symptoms and Treatment.

PAIN of a neuralgic character is sometimes felt in the external and middle portions of the ear, while careful examination fails to detect any evidences of inflammatory or other changes. In the auricle and meatus, neuralgic pain may be due to some affection of the fifth nerve or of the upper branches of the cervical plexus which supply the back of the ear. Slight redness and swelling are sometimes noticed when these parts are the seat of pain. The sensory nerves of the tympanum are supplied by the fifth pair and the glosso-pharyngeal. In the tympanic plexus, a branch from the petrous ganglion of the latter nerve communicates with the great superficial petrosal, which is connected with Meckel's ganglion. The small nerve of the same name joins the otic ganglion, and a filament from the sympathetic unites the tympanic with the carotid plexus. The numerous relations thus formed account for the radiating character of the pain, which is sometimes noticed.

Causes.—The most common cause of otalgia is a decayed tooth, which may itself be quite free from pain. In these cases, the pain may extend to the neck, shoulder, and arm. Ulceration in the larynx and in the upper part of the pharynx is often accompanied by pain in the ear; and cancer of the tongue,* and thoracic aneurisms† sometimes produce the same symptom. Other less common causes of otalgia are exposure to cold, anæmia, neurasthenia, disorders of the sexual organs, irritative

* Hilton, *Lancet*, 1860, vol. ii. p. 257.

† Gull, *Medical Times and Gazette*, 1864, vol. i. p. 34.

processes involving the Gasserian ganglion and the second and third divisions of the fifth nerve, caries of the bones, and tumours of the brain. Otagia is sometimes due to the influence of malaria, and is sometimes connected with syphilis.

In young children pain in the ears is often due to teething. In such cases it is probably caused by extension of inflammation from the mouth and pharynx along the Eustachian tube. Reflex irritation may, however, take part in its production. The tympanum is supplied by the tympanic branches of the internal carotid, and by branches of the internal maxillary and stylo-mastoid arteries, from the external carotid trunk. Irritation from inflamed gums is communicated to the otic ganglion, and dilatation of the tympanic vessels results from inhibition of the vaso-motor nerves. If the process become severe, it may result in acute catarrh of the tympanum.

The pain in otalgia is either intermittent or continuous; when due to the influence of malaria the attacks are distinctly periodical. In some cases the pain is not confined to the ear, but radiates to the neck and shoulders. It is sometimes accompanied by subjective auditory sensations and deafness, and by hyperæsthesia of the skin of the auricle and temple. The pain is apt to be increased by loud noises and by movements of the head. Urbantschitsch records a case in which bilateral otalgia, which had troubled the patient for eighteen months, was traceable to piano-playing in a room in which resonance was very marked. The pain was decidedly aggravated by loud sounds, and was relieved by galvanism.

It must, of course, be borne in mind that otalgia may co-exist with carious teeth without being in any way dependent upon them. In all cases the ears must be carefully examined, and if no disease can be detected, the condition of the teeth, larynx, and throat should next be ascertained.

Treatment.—This must depend upon the cause and duration of the complaint. Decayed and aching teeth must be extracted or otherwise treated; anæmia and debility will require tonics, such as iron and quinine. The latter drug will be useful when the otalgia is accompanied by symptoms of *tic douloureux*, and especially in cases with a history of exposure to malaria. Gelseminum, arsenic, salicylate of sodium, and bromide of potassium or ammonium sometimes do good in these cases. In syphilitic subjects,

full doses of iodide of potassium will, of course, be indicated. This remedy sometimes relieves the pain in non-syphilitic cases. When the attack is very severe, morphine may be given either internally or by subcutaneous injection.

In chronic cases, besides the remedies already mentioned, turpentine, belladonna, oxide of zinc, and antipyrin have been recommended by various authorities. Weber-Liel has seen good results from oil of turpentine, in doses of ℥xv.—xx. Belladonna is used either in the form of ointment applied to the mastoid process, or internally, in doses of ℥v. of the tincture. Atropin, in doses of five drops of a 1 per cent. solution several times daily, has been found efficacious. Antipyrin has been used in doses of five grains three or four times a day. The local application of veratrine in the form of ointment is worthy of a trial. The following combination has also been recommended: menthol and camphor, of each, one part; liquid vaseline, twenty parts. Politzer states that galvanism is occasionally useful when all other means have failed. The positive pole is placed on the ear; the negative, on the back of the neck. The induction-current is not recommended, on account of the cutaneous hyperæsthesia which often co-exists. Relief may sometimes be obtained by the application of a blister (*see* page 315) to the mastoid process. In cases in which the pain is not confined to the deep parts of the ear, but affects the entire aural region, and is increased by pressure beneath the tragus, massage has been followed by great relief, and complete subsidence of the discomfort in the course of a few days. For intermittent otalgia, Urbantschitsch recommends, besides quinine, the inhalation of a few minims of amyl nitrite.

CHAPTER XXXVIII.

THE ANATOMY AND PHYSIOLOGY OF THE INTERNAL EAR.

The Auditory Nerve and the Divisions of the Labyrinth—The Vestibule—The Semi-Circular Canals—The Cochlea—The Membranous Semi-Circular Canals—The Cristæ Acusticæ—Otoliths—The Cochlear Nerves—The Scala Media—Corti's Membrane and Organ—The Membrana Basilaris—The Auditory Teeth—Corti's Pillars and Cells—Connections of Cells with Nerves—Reissner's Membrane—Blood-Vessels of the Internal Ear—Origin of the Auditory Nerve—Its Connections and Divisions—The Physiology of the Labyrinth—Functions of the Utricle, Saccule, and Semi-Circular Canals—Flourens' Experiments and their Results—Functions of the Cochlea—The Psycho-Acoustic Centre.

The Auditory Nerve, on leaving the base of the skull, enters the petrous portion of the temporal bone, and passes into a complicated organ, the osseous labyrinth. When this is opened, the internal surface is found to be covered by a connective tissue membrane, the periosteum, which immediately incloses the perilymph. The latter covers the membranous labyrinth, which has for the most part the shape of its osseous capsule. The osseous labyrinth is divided into three portions: the semi-circular canals, the vestibule, and the cochlea. The first of these contains the membranous canals; the second, the utricle or *sacculus ellipticus*, and the *sacculus rotundus*; while the third contains the windings of the *ductus cochlearis*. All these three divisions of the membranous labyrinth communicate with each other; the semi-circular canals and the utricle directly; the sacculus and the ductus cochlearis through the *canalis reuniens*; the utricle and the saccule through the membranous *aquæductus vestibuli*, which, being connected by a short limb with each sac, passes

through the osseous canal of the same name, to the dura mater, where it ends in a dilated extremity, the *saccus endo-lymphaticus*. A communication between the sub-arachnoid spaces of the brain and spinal cord and the peri-lymphatic space of the cochlea is provided by the *aquæductus cochleæ*, while the arachnoid sheath of the auditory nerve furnishes a passage for the endolymph. The perilymph which surrounds the sacculæ is in contact with the membrane of the fenestra ovalis, and receives from it the vibrations of the air in the tympanic cavity. A lax series of connective bands traverses the fluid, and keeps the membranous parts in their place.

The Vestibule is irregular in shape, and measures about one-fifth of an inch from above downwards and from behind forwards; from its outer to its inner wall, the distance is about one-tenth of an inch. The cochlea opens into it in front by a single opening; and the semi-circular canals, by five orifices behind. On its outer wall is the *fenestra ovalis*; and above this, the anterior opening of the anterior semi-circular canal. Its inner wall presents several minute apertures, through which a portion of the auditory nerve enters from the internal auditory canal. At the posterior part of this wall, is the opening of the *aquæductus vestibuli*.

The openings on the inner wall of the vestibule are about twenty in number, and are collected into four groups, each group constituting a *macula cribrosa*. Through the upper *macula*, the nerves pass to the utricle and to the ampullæ of the anterior vertical and horizontal semi-circular canals. The other *maculae* give passage to the nerves for the posterior semi-circular canal, and to a small branch of the cochlear nerve. At the anterior portion of the vestibule is the commencement of the *scala vestibuli* of the cochlea.

The outer wall of the vestibule, which separates it from the cavity of the tympanum, is perforated by the fenestra ovalis, but this aperture is so completely closed by the base of the stapes that the inner surface appears quite even. At the fore part of the inner wall is a small round pit, the *fovea hemispherica*, which is limited behind by a vertical ridge, called the *crista vestibuli*. Partly in the roof and partly in the inner wall, is an oval depression, the *fovea hemielliptica*, the inner part of which is separated by the crest from the hemispherical fossa.

The Semi-circular Canals are three osseous tubes, situated

above and behind the vestibule, into which they open by five apertures, the contiguous ends of two of the canals being joined together. They are unequal in length, but each is bent so as to form about two-thirds of a circle, and each canal has at one end a slightly dilated part, or *ampulla*.

The canals differ from each other in length, direction, and position with regard to the vestibule, and each canal lies in a different plane. The *superior canal* is vertical and anterior, and lies across the petrous bone. It forms about two-thirds of a circle, and its extremities are more divergent than those of the others. It rises higher than any other part of the labyrinth, and its place is indicated by a smooth elevation on the anterior surface of the petrous bone. The *ampulla* is on the outer extremity; the opposite end opens by a common extremity with the posterior semi-circular canal into the back part of the vestibule. The *posterior semi-circular canal* is vertical and longitudinal in direction, and runs parallel to the posterior surface of the petrous bone, and therefore at right angles to the former. It is the longest of the three tubes; its *ampulla* is at its lower extremity, and its opposite end terminates as above described. The *external semi-circular canal* is inferior and shorter than either of the others; its arch is directed horizontally outwards, and it opens by two distinct orifices into the upper and back part of the vestibule.

The length of the superior vertical canal along its convex border is about four-fifths of an inch; that of the posterior is about eleven-twelfths of an inch; while the external or horizontal measures only one-fifth of an inch. The diameter varies from one-twentieth to one-fifteenth of an inch. As age advances, the semi-circular canals increase in length, and also very slightly in width.

The Cochlea is so named from its resemblance to a common snail-shell. It lies in front of the vestibule, and is placed almost horizontally; its apex is directed forwards and outwards, its base is near the bottom of the internal meatus, and is marked by a depression with a spiral arrangement of pores for the reception of the cochlear division of the auditory nerve. From its base to its apex extends a conical axis or central pillar, the *modiolus* or *columella*, which is perforated by many channels, through which nervous filaments pass in regular succession to the spiral cochlear canal which winds round the axis. This canal is about an inch

and a half in length, and diminishes gradually in size from the base to the apex, where it ends in a cul-de-sac. At its commencement, it is about one-tenth of an inch in diameter, but scarcely half that size at its termination. At its base, the canal presents *three openings*: one of these communicates with the vestibule; another is the *fenestra rotunda*, shut off from the tympanum by a membrane; while the third is the opening of the *aquæductus cochleæ*, which leads to the jugular fossa and transmits a small vein. The spiral canal makes about two turns and a half, of which the first takes the widest sweep, so as to encircle most of the second turn.

The spiral canal of the cochlea is divided into two parts or passages by a thin osseo-membranous lamina, stretching between its modiolar and peripheral wall, and on which the nervous filaments are distributed. This lamina is made up of two parts: one, a brittle osseous process, extends from the modiolus; the other part is membranous, and connects the outer thin edge of the osseous zone to the outer wall of the canal. In this way a complete septum is formed between the vestibular and tympanic openings of the cochlea, and the two passages into which the spiral lamina divides the canal correspond respectively to those chambers. The upper passage, towards the apex of the cochlea, is termed the *scala vestibuli*; the lower, towards its base, the *scala tympani*. In the last half turn of the canal the spiral lamina ceases, and the two scalæ communicate by a common orifice called the *helicotrema*. The axis terminates in a delicate lamella at about half a turn from the dome-like summit or cupola. This lamella, as viewed from below, resembles a funnel, open on the side, while above it blends with the cupola.

The cavity of the osseous labyrinth is occupied by a limpid fluid, the *perilymph*, so called from its surrounding, in the vestibule and semi-circular canals, a hollow membranous apparatus, the membranous labyrinth, which latter contains a similar fluid, the *endolymph*.

The Membranous Semi-circular Canals are separated by the perilymph from their osseous case; their concave borders are almost adherent thereto, but the remainder of their circumferences is at a greater distance from the bone, and is connected with it by blood-vessels and connective tissue. These canals have the same names, shape, and arrangement as the osseous canals which

inclose them; but are only one-third of the diameter of the latter. As the osseous canals open into the vestibule, so the membranous ones open at both extremities into the utriculus, and near this latter structure each tube presents a slightly dilated part, called the *ampulla*. These portions are closely adapted to the surrounding bone, and contain in their interior the terminal ramifications of a portion of the vestibular branch of the auditory nerve. The remaining part of this division of the nerve passes to the *sacculus ellipticus* and *sacculus rotundus* of the vestibule, where it is distributed to certain structures, the *maculæ acusticæ*. The other portion of the membranous labyrinth, the *cochlea*, contains the terminations of the second branch of the auditory nerve, which are to be found in the organ of Corti. The internal ear may therefore be said to present six parts characterised by peculiar nerve-endings.

The membranous semi-circular canals and the other structures of the labyrinth are filled and kept tense by a watery fluid, the endolymph. In the recent condition, the walls of these structures are quite transparent; though of great delicacy, they are composed of several layers: (1) an external connective-tissue layer which contains the vessels; (2) a homogeneous transparent basal membrane, lined by (3) pavement epithelium. Close to the utricular orifices of the ampullæ, and on the surface which projects from the convex border of the arch, all these layers become thickened, and form a prominence in the cavity resembling a comb, and distinguishable to the naked eye by its yellow colour: the term *crista acustica* is applied to each of these spots. At certain parts of their walls, the utricle and saccule present similar changes; in each of these cavities there are two enlargements, sharply circumscribed, roundish in form and whitish in colour. The fibres of the vestibular branch of the auditory nerve can be traced to these spots in the ampullæ, utricle, and saccule, and are here found to terminate in a peculiar manner.

The fibrils which enter the *maculæ* and the *cristæ acusticæ* form a close dendroid plexus in the *membrana propria*; there are no terminal loops, but the fibrils, without exception, pass to the basal membrane and the epithelial layer. In the former they lose their medullary and connective tissue sheath, and present only axis cylinders. A longitudinal section of an ampulla exhibits the following structural arrangements; about the middle of the

concavity there is a crescentic projection, the *crista acustica*, which on section appears conical or mushroom-shaped. Its extremity is formed by the epithelial coating, which covers the wall of the ampulla; and, where the latter becomes free, is converted into a closely adherent, thick mass of cells, from the surface of which long stiff bristles project in a radiating manner. The trunk of the ampullary nerve runs in a portion of the wall from which the crest rises; and as soon as it reaches the base of the latter, its fibres gradually turn inwards, and continue as broad medullary fibres to the epithelial margin of the swelling, where they are lost to view. After removal of the thick epithelial layer of the *crista*, these fibres may be seen to break up suddenly into close broom-like tufts of very fine fibrils, destitute of a medullary sheath, which run towards the free surface of the epithelium.

The above account is based on M. Schultze's researches, published about thirty years ago; they have been somewhat modified and expanded by subsequent observers. Schultze thought that the bristles originated between the epithelial cells of the *crista*; but Hartmann has shown that they are firmly adherent to the cells which form their bases. Cells bearing stiff bristles are not confined to fishes; they are found also in the human subject. Certain deviations exist in some classes of animals: in pteropods, the hairs or bristles are very abundant; in fishes, birds, and mammalia, only a single bristle is connected with each epithelial cell. The term "bristle-cell" is applied to these structures, to distinguish them from ciliated cells bearing true vibratile cilia. The *crista acustica* is coated by a single layer of cylindrical epithelium, which, by gradual transitions, replaces the pavement cells of the remainder of the ampullary wall. The perfectly developed cylindrical cells are divided into two sharply defined groups, viz., epithelial cells without hairs (supporting cells), and bristle-cells. The former are represented by small truncated cones, whose blunt terminations, often indented, are firmly adherent to the connective tissue basis, while their broader extremities project into the ampullæ, saccule, or vestibule. The cells belonging to the second category have a flask-like shape, and at their free borders there is a peculiar lid-like structure which strongly refracts the light (the basal seam), beyond which there is a stiff bright prolongation consisting, according to Retzius, of many minute fibres. The epithelial cells proper often contain

yellowish pigment-granules, which give a peculiar tint to the *maculæ* and *cristæ*. The cells of both kinds are so arranged that almost every hair-cell is surrounded by five cylindrical cells.

The histological peculiarities, just described, of the epithelium of the *cristæ*, are repeated in the epithelium of the *maculæ acusticæ*, and the terminations of both branches of the auditory nerve are alike in the fact that their cilia are enveloped in a semi-fluid, tenacious substance which, after treatment with certain reagents, stiffens so as to resemble a membrane, which has received the name of *cupula terminalis*. There is only this important difference between the two parts, that the mucous stratum of the *maculæ acusticæ*, on its free surface which is washed by the endolymph, is strewn over with many small concretions, of an inorganic nature, the so-called "otoliths," which are wanting in the *ampullæ*. The otoliths are composed partly of many small amorphous and crystalline bodies, and partly of large bunches of crystals of carbonate of lime. The chalk-like tint of the *maculæ acusticæ* is due to these bodies.

With regard to the relations of the nerves to the *cristæ* and *maculæ acusticæ*, there is the same obscurity as that in which the question of the peripheral termination of other nerves is involved. The assertion is sometimes made that the axis-cylinders, devoid of medulla, or the axis-fibrils, pass directly into the substance of the hair-cells; but a very intimate connection, without fusion, is more often described. At any rate, all the histological facts at present known lead us to regard the modified epithelial forms of the bristle-cells as the proper terminal apparatus of the auditory nerve in the vestibule.

The second portion of the auditory nerve, **the cochlear branch**, contains a large number of medullary fibres. Connected with it is "Corti's organ," which includes not only the nervous terminal apparatus, but, as in the vestibule, hair-cells, which receive the last prolongations of the auditory nerve. It is unnecessary to describe all the investigations that have been made into the histological structure of Corti's organ; it is sufficient to mention those points which have a special physiological significance.

The canal of the cochlea is divided into two distinct spaces, separated by bony and membranous septa. The principal septum is the lamina spiralis, which is composed of a portion, the *zona ossea*, proceeding from the modiolus, and a membranous layer, the

zona membranacea or *membrana basilaris*, attached to the external border of the latter, and to the outer wall of the cochlea. Formerly this septum was the only one that was recognised; and the portion of the canal above it was called the *scala vestibuli*, the portion below it, the *scala tympani*. There is, however, a third membranous septum, first properly described by Reissner, and named by Köl liker, Reissner's membrane, which, springing from the upper surface of the zona ossea, close to its outer border, stretches obliquely towards the outer wall of the cochlea, cutting off a third canal between the *scala vestibuli* and *scala tympani*, termed the *canalis* or *ductus cochlearis*, or the *scala media*. All three canals are filled with endolymph. The middle one contains Corti's organ, with the termination of the cochlear nerves.

The osseous portion of the lamina spiralis is traversed in its interior by a system of anastomosing canals, which run together to a cleft situated close to its outer border, and dividing it into two laminae. In these canals, and in the marginal cleft, run the cochlear nerves radiating from the modiolus, which they enter by a number of fine openings arranged in a spiral, the *perforate spiral tract*. The spiral shape is due to the linear extension of the cochlear tube, and of these nerves which have increased in number while constrained in capacity of linear extension. The lamina spiralis is simply the projecting plate around the nerves as they pass to their distribution in the cochlear canal (Macalister). The perilymph enters through the *scala vestibuli*, and passes down the *helicotrema* to the *scala tympani*, whence its escape is prevented by the *membrana tympani secundaria*.

In the cochlea the acoustic area is continued as a stripe along the wall of the cochlear canal. The canal itself is roughly triangular on section; one side, the most vascular, is attached to the outer convex whorl; the second (Reissner's membrane) extends from this to form the floor of the *scala vestibuli*; while the third, stretching to the tympanic edge of the lamina spiralis, forms the roof of the *scala tympani*. On the osseous portion, the projecting *crista spiralis* is prolonged above and below, and forms a notch, the *sulcus spiralis internus*. The upper or vestibular lip is covered by a cuticular structure, **Corti's membrane**; while the lower or tympanic lip passes into the *membrana basilaris*, which extends over the membranous *lamina spiralis*, and supports the peculiar epithelial structure, known as **Corti's organ**.

At the ending of the *labium tympanicum* the auditory nerve-fibres pass through foramina in the basilar membrane, and, devoid of their medullary cylinders, they reach Corti's organ and the neuro-epithelial cells. In the *lamina spiralis ossea*, the auditory nerve runs to the *zona perforata* in the *labium tympanicum*. Corresponding to the vestibular *labium*, the *crista spiralis* is furnished with radiating ridge-like elevations, termed "auditory teeth," the number of which is estimated at about 2,500. Besides having a connective tissue stroma and a periosteal layer, the *crista spiralis*, which contains many vessels, is likewise covered by a glassy stratum in which no cells can be discovered.

The *membrana basilaris* extends from the *labium tympanicum* of the *crista spiralis* to the *ligamentum spirale*. Rising from its surface is the **Organ of Corti**, composed of Corti's pillars, which converge and meet above so as to form a series of arches, whose base is the tympanal wall. Between the lower ends or feet of the pillars is a strip called the *zona arcuata*, and extending outwards as far as the *ligamentum spirale* is the *zona pectinata*. The *membrana propria* presents radiating streaks, caused by fibres running in a definite direction. These are termed basilar fibres or auditory cords, and are most marked in the *zona pectinata*.

On the *labium vestibulare* of the *crista spiralis* cylindrical cells are placed between the "auditory teeth," and are in immediate contact with the flat pavement epithelium of the *sulcus spiralis*. On the *labium tympanicum*, the inner supporting cells appear as elevations from the epithelium, and the inner series of rods appear between these cells and the inner pillars of Corti. These latter and the outer pillars are slightly curved in the shape of the letter S, and their upper and lower extremities are larger than the connecting portions. The inner pillars are somewhat shorter than the outer. They number about 5,600, while the outer are estimated at 3,850. Each of the latter is in contact with two or three inner ones. Connected with the outer pillars are four rows of rod-shaped cells (Corti's cells); these are furnished with hairs, and alternate with Deiter's cylindrical cells which are devoid of such prolongations. Next to these come the external supporting cells (Hensen), and lastly some small cells, which diminish in size as they pass into the cylindrical epithelium of the *zona pectinata*. Corti's tunnel is an intercellular space filled with fluid.

Fine nerve fibres pass from within outwards through the intervals between the pillars to reach Corti's cells.

The inner and outer rods are furnished with fine prolongations, which are not hairs; they penetrate the cuticular disk-like side of the cells. In the outer rods, the phalangeal prolongations of the external pillars and the terminations of Deiter's cells form a cuticular layer, the *lamina reticularis*, which is penetrated by the rods. Between every two rows of these cells is a space filled with fluid, and a similar arrangement exists between the outer columns and the first row of the outer rods.

Corti's membrane, the *membrana tectoria*, extends from the tympanal commencement of Reissner's membrane to the last series of the external rods. The substance of the membrane is stratified, but quite homogeneous; the tissue is a cuticular formation, having its origin in the epithelium of the *limbus laminae spiralis*.

The physiological importance of Corti's cells and of their hair-like prolongations becomes the more intelligible when they are compared with the *maculae* and *cristae acusticae*, and on considering their intimate connection with the axis-cylinders of the nerves in close contact with them. The cells of Corti with their projecting hairs may be assumed to be the terminal apparatus of the cochlear nerves. The connection has not been absolutely demonstrated; no statements have been made with regard to the relations of the *outer* cells of Corti to the terminal nervous fibrils; it is alleged by Lavdowski that the middle portion of each *inner* hair-cell is penetrated by an axis-fibril. According to Retzius, the number of the inner hair-cells, which are arranged in one row, reaches in the human subject 3,500; that of the outer, which are arranged in three or four rows, may be estimated at 12,000. The principal trunk of the cochlear nerve is to be found in the axis or modiolus of the cochlea. The bundles of fibres given off from it penetrate the anastomosing clefts in the lamina ossea along its whole length, and form therein a close plexus, which runs towards the outer border of the osseous band. Not far from this border many closely packed, small, bipolar ganglion-cells are inserted between the fibrils, each ganglion being probably traversed by a primitive nerve-fibre. On leaving the ganglia, the nerve-fibres at first constitute a network, but afterwards they run, parallel to each other, to the

border of the *lamina ossea*, then pass through openings in the *habenula perforata* to the cochlear canal, and appear as fine varicose fibrils devoid of a medullary sheath, and resembling the terminations of the vestibular nerves in the epithelium of the *cristæ acusticæ*, and like portions of the olfactory nerve in the olfactory mucous membrane. One portion is directed immediately outwards, between the inner rods of Corti and the supporting cells which surround them; while another portion unites to form loose bundles, which wind round the turns of the cochlea. From these latter, fibrils pass through the clefts between the outer rods of Corti into the tunnel of the cochlea, and form a second compact spiral strand, from which delicate sets of fibrils are given off in radiating lines. These fibrils cross the tunnel and pass through the clefts between the outer rods of Corti to the outer hair-cells, where they again become spiral and terminate, in a manner as yet unknown, between the outer cells.

Reissner's membrane, or the vestibular wall of the ductus cochlearis, begins at the limbus of the osseous spiral lamina, and ends at the vestibular border of the outer wall of the duct. It consists of an extremely delicate connective-tissue layer, either structureless or faintly striated, its vestibular surface is covered by a simple layer of endothelium, with a few spindle-shaped cells, sometimes containing pigment; while its tympanal surface, which looks towards the cavity of the ductus cochlearis, is lined by polygonal flattened cells. Reissner's membrane is curved and bulges into the scala vestibuli, the curvature being the result of unequal pressure on the two sides. Pressure upon the inferior surface can be more easily rectified by escape of fluid through the aquæductus cochleæ, and the tension of this wall is therefore less.

Blood-Vessels of the Internal Ear. — The internal auditory artery is a branch of the basilar; it passes with the seventh pair of nerves into the internal meatus, and divides into a vestibular and cochlear branch. The latter breaks up into several small twigs, which pass through the openings in the tractus spiralis, and between the layers of the spiral lamina, and are finally distributed to the structures of the cochlea. The largest branch runs in the central canal of the cochlea. The artery to the vestibule divides into small branches which pass through the posterior wall of the vestibule, and are distributed to the

structures it contains and to the semi-circular canals. Each of the latter receives two branches, one at its ampullary, and the other at its non-ampullary extremity; these anastomose with each other on the curvatures of the canals. The labyrinth also receives a few branches from the stylo-mastoid artery.

The *veins* have the same names as the arteries, and unite at the bottom of the internal meatus to form the commencement of the internal auditory vein, which opens into the superior petrosal sinus. It is doubtful whether any veins pass through the aquæductus vestibuli and cochleæ. Nothing can be definitely stated with regard to the lymphatics of the internal ear.

The Origin of the Auditory Nerve.—Many investigations have been made for the purpose of discovering the deep origin of the auditory nerve; according to Politzer, the recent researches of S. Freud* have thrown much light upon this very difficult question. A transverse section through the medulla oblongata close to the lowest part of the auditory nerve, and through the apex of the large olive, shows that this nerve occupies an external area of the medulla, which extends to the large ascending root of the trigeminus, and contains a section of the restiform body. Above and internal to the latter is a distinct area, which Freud attributes to the auditory nerve, and which is called Deiter's nucleus. At the outer corner it presents a large nucleus of the auditory nerve (the anterior or external nucleus), and cross sections of nerve-fibres.

Bundles of the auditory nerve-fibres are seen to arise from spots just above those involved in this section, and pass through the restiform body. Other portions of the nerve, occupying the space between the anterior nucleus and the section of the large root of the fifth nerve, pass directly into the lateral area of the grey floor of the fourth ventricle. These latter fibres, the central portions of the nerve, belong to the vestibular division, and not to the auditory nerve proper. These vestibular nerves can be traced at the lower border of the pons, the facial nerve and the sixth appearing on the inner side. Deiter's nucleus, or the inner portion of the peduncle of the cerebellum, cannot be traced any further; but the fibres which it contains bend round and pass into the auditory nerve. The margin which separates it from the pons is formed by a somewhat thick transverse bundle, which is

* *Monatsschrift für Ohrenheilkunde*, 1886, No. 8, u. 9.

easily demonstrated in animals, and is visible in the human brain, though covered by fibres of the pons. It arises in the anterior auditory nucleus, and, therefore, as an indirect prolongation, belongs to the auditory nerve proper, and crosses the median line. It terminates, at least in part, in a grey mass, the superior olive, which is proved by its connections with other parts to be the reflex ganglion of the auditory nerve. Other central connections of the auditory and vestibular nerves, the *fibrae arcuatae*, pass across the raphé. Among these, the so-called *striae acusticae*, which are more or less clearly marked on the floor of the fourth ventricle, have attracted particular notice. They are, however, not the roots of the auditory nerve, but central prolongations, probably from the anterior nucleus.

The following are the principal facts that have been ascertained with regard to the origin and central prolongations of the auditory nerve. Its two portions, labyrinthine and vestibular, arise from the grey masses, already described, in the medulla oblongata, and closely resemble a posterior spinal nerve; most of its central prolongations pass across the raphé. The most external and posterior portion, the auditory nerve proper, ends in the large anterior nucleus, and its prolongations therefrom are seen as bundles which pass round the restiform bodies towards the raphé, and have not been traced any further, while other fibres pass into the thick transverse bundle, already mentioned. This latter is composed of several constituents: one portion connects the borders of the anterior nucleus together; another bundle goes to the superior olive of the same side, and a thicker strand to the same part on the opposite side; while some bundles are supposed to pass downwards, towards the spinal cord. The superior olive appears to be the ganglion through which auditory impressions produce reflex movements of the eyes; it is connected with the nucleus of the sixth nerve, and also with the posterior corpora quadrigemina.

A second portion of the auditory nerve passes into fibres which are distributed in Deiter's nucleus, and originate therefrom. This portion is morphologically significant; it forms the ascending root, which the nerve possesses in common with the fifth and the facial nerves.

A third portion, consisting of the central and superior fibres, furnishes the nerves to the semi-circular canals. It runs partly

through and partly on the inner side of the restiform body, and terminates in the inner auditory nucleus, which replaces Deiter's nucleus when the latter becomes atrophied. The further connections of the vestibular nerves are as follows:—the fibres to the canals are connected with the nucleus of the sixth nerve and cross the raphé; these produce the ocular movements in giddiness; a bundle of fibres proceeds downwards to the spinal cord, and other bundles pass round the sides of the ventricle to the opposite central ganglia of the cerebellum.

The Physiology of the Labyrinth.—The labyrinth consists of a cavity, of very complicated shape, filled with fluid and surrounded by firm osseous walls. In the latter are two openings into the tympanum, of which one, the fenestra ovalis, in the vestibule, is closed by the base of the stapes; the other, the fenestra rotunda, opens into the cochlea, and is closed by the so-called *membrana tympani secundaria*. The osseous labyrinth contains the membranous structures and the terminations of the nerves. The sonorous vibrations reach the latter either in the form of fluid undulations which are transmitted by the perilymph and endolymph of the labyrinth, or directly as condensation and expansion waves which are conducted by the solid walls of the osseous labyrinth to the membranous structures and nerves. The displacement of the perilymph is greater for low than for high tones; the latter causing only the slightest movements in the fluid of the labyrinth. The normal and essential route for sonorous vibrations in the human subject is through the *membrana tympani* and the chain of bones; and the undulations of the fluid in the labyrinth, caused by the movements of the base of the stapes in the fenestra ovalis, are the necessary excitants of auditory perception. All undulations, starting from the stapes, must be propagated in every direction, and traverse all parts of the labyrinth, that is to say, not only the vestibule and semi-circular canals, but also the entire tube of the cochlea. They are transmitted from the vestibule along the *scala vestibuli* to the apex of the cochlea and the fluid in the *scala tympani*, and thence to the fenestra rotunda, while a second route from the *scala vestibuli* is through the fluid in the cochlear canal. It is owing to the elasticity of the membrane covering the fenestra rotunda, which yields to the pressure of the fluid of the labyrinth, that the base of the stapes is able to move. The membrane of the fenestra rotunda is incapable of

receiving sonorous vibrations from the air in the tympanum and of conveying them to the cochlea.

The **functions of the various portions** of the internal ear will now be considered in detail. The *utricle* and the *sacculæ* are supposed to be adapted for the perception of noises, as distinguished from tones, the perception of which is thought to be the function of the cochlea. It would appear, however, from the results of experiments, that these parts have a share at least in the perception of tones; in some heteropods examined by Ranke, when certain notes were sounded, the auditory hairs were seen to vibrate freely, and to cause movements of the otoliths. Politzer also refers to some experiments by Hensen, on the auditory apparatus of crabs; when certain definite sounds were produced, a certain number of hairs were thrown into vibrations. Such experiments prove that not only noises but sounds of various pitch affect the terminal apparatus in the *maculæ* and *cristæ acusticæ* of the vestibule and ampullæ.

The Semi-circular Canals.—Opinions have differed very widely as to the functions of the semi-circular canals. At one time they were regarded as the organ through which the direction of sounds was estimated; according to another theory, they are not concerned in the perception of sound, but are the organs through which co-ordinated movements are performed. As a matter of fact, such tubes containing air and water, will conduct sonorous vibrations without loss of force; and vibrations, passing in the axes of the canals, must necessarily reach the nervous structures of the ampullæ. It is, however, pretty clear that the tubes are not designed to fulfil this purpose, for the vibrations can reach the ampullæ direct from the vestibule. The fact must not be overlooked that these portions of the canals are furnished with peculiar nervous structures, which are certainly adapted for the perception of sound. According to another view, the canals receive the vibrations which are conducted by the bones of the head, and convey them to the nervous expansions in the ampullæ. This theory of their functions was based upon their form and position; from whatever direction a sonorous vibration may traverse the cranial bones, it must impinge upon one or other of the canals almost or quite at a right angle. In the human subject, however, the bones constitute a very subordinate channel for the conduction of sonorous vibrations, and it is very unlikely

that the functions of the canals should be thus restricted. Equally improbable is the theory which assigns to the canals the faculty of conveying impressions as to the direction of sounds; this latter is determined by the relation of the meatuses to the source of the stimulus to the auditory nerves.

The well-known experiments of Flourens prove that destruction of the membranous canals is attended by consequences unconnected with the sense of hearing, and that it causes symptoms generally described as vertigo. Admitting that the phenomena in question are due to the injury of the canals alone, it by no means follows that the nervous expansions in the *cristæ acusticæ* play no part in the reception of sonorous impressions.

In Flourens' experiments, which have been often repeated, one or more semi-circular canals were divided on one or both sides, pigeons being usually selected for the operation. The results appeared in the form of movements, divisible into three classes. In the first, there were to-and-fro pendulum-like movements of the head, associated with intermittent oscillations of the eyes. In a second set, the pigeon moved round in a circle; while in a third form, the head was bowed down so as to come in contact with the ground, and the beak was directed backwards. Vomiting is generally superadded to the other symptoms. The pendulum-like movements differ according as different canals are divided; thus, when the horizontal canal is injured, the movement is also horizontal to the left and right; injury to a vertical canal is followed by an up-and-down movement; and when both classes of canals are injured, the two kinds of movements are combined.

Opinions differ as to the relations existing between the injuries and the motor phenomena; some observers think that the latter are due to the altered conditions of excitement of the ampullary expansions of the nerves, while others assert that they are caused by injury to adjacent parts of the cerebellum. Those who advocate the first theory differ as to the manner in which the canals are affected, some supposing that the disordered movements are due to the decrease in the stimuli which normally originate in the influence of the labyrinthine fluid, and vary with the position of the head. According to another view, the injury produces fresh irritation of the peripheral apparatus, and this, being transmitted to the cerebrum, causes the peculiar movements. Goltz

believes that the pressure of the endolymph upon the ampullary endings of the nerves varies with the position of the head; others suppose that movement of the endolymph is always associated with movement of the latter part. The mechanical irritation, thus produced, must vary in the different ampullæ with the cranial movements, and hence it gives rise to specific sensations in the central organs, enabling animals and human beings to form correct ideas as to the position of the head. When the endolymph escapes, as the result of injury, the normal stimulus to the ampullary nerves, and the necessary condition for the discharge of their functions, is either lessened or altogether abolished; and the absence of any message from the periphery renders the animal incapable of estimating the position of its head. The resulting sensation of vertigo is the final cause of the pendulum-like and other movements. Goltz therefore regards the semi-circular canals as specific sense-organs for maintaining the position of the head, and indirectly for the equilibrium of the whole body.

Another view, of a somewhat similar character, is that maintained by Cyon. He assumes that the disorder of equilibrium is due to the vertigo, but he thinks that the latter is the result of the auditory sensations which are transmitted by the ampullary nerves now placed under abnormal conditions of excitement. The movements, however, continue during sleep, and this fact tends to show that they cannot be due to sensations of sound. It has been stated that disorders of equilibrium continue after the wounds have completely cicatrised, and the head remains in its new position; hence it would seem that the phenomena are not due to peripheral irritation. Dr. Brown-Sequard states that the symptoms do not depend on the section of the canals, "but are the results of an irritation of the auditory nerve, from the traction upon it by the membranous semi-circular canals at the time of division." He does not think that auditory sensations play any part in the production of the movements. It has also been shown that, when the operation has been very carefully performed, after a time, the pendulum-like movements either partially or completely cease, and that rotatory movements are developed only when the cerebellum has been injured or has subsequently become affected.

Amid so many conflicting opinions it is difficult to determine the real functions of the semi-circular canals; some recent

experiments, however, throw more light upon the subject. It has been ascertained that laceration and the application of caustics to the membranous canals are followed by convulsive action of various muscles, and that the same result is witnessed after crushing the trunks of the auditory nerves; but if both nerves are separated from their origins in the brain, there is no permanent disorder of equilibrium. There is, therefore, no foundation for the hypothesis which assumes that the effects of injury to the canals are referable to defective stimulation of the auditory nerves. In rabbits, injuries to the membranous canals are followed by contraction of the sphincter of the pupil on the affected side; this muscle is not under the control of the will, and the change which takes place is clearly the result of reflex action, and is analogous to the muscular contractions observed in other parts. Even after the brain has been removed, injuries to the canals will produce movements. Reflex impressions are obviously conveyed by the vestibular branch of the auditory nerve, but it is doubtful whether auditory stimuli are thus propagated. Contractions of the tensor tympani always cause sensations of sound, and the change in position made by animals after such impressions may be regarded as an involuntary reflex movement. The general movements of the body and the start of alarm which are caused by unexpected and loud noises are to be referred to the same category. It may be that some fibres of the vestibular branch are the channels for reflex action, while those connected with the *cristæ* and *maculæ acusticæ* convey impressions of sound. Other theories with regard to the functions of the semi-circular canals will be discussed in the chapter on "Ménière's Group of Symptoms."

The Function of the Cochlea.—The cochlea is the peripheral organ for auditory sensations, which commence in excitement of the terminal fibres of the cochlear nerves. Certain structures in this part of the ear resolve the complicated wave-forms of musical tones into their components. It was once considered that the rods of Corti were the apparatus that vibrated and stimulated the terminations of the nerves; but this view appears to be incorrect. In birds and amphibians, which are able to distinguish musical tones, these rods are absent; and it is now believed that the stretched radial fibres of the *membrana basilaris*, on which Corti's cells are placed, are the essential organs in

question. These cells have cilia on their upper ends, and are about 2,000 in number; their connection with the terminations of the cochlear nerve has been pretty clearly demonstrated. The membrane is not of equal width throughout its extent; but increases from the lowest winding of the cochlea to the cupola. Thus, a string-like fibre of the membrane which is capable of vibrating corresponds to every possible simple tone. Different parts of the membrane are adapted for different tones; the lower portions receive impressions of high notes, while the upper part of the membrane towards the cupola is adapted for the reception of low notes. This division of function has been demonstrated by experiment and by pathological observation. In dogs, destruction of the apex of the cochlea causes deafness for low notes, when the lower winding is injured, the animal fails to perceive high tones. In a case recorded by Moos, of deafness for high notes, atrophy of the nervous structures in the first turn of the cochlea was found after death.

When a definite note is sounded a certain group of fibres is thrown into vibration; the fibres in the neighbourhood do not remain altogether at rest, but likewise vibrate to a certain extent. This secondary vibration explains the fact that when a sound continuously increases, the perception of it increases in a similar manner, and not in separate stages, such as would be noticed if only isolated portions of the membrane, one after another, were thrown into vibrations. It must also be remembered that, as a general rule, a sound contains a number of overtones, and therefore excites simultaneously groups of fibres of the basilar membrane corresponding with these tones. Every sound which reaches the ear excites pendulum-like vibrations, some belonging to the fundamental tone, and others to the overtones.

Recent investigations by Ferrier* and others have shown that the psycho-acoustic centre lies on both sides in the temporal lobe, and more especially in the superior temporal gyrus of this lobe: when it is completely removed deafness results. Irritation of the superior temporal convolution in monkeys causes quick retraction and erection of the opposite ear, associated frequently with opening of the eyes, dilatation of the pupils, and turning of the head and eyes to the opposite side. Dr. Ferrier's view is supported by the post-mortem examinations of several cases in which

* Croonian Lectures on Cerebral Localisation, *Brit. Med. Jour.*, June 23, 1890.

complete bilateral deafness was associated with atrophy of the angular gyri and superior temporo-sphenoidal convolutions of both hemispheres. Word-deafness has been found associated with lesions of the superior temporal gyrus in the left hemisphere. In this condition, the patient is not altogether devoid of auditory sensation, for he can hear the ticking of a watch, and can recognise and hum an air; but articulate sounds, except perhaps his own name, or some simple combination of words, have no meaning and cannot be repeated. Further confirmation of the localisation of the auditory centre in the convolution referred to is afforded by cases in which auditory symptoms of various kinds were connected with irritative lesions implicating this gyrus. Two cases of this nature have been reported by Dr. Gowers.* It would appear that the fibres of the auditory nerve decussate in the brain, for if the cochlea be destroyed on the side on which the temporal convolution is injured, the animal becomes completely deaf.

* *Diseases of the Nervous System*, vol. ii. p. 21.

CHAPTER XXXIX.

ETIOLOGY, SYMPTOMS, AND DIAGNOSIS OF DISEASES OF
THE INTERNAL EAR.

Comparative Frequency of Diseases of the Labyrinth—Three Classes of Causes: General, Local, and Traumatic—Infectious Diseases—Liability of Auditory Nerve to be Attacked—Nervous Deafness—Morbid Conditions of Organs of Circulation, etc.—Effects of Certain Drugs upon the Internal Ear—Diseases of the Brain—Extension of Morbid Processes from the Middle Ear—External Influences, Cold, Shocks, etc.—Symptoms of Disorders of the Labyrinth—Deafness—Paracosis—Subjective Sensations—Giddiness and Disorders of Co-Ordination—Nausea and Vomiting—Diagnosis between Diseases of the Labyrinth and those of the Cerebellum—Acoustic Hyperæsthesia—Prognosis—Diagnosis of Diseases of the Labyrinth—Deafness as a Symptom—Bone-Conduction—Rinne's Test—Bezold's Method—Drawbacks Connected with Rinne's Test—Testing with High and Low Notes—Galton's Whistle—König's Rods—Condition of Membrana Tympani and Eustachian Tube.

Diseases of the Labyrinth are either of primary or secondary origin; those of the former class are relatively infrequent, constituting about 5 per cent. of all cases of affections of the ear. Secondary disease of the labyrinth is not uncommon, for it is apt to supervene upon adhesive and other processes in the middle ear.

The **Causes** of affections of the labyrinth may be divided into three classes. The first will include those of a general character, and depending on disorders of nutrition and circulation; the second, those which are local in their origin, the labyrinth participating in morbid conditions of neighbouring

parts. The third class includes external influences, such as cold and injuries of various kinds.

I. Among the causes belonging to the first class various infectious diseases occupy a prominent place. The part that the acute exanthemata, the continued fevers, syphilis, mumps, etc., often take in the causation of middle-ear affections has been fully discussed in a previous chapter; in a smaller proportion of cases, grave disorders of the labyrinth originate in a similar manner, either with or without any implication of the structures of the tympanum.

Politzer draws attention to the fact that the auditory nerve is more readily affected by morbid poisons circulating with the blood than any other nerve of special sense. Affections of the optic, gustatory, and olfactory nerves are seldom associated with infectious diseases. It must be confessed that little is known with regard to the changes in the auditory nervous apparatus; but their existence may be inferred from the symptoms.

Auditory perception sometimes becomes weakened during the course of non-infectious chronic disorders, of an exhausting character, and such a loss of function may eventually become permanent. Closely allied to these cases are those of so-called "nervous deafness," in which there is no recognisable disease, either in the organ of hearing or in the system generally, but the patients are weak and low, and their hearing-powers are more or less diminished. Some authorities—*e.g.*, Dr. Roosa and the late Mr. Hinton—have refused to acknowledge such a causation, but mainly on the grounds that in many cases described as instances of "nervous deafness," some affection of the middle ear can be detected on examination. "Besides, it cannot be said that nervous people are especially liable to deafness from lesions of the labyrinth, any more than they are to atrophy of the optic nerve. On this point, Mr. Hinton says that it is difficult for him to accept debility, nervous or other, as a cause of nervous deafness."*

There is, however, more probability attached to Dr. McBride's view to the effect that functional impairment of the auditory nerve may occur in cases of debility and nervous depression, and without any demonstrable lesion. He suggests two possible

* Roosa, *Diseases of the Ear*, 7th Edition, p. 614. See also Hinton, *The Questions of Aural Surgery*, pp. 153, 245.

explanations as to the manner in which the organ of hearing is influenced by the state of the general system. 1. The auditory nerve may become impaired in its function by sharing in the general nervous depression, the resulting condition being analogous to nervous asthenopia. 2. As suggested by Dr. Woakes, the deafness may depend, in part at least, upon atony or paresis of the tensor tympani muscle. Should there be partial deafness, due to middle-ear disease, any condition of debility is likely to increase the loss.

It is necessary to remark that the diagnosis of "nervous deafness" must not be too hastily made. The results of many post-mortem examinations, made by the late Mr. Toynbee, go to prove that not a few disorders of hearing, formerly classed as nervous deafness, are really caused by ankylosis of the stapes.

Various morbid conditions of the heart and lungs are liable to affect the auditory nerve by obstructing the circulation of blood in the cerebral vessels. Degenerative diseases of the kidneys and liver, and some gastric and uterine disorders, are occasionally associated with symptoms referable to the same nerve. In some cases, the association is doubtless accidental; but in others, the connection would seem to be direct, inasmuch as the aural symptoms are wont to vary from time to time, their gravity seeming to depend, in some measure at least, upon the condition of the original lesion. In women at the menopause, the general and local neurotic disorders tend to aggravate any existing aural affections, and to cause the reappearance of those that have subsided. Noises in the ears are apt to become very troublesome at this period, and are sometimes associated with vertigo and diminution of hearing-power. Adhesive processes in the middle ear advance with increased rapidity.

Effect of Drugs upon the Ear.—Akin to the functional disorders of hearing noticed in the above paragraphs are those symptoms which are liable to be produced by certain drugs, such as quinine, salicylic acid, morphine, and lead, and by the immoderate use of alcohol and tobacco. Large doses of quinine almost invariably affect the organ of hearing, and produce subjective noises, as of bells ringing in the ear, while the patient becomes more or less deaf for a time. Ringer states that sometimes, though very rarely, the deafness becomes permanent and

complete; as a general rule, however, the noises cease in a short time (in a few hours or days), and the hearing again becomes natural. Dr. Kirchner, of Würzburg, gave large doses of quinine to rabbits, and on killing the animals and examining the ears, found hyperæmia and hæmorrhages in the mucous membrane of the tympanum and in the labyrinth. He attributes these appearances to vaso-motor disturbance, leading to congestion and exudation. Among other marked symptoms caused by salicin and its derivatives, deafness and noises in the ears are commonly noticed. Opium produces some amount of deafness; "it is said to lessen the conductivity of sensory nerves, though this blunted sensibility must be due in some measure to the effect of opium on the grey matter of the brain, depressing the power of perception" (Ringer). Subjective auditory symptoms, in the form of hallucinations, have been traced to the effects of lead; small doses of alcohol increase the perceptive faculty, while large quantities act decidedly in the opposite direction.

II. The second category includes causes of a local character, the labyrinth participating in, or becoming affected by, morbid conditions of neighbouring parts. In diseases of the brain and its membranes, the connection between the original lesion and the affection of the labyrinth can often be clearly made out. In simple and epidemic cerebro-spinal meningitis (*see* page 524) and in tumours of the brain the morbid process extends either by the blood-vessels or along the auditory nerve. It is easy to understand how such conditions as congestion, exudation, and even hæmorrhage in the structures of the labyrinth and atrophy of the nervous structures, may be caused by pressure upon the vessels or upon the auditory nerve. Disorders of hearing, having their seat in the labyrinth, are occasionally associated with lesions of the spinal cord. Aural symptoms of a like character have been known to supervene, as a result of shock or great mental excitement; several cases of this nature are recorded in Mr. Toynbee's work on "Diseases of the Ear." In the absence of any discoverable change in any part of the organ of hearing, such symptoms may probably be referred to some marked circulatory disturbance in the terminal apparatus of the auditory nerve.

The labyrinth is sometimes affected by extension of morbid processes in cases of severe inflammation of the middle ear, especially when occurring in the course of scarlet fever, diphtheria,

and measles. The labyrinthine complication may likewise be caused by increased pressure upon the fenestræ. In either case, the prominent symptoms are deafness, noises in the ears, giddiness, and diminished conduction of sound through the bones of the skull. Disorders of hearing referable to the auditory nerve are more common in chronic adhesive catarrh. In this latter affection, which often results in ankylosis of the stapes, signs of labyrinthine disease are not infrequent, and are sometimes noticeable even in the early stages. In these cases the disorder of nutrition, leading eventually to loss of function, appears to involve the auditory nerve simultaneously with the middle ear and Eustachian tube. The course of the process is more evident in those severe cases of tympanic suppuration in which the walls of the cavity become carious or necrotic, and the pus finds its way into the cochlea or vestibule, with complete destruction of the terminal nerve-apparatus as the necessary result. In such cases, portions of the osseous walls of the labyrinth, fragments of the semi-circular canals, and even the entire cochlea, are sometimes detached.

III. Disorders of the labyrinth are liable to be produced by external influences of various kinds—*e.g.*, exposure to cold; injuries from blows or falls; alterations of atmospheric pressure, and the shocks resulting from very loud or continuous sounds. In cases due to exposure to cold, catarrh of the middle ear generally precedes or accompanies the affection of the labyrinth. Traumatic lesions of the internal ear may result either from direct or from indirect violence. In the former case, the external ear and the tympanum are likewise injured, as in penetrating wounds; the second category includes (1) those cases in which the bones of the head primarily suffer, and the shock is transmitted to the labyrinth, and (2) those in which the injury is effected by shocks or concussions due to changes of pressure, loud noises, etc. Questions as to the influence and frequency of such causes will be fully discussed in subsequent chapters.

In the majority of cases of labyrinthine disorder both ears are affected, either simultaneously or in more or less rapid succession. The impairment of function is, however, likely to be confined to one ear in cases due to the shock caused by a single loud sound. The predisposition to diseases of the internal ear is greatest in children and in persons over sixty years of age. In

the latter, the auditory nerve and its terminal expansion are liable to atrophy and fatty degeneration; while children are especially prone to suffer from those infectious diseases which are so often attended by aural complications. As an additional reason for the frequency with which children are attacked, Politzer lays great stress upon the anastomoses which the vessels of the labyrinth form with those of the middle ear, on the one hand, and of the cranial cavity on the other. These are more frequent in children than in adults, and there is also in the former a freer communication, through the aqueducts, between the fluid of the labyrinth and the cerebro-spinal lymph-spaces. The greater development of such channels accounts for the more frequent propagation to the labyrinth of inflammatory processes originating either in the middle ear or in the cranial cavity.

Symptoms.—Disorders of the labyrinth give rise to (1) Deafness of varying degrees, but generally severe. (2) Subjective sensations (noises in the ears) of various kinds. (3) Giddiness and disorder of co-ordination. (4) Nausea or vomiting. (5) Acoustic hyperæsthesia, evinced by undue sensitiveness to sounds. Two or more of these symptoms frequently coexist; even severe deafness is sometimes associated with peculiar sensitiveness to loud sounds. In one well-marked class, viz., the apoplectic form of Ménière's disease, the deafness and other symptoms come on very suddenly. The patient, if standing or walking, falls to the ground, and the attack resembles one of cerebral apoplexy. In syphilis of the labyrinth, the deafness, which is a prominent symptom, may become complete within a few hours. In other cases, such as those in which an affection of the labyrinth complicates adhesive catarrh of the tympanum, the symptoms of the former are apt to be slowly and insidiously developed.

(1) **Deafness** due to labyrinthine disease varies considerably in degree in different cases. Thus it may be either very slight or total and absolute; and between these extremes every possible variation exists. Total deafness is pathognomonic of disease of the auditory nerve in some part of its course. Labyrinthine deafness is apt to be progressive; but sometimes the impairment remains stationary for a time. In other cases the gradual progress of the disorder is interrupted by a sudden change for the worse. The hearing-power in any given case is liable to be influenced by the general health of the patient, by excitement,

by excesses of all kinds, and by fatigue of the acoustic nerve. As a general rule, the hearing-power in these patients is at its best in a quiet place, where there are no other sounds to distract the attention.

Deafness to certain notes is sometimes experienced by persons suffering from disease of the labyrinth. Inability to perceive high notes is not infrequent in old people; this fact was mentioned by Wollaston in the *Philosophical Transactions* for 1820. Sudden deafness for low notes has been observed to follow concussions of the labyrinth from explosions of gunpowder, and in other cases of a similar character high notes are lost. In rare instances there is loss of perception of notes in the middle octaves. Symptoms of this nature point to some affection of the auditory nerve; their gradual development would show that the change was probably of a secondary character, such, for instance, as results from pressure on the labyrinth caused by middle-ear disease. Helmholtz's theory that the perception of tones of different pitch depends upon different nerve-fibres serves to explain the pathology of the cases under discussion. Experiments show that destruction of the apex of the cochlea, which contains the longest fibres of the basilar membrane, causes deafness to the lower notes. Urbantschitsch points out that partial tone-deafness may also be due to central lesions, and that it must often be difficult to determine whether the cause of the symptom is located in the peripheral apparatus or trunk of the nerve, or in the nerve centres. It must also be remembered that obstacles to sound-conduction are apt to affect certain notes more than others; imperfect perception may therefore be due to purely physical causes.

Another, but somewhat rare, symptom of labyrinthine disease, is the phenomenon termed *paracusis*, or "false hearing." In this condition, a note is not heard correctly, but appears to be higher or lower than it really is, and the difference may amount to half a tone, several tones, or even an octave. If only one ear be affected, two sounds are heard, one being true and the other false, and this condition is termed *paracusis duplicata*.

A case of this latter kind was reported by Sir Everard Home;* the patient, a music-master, when suffering from catarrh, noticed that there was a confusion of sounds in his ears, and also that the

* *Philosophical Transactions*, 1800.

pitch of one ear was half a note lower than that of the other. A single note was not perceived as such, but as two distinct sounds following each other in quick succession, the last being the lower and weaker. Several other cases of double hearing have been placed on record; one of the most interesting is that of Von Wittich,* described by himself. A month after a violent attack of suppurative middle-ear inflammation, he observed that the note of a tuning-fork appeared exactly half a tone higher in the diseased ear than in the healthy one. The same difference was perceived in notes of the middle octave, either when whistled or struck upon the piano. Similar results were obtained when the meatus was plugged with wool or filled with water, and after inflation of the tympanum. Two tuning-forks, one half a tone higher than the other, appeared to yield the same note when the higher was held near the sound ear, and the lower near the diseased one.

Similar phenomena may be due to the effects of certain medicines. Thus, Dr. Moos, of Heidelberg,† has reported a case of "Double Hearing during the Exhibition of Iodide of Potassium." The patient, who had suffered for a long time from nervous asthma, had been taking the iodide in doses of gr. x. daily for a fortnight, when the remedy was discontinued on account of nasal catarrh and loss of appetite. On the following day there was double hearing for certain notes; this subsided in the course of a few days. In another case, reported in the same number of the *Archives of Otology*, the double hearing came on suddenly in a patient who had for a long time been almost completely deaf on the left side. One evening, when humming a tune, he heard the true tone as well as the major third above. He was not, however, sure as to the side on which he heard the higher tone; nor could he define the number of octaves which were affected with the double hearing. While the condition lasted, all varieties of music created great dissonance; subjective noises and vertigo were also complained of. After continuing for seven months, the double hearing passed away, all tones seemed pure, both high and low tones were heard with equal clearness, and music became a source of pleasure as before.

* Quoted by Gruber, *l.c.*, p. 162, from *Königsberg. Medicin. Jahrb.*, III. Bd. 1861.

† *Archives of Otology*, vol. xi. p. 27.

The origin of the symptoms was attributed to inflammation involving the cochlea on the left side and the region to which the vestibular branch is distributed. Their cessation was presumably due to destruction of the conductive capacity of the left auditory nerve, or of its terminal branches within the labyrinth. The results of testing the hearing showed that the left ear was completely deaf for aërial and bone-conduction.

The phenomena of double hearing are explained by Helmholtz's theory, as modified by Hensen, with regard to the resolution of sounds by the cochlea. The stretched radial fibres of the membrana basilaris, on which Corti's organ is placed, and which are shortest in the first turn of the cochlea, "are now regarded as the vibrating threads. Thus, a string-like fibre of the membrana basilaris, which is capable of vibrating, corresponds to every possible simple tone."* With a normal condition of the organ of hearing on both sides, a given note throws into vibration corresponding fibres of the basilar membrane, and the proper sound is perceived. When, however, the membrane is more tense on one side than on the other, its pitch becomes raised in proportion to the increased tension, so that a fibre, or a series of fibres, which normally makes 300 vibrations in a second, may execute 350 in the same space of time. When a note corresponding with the latter number is sounded, the healthy ear perceives it correctly; but in the diseased ear, the fibres receiving the impression transmit it to a portion of the sensorium accustomed to receive 300 vibrations, and double hearing is the result.

An opposite condition is assumed to exist in cases in which the false note is higher than that perceived by the normal ear. The affected fibres of the basilar membrane are supposed to be in a state of relaxation, for example, so as to perform 300 vibrations instead of 325. When a note consisting of the former number is sounded, it throws into vibrations those fibres of the membrane which correspond therewith. On the healthy side, the right note is heard; on the other, those fibres vibrate which normally transmit a sensation corresponding to 325 vibrations, and a note of that pitch is perceived by the sensorial apparatus on that side.†

* Landois and Stirling's *Physiology*, Third Edition, p. 818.

† For an elaborate explanation of the phenomena of "Double Hearing," see Knapp's paper in *Archiv f. Aug. u. Ohr.*, Bd. I. Abth. 2, S. 96.

In connection with paracusis, as in the case of deafness to certain notes, the fact must be borne in mind that morbid changes in the sound-conducting apparatus are apt to facilitate the conduction of certain tones, and to make them appear louder and more distinct. It must also be remembered that under normal circumstances a feeble sound of a given note seems to be of a higher pitch than a loud sound. When any difference in sounds conducted through the air is noticed between the two ears, osseous conduction should, of course, be tested. If the sound then appear to be the same on both sides, the alteration by aerial conduction must be due to some change in the sound-conducting apparatus.

It is highly probable that partial tone-deafness and "double hearing" are by no means infrequent. As a general rule, however, the changes are perceptible only by persons whose hearing organs have been well trained. Akin to the phenomena in question are those echo-like sounds which are sometimes super-added to words and musical notes, without any alteration in pitch.

(2) **Subjective Sensations** (noises in the ears) will be fully described in the chapter on "Neuroses of the Auditory Nerve." It is here sufficient to mention that in the majority of cases they are caused either by pathological changes in the sound-conducting apparatus or by some affection involving the nerve. In the former case, the noises are most often associated with such lesions as produce rigidity of the membrane of the fenestra rotunda, or undue pressure of the base of the stapes upon the fenestra ovalis. Tinnitus may also be due to peripheral irritation of various sensory nerves, and especially of branches of the fifth pair.

(3) **Giddiness and Disorder of Co-ordination** are frequently due to some disease of the ear. Symptoms of this character, but usually of a slight nature, are sometimes caused by foreign bodies in the external meatus. The pressure upon the membrana tympani increases the tension in the labyrinth, and irritates the vestibular and ampullary nerves. Even syringing the ear, particularly if cold water be used, produces vertigo in some patients. Middle-ear disease, by involving the labyrinth, not infrequently causes marked giddiness and staggering, and sometimes even loss of consciousness. Changes of tension in the tympanum produce more or less corresponding changes in the endolymph,

and these latter are regarded as the immediate cause of the vertigo. In a case of middle-ear catarrh, recorded by Dr. McBride,* vertigo, tinnitus, vomiting, and loss of consciousness were all well-marked symptoms, and a very peculiar effect was produced by the first attempt to inflate the tympana. Air passed into the middle ear only on the left side; "but whereas before the operation the patient had great difficulty in standing and walking, even with assistance, after the inflation he declared himself greatly relieved, and was able to walk about alone and unsupported." After a short course of treatment, which consisted mainly in inflating the middle ear, "the only symptom of vertigo left was that looking down suddenly produced slight giddiness." The connection between the nervous phenomena and the condition of the left tympanum was proved by the fact that inflation produced an immediate and marked improvement.

The capability of pressure to produce vertigo is further demonstrated by a case recorded by Dr. Hughlings Jackson.† The patient, a woman, aged forty-nine, had suffered from disease of the right ear since childhood, and for three months from giddiness and inability to walk without staggering. Pressure on the tragus was followed by movements of the eyes from side to side, giddiness, and a sensation of falling towards the left side. On examination, the right meatus was found to contain much pus; the membrana tympani could not be seen (owing to swelling of the walls of the meatus), and the watch could not be heard on that side. After some weeks' treatment, the condition became so far improved that to produce the giddiness and movement of external objects, she had to put the finger into the meatus. The symptoms eventually altogether subsided, the improvement coinciding with the cessation of the discharge from the ear.

The pathogeny of vertigo as a symptom of disease of the labyrinth will be fully discussed in the chapter on Ménière's disease. It is probable that in the large majority of cases of auditory vertigo, the affection of the labyrinth is secondary to disease of the tympanum. Primary inflammation of the membranous labyrinth is a very rare disease. Those cases which Voltolini, of

* Auditory Vertigo, *Edin. Med. Journ.*, Jan. 1881.

† On "Ocular Movements, with Vertigo, produced by Pressure on a Diseased Ear," *Ophthalmol. Soc. Trans.*, vol. iii.

Breslau, described as otitis labyrinthica, with deafness and a staggering gait as prominent symptoms, were proved by Gottstein to be in reality mild cases of epidemic cerebro-spinal meningitis. The disorder of the labyrinth cannot be regarded as primary unless it occur in the absence of any sign of middle-ear disease. In such a case, the sudden development of noises in the ears, or the exaggeration of those previously heard, and giddiness, followed by more or less marked deafness, point to implication of the labyrinth; and the diagnosis is supported if perception through the bones of the skull be lost or decidedly impaired. Nausea and vomiting may also be expected to occur, and in some cases the paroxysms of vertigo are followed by loss of consciousness. This latter symptom has been ascribed to the mental effect of the alarming sensations experienced by the patient, and also to vaso-motor changes produced reflexly through the auditory nerve. Dr. McBride has suggested a different explanation; he assumes that the nerves of the semi-circular canals are in direct communication with a central brain-area, which, when stimulated, gives rise to the sensation of vertigo. "It seems not improbable that a stimulus applied to this centre is very apt to overflow, and involve the vomiting and cardiac inhibitory centres. That the two last are in intimate relation is rendered probable by the frequent concomitance of nausea and faintness." If the cardiac inhibitory centre be sufficiently affected, syncope and unconsciousness are produced.

(4) **Nausea and Vomiting**, as symptoms of labyrinthine disorder, are consecutive to the giddiness and disturbance of equilibrium. The phenomena, taken as a whole, are by no means characteristic of aural affections; for they are of frequent occurrence in various forms of cerebral disease. In aural cases, their starting-point is assumed to be the semi-circular canals; and if Dr. McBride's theory be the correct one, the vomiting is due to the overflow of the stimulus conveyed to the vertiginous centre, and consequent involvement of the vomiting centre.

Lesions of the cerebellum, especially those affecting the middle lobe, often give rise to disorder of equilibrium and vomiting, and the symptoms therefore resemble those of disease of the labyrinth. "There may be lesion of the hemispheres without any marked symptoms; but if the middle lobe be injured or pressed upon by a tumour, there is usually a reeling

or staggering gait, like that of a drunken man. Ross points out that if the tumour affect the upper part of this lobe, the tendency is to fall backwards, and if the lower part to fall forwards, or to revolve round a horizontal axis.*

The diagnosis between affections of the cerebellum and those of the labyrinth may be made by considering the additional symptoms in each case. According to Prof. Rosenthal,† in cerebellar disease, the reeling, staggering gait of the patient is but little improved when support is afforded; he walks and stands with his legs far apart, the toes and the metatarsus are alternately raised and depressed, so that sometimes the balls of the toes, sometimes the heel, and sometimes the flattened sole come into contact with the ground. Not infrequently the patient complains of a feeling of numbness in the legs, especially in the soles of the feet; tactile cutaneous sensibility is at the same time much diminished, or even completely lost; the temperature sense and common sensation remain unchanged. Other symptoms occasionally present are: disorder of speech, nystagmus, deviation of the eyeball or inability to raise the eye beyond the horizontal line, contraction of the pupil, and amblyopia with optic neuritis. Violent pain in the back of the head, coming on in paroxysms, and sensitiveness to pressure, are also symptomatic of disease of the cerebellum.

Vertigo, nausea, and vomiting, accompanied by deafness and subjective auditory sensations, indicate some affection of the ampullary nerves, especially when such symptoms are superadded to aural disease, and are unaccompanied by others referable to the cerebellum. It must, however, be remembered that reflex symptoms of the latter kind may have their starting-point in some disease of the ear—*e.g.*, in suppurative inflammation of the tympanum. Urbantschitsch points out that symptoms indicative of cerebellar irritation, appearing from time to time during the course of an aural affection, and decidedly corresponding with its stage and condition, are to be regarded as of reflex origin, and not as proofs of cerebellar mischief.

(5) **Acoustic Hyperæsthesia** is a symptom of hyperæmia and inflammation of the membranous labyrinth. It also occurs in some patients presenting symptoms of general anæmia, and is

* Landois and Stirling's *Physiology*, p. 725.

† Cited by Urbantschitsch, *l.c.*, p. 389.

then probably due to passive congestion of the labyrinth. Certain lesions affecting the auditory nerve are apt to cause increased sensitiveness to loud noises and even to ordinary sounds. The sensation, under such circumstances, may be accompanied by pain and distress, and this peculiarity is noticed even in deaf people to some of whom loud sounds are apt to cause great annoyance. Further details on the subject of acoustic hyperæsthesia will be given in the chapter on "Neuroses of the Auditory Nerve."

The **Prognosis** in the majority of cases is very unfavourable; as a general rule, pronounced affections of the labyrinth are not amenable to treatment. Some of the worst cases are those in which the symptoms have appeared during the course of an acute infectious fever, and those of which a gradual development is the marked characteristic. Before venturing upon a prognosis, it is generally desirable to keep the patient under observation for some time. Variations in the severity of the symptoms are not uncommon; the hearing-power is sometimes influenced by the patient's general condition, and other circumstances. In traumatic cases, with comparatively slight symptoms, the prognosis is much more hopeful. In recent syphilitic cases also, recovery may be expected under proper treatment, even when the deafness is considerable, and noises in the ears form a prominent symptom.

Diagnosis of Diseases of the Labyrinth.—In all cases of deafness, the determination of the seat of the lesion is, of course, indispensable for prognosis and treatment. The external and middle portions of the ear are to a great extent accessible to direct examination, and many affections of these parts can be distinguished with absolute accuracy. The case, however, with regard to the labyrinth is altogether different. We have here to deal with a complicated nervous apparatus, closely connected with the brain on the one side and with the tympanic cavity on the other, liable to become implicated in diseases of adjacent structures, and altogether inaccessible to direct examination. Moreover, the pathological changes to which the internal ear is liable have not as yet been fully investigated, and the connection between symptoms and lesions is sometimes very difficult to trace. There are other sources of obscurity in the diagnosis of diseases of the labyrinth. It seldom happens that this part alone is the seat of change; in the majority of cases, the middle ear is like-

wise affected, and the task of assigning to each part its due share in the production of the symptoms is often beset with difficulties, and is sometimes quite impossible.

The methods of diagnosing aural affections in general have been described in a preceding chapter; a few pages will now be devoted to a special consideration of the means to be adopted for detecting disorders of the labyrinth and for distinguishing them from affections of the middle ear.

The existence of disease in the labyrinth is ascertained (1) By reviewing the symptoms and history of the case; (2) By examining the state of the auditory function; (3) By determining the condition of the external and middle ear.

(1) The general symptoms of diseases of the labyrinth have been discussed in preceding pages; those most frequently met with—viz., deafness, subjective sensations, giddiness, and disorder of co-ordination—even when associated, are by no means pathognomonic of primary labyrinthine disease, for they are sometimes present in catarrh of the middle ear, and are then due to pressure of the effusion upon the fluid of the labyrinth. When, however, the deafness and the subjective sensations have occurred suddenly; when both ears are involved; when there is a history of syphilis, of injury to the head, or of exposure to loud or to continuous sounds, the labyrinth, in all probability, is the primary seat of the disease. The conviction is strengthened if no disorder of the external or middle ear can be detected on examination made soon after the appearance of the symptoms. After the lapse of some time the diagnosis is not much aided by such an examination, inasmuch as changes in the middle ear—*e.g.*, a copious exudation—may have passed away, and the disordered function may be due to the condition of the ossicles or fenestræ.

(2) The state of the auditory function may be ascertained in several ways. The hearing-distance for speech and the watch is determined in the manner already described (*see* page 82), and when the watch cannot be heard, Politzer's acoumeter should be substituted for it. Several tuning-forks, each having a different pitch, are the most important instruments for diagnostic purposes; and for determining the upper limits of audible sound, Galton's whistle and König's rods supply the most convenient tests. The piano or harmonium may be employed to ascertain the perception of single tones.

Absolute deafness is pathognomonic of disease of the labyrinth, but is very rarely met with, for there are few patients who are utterly unable to perceive sonorous vibrations conducted through the bones of the head. On the other hand, a considerable amount of hearing-power may co-exist with disease of the labyrinth. The latter may be suspected to exist when, associated with other symptoms, the deafness, as determined by the watch and speech, is comparatively slight, and conversation is heard relatively better than the ticks of a watch.

Having determined the hearing-distance for voice and speech, the next step is to ascertain the acuteness of the perception of sound conducted by the bones of the head. If a loudly ticking watch, placed on the vertex or in contact with the mastoid process, be not heard at all in a patient under sixty years of age, there is reason to suspect disease of the labyrinth; and if a still louder sound, such as that produced by the acoumeter, be scarcely audible under the same circumstances, the probability is decidedly increased.

Still more definite information is derived from the use of tuning-forks. In some cases, the hearing-power is diminished for certain tones, while others are distinctly heard; it is therefore necessary to employ a series of tuning-forks, extending over several octaves. A complete set would include C, with 128 vibrations; G, 192; c^1 , 256; a^1 , 420; d^2 , 576; g^2 , 768; and c^3 , 1,024. For most purposes, however, three are sufficient, viz., C, with 128; c^2 , 512; and c^4 , 2,048. In deafness due to disease of the nerve, the hearing-power for high notes is apt to be considerably diminished or even lost, while low notes may be distinctly heard. This symptom, however, even when very marked, is not sufficient to establish the diagnosis, for it is sometimes noticed in connection with altered tension of the membrana tympani and chain of ossicles.

The bone-conduction of sound is tested in the usual way; to determine the relative capacity of the two nerves, the fork is placed on some point of the median line of the head, the spots usually selected being the vertex, forehead, and central incisors of the upper jaw. When the perceptive capacity of the nerve on one side is the point to be determined, the fork should be placed on the mastoid process. As explained in a previous chapter (*see* page 91), in a unilateral disorder, or when both ears are affected

in different degrees, if the tuning-fork placed on the vertex be best heard on the affected or worse side, it may be assumed that the nervous apparatus is either normal or, at all events, not seriously involved. If, on the other hand, there be diminished perception on the affected or deafer side, some lesion of the nerve may be inferred to exist.

Comparison of the aërial with the bone-conduction of the sound of the tuning-fork yields valuable evidence as to the condition of the labyrinth, and there are three ways in which this comparison may be effected.

(a) The tuning-fork is struck and held in front of the ear until the sound is no longer heard. It is then again made to vibrate, and placed on the skull; the time during which the sound is heard in both experiments being carefully noted. The results are, however, vitiated by the fact that in the ordinary way it is impossible to strike the tuning-fork twice in succession with the same force. Besides this, the force with which the tuning-fork is held against the skull affects the intensity of the sound. To obviate the former objection, Dr. Eitelberg,* of Vienna, has designed a tuning-fork which is made to vibrate by a hammer of soft rubber, and thus yields a tone of unvarying and moderate intensity.

(b) The error can be partially corrected by attaching to the tuning-fork a few inches of india-rubber tubing terminating in an ear-piece (*see* page 92). The surgeon can thus compare his own hearing-power (supposed to be normal) with that of the patient.

(c) Rinne's experiment compares aërial with bone-conduction in a manner which renders it very convenient for diagnostic purposes. A vibrating tuning-fork is applied to the vertex, the mastoid process, or against the incisor teeth. When the sound ceases to be heard, the instrument is removed and held in front of the ear, when the sound again becomes audible. This result is termed *positive*, and is always obtained with a healthy ear. When the sound, conducted through the bones, is heard for as long a time as, or longer than, through the air, the result is described as *negative*. Rinne's experiment does not directly show to what extent the hearing-power by aërial or bone-conduction is

* *Archives of Otology*, vol. xv. p. 324. Similar instruments have been devised by Dr. C. J. Blake and Prof. Lucae.

actually diminished; but it measures the difference which is proved by experience to be subject to the greatest variations in disease of the internal ear. If, in a case of marked deafness—*e.g.*, when a whisper is heard only close to the ear—Rinne's experiment yields a positive result, the existence of disease in the nervous apparatus may be fairly assumed, inasmuch as the relations between ærial and bone-conduction have undergone no alteration. On the other hand, if the result be negative, that is, if the patient hears the sound conducted through the cranial bones as long as, or even longer than that conveyed through the meatus, disease of some portion of the conducting apparatus may be diagnosed. There may at the same time be some amount of disease in the labyrinth, and the probability is much increased if perception for high notes, as tested by a tuning-fork held near the ear, be much diminished or altogether lost. It must always be borne in mind that Rinne's experiment, like others based on the patient's own personal observation, furnishes satisfactory information only in the more intelligent classes.

Dr. Schwabach, of Berlin,* has shown that in applying Rinne's test, the result on the same ear, in some cases, may be either positive or negative, according to the tuning-fork employed. He used two forks; one, *c* with 128 vibrations, and the *c*¹ of the next higher octave. In 4·8 of all cases, with demonstrable changes in the sound-conducting apparatus, this doubtful result was obtained. Besides pointing out this drawback connected with Rinne's test, Dr. Schwabach has shown that the conclusions to be deduced from a positive result are not in accordance with Rinne's assertion, for in many cases of indisputable affections of the sound-conducting apparatus, one or other fork could be heard at the meatus after perception through the bones had ceased, and only in a few such instances could it be assumed that the auditory nerve was implicated. Lucae's statement likewise that Rinne's assertions are correct only when marked deafness exists—*e.g.*, when whispered speech can be heard at no greater distance than three feet—does not hold good of all cases. Dr. Schwabach admits that in cases with no objectively demonstrable changes in the sound-conducting apparatus, a positive result with Rinne's experiment justifies the assumption of disease in the nervous apparatus. He has proposed an additional method of distinguishing between

* *Archives of Otology*, vol. xv. p. 195.

affections of the sound-conducting apparatus and those of the labyrinth. "If a tuning-fork be struck, and immediately applied to the vertex of a partially deaf person, and the time measured until the tone dies away, in diseases of the sound-conducting apparatus, the duration of perception is much longer than in health; but in affections of the perceiving apparatus this period is either the same as or less than the normal." This method of examination may aid in settling the diagnosis in difficult cases, especially when objectively demonstrable changes are present in the sound-conducting apparatus and Rinne's experiment at the same time gives a negative result.

Dr. Bezold,* of Munich, recommends that Rinne's experiment should always be supplemented by a comparison of the surgeon's hearing-power (supposed to be normal), with that of the patient. He uses two tuning-forks; one corresponding with a^1 (420 vibrations) and the other A^1 , two octaves lower (106). The former, if permitted to vibrate freely in the air, can be heard for eighty seconds by a person of normal hearing; for eleven seconds if placed on the vertex, and then for thirty seconds more by aërial conduction if held in front of the meatus. Under similar conditions, the second fork, if struck moderately hard, can be heard for ninety, twenty-four, and forty-two seconds respectively. It must be remembered that the greater the pressure with which the tuning-fork is held against the skull, the sooner the instrument comes to rest and the sound ceases. When using a large tuning-fork, the pressure can easily be regulated by holding the handle perpendicular to the surface of the skull, and letting its own weight keep the fork in its place.

Dr. Hartmann,† of Berlin, recommends that five tuning-forks should be employed for testing the hearing, viz., c , 128; c^1 , 256; c^2 , 512; c^3 , 1024; and c^4 , 2048. The low-pitched are made to vibrate by squeezing them with the fingers, and suddenly letting them go; the high-pitched, by striking them sharply and forcibly on a block of wood. Dr. Hartmann's experiments show that the mechanical arrangements suggested by Blake, Lucae, and Eitelberg are unnecessary, and that for all practical purposes equal durations of sound can be obtained by striking the fork in the

* "On the Diagnostic Value of Rinne's Experiment," *Archives of Otology*, vol. xvi. p. 188.

† *Archives of Otology*, vol. xvi. p. 236.

ordinary manner. A similar conclusion has been arrived at by Dr. Emerson.*

Before considering the inferences to be drawn from variations in the perception of high and low notes, it is necessary to allude to certain other advantages and drawbacks connected with Rinne's test. It must be borne in mind that as a general rule the test is applicable only in bilateral affections, which, however, are much more common than disease involving one side only. In the latter, the impossibility of excluding perception by the healthy ear lessens the accuracy of all tests by means of the tuning-fork. It is extremely improbable that bone-conduction should ever be increased by pathological processes involving the labyrinth or the trunk of the auditory nerve; and when Rinne's test yields decidedly negative results, the conclusion is justifiable that disorder exists in the sound-conducting apparatus, favouring bone-conduction in consequence of increased resonance or of obstruction to the escape of the sonorous vibrations. The frequency with which disorder of the nervous apparatus is combined with affections of the middle ear accounts for the anomalous results of Rinne's test. In some cases of nervous deafness the anticipated preponderance of aerial conduction may fail to appear, by reason of the co-existence of an affection of the sound-conducting apparatus. A plug of cerumen, for example, may cause a decided preponderance of bone-conduction in a case of labyrinthine disorder. On the other hand, as pointed out by Dr. Brunner,† in an affection of the sound-conducting apparatus (*e.g.*, middle-ear catarrh), the expected preponderance of bone-conduction over air-conduction can be weakened or even reduced to a minimum by a simultaneous affection of the labyrinth, or more generally speaking, of the sound-perceiving apparatus.

In mixed cases there are therefore two causes which modify the results of Rinne's test. The first (an affection of the external or middle ear) more or less intensifies bone-conduction; the second (the lesion of the nervous apparatus) diminishes conduction through the bones as compared with that through the air. In cases of this character, the difficulty is to determine to what extent each of the two divisions of the organ of hearing is affected by disease.

* *Archives of Otology*, vol. xii. p. 64.

† *Ibid.*, vol. xiii. p. 264.

Dr. Brunner lays stress upon the fact that any given spot upon the skull may differ exceedingly in its conducting powers from all other points on the same side of the head; and he recommends the mastoid process as the spot most suitable for the application of the tuning-fork, which should always be pressed firmly against the bone. Low-pitched forks are heard better and with more facility by bone-conduction than forks yielding a note of high pitch.* This difference, according to the same authority, depends less upon the greater mass of the low-pitched forks than upon the number of vibrations, and is probably due to the fact that the slower vibrations of these forks possess a greater potential agency, and are therefore more capable of exciting vibrations in the bones and labyrinth.

Testing with high and low notes is another means of aiding the diagnosis, and for this purpose Galton's whistle and König's rods are convenient instruments. When, in any given case of impaired hearing, the perception of low notes is but slightly affected, whereas that of high notes is much diminished, and Rinne's test yields a positive result, disease of the nervous apparatus of the ear may generally be inferred to exist. Galton's whistle (*see* page 87) can be made to produce notes of varying pitch by advancing or withdrawing a plug in its base. The more nearly the plug is screwed home the less is the depth of the whistle, and the higher its note.

In most diseases of the external and middle ear high notes are perceived more readily than low ones. By way of explaining the opposite condition which generally obtains in labyrinthine disease, Brunner supposes that the perception of high notes makes greater demands upon the sensibility of one portion of the nervous apparatus, and consequently that the function of this portion is much more easily and rapidly interrupted by increased waste and pathological processes than happens elsewhere. It is a matter of common experience that in advanced age perception of the highest notes is considerably diminished and that bone-conduction is also decreased. These alterations are due to senile torpor of the nervous apparatus of the labyrinth. Mr. Galton refers to a proverb in Dorsetshire, that no agricultural labourer who is more than forty years old can hear a bat squeak.

* On this subject see also Dr. Emerson's paper in the *Archives of Otolaryngology*, vol. xii. p. 63.

Diminished perception of high notes is not, however, always met with in cases of labyrinthine disorder. On the contrary, in some instances, low notes are less distinctly heard than high ones; and in very rare cases the perception for both classes of notes is uniformly diminished. The loss of a series of notes (partial tone-defects) points, almost certainly, to some affection of the labyrinth.

König's rods are employed for the same purposes as Galton's whistle, viz., to ascertain the perceptive power for high notes. The rods are suspended by loops of silk or fine wire, and in order to obtain a definite intensity of sound, a small steel pendulum, swinging through an arc of 90° , hangs from the same beam as the steel rod. A graduated scale, over which the pendulum swings, is also attached to the beam, and by its means the force with which the rod is struck can always be estimated and repeated as often as necessary. These additions were suggested by Dr. Blake, of Boston, U.S., who has found that the perceptive faculty for high notes varies with the age. At twelve or thirteen a note of 40,960 vibrations per second was heard at a distance of thirty-four feet. At from twenty-eight to thirty years, only notes of 32,768 vibrations were audible, and above the age of fifty the limit of perception had still further diminished. For testing the condition of the labyrinth a series of rods are required, yielding 20,000 vibrations and upwards per second.

(3) In cases of suspected disease of the labyrinth, the condition of the membrana tympani and of the Eustachian tube must of course be carefully noted. If these structures are apparently normal, if the disorder of hearing is of recent date, and has come on suddenly, the case is probably one of disease of the labyrinth. The other tests, already mentioned, must be used to confirm the diagnosis. If some months or years have elapsed since the appearance of the symptoms, a normal condition of the membrane and Eustachian tube will not necessarily suggest disease of the labyrinth, as it is quite compatible with the existence of ankylosis of the stapes to the fenestra ovalis. When changes are discovered in the tympanic membrane, the attempt must be made to determine whether they are sufficient to account for the symptoms, or whether some disease of the labyrinth likewise co-exists. A consideration of the history and symptoms of the case, and the employment of Rinne's test, will

assist in establishing the diagnosis. It is evident that the nature of the disease must be determined not by the presence of any one symptom or the use of any single test, but only after a careful examination by all the methods at our disposal, and due attention to the history and special features of the case.

CHAPTER XL.

DISORDERS OF CIRCULATION IN THE LABYRINTH.

ANÆMIA—HYPERÆMIA—INFLAMMATION OF THE
LABYRINTH.

Anæmia of the Labyrinth, Causes and Symptoms—Hyperæmia of the Labyrinth, Causes and Symptoms—Diagnosis—Treatment of Disorders of Circulation—Inflammation of the Labyrinth—Pathology—Question as to Primary Origin—Causes—Gruber's Classification—Exudative and Plastic Forms—Cases due to Diphtheria—Appearances in Cases of Cerebro-Spinal Fever—Symptoms—Prognosis—Treatment.

DISORDERS of circulation in the labyrinth often accompany the various forms of middle-ear inflammation, and are discoverable in fatal cases on examination after death. More or less extensive hyperæmia and hæmorrhage are the appearances most often noticed; but their connection with the symptoms has not been clearly determined. There is, however, reason to believe that these changes in the labyrinth set up irritation of the sound-perceiving apparatus, and cause tinnitus, impairment of hearing, giddiness, nausea, vomiting, etc. As a matter of fact, however, the cranial contents are often simultaneously involved in the circulatory disorder, and the symptoms thus produced may mask or modify those due to the condition of the internal ear.

A general condition of **Anæmia** does not necessarily produce any special symptoms referable to the labyrinth, unless hæmorrhage occur into the part itself. In that case sudden deafness is likely to be developed. More or less impairment of hearing-power is not infrequent in cases of general debility, exhausting diseases, hæmorrhages, repeated pregnancies, and prolonged

lactation; and these conditions tend to aggravate any existing disorder of the middle ear, and increase the liability of the labyrinth to become affected.

Murmurs produced in the cervical vessels are often distinctly perceived by the patient, and seem to originate within the ears, especially when the resonance is abnormally increased, as occurs in middle-ear inflammation, and as a result of accumulation of cerumen. Symptoms in the labyrinth, due to functional disorders—*e.g.*, anæmia—are less troublesome when the patient assumes the horizontal position.

Disorder of hearing, as a result of anæmia of the labyrinth and brain, often precedes faintness and syncope; all sounds appear less intense, and tinnitus of various kinds is associated with giddiness and dimness of vision.

A condition of anæmia, limited to the labyrinth, may be due to narrowing or closure of the internal auditory or basilar artery. Sudden deafness has been produced by embolism of the latter vessel.

Hyperæmia of the structures of the labyrinth is a usual accompaniment of inflammation of the middle ear, and in neighbouring tissues, but it also occurs in the absence of any inflammatory processes. Thus tumours, *e.g.*, scrofulous glands in the neck, by compressing the veins, may produce marked congestion in the aural structures. A similar result is sometimes due to irritation of the sympathetic and fifth pair of nerves, and to affections of the spinal cord. In Bernard's well-known experiment, hyperæmia and increased temperature in the ear are immediately produced by section of the cervical sympathetic. Congestion of the head from any cause is liable to be attended by hyperæmia of the labyrinth; and in most febrile affections, but especially in scarlatina and typhus, there is often more or less congestion of the internal ear. Alcohol in full doses, quinine, salicylate of sodium, and amyl nitrite are capable of producing the same condition. Thrombosis of the superior or inferior petrosal sinuses, or of the internal jugular vein, must obstruct the escape of blood from the internal ear and give rise to congestion. A similar condition is often developed as a result of violent exercise, and in performers on wind-instruments.

The **Symptoms** of hyperæmia of the labyrinth are much the same as those of anæmia; they consist of more or less deafness,

subjective auditory sensations, often of a pulsating character, giddiness, nausea, and perhaps vomiting. The symptoms are aggravated by alcohol and by the horizontal position. Hyperæsthesia of the auditory nerve may be due to congestion of the labyrinth.

The **Diagnosis** is aided by observation of the general condition of the patient and by examining the ear. Hyperæmia of the labyrinth may be assumed to exist when bone-conduction is diminished or altogether lost, and when the osseous portion of the meatus and the membrane are somewhat hyperæmic, but no change can be discovered in the middle ear. In cases in which the latter part is already the seat of disease, congestion of the labyrinth will be followed by increase of deafness and of subjective sensations and by impairment of bone-conduction. These symptoms will not be relieved but probably aggravated by the air-douche. It must be remembered that the two conditions, anæmia and congestion, are for the most part symptomatic either of some general affection or of some disease of the ear.

The **Prognosis** will depend upon the nature of the associated disorder. As a general rule, more or less relief can be afforded in all cases of disordered circulation in the labyrinth.

The **Treatment** must be adapted to the co-existing conditions. When the anæmia is part of a general disorder, the various preparations of iron, stimulants, rest, good food, and fresh air are likely to prove serviceable. When, however, there are evidences of congestion of the head, and the vessels of the tympanum are enlarged and prominent, it will be desirable to apply a few leeches over one or both mastoid processes. If the cerebral congestion be very marked, it will be better to take a few ounces of blood by cupping at the back of the neck. At the same time, the bowels should be freely relieved by calomel or saline purgatives. In chronic cases, warm foot-baths, with a little mustard, every night, will be of service, and the cerebral symptoms will be further relieved by blisters behind the ears and to the back of the neck. The application of tincture of iodine to the mastoid process is sometimes useful. Massage to the neck is also recommended. The diet and mode of living in other respects must, of course, be carefully regulated. The patient should avoid everything likely to cause determination of blood to the head—*e.g.*, excessive mental work; and if compelled to

continue in any such occupation, should, as far as possible, refrain from stooping over it. Bathing the head in cold water is generally unadvisable; it is liable to aggravate the subjective symptoms.

As a matter of course, any existing affection of the ear will require careful attention. In many cases the subjective sensations are relieved, though only for a time, by rarefying the air in the external meatus. The application to the ear of rectified spirit of wine with a little ether has sometimes a good effect, and in cases in which the subjective symptoms are very troublesome, the bromides may be prescribed with advantage.

INFLAMMATION OF THE LABYRINTH—OTITIS INTERNA.

Inflammatory processes are apt to extend to the labyrinth from neighbouring parts; and the complication is most often observed in cases of caries and necrosis of the temporal bone. It is comparatively rare for inflammation to extend from the tympanum or mastoid cells to the internal ear, and cases of this kind are probably due to the influence of micro-organisms. Drs. McBride and Bruce* have recorded a remarkable instance of this character; the morbid process had extended not only to the labyrinth, but to the cerebellum. The patient had suffered from chronic middle-ear suppuration on the right side, with destruction of the membrana tympani and ossicles. Three days before death the tuning-fork was heard best by the diseased ear, hence the nerve and labyrinth were then normal. Sections of the semi-circular canals showed copious infiltration with rod-shaped bacteria, masses of which were found between the osseous lamellæ, in the coats of the arteries, and in the diploetic spaces. The veins for the most part contained plugs, made up of enormous numbers of bacteria. Similar organisms were found in the sheath of the facial nerve and in the connective tissue between the fibrillæ. An abscess as large as a walnut, and containing bacteria, was found in the cerebellum on the same side.

In very rare cases the inflammation in the labyrinth is secondary to some morbid process within the cranium. In cases of cerebro-spinal meningitis, purulent matter has been known to

* "The Pathology of a Case of Fatal Ear-disease," *Journal of Anat. and Physiol.*, vol. xiv.

find its way along the auditory nerve to the internal ear. On the other hand, in cases of injury of the osseous capsule, sero-purulent or hæmorrhagic exudation into the labyrinth may lead to purulent meningitis.

The occurrence of primary inflammation of the labyrinth must now be regarded as proved; though some of the cases recorded under that heading are really instances of secondary mischief. Primary inflammation of the internal ear is especially apt to occur in children, but adults are not exempt from it. A case is recorded by Schwartz* of acute purulent inflammation of the labyrinth, leading to suppurative meningitis, and occurring in a woman, thirty-two years of age, and who had been syphilitic for eight months. There had been constant pain in the head, giddiness, and uncertain gait, for some weeks before death; and these symptoms were followed by fever, vomiting, delirium, and coma. On post-mortem examination pus was found at the base of the brain, and along the course of the vessels in the fissure of Sylvius. The auditory nerve, temporal bone, and tympanum were normal. The cochlea, vestibule, and semi-circular canals were filled with a sero-purulent fluid; the blood-vessels of the ampullæ were congested and tortuous, and the saccules of the vestibule were reddened and infiltrated with pus.

Moos† has described a case in which inflammation of the labyrinth on both sides was found in a child that had died from scarlatina and diphtheria. The saccules, the semi-circular canals, and the membranous *lamina spiralis* were infiltrated with a purulent small-celled exudation. It would, moreover, appear that labyrinthine inflammation may consist of a periostitis. Thus, in the case of a boy, aged fourteen, who had suffered from otorrhœa and convulsions for two and a-half years, Politzer‡ found the cochlear spaces to be completely choked up by new-formed osseous material. The vestibule was so narrowed by the hyperplastic process as to form only a small cleft, and the semi-circular canals had altogether disappeared. In this case, purulent inflammation had been the first stage, and this had excited connective tissue proliferation from the lining membrane, and ossifying periostitis. Cases of partial and total ossification of the labyrinth as a result

* *Archiv für Ohrenheilkunde*, Bd. xiii.

† *Archiv für Augen- und Ohrenheilkunde*, Bd. v.

‡ *Lehrbuch der Ohrenheilkunde*, S. 496.

of inflammation have also been described by Kundrat, Burckhardt-Merian, and others.

Causes.—Nothing definite can be stated with regard to the causes of primary inflammation of the labyrinth. It has been attributed, in different cases, to exposure to cold, to metastasis, and to injuries. The pathological appearances show that various forms of inflammation are liable to occur in the internal ear, and Gruber thinks that at least two kinds may be distinguished, which he terms “exudative” and “plastic.” In the former, the exudation may be serous, sero-hæmorrhagic, or purulent; the latter is characterised by hyperplasia of tissue. He thinks that serous exudation occurs in those cases where, without obvious cause except exposure to cold, an ear previously normal becomes deaf in various degrees, and is the seat of more or less marked subjective sensations. Nothing morbid can be detected in the remaining parts of the ear; there are no reasons for suspecting the existence of any central lesion, and all the symptoms disappear in the course of time. It is possible that the exudation may have taken place only in the canal of the osseous spiral lamina. The bundles of nerve-fibres are compressed, and their functions rapidly abolished; but with the absorption of the exudation all the symptoms pass away. In such cases, it is more probable that the labyrinth is affected than that the trunk of the nerve is compressed, for in the latter case the lesion would certainly be associated with symptoms referable to other nerves.

If copious exudation be rapidly poured out, as would occur with rupture of vessels, the resulting disorder would be very severe and probably irreparable. In this category may be placed, according to Gruber, certain cases of loss of hearing occurring in syphilitic subjects. With or even without previous catarrh of the middle ear, and perhaps after exposure to cold, an acute affection of the labyrinth comes on, the permanent result of which is total loss of hearing.

Purulent inflammation may occur in the labyrinth as the result of injury and of the invasion of bacteria of various forms. Lesions of the internal ear, of this type, occur in the course of small-pox, scarlet fever, diphtheria, typhus, and measles. In all these disorders, the morbid process probably extends from the throat to the middle ear and thence to the labyrinth; and it is in this last portion that the most decided effects may be produced.

Moos* has recorded an account of three cases of fatal diphtheria, in which the labyrinth was involved, while the tympanum was affected only by catarrhal inflammation. The membranous semi-circular canals, in many spots, were partially or entirely blocked-up with masses of cells and coagulated lymph. The development of connective tissue, bone and vessels had already taken place in some of these deposits. In the osseous walls of the labyrinth there were evidences of inflammation, of hyperplasia, and of disintegration. The medullary spaces of the petrous portion and the aquæductus vestibuli were filled with chains of micrococci, which were also found in the endo- and peri-lymphatic spaces of the semi-circular canals, but not in the cochlea or vestibule. These micro-organisms were thought to be accidental in diphtheria, but to be capable of producing severe disease of the labyrinth. They may reach the internal ear through the vessels, but they may also find their way thither from the sub-dural spaces, which, according to Schwalbe, are connected with the deep cervical glands, the sub-dural spaces of the nerve-roots, especially of the auditory nerve, and the lymphatics of the nasal mucous membrane.

The labyrinth is not infrequently affected in severe typhoid. In six cases, examined by Moos, there were evidences of inflammation and hyperplasia in the utricle, sacculus, ampullæ, and membranous *lamina spiralis*, and the semi-circular canals were implicated to a less extent. The infiltration consisted of lymphoid and smaller cells.

The appearances found in disease of the labyrinth connected with cerebro-spinal fever more or less resemble those already described. They consist in destruction of the soft parts and new formation of connective tissue and bone. Many pus-cells pass between the nerve-fibrils; a large number of epithelial cells are detached and become indurated; patches of extravasated blood are frequently noticed, and there is more or less degeneration of nerve fibres. Pus cells and extravasated blood are sometimes found in the facial canal and in the aquæductus cochleæ; the structures of the ductus cochlearis may be entirely destroyed, and the cochlea itself filled up with pus, masses of epithelium and detritus, and particles of necrosed bone. In extreme cases, the semi-circular canals, the ampullæ and the vestibule may all

* *Archives of Otology*, vol. xvii. p. 1.

be destroyed, and the process not infrequently extends to the middle ear. It has been shown that the lymph-passages of the nose may act as channels for the micro-organisms, which may pass thence into the sub-arachnoideal spaces of the brain, and then into the perilymph. The existence of these means of communication serves to account for the early development of the processes in the ear and their bilateral character.

Symptoms.—The evidences of primary inflammation of the labyrinth are by no means clearly defined. In Voltolini's cases, the disease was ushered in by a short stage of cerebral congestion and vomiting. This was followed by elevation of temperature, delirium, and convulsions, which subsided in the course of several days, when absolute deafness and a staggering gait were clearly noticeable. Anatomical investigations were wanting, and in all probability the symptoms were due to meningitis of a rapid type.

Secondary inflammation of the labyrinth is doubtless much more common, though the symptoms are by no means distinct. The diagnosis is mainly effected by testing the hearing-power. If bone-conduction be altogether lost on the affected side, and Rinne's test yield positive results as far as can be made out; if in Weber's experiment the tuning-fork is heard exclusively or much more distinctly on the better side; if high notes are either badly heard or not perceived at all, the evidence in favour of labyrinthine complications is exceedingly strong. The tests must be applied very carefully and on several occasions, and it must be remembered that impairment of hearing for high notes is not a constant symptom, even when the labyrinth is decidedly involved.

The subjective symptoms are not pathognomonic; the patients usually complain of very severe tinnitus, impairment of hearing or complete deafness coming on suddenly, pain in the head, pressure or fulness in the ear, vomiting, giddiness, and loss of balancing power.

In cerebro-spinal meningitis the aural symptoms may appear at the commencement or not until the termination of the disease; the patient, on recovering consciousness, is found to be deaf, probably on both sides, and to stagger when attempting to walk. Labyrinthine disease, occurring in the course of scarlatina and diphtheria, is generally preceded by suppurative inflammation of

the middle ear. The symptoms of labyrinthine complications connected with influenza, mumps, and other kindred diseases have been described in a previous chapter (*see page 538, et seq.*).

Prognosis.—This is for the most part unfavourable, but there is some hope for those cases which occur without fever and are unilateral. Improvement can sometimes be effected in recent cases of syphilitic internal otitis, to be subsequently described. In most patients, however, the impairment of function either remains without change, or gradually proceeds until the stage of total deafness is reached. The subjective sensations are often very obstinate and troublesome, but the evidences of disorder of equilibrium may pass off after a time, perhaps not until the patient has become quite deaf. If children become affected before they have learned to speak, or shortly afterwards, deaf-mutism is the ordinary result, unless great care be taken.

Treatment.—In all cases in which there is reason to suspect that the labyrinth is the seat of inflammation, the treatment must be regulated according to the general condition of the patient, and the co-existing circumstances. Any existing disease in the middle ear or nares must be carefully attended to. When there is high fever and the patient is fairly robust, a few leeches may be applied behind the mastoid process on each side, and the bowels should be freely opened by a dose of calomel followed by saline purgatives. Antipyrin, in doses of gr. v.—xv. hourly, for four or six hours, is recommended to reduce the temperature. Cold may also be applied to the head by means of ice-bags. If copious exudation have already taken place, as shown by total deafness, there is not much chance of recovery under any treatment; but it is worth while to try the effects of iodide of potassium internally, and of mercurial ointment applied behind the ear. In later stages blisters to the mastoid process may possibly do a little good. When there is a history of syphilis, a prolonged course of mercury is likely to prove beneficial; and in addition, Politzer recommends the daily subcutaneous injection of two to six drops of a 2 per cent. solution of pilocarpin, and that the dose should be gradually increased. If the remedy cause nausea, giddiness, prostration, and other unpleasant symptoms, it should be replaced by two drops of a solution of atropin (gr. one-third per cent.). In recent syphilitic affections of the labyrinth, and also in some non-syphilitic cases, a remark-

ably good result is sometimes produced by these remedies. They are, however, useless in hereditary syphilis, in deafness due to epidemic cerebro-spinal meningitis, and in cases complicated by middle-ear catarrh. When the complaint occurs in young children and deafness ensues, the greatest care is necessary to prevent them from losing the faculty of speech. They should be trained to talk as much as possible, and forbidden to make use of signs to express their wants. This subject will be again referred to in the chapter on Deaf-mutism.

CHAPTER XLI.

CONCUSSION OF THE LABYRINTH—INJURIES TO THE LABYRINTH.

Causes of Concussion—Symptoms—Diagnosis—Prognosis—Treatment—
Injuries to the Labyrinth—Modes of Production—Variations in
Results and Appearances—Symptoms—Diagnosis, Prognosis, and
Treatment.

THE labyrinth is liable to be affected, in common with other nervous structures, in cases of concussion of the brain from any cause; but it sometimes happens that the effects of an injury are exhibited principally or almost exclusively by the structures of the internal ear. Thus gunpowder-explosions may do little or no injury to the body in general, while their results are evidenced by the symptoms of auditory disturbance. When due to this cause the concussion may act upon both ears; but, as a general rule, the effects are confined to the ear which is turned towards the source of the explosion. Similar results may be produced by blows or kicks on the head, and even in these cases the symptoms of labyrinthine disorder are not necessarily accompanied by any external injury. Nothing can be definitely stated as to the changes which take place in the implicated nerves or nerve-centres: even in fatal cases there may be an absence of marked structural changes in the various parts of the internal ear.

The **Subjective Symptoms** vary both in kind and degree. When the patient is knocked down by the blow or the force of the explosion, he may be rendered unconscious, and remain in that condition for an indefinite period. In slighter cases, after the shock has passed off, there may be pain in the ear and giddiness, lasting for some hours or even for some days. Subjective auditory

sensations, such as noises in the ears of various kinds, are sometimes complained of, and more or less impairment of hearing is an almost constant symptom. Hearing-power for high notes is apt to be especially affected. In other cases there is abnormal acuteness of hearing for certain notes, or the latter may appear to be higher or lower than usual. Sometimes other notes are heard, mingled with the normal sound. Diminished cutaneous sensibility of the auricle and meatus, even amounting to complete *anæsthesia*, is sometimes noticed. These symptoms may remain for long periods, disappearing from time to time, and then recurring, or they may soon altogether cease.

Objective Symptoms may be altogether absent: when present, they will consist of marks of injury to the head, and especially to the parts about the ear.

The **Diagnosis** will often present considerable difficulties; in many cases, the patient's own statements will be all that the surgeon has to depend upon, and wilful misrepresentation is not uncommon. Impairment of hearing may be magnified into complete deafness. It is necessary to apply all possible tests for discovering the state of the auditory organs, and also to ascertain their condition previous to the accident. However, after every precaution is taken, the diagnosis in some cases will be one of probability only.

The ear must be tested with the watch and with tuning-forks of various pitch. As a general rule, impairment of bone-conduction is an unmistakable symptom of labyrinthine disorder; but it must be remembered that accidental affections of the bones may impair their conducting power, and a mistake may thus arise. A plug of wax in the meatus may prevent a watch from being heard even when in contact with the auricle; but when the wax is removed the sound is distinctly perceived. When bone-conduction is unimpaired there is every probability that the labyrinthine structures are in a normal condition. Weber's experiment yields good results as a test in these cases. When the effects are positive—*i.e.*, when the tuning-fork is best heard on the side on which the meatus is closed—there can be no serious affection of the labyrinth. When, however, the results are negative—that is to say, when the change is either not observed, or is of an opposite character—there is strong evidence of the existence of some lesion of the internal ear. Rinne's experiment

is of little use as a test in the class of cases now under consideration. In complete deafness it cannot, of course, be employed; but in less severe cases it may be used to test the accuracy of the patient's statements.

Gruber lays great stress on the value, in all doubtful cases, of his method of testing the ear. It consists in holding a vibrating tuning-fork in front of the ear, until the sound is no longer heard. A finger is then inserted into the meatus, and the handle of the tuning-fork is placed in contact with it, when the sound is again perceived. The change is due to the fact that the closure of the meatus produces a resonant column of air, which strengthens the sound. It is likewise probable that altered conditions of pressure and tension in the middle and internal ear play a certain part in causing the alteration, and also that sonorous vibrations, previously dispersed in the atmosphere, are conveyed through the finger to the bones, and thence to the sentient parts of the internal ear.

The symptoms of concussion of the labyrinth resemble those of injury, but they generally come on suddenly and pass off after a time. When hæmorrhage takes place into the structures of the labyrinth, the impairment of hearing is developed, either slowly or rapidly, according to the extent of the lesion and the quantity of blood effused; other symptoms, as described by Ménière, are prone to supervene.

Prognosis.—This depends, first, upon the degree of the concussion; and secondly, upon the absence or the co-existence of injury to the ear and adjacent parts. If total deafness has resulted from the shock the prognosis is unfavourable, though recovery is not impossible. In some cases many months elapse before any improvement is noticed, and in others an opposite course is witnessed. Politzer* records an interesting case in which the hearing (which had been totally lost for many months as the result of concussion) was suddenly restored. The patient, a man aged twenty-one, had received a severe blow on the head when passing under a doorway. When he recovered from the shock he complained of headache, noises in the ears, and deafness, which latter became complete in the course of a month. No change took place during the ensuing ten months, and he then came under treatment. Improvement was regarded as impossible;

* *Lehrbuch der Ohrenheilkunde*, S. 526.

but the experiment was made of injecting a warm solution of iodide of potassium ($2\frac{1}{2}$ per cent.) into the meatus. On the third day the patient could understand a few words spoken into his right ear; and a gradual though slight improvement took place during the next three weeks, when headache became troublesome. One night, shortly afterwards, the patient was roused from sleep with a sensation of giddiness, and he then found that he could hear the ticks of his watch. When examined by Politzer on the following day, his hearing, tested by the watch and by conversation, was found to be normal. Whether the symptoms were due to concussion of the labyrinth or of the nerve-centres must be regarded as doubtful; but the latter hypothesis would seem the more likely.

The above-mentioned case must be regarded as very exceptional, and, as a general rule, the longer the symptoms last the worse the prognosis. The prospect is, moreover, unfavourable whenever subjective sensations and giddiness are prominent symptoms, and especially when they are accompanied by abnormal acuteness of hearing. It is impossible to forecast the duration of the symptoms, for even in cases of slight concussion they may remain unaltered for many months.

Treatment.—Rest, bodily and mental, is the most important agent in the treatment of concussion of the internal ear. In strong full-blooded subjects, with signs of cerebral congestion, leeches may be applied to the mastoid process, or a blister to the nape of the neck. The bowels should be kept freely open, and the diet should be of a suitable character. When the symptoms have become chronic, tincture of iodine may be painted over the mastoid process, or blisters may be applied. A warm solution of iodide of potassium dropped into the meatus, as used by Politzer, is worthy of trial. When noises in the ears are very troublesome a course of the bromides is likely to prove beneficial.

INJURIES TO THE LABYRINTH.

Owing to its protected and deep-seated position the labyrinth alone is seldom, if ever, the seat of injury; but it may, of course, be implicated in wounds of adjacent parts. Thus the internal ear may be affected in fractures of the temporal bone, the result of blows or falls; it may also be wounded by foreign bodies,

instruments, etc., introduced into the external meatus. Severe concussions may likewise cause rupture of the membranous structures, or even fracture of the osseous walls of the labyrinth.

The structures of the internal ear are liable to be involved in ulcerative processes, affecting its osseous walls, the fenestræ, or the semi-circular canals. Suppuration sometimes extends from other parts along the connective tissue and vessels of the labyrinth; and purulent inflammation of the middle ear has been known to extend to the same part through the fenestræ.

Gruber relates the case of a man who had been working for several hours in a caisson, and on coming into the open air became giddy and vomited. These symptoms soon passed off, but the man was noticed to be deaf on both sides. On examining the ears there was found to be rupture of both tympanic membranes, and the symptoms pointed to injury and extravasation of blood into the internal ear on both sides. The membranes cicatrised, but the deafness still remained two years after the accident. It is worthy of note that in cases of injury from falls or blows the membrana tympani may be unaffected, even though the petrous portion of the temporal bone be seriously fractured. The escape of cerebro-spinal fluid from the meatus is generally regarded as a symptom of fracture of the base of the skull; but this symptom is not always present, for the membrane, as just mentioned, may be intact and prevent the flow. On the other hand, in some cases the extravasated blood rapidly coagulates between the surfaces of the fracture; in others, the portions of bone remain in close apposition, and, under such circumstances, the fluid will be prevented from escaping into the meatus, even if there be a large rent in the membrane (*see page 563 et seq.*).

When blood is extravasated among the tissues of the internal ear, and the patient survives, it undergoes the same changes as in other parts of the body. The fluid portion is absorbed, and in the course of time deposits of pigment are all that remain. The extravasated matters may, however, be the cause of inflammation, with more or less destruction, of the internal ear.

Extravasation of blood into the labyrinth may occur in the absence of any external injury to the part. The labyrinth may be affected in cases of meningitis, and especially in hæmorrhagic pachymeningitis. In cases of this latter character Moos found hæmorrhagic infiltrations in various parts of the labyrinth, viz.,

in the utricle, in Rosenthal's canal, and between the layers of the *lamina spiralis ossea* and the *zona dentata*. The infiltrations varied in size; and some followed the course of the veins, and others that of the nerve-fibres. In the case of a boy, aged four, who became totally deaf in the course of tuberculous basilar meningitis, Lucae found evidences of hæmorrhagic inflammation in the semi-circular canals and vestibule on both sides.

Symptoms.—The symptoms of injuries of the labyrinth are for the most part the same as those of concussion. The loss of hearing may, however, come on later, as it results from hæmorrhage, rather than from shock. High notes especially fail to be heard, and sometimes a series of notes are inaudible. Some of the symptoms known as Ménière's are also likely to occur: these will be described in a succeeding chapter. Any objective symptoms that may be present will depend upon the nature of the injury, and if no external parts be involved such symptoms may be altogether wanting.

The **Diagnosis** of injuries of the labyrinth is made by considering the symptoms and the nature of the injury. If there be pronounced deafness on the affected side, and the tuning-fork, applied to the skull, be not heard, it may be regarded as certain that the labyrinth is involved. Sometimes the diagnosis can be made only *per viam exclusionis*.

The **Prognosis** likewise depends upon the symptoms, the nature of the injury, and the existence of complications. In total deafness, due to injury of the labyrinth, the chance of restoration is very slight indeed.

The **Treatment** is much the same as that recommended for concussion of the internal ear, complete rest being the all-important detail. Such local measures as syringing the meatus and the use of the air-douche are to be avoided; they are almost certain to aggravate the symptoms. If there be much local pain a few leeches should be applied to the mastoid process; while troublesome subjective symptoms may be relieved by the bromides. When all active symptoms have subsided, and the deafness alone remains, the iodide of potassium may be given with the view of promoting absorption, and for the same purpose counter-irritation may be applied behind the ear.

CHAPTER XLII.

CARIES AND NECROSIS OF THE LABYRINTH.

Caries of the Labyrinth as a Result of Extension—Necrosis of the Labyrinth—Causes—Symptoms, as Otorrhœa, Pain, Polypous Growths, Disorders of Equilibrium, Subjective Sensations, Loss of Hearing-Power, and Facial Paralysis—Forms of Sequestra—Prognosis—Treatment.

Caries of the Labyrinth is always associated with a similar affection of the adjacent parts of the internal ear; no case in which the labyrinth alone was thus diseased has yet been recorded. Minute apertures are sometimes found in the osseous semi-circular canals, but these, in the absence of symptoms of inflammation, are to be regarded as dehiscences, and not as the result of caries.

Necrosis of the Labyrinth, as an independent affection, is not very rare. It generally results from purulent inflammation of the middle ear, the process extending from the tympanum and mastoid cells to the air-spaces in the osseous walls of the labyrinth. The inflammatory process in the middle and internal ear is not only prejudicial to the organ itself and the adjacent structures (particularly to the facial nerve in the temporal bone), but the attendant suppuration, which may continue for weeks or months, is a source of considerable danger. Toynbee drew attention to the relatively somewhat common occurrence of partial or total necrosis of the labyrinth, and Bezold,* of Munich, has collected some forty-five instances of exfoliation of this part in the living subject.

* *Archives of Otology*, vol. xvi. p. 297. See also Report of Case of Necrosis of the Cochlea, by Dr. Hartmann, in the same vol. p. 252.

Causes.—In nearly half the number of cases referred to, the patients were under fifteen years of age when the sequestrum was removed from the ear; the age at which the inflammatory process commenced could seldom be ascertained. The first decade of life furnishes the largest proportion of patients. This proclivity is, no doubt, due to the frequent occurrence of catarrhal and suppurative processes of the middle ear at that period of life, and particularly of the more severe forms resulting from the acute exanthemata. In children, also, the labyrinth is proportionately much larger than in the adult; for at birth this part has already attained nearly its normal development. In many of the cases the commencement of suppuration dated from an attack of scarlatina; while measles was the cause in a smaller number. The acute suppuration in the middle ear does not necessarily attack the labyrinth at the same time; it usually extends to it after an uncertain interval. In thirty-eight cases only two lasted less than a year before exfoliation of the sequestrum; the rest of the patients had a discharge for periods varying from one to forty years before separation took place. The necrosis of the internal ear is frequently accompanied by destructive disease of the mastoid portion, resulting in fistulous openings in its external wall. There is no reason for supposing that any peculiar diathesis is a predisposing cause of necrosis of the labyrinth.

Symptoms.—Otorrhœa is, of course, present, the discharge varying in quantity, but being profuse and continuous while the necrosis is advancing, and until the sequestrum has separated. The other symptoms are (1) more or less pain, (2) the formation of polypous growths, (3) disturbances of equilibrium, (4) subjective sensations, (5) loss of hearing-power, and (6) facial paralysis.

The *pain* involves the side of the head, and sometimes extends to the other side; mastoid tenderness is occasionally present. The pain is due at first to the inflammatory process; and in later stages to the separation and passage of the sequestrum. When this latter process is taking place, the pain is apt to be continuous and violent; and the patient wears a characteristically anxious expression. The loss of sleep induces much disturbance of nutrition, and the patient becomes pale and thin; but these symptoms rapidly subside after the sequestrum has come away. Rigors and febrile attacks are not uncommon during the course of the pro-

cess. *Polypous growths* are invariably present; they are most abundant in the tympanum, on the edges of the membrana tympani, and in the external meatus; in some cases they are found in the Eustachian tube. They may completely fill the auditory canal, and they continue to sprout so long as the sequestrum lies imbedded behind them. After the latter has separated most of them spontaneously disappear.

Disturbances of equilibrium were noticed in a few cases, but mostly in the early stages, and not continuing throughout the progress of the disorder. In twenty-three of the cases alluded to, no such symptom was experienced, and it is certain that vertigo is not regularly present as an initial symptom of necrosis of the labyrinth. Its existence indicates the extension of the suppurative process from the middle to the internal ear. Moreover, when present, it may be owing to cerebral and meningeal complications. After exfoliation of the sequestrum, any disturbance of equilibrium must be due to continued irritation of the centre.

It is somewhat curious that *subjective sounds* are seldom complained of in cases of necrosis of the labyrinth; they were present in only three cases. Their frequent absence seems to prove that the part in which they originate is more easily destroyed than the terminal distribution of the vestibular branches in the ampullæ, whose irritation would seem to cause the vertigo and disturbance of equilibrium.

The loss of hearing-power varied considerably in different cases: in twenty-three, complete deafness was observed. In four, there seemed to be more or less capacity for hearing after exfoliation of the cochlea itself; but these results are in contradiction to a proportionately large number of other cases. Hearing is completely lost when the labyrinth is destroyed. Bezold points out that one of the principal sources of error in our tests of hearing is the difficulty and partial impossibility of completely excluding the other ear from receiving any sonorous impressions. It is very difficult to occlude the meatus thoroughly, and the least chink is sufficient to allow the passage of the waves of sound. The tuning-fork is the most efficient means of testing the hearing in these cases. When a very weak sound is given off, the other ear may be left out of consideration; with deeper tuning-forks it is hardly necessary to close it.

The facial nerve is intimately connected with the labyrinth, and is generally involved when the latter is the seat of inflammatory processes. Paresis or paralysis of this nerve is a constant result of exfoliation of the cochlea; the loss of function may be due to pressure and may be only temporary; but the nerve may be partially or entirely destroyed, and in that case the paralysis is likely to be permanent. In thirty-five of the cases above alluded to the facial nerve was partially affected in six instances; in three of these the necrosis was limited to the cochlea; in one, to the cochlea and a small part of the vestibule; in a fifth, to the semi-circular canals; and in the sixth, there was extensive caries of the labyrinth with exfoliation of the lamina spiralis. In twenty-eight of the cases there was decided paralysis of the nerve. This frequent participation of the facial, which is one of the most common symptoms of necrosis of the labyrinth, is due to the intimate connection between the latter part and the aquæductus Fallopii. The course of the facial nerve may be divided into four parts, and the implication of each of these in exfoliation of the labyrinth leads to entirely different sequelæ. In the first part of its course, within the internal meatus, it is liable to be affected in cases of exfoliation of the entire labyrinth, and the result is permanent loss of function, either partial or complete, of the facial, as well as of the auditory nerve. In the second part of its course, which extends from the beginning of the aqueduct to the geniculate ganglion, the nerve is not so liable to be involved; but in the third section it is in more danger, especially if the osseous vestibular walls be necrosed. In the fourth part of its course the nerve is seldom exposed to primary destruction by necrosis of the labyrinth; but it may be affected secondarily, especially when the sequestrum escapes into the mastoid antrum. In some cases paralysis of the nerve is due to pressure of the granulations surrounding the sequestrum.

Paralysis of the facial nerve, of a temporary character, sometimes complicates middle-ear suppuration; it is said to occur in about 1 per cent. of such cases. It is seldom, if ever, noticed in simple non-purulent, acute middle-ear catarrh. Bezold lays it down as a rule that in every case of facial paralysis accompanying long-continued suppuration of the middle ear, we are justified in excluding superficial disease, and in assuming the existence of extensive destruction of the bone, in most instances of the

labyrinth. It must not be forgotten that the facial, like other nerves, possesses considerable regenerative capacity. In six of the cases alluded to there was no doubt as to the partial or total restoration of the function of the facial, in spite of its division. In one such case, the sequestrum consisted of the whole of the labyrinth; and, judging from the results of several others, we may anticipate, under very favourable circumstances, complete restoration, not only in simple division, but also where there has been a considerable loss of substance of the facial nerve.

As might be expected, the *chorda tympani* is much more often injured than the facial nerve in cases of necrosis of the labyrinth, and it is equally capable of regeneration. The large superficial petrosal nerve is very rarely implicated.

The *sequestra* vary much in size and character. Thus, there may be (1) necrosis of the entire labyrinth, and of the wall of the internal meatus; (2) necrosis and exfoliation of the cochlea, with other portions of the petrous bone; (3) the cochlea alone or only a portion of it; (4) a semi-circular canal; (5) the pars petrosa, with the external canal and a portion of the mastoid process, etc.

Prognosis.—Death occurred in 19·6 per cent. of Bezold's cases, and in the majority from implication of the neighbouring meningeal and cerebral regions, extension of the suppurative process taking place from the posterior surface of the bone corresponding to the position of the internal meatus. The cerebellum was most frequently involved. In the thirty-seven cases, the terminations were as follows: in twenty-nine the sequestrum was removed through the auditory canal; in seven, through the mastoid process, previous artificial widening of the openings being necessary in some of the cases. In one instance the sequestrum passed through the Eustachian tube. Cessation of the discharge in a few weeks or months took place in eighteen of the cured cases. Notwithstanding the dangerous proximity of the suppuration to important parts, the long duration of the process, with its dangers to the constitution, and the obstacles to the elimination of the sequestrum, the prognosis would appear to be remarkably good, so far as recovery is concerned. Moreover, even where there has been extensive loss of substance of the facial nerve, there is a probability of complete restoration of the function.

Treatment.—The most important result to be attained is the

removal of the luxuriant growths which obstruct the passage of the sequestrum through the tympanum and external meatus. These granulations must be removed by a curette or Wilde's snare, or destroyed with a concentrated solution of chromic acid, according to their size and position. When the sequestrum has come away, the application of alcohol or boric acid will serve to check secretion and to reduce the size of any remaining granulations. When the mastoid process is implicated, it is desirable to make an opening as soon as possible, so that secretion, etc., may escape. Any existing fistulous openings should be enlarged; and, if a sequestrum be found, it should then be removed. With large sequestra, it may be necessary to cut away the posterior wall of the external meatus. In the after-treatment, the wound should be frequently washed out with a solution of carbolic acid (1 per cent.), and subsequently covered with an iodoform or other antiseptic gauze. The introduction of a drainage-tube will facilitate the escape of the discharge.

CHAPTER XLIII.

NEW FORMATIONS IN THE LABYRINTH AND CONNECTED
WITH THE AUDITORY NERVE—SYPHILIS OF
THE LABYRINTH.

Primary and Secondary Growths—Epithelioma—Sarcoma and Glioma—
Cases of Fibro-Sarcoma—Cavernous Angioma—Syphilitic Disease
of the Internal Ear—Morbid Appearances—Symptoms—Diagnosis—
Prognosis—Treatment.

THE labyrinth is very rarely the seat of new formations of a primary character; it is sometimes invaded by morbid growths originating in neighbouring parts. Tumours are occasionally found connected with the trunk of the auditory nerve; Virchow states that of all the cerebral nerves the auditory is the most liable to be thus affected.

In the labyrinth new formations of connective tissue, in the form of minute threads and membrane, have been found by Gruber* and Voltolini.† Moos and others have met with bony growths in the vestibule and scala of the cochlea. Calcareous deposits have likewise been found in the periosteum of the internal meatus. These are composed of phosphate of lime, and are said to be not uncommon after middle life. Gruber describes a case in which he found chalky deposits in the cochlea and semi-circular canals.

New formations originating in other parts and involving the labyrinth are always of a malignant character, and belong either to the epitheliomatous or sarcomatous class. A case of secondary

* *Lehrbuch der Ohrenheilkunde*, S. 620.

† *Virchow's Archiv*, Bd. xviii.

epithelioma of the cochlea has been described by Politzer.* When first seen the patient, a man aged forty-seven, had an ulcerating growth the size of a nut behind the right ear, and cancerous masses projecting from the meatus. The growth behind the ear rapidly increased, the ulceration spread, and in the course of a few weeks the patient died with symptoms of cerebral compression. On post-mortem examination the apex of the cochlea was found to have been destroyed by the cancerous growth, the lamina spiralis in the second and third coils was broken through in places, and masses of cancer cells occupied the scala tympani and scala vestibuli. The elements of Corti's organ were infiltrated with many cancer cells.

In another and more numerous class of cases the growth commences in the cranial cavity, and extends thence to the auditory nerve or labyrinth. Formations of this kind are usually of a sarcomatous or fibro-sarcomatous character; a case of cavernous angioma of the petrous bone, implicating the auditory nerve, has been described by Politzer; and one of glioma, by Brückner.†

Mr. Field‡ has recorded a case of sarcoma involving the auditory nerve on the right side. The tumour sprang from the internal auditory meatus, originating apparently from the dura mater lining the canal, and ensheathing the auditory nerve. The growth was as large as a Maltese orange, and was attached to the bone just above the internal meatus; its surface was fissured and corrugated, and its structure on section not unlike cerebral tissue. Microscopical examination proved it to be a round-celled sarcoma, abounding in vessels; it appeared to have grown with a moderate degree of rapidity. The symptoms during life were pain in the head, vomiting, deafness on both sides, marked paralysis of right side of face, and impairment of power in right limbs. There was also double optic neuritis with consecutive atrophy. All the symptoms pointed to a cerebral tumour as their probable cause.

In another case, reported by Burckhardt-Merian, a fibro-sarcoma of the dura mater involved the labyrinth. It originated close to the jugular fossa, where it divided into two branches, one

* *Lehrbuch der Ohrenheilkunde*, S. 509.

† *Berlin. Klin. Woch.*, 1867, Nr. 29.

‡ *Diseases of the Ear*, p. 271.

entering the vestibule as a round cord through the enlarged aquæductus cochleæ, the other passed under the floor of the internal meatus, partly encircling the necrosed cochlea, to the tunica adventitia of the carotid artery.

Dr. Moos has recorded a case in which a round spindle-celled sarcoma was found on the outer side of the left internal meatus; the auditory nerve entered the tumour and could be followed for only a very short distance. The symptoms were headache, vertigo, deafness, anæsthesia of the left side of the face, and ptosis. A case of sarcoma of the cerebellum, involving the auditory nerve, is described in detail by Dr. Stevens.* The tumour occupied half of the right side of the cerebellum, and a portion projected into the internal meatus. The connection between the peripheral and central fibres of the nerve was lost in the tumour. The symptoms had been total deafness on the left side, dulness of hearing on the right, imbecility, unsteady gait, drawling speech, and pain in the left side of the forehead and occiput, with a comatose condition lasting for a month before death.

A remarkable case of tumour of both auditory nerves is recorded by Dr. C. H. Burnett. The patient, a woman forty-two years of age, had suffered from deafness, tinnitus aurium, unsteadiness in gait, pain in the limbs, impairment of sensation in the legs, vertigo, and nausea. Some weeks before death there was loss of power over the legs, and inability to rise from bed; both optic discs became indistinct in outline. After death a large tumour was found pressing on the left half of the pons, crus cerebri, and left hemisphere of the cerebellum. "The seventh nerve wound inward, forward, and then downward round the tumour, to which it was tightly adherent, and by which it was flattened into a ribbon-like band, appearing transparent. The tumour extended with the left nerve into the left internal auditory meatus, and after removing the brain a second tumour was found on the posterior surface of the right petrous bone. This had, as on the other side, considerably enlarged the internal auditory meatus. On a minute examination of the internal ear no trace could be found on either side of Corti's organ."

In the case of glioma, described by Brückner, the tumour had completely obliterated the auditory nerve on the left side. The

* *Zeitschrift für Ohrenheilkunde*, vol. viii.

symptoms noticed during life were uncertainty in the movements of the upper and lower limbs, deafness on the left side, giddiness, and catarrh of the middle ear. A whirring sound was sometimes audible on applying the ear to the patient's left temple.

Politzer's case of cavernous angioma of the temporal bone would appear to be unique. The patient, a girl aged twelve, had suffered for a year and a-half from otorrhœa and periodical hæmorrhages from the right ear: facial paralysis had existed for several weeks. On admission a bluish-red polypoid growth, bleeding profusely on the slightest touch, was found to occupy the inner half of the meatus; there was deafness on the affected side and increased perception of sound through the bones. Removal of the polypus with a snare was followed by very profuse bleeding, and the growth rapidly recurred in spite of repeated operations. The facial paralysis and some roughness of the bone on the posterior wall of the meatus indicated the presence of a carious process in the bone, complicated by the polypi. Two months afterwards death occurred with symptoms of suffocation. On post-mortem examination openings, partly filled up by small, ragged growths, were found in the membrana tympani and posterior wall of the meatus. At the base of the skull there was an irregular, tuberculated, ovoid tumour, as large as an orange, projecting forwards into the right middle cranial fossa, and backwards into the posterior fossa. The growth was partly osseous and partly spongy in texture. Its base was formed by the superior and posterior pyramidal surfaces and the inner surface of the mastoid portion. On a section through the petrous bone, the osseous mass of the pyramid was seen to be traversed by numerous small and large cavities, with round excrescences growing from their walls. From the upper section of the pyramid grew a radiating osseous framework, composed of lamellæ and large cavernous compartments. The polypus was also found to be a cavernous angioma, connected with the growth in the petrous bone, and containing osseous trabeculæ. The starting-point of the tumour was the lateral sinus, which communicated with the cavities of the angioma.

SYPHILITIC AFFECTIONS OF THE INTERNAL EAR.

As a result of syphilis, the internal ear is less frequently affected than the tympanum; but the lesions which sometimes

occur in it are apt to cause very grave impairment of hearing-power. There is abundant reason for believing that a form of deafness, generally complete, is sometimes connected with the acquired disease, but far more frequently with the inherited form. In both cases the symptoms probably depend upon similar changes, either in the internal ear or in the nervous apparatus.

The period at which the symptoms occur varies in different cases: sometimes they show themselves simultaneously with the eruption on the skin or in the throat; in other cases, they appear many years after the primary infection, and when other traces of the disease have apparently subsided. Sometimes they are super-added to an old-standing affection of the middle ear, of non-specific origin.

But little is known as to the nature of the changes which take place in the affected structures; but from the rapidity with which the symptoms are sometimes developed, it may be supposed that exudation of plastic material takes place in the labyrinth. In chronic cases, post-mortem examination has discovered thickening of the periosteum of the vestibule, immobility of the stapes, round-cell infiltration between the membranous and osseous labyrinth, among Corti's rods and cells, and in the ampullæ and semi-circular canals. In a case recorded by Moos and Steinbrügge,* of deafness resulting from tertiary syphilis, there was enlargement of the cells in the temporal bone, and in the capsule of the labyrinth, with hæmorrhage and development of connective tissue, infiltrated with small cells. Blood was effused between the fibres of the auditory nerve and in the cochlea. Evidences of osseous formation as the result of the chronic periostitis have also been discovered. Politzer has noticed degeneration of the ganglion cells in Rosenthal's canal (*canalis spiralis modioli*).

The **Symptoms** are more or less marked deafness, tinnitus, and pain in the ear and side of the head; giddiness and defective balancing power are present in some cases. The tinnitus is seldom absent, and is liable to come on suddenly as the first symptom. The kind of noise varies in different cases, and also at different times in the same case.

The deafness comes on with or after the tinnitus; it is generally severe from the first, and soon becomes complete. Both ears are usually affected, one perhaps more than the other; the loss is

* *Zeitschrift für Ohrenheilkunde*, Bd. xiv.

seldom unilateral. Inflation of the middle ear makes little or no difference in the hearing-power. The impairment of bone-conduction is early and marked, and the loss of power soon becomes complete; when one side only is affected, the tuning-fork is heard by the normal ear. When there is severe impairment, Rinne's test gives positive results. It would seem that in most cases of syphilitic disease of the labyrinth, the power of appreciating low notes is the last to become affected and the first to be recovered: hence the probability that the cochlea is the seat of the disease.

The objective symptoms vary, according as lesions of the membrana tympani or throat are present or absent. Politzer has noticed whitish, well-defined patches dotted over the membrane. Mucous patches or perhaps superficial ulceration in the fauces and neighbouring parts, with general congestion of the throat, involving the naso-pharynx and the mouths of the Eustachian tubes, are likely to be present if the disease occur in connection with the secondary stage of syphilis.

Pain, when present, varies as to locality, being felt in some cases in the side of the head, and in others about the eyes. Sometimes there is severe nocturnal bony pain in the scalp, and this is likely to be present when the aural complication occurs during the latter part of the secondary stage. Under such circumstances the complaint is analogous to iritis and neuro-retinitis, the result of acquired disease.

Mr. Hutchinson points out that when the ear-affection is due to an inherited taint, severe deafness is seldom noticed till the patient is eight years old. It usually occurs at a later period and is accompanied by keratitis, whereas iritis is an earlier symptom. In this class of cases total deafness is very liable to ensue, and the disease is a frequent cause of acquired deaf-mutism. The late Mr. Hinton stated that one in twenty of his patients suffered from it, and that it was by far the most common cause of non-congenital deaf-mutism. Sir William Dalby places it next to scarlet fever as a cause of that condition, and he states that the most general time at which the aural affection shows itself is from five to fifteen years of age; the earliest age at which he has seen it being five, and the latest twenty-three years. The changes found in the ears *post mortem* consist of suppuration in the tympanum; thickening of the membrane and adhesions between it and the promontory; hyperæmia and hæmorrhage in the labyrinth;

pus cells in the vestibule, and disintegration of Corti's organ. Hereditary syphilis of the labyrinth is often accompanied by middle-ear catarrh, suppurative inflammation or adhesive processes, interstitial keratitis, and the peculiarly notched teeth described by Mr. Hutchinson (*see* page 560).

Labyrinthine affections connected with acquired syphilis usually run a rapid course, the loss of hearing-power sometimes becoming complete in the course of a few days. In other cases the deafness is more gradually developed, and remains for some time stationary after reaching a certain degree, and then becomes aggravated. Slight injuries to the head have a very unfavourable influence on the course of the disease. The deafness, once fully developed, is not liable to alterations, and any improvement that may take place is usually very gradual in its progress.

The **Diagnosis** will be determined by the history of the case and the nature of any co-existing symptoms. The suddenness with which the tinnitus and deafness usually come on and the early loss of bone-conduction are important features in the complaint. The loss of hearing is likewise symmetrical, and the middle ear is often found to be healthy. If there be at the same time evidences of syphilitic infection—*e.g.*, a characteristic eruption, enlarged inguinal or cervical glands—there can be little doubt as to the nature of the aural disease. When, as sometimes happens, the deafness supervenes gradually, and many years after the primary infection, and there are no evidences of syphilis, the determination of the true nature of the case may prove very difficult. The results of treatment may, however, supply some information.

Prognosis.—This, as a general rule, is decidedly unfavourable; but it varies with the patient's condition and with the duration of the symptoms. The deafness is likely to be permanent in cases of acquired syphilis when the patient is middle aged, and has become much reduced, and likewise suffers from congestion of the throat and closure of the Eustachian tubes. In young subjects, on the other hand, of good constitutions, and coming early under treatment, the prognosis is more favourable. In the hereditary form, little, if any, benefit can be anticipated from treatment.

Treatment.—The patient, if young and in fair health, should at once be put upon a course of mercury and iodide of potassium. One grain of blue pill or of mercury with chalk may be given

twice or three times a day, the results being carefully watched. The addition of a grain of reduced iron is often beneficial (*see* page 199). Salivation must, of course, be avoided, if possible. If no improvement take place after three or four weeks, the dose of iodide of potassium should be gradually increased, until a drachm or more is taken daily. In old-standing cases, a combination of mercury with iodine will sometimes prove more efficacious than either drug alone. Improvement will be indicated by increase of hearing-power and of bone-conduction.

For recent cases Politzer recommends the subcutaneous injection of from four to twelve drops daily of a 2 per cent. solution of pilocarpin. He states that he has obtained very good results from this treatment, and advises its adoption in the cases specified. If no improvement be discoverable in from eight to fourteen days, mercury must be prescribed. He likewise recommends such local treatment as injections into the meatus of solutions of the iodide of potassium, and the application of iodoform or mercurial ointment behind the ear. Warm baths and the internal administration of iodine and sulphur waters are, he states, valuable adjuncts to other kinds of treatment.

The author is strongly of opinion that mercury should be administered in *all* cases of syphilis irrespective of the stage, and that iodide of potassium should be given *in addition* as long as the so-called secondary symptoms are present, and in the later stages of the disease.

As a subsidiary measure it is well to guard the patient's ears from the irritation produced by sounds and noises of various kinds. Relief is not infrequently obtained by a change of residence to some quiet sea-side or country place. Dr. Roosa thinks that for the effective treatment of some aural diseases it is just as necessary to protect the ears from loud or continuous sounds, as to keep the eyes from the effect of light in many diseases of these organs.

CHAPTER XLIV.

MÉNIÈRE'S GROUP OF SYMPTOMS.

Ménière's Account of his First Case—Phenomena of the Attacks and Consequences—Pathology—Flourens' and Crum Brown's Experiments—Dr. Wilks' View—Drs. Woakes' and Gruber's Theories—Effects of Intra-Labyrinthine Tension—Prof. Steiner's Experiments—Diagnosis—Prognosis—Treatment.

AFFECTIONS of the labyrinth often give rise to disorders of hearing, noises in the ears, giddiness, unsteady gait and nausea; and these symptoms more frequently occur in combination than singly, though sometimes one and sometimes another predominates over the rest. Impairment or even loss of hearing-power, accompanied by the other symptoms above mentioned, may come on suddenly, and so far resemble an attack of apoplexy, and doubtless many such cases have been regarded as due to cerebral or meningeal disease. The connection between these symptoms and lesions of the internal ear was first suggested by Ménière,* who met with a case in which deafness, giddiness, and vomiting suddenly came on, and death ensued on the fifth day. The patient was a young girl who had been exposed to cold during a catamenial period. On post-mortem examination nothing abnormal was found in the brain or spinal cord; but the semi-circular canals were filled with a reddish plastic material, which extended into a portion of the vestibule, but was absent from the cochlea. This and other similar cases induced Ménière to believe that the attack was due to a peculiar lesion of the labyrinth, in which the sudden effusion of blood, or other fluid, produced symptoms akin to those caused in animals by injuries to the

* "Mémoire sur les lésions de l'oreille interne donnant lieu à des symptômes de congestion cérébrale apoplectiforme."—*Gazette Méd. de Paris*, 1861, p. 598.

semi-circular canals. Ménière did not merely wish to draw attention to the fact that vertigo was a common symptom in patients suffering from deafness, or from some disease of the organ of hearing. He wished to show that sudden, apoplectiform symptoms, including at least a transient form of unconsciousness, might occur in a person previously healthy, and be followed by deafness, and that disease of the internal ear might be the cause of all the symptoms.

The **Phenomena** characteristic of Ménière's disease are as follows:—Without obvious cause a person suddenly becomes conscious of noises in the ears, and feels giddy and sick; the expression is anxious and the face pale and often covered with perspiration; the power of hearing ordinary sounds is much impaired or even altogether lost. Sometimes the patient falls to the ground, but without becoming unconscious. Charcot states that during the attack, "whatever may be its intensity, the patient absolutely preserves perfect consciousness of his actions," and that as soon as the first effects have passed off he is able to render, without hesitation, an account of all he has felt. The duration of the symptoms varies greatly; they may last only a few minutes, or may continue for several hours. After the attack is considered to be over some amount of giddiness often remains; the patient walks with difficulty owing to loss of balancing power. Seizures of a like character recur at varying intervals; in some patients they appear to assume an intermittent type, coming on at much the same hour. The impairment of hearing, generally affecting both sides, continues for an indefinite time, and is apt to be progressive, until total deafness results. When this latter stage has been reached, the attacks usually cease to trouble the patient; but there are exceptions to this rule. Mental depression is often a prominent symptom.

In some cases the attacks are preceded by premonitory symptoms, such as noises in the ears, of various kinds, and these have been regarded as corresponding with the *aura* of epilepsy. On the other hand, cases occur in which the attack is preceded by a cessation of the *tinnitus*, which had previously been constant. Ocular symptoms, such as hemiopia, dilatation of the pupils, and *muscæ volitantes* are sometimes observed during the attack.

The deafness presents several peculiarities; it may be complete or incomplete, or only the power of hearing certain sounds

may be lost. When both ears are involved, perception through the bones of the skull is almost or altogether absent.

Pathology. — The exact causation of Ménière's group of symptoms is as yet far from clear; it is a matter of common experience that giddiness, faintness, and sickness may occur in connection with diseases of the middle and external ear, and may even be caused by accumulations of cerumen. Paroxysmal vertigo is often associated with more or less deafness, buzzing and singing in the ears. In most of these cases the external parts are free from disease; but the tuning-fork applied to the vertex is not heard on the affected side, and hence it may be inferred that the internal ear is the seat of the mischief. The experiments of Flourens and Crum Brown show that artificial lesions of the semi-circular canals give rise to disturbances of equilibrium, due to the feeling of giddiness; and the latter experimenter believes that the function of these canals is to furnish the impressions which form the chief basis of our knowledge as to the relations between our movements and those of surrounding objects. If the horizontal canal be divided, the head of the animal is turned alternately to the right and left. Injury to the posterior vertical canal causes an up and down movement, a nodding of the head, and the animal not infrequently falls forwards or backwards. Injury to the superior vertical canal causes similar movements of the head, and the animal tends to fall forwards. When all the canals are destroyed, various pendulum-like movements are performed, and standing is impossible. The movements are supposed to be reflex results of impressions conveyed to the co-ordinating centre for the various canals, which, under normal conditions, balance each other, but fail to do so when some canals are diseased or injured. It has been suggested by some writers that the cause of the vertigo is disorder of the labyrinth. Pressure on the fenestra ovalis causes increased tension in the semi-circular canals, and thus all cases of aural vertigo have been thought to be examples of Ménière's disease. Dr. Hilton Fagge* considered that the case recorded by Ménière himself was not satisfactory as a basis for the generally accepted theory, and that the explanation was improbable. It is generally assumed that in cases of this kind hæmorrhage takes place into the semi-circular canals; but the blood must be effused

* *Text-Book of the Principles and Practice of Medicine*, vol. i. p. 769.

on both sides, since the deafness is generally in both ears. In some cases also the cerebral symptoms come on suddenly, and as suddenly pass off.

Dr. Wilks suggests a different view from that usually accepted as to the causation of Ménière's symptoms. He thinks that in cases in which there is no affection of the meatus or tympanum, both the deafness and cerebral symptoms are generally due to changes in the nervous centres. In Ménière's disease, strictly so-called, the sudden loss of hearing may be due to some affection of the auditory centre, and the giddiness to a similar affection of the centre for equilibrium, probably adjacent, since its most important afferent nerves come from the semi-circular canals. The vertigo often presents marked peculiarities, supposed to depend upon affections of particular ampullæ, but these can all be referred to corresponding changes in the centre, in which the functions of each canal must necessarily be fully represented. In support of this view, Dr. Fagge adduced the analogy with other paroxysmal neuroses. Impairment of sight is frequent in migraine, and is due to affection of the brain and not of the eyes. In some recorded cases of Ménière's disease, cloudiness before the eyes and obscuration of the visual field were associated with the vertigo. The two neuroses may perhaps have been combined, the nerve-storm spreading beyond its usual limits and encroaching on the area concerned in migraine. In the apoplectiform cases described by Ménière, the disturbance was diffused over the hemispheres, and occasioned the loss of consciousness. Another argument, adduced by Dr. Fagge, in favour of Dr. Wilks' view, is suggested by the fact that bromide of potassium is capable of removing giddiness and loss of hearing at the same time. In Mr. Hinton's cases of Ménière's disease, paroxysmal vertigo and sickness with transient deafness were all caused to recur by administering quinine, and removed by other treatment.

In some cases it was observed that the impairment of hearing was especially marked for certain musical tones, those of the middle octaves being distinctly perceived, while those of the lower and still more those of the higher octaves were heard very imperfectly. In some of Charcot's patients it was noticed that the vertigo and buzzing were complained of so long as the deafness was partial; but that those symptoms disappeared when the hearing was completely lost. But even if in these cases the

internal ear is the part primarily affected, it does not follow that the same thing is true of the apoplectiform cases, or that the vertigo is anything but a neurosis. The same symptoms may be produced in many different ways, but are themselves always the direct result of one particular kind of nervous disturbance, just as migraine may be excited by a variety of causes.

Two other theories with regard to Ménière's disease require a brief notice. The first of these, advanced by Dr. Woakes, is to the effect that the symptoms are due to an affection of the inferior cervical ganglion of the sympathetic. This ganglion exercises an influence upon the vertebral artery, and therefore upon the vessels of the labyrinth; and it is also connected with the branches of the vagus. When the action of the ganglion is weakened, deafness, noises in the ears, and giddiness result from labyrinthine disorder, while nausea and vomiting are caused by implication of the vagus. Quinine and tobacco depress the action of the ganglion, while hydrobromic acid has an opposite effect.

Another theory, advanced by Professor Gruber,* refers Ménière's group of symptoms to pressure on the base of the brain by fluid passing through the aquæductus cochleæ and vestibuli. He considers that variations in the size of the *recessus Cotugnii*, in which the endo-lymphatic duct terminates, are principal factors in the causation of the symptoms. In different cases this *recessus* is found to be sometimes as large as a hazel-nut, and sometimes so small as to be scarcely perceptible. When the intra-labyrinthine tension is increased, the perilymph is first affected and yields to the pressure; fluid passes through the aquæductus cochleæ into the sub-arachnoid space, and if the movement be rapid, the effects of pressure are produced on the brain. Moreover, when tension is excessive in the saccule, the endolymph escapes directly through the aquæductus vestibuli towards the cranial cavity; and if the *recessus Cotugnii* be fully developed, it becomes proportionately enlarged, and by pressing upon the centre for equilibrium, the cerebellum, it causes the giddiness and other similar symptoms. If the *recessus Cotugnii* is but feebly developed, the symptoms will fail to appear. It must be remembered that fluid passing through the aquæductus cochleæ into the sub-arachnoid space causes very slight pressure over a large area; whereas enlargement of the *recessus Cotugnii* gives rise to considerable pressure

* *Lehrbuch der Ohrenheilkunde*, S. 613.

limited to a small space, but affecting the auditory nerve, the sixth nerve, and the centre for respiration.

It is certain that Ménière's symptoms may originate in various organs; they are especially liable to happen when the semi-circular canals are irritated, but this fact does not prove that these parts are the sensory organs for the equilibrium of the head, and indirectly of the whole body. In support of his view that the semi-circular canals are not necessarily concerned in the production of Ménière's symptoms, Gruber cites cases in which, during long periods, there was never any trace of giddiness or involuntary movements, and yet post-mortem examination showed that the canals were the seat of various lesions, or were completely destroyed. Moreover, in deaf-mutes these parts may be defective or altogether wanting, and yet there may be no giddiness. There is also another consideration which is worthy of notice. Increased labyrinthine pressure and consequent irritation of the semi-circular canals must often exist in cases of acute middle-ear inflammation, and yet the occurrence of Ménière's symptoms is comparatively rare. It must, of course, be admitted that disturbances of equilibrium often originate in the labyrinth; but they do so because of the relations of this structure to the central nervous organs, the degree of irritation required to produce them being dependent upon individual peculiarities of the auditory organ and adjacent parts.

Still more serious objections to the ordinary theory of the function of the semi-circular canals have recently been raised by Professor Steiner,* of Cologne, who has experimented on sharks caught in the Bay of Naples. In these fish the canals are particularly well developed, and are superficially arranged beneath the skin and separated from the brain by a considerable mass of cartilage. They can, therefore, be laid bare without injury to other parts. When this has been done, and the canals excised and the wound closed, no disturbance of locomotion is seen when the fish is replaced in the water. But if, after laying bare the labyrinth, the auditory nerve, or the ossicles surrounding the same, are pulled or displaced, the result is always a disturbance in the form of rotatory or circular compulsory movements. The same effects can be produced by similar operations on frogs and lizards. In the higher vertebrates, the structures concerned are

* *Deutsche Med. Woch.*, Nov. 21, 1889; *Brit. Med. Journ.*, April 5, 1890.

so complicated that other parts are necessarily injured in the experiments. Ménière's symptoms would appear to originate rather in lesions affecting the brain or its membranes, and, as Gruber supposes, causing increase of pressure.

Diagnosis.—This is made by a careful observation of the symptoms, and by noticing the absence of signs of paralysis of any other cerebral or spinal nerves. According to Ménière, the fact that the symptoms are confined to the organ of hearing excludes the possibility of a cerebral affection, for if there were any central lesion of the auditory nerve, other symptoms would make their appearance, inasmuch as other nerve-centres are very close to the origin of the nerve in question. But Politzer points out that in cases in which the attacks are preceded by tinnitus, sensations of pressure and fulness in the ears, giddiness and impairment of hearing, the diagnosis of Ménière's disease must not be made as a matter of course. Such symptoms are certainly suggestive, but they occur also in cerebral congestion, at the commencement of several diseases of the brain, and particularly in connection with cerebral tumours. It may be mentioned that disturbances of hearing are only exceptionally present in lesions of the cerebellum; they are due to accidental pressure upon some of the adjacent fibres of the auditory nerve.

If, on the other hand, the attacks, as already described, occur without prodromal symptoms and in a marked form—that is to say, if, in a person previously possessing normal hearing, noises in the ears and more or less deafness suddenly supervene, accompanied by giddiness and staggering, but no other signs of paralysis, and if the external parts of the ear, the membrane and Eustachian tube are found to be normal—the existence of an affection of the labyrinth may fairly be assumed. After some time the diagnosis may become very difficult; the loss of hearing may be due to rigidity of the ossicles, supervening after all symptoms of a severe tympanic affection have completely disappeared.

Prognosis.—This is decidedly unfavourable in cases in which months or years have elapsed since the hearing was lost. On the other hand, in recent cases, with only partial impairment, some improvement may be anticipated from treatment. Restoration of hearing-power, with freedom from further liability to attack, is, however, quite exceptional.

Treatment.—An attempt should be made to ascertain the con-

dition of the ears, and the patient should be carefully examined in other respects. If there be indications of cerebral hyperæmia, cold should be applied to the head and mustard plasters to the calves of the legs: laxatives are generally indicated. The patient must, of course, be kept as quiet as possible; his symptoms will cause him to adopt the recumbent posture, with the head raised. The diet should be restricted to light and non-stimulating articles.

Various remedies have been recommended for the relief of the symptoms, and good results are sometimes obtained from quinine and iodide of potassium. The former is given in daily doses of from five to fifteen grains; but its use requires care. Sometimes the giddiness is decidedly diminished after a few doses; but in other cases, the symptoms are increased. If no good result be obtained after three or four days' treatment with quinine, the medicine should be discontinued. Gruber mentions a case which illustrates the necessity of great care in the use of quinine in this affection. A woman, otherwise in good health, had suffered from chronic middle-ear suppuration for some years. Ménière's symptoms appeared in an acute form, and quinine was given in daily doses of fifteen grains. No improvement resulted; but on the third day symptoms of acute glaucoma supervened, for which iridectomy was performed. Reports differ as to the effect of quinine upon the blood-vessels.* According to some authorities, the drug causes anæmia of the retinal vessels; while others assert that they have seen hyperæmia and extravasation follow its administration. Other experiments showed a reduction of the temperature in the external meatus, and no hyperæmia of the membrane, after the use of quinine. Its good effects upon Ménière's symptoms have been ascribed to its power of lowering the blood-pressure, and of producing anæmia of the labyrinth.

The iodide of potassium should be given in daily quantities of from eight to fifteen grains, and continued for at least a month. It is, of course, especially indicated whenever there is a history of syphilis. If, in such a case, the symptoms continue unchecked, the dose should be gradually increased; and if no result be obtained, mercury should be cautiously administered. In non-syphilitic subjects, the bromide of potassium, combined with tincture of aconite, has been found beneficial.

* See Dr. Brunner's Paper in *Archives of Otology*, vol. xvii. p. 206.

In recent cases exhibiting Ménière's symptoms, Politzer recommends the daily subcutaneous injection of pilocarpine, four to ten drops of a 2 per cent. solution, or the same quantity internally. Gruber recommends tincture of arnica internally, five drops with a little tincture of nux vomica, twice daily; the dose to be gradually increased until ten drops are taken, and the medicine is to be continued for several weeks. When the symptoms occur in women shortly after the menopause, leeches should be applied to the mastoid process and laxatives should be given somewhat freely. In gouty subjects, colchicum and potash are indicated; and if there be much nervous excitement, the bromides may be tried in combination with belladonna.

Not much can be expected from local treatment, but Politzer recommends that, after the acute symptoms have subsided, either the pilocarpine solution, or eight to ten drops of a warm solution of iodide of potassium, should be injected into the tympanum with the catheter every other day for three or four weeks. In chronic cases, change of air and warm or tepid baths are likely to prove useful.

CHAPTER XLV.

NEUROSES OF THE AUDITORY NERVE.

Acoustic Hyperæsthesia—Various Forms—After-Sensations—Neuralgia of the Ear—Hyperacusis of Willis—Acoustic Anæsthesia—Deafness Caused by Occupations—Symptoms of Nervous Deafness—Paracusis Loci—Subjective Auditory Sensations—Peculiarities and Causes—Changes in the Middle and Internal Ear—Effects of Certain Drugs—Reflex Causes—Question as to State of Auditory Nerve—Variations in Sensations—Entotic Noises—Effects of Subjective Sensations—Noises Produced in Throat—Peculiarities in Individuals—Prognosis—Treatment.

VARIOUS perversions of hearing are caused by disorders of the labyrinth and auditory nerve and acoustic centres, and the faculty of hearing may be increased, diminished, or altered in various ways. Subjective sensations, disorders of equilibrium, and disorders of the stomach are other symptoms of functional and organic disease of the nervous structures of the ear.

The hearing-power may be either increased or diminished; the degree of alteration varying considerably in different cases. Increase of power is exhibited in two forms: in one, there is abnormal acuteness of hearing; in the other, unpleasant or painful sensations are caused by sounds or noises. **Acoustic Hyperæsthesia**, or **Hyperacusia** in the strict sense, is a condition which may be manifested in several ways. (1) The acuteness is so great that sounds used for testing are heard at abnormally long distances; (2) sounds, previously inaudible, are clearly perceived; (3) exceedingly slight differences in the pitch can be readily distinguished. This last condition is often physiological; it may be observed in persons with highly trained ears, such as musicians, some of whom, by practice, can distinguish

sounds differing no more than in the proportion of 10,000 to 10,001 vibrations. Hyperacusia, of a pathological kind, may be associated with increased power of other special senses—*e.g.*, sight, smell, etc.; and such instances are seen in somnambulists, and in persons in a state of ecstasy. The hearing may be abnormally acute for all tones and noises, or only for certain sounds. In some instances, persons can hear at great distances sounds which to others are either indistinct or quite inaudible. This condition is sometimes noticed in cerebral congestion, produced by stimulants, and in excitable persons, in the absence of any other affection of the ear; sometimes it comes on after subsidence of catarrh of the tubes and tympanum.

In acoustic hyperæsthesia more or less painful sensations are caused in the ear by various tones or noises. Even in normal ears such sensations are often caused by tones of high pitch, and instances of this kind are frequently seen in anæmic, nervous, and excitable persons.

This auditory hyperæsthesia is sometimes the precursor of deafness and of cerebral disorder; it has been often observed in cerebro-spinal meningitis and after injuries to the head. When associated with sleeplessness and irritability, it is an occasional precursor of apoplexy. It is sometimes noticed in the early stage of fevers, and during excitement from any cause; after the effects of chloroform have passed away, there is sometimes auditory hyperæsthesia of a transient character. In certain phases of sleep, there is increased sensitiveness of the auditory nerve; Diday says that this nerve is the last to go to sleep and the first to awake. The same condition may be caused by over-exertion, and by want of sleep; it is frequently noticed in neurasthenic conditions, and as a concomitant of migraine. It is often symptomatic of acute and chronic affections of the sound-conducting apparatus and of the labyrinth, and especially of the worst forms of adhesive inflammation, the sensitiveness to sound being in inverse ratio to the amount of hearing-power. Acoustic hyperæsthesia may, indeed, coexist with almost absolute deafness, and may then cause distress, spasmodic movements, confusion of ideas, and nervous excitement. The sensitiveness is sometimes remarkably displayed towards particular sounds—*e.g.*, the human voice; and when this peculiarity accompanies severe deafness, the use of a speaking-tube becomes impossible. Temporary hyperæsthesia

has been observed after the removal of an obstacle to the conduction of sound—*e.g.*, a plug of wax. Unpleasant sensations may likewise be caused by sounds, in the absence of increased irritability of the auditory nerve. Instances of this kind are due to lesions of the sound-conducting apparatus. Thus, peripheral paralysis of the facial nerve involves the stapedius muscle, which counteracts the tensor tympani, and the result is increased tension of the membrane and loudness of sounds.

In a peculiar form of acoustic hyperæsthesia there is a long-continued after-sensation; sometimes this is so closely connected with the original tone that both appear to be continuous. There are also some after-sensations, where a pause intervenes between the end of the objective and the beginning of the subjective tone. The latter may last for a considerable time; thus in a case of chronic middle-ear catarrh, recorded by Urbantschitsch, the notes of a piano were heard many hours after the music had stopped. The ticking of a watch is not infrequently heard several seconds after the instrument has been removed, and in one case recorded by the same author the sensation was prolonged for several minutes.

Neuralgia of the ear, properly so-called, must be distinguished from those conditions in which auditory sensations are accompanied by discomfort and pain (*see* p. 570). In nervous otalgia the pain comes on spontaneously, and is unaccompanied by any local changes in the auditory apparatus. The diagnosis is made chiefly *per viam exclusionis*. There is no abnormality in the function of hearing, and subjective sensations are absent. In such cases it is assumed that the neuralgia is located in certain branches of the third division of the fifth nerve, or in the tympanic plexus. It is sometimes cured by the extraction of carious teeth, and by the removal of neuromata from the neighbourhood of the ear.

In one form of auditory hyperæsthesia, the so-called *hyperacusis* of Willis, a definite sound is heard better during a noise. This condition was once supposed to be merely imaginary, or, at least, to be due to the general elevation of the voice which is spontaneously assumed during a noise; but it has a real existence. Those who are the subjects of this condition are found to hear the ticking of a watch better when travelling in a train, or when near machinery in action. The explanation of this phenomenon is not

altogether clear; but, as a matter of fact, the perceptive power of the organ of hearing is increased by every appropriate stimulus, and the ear, after a time, becomes able to perceive the effects of vibrations, which alone would have been insufficient to excite it. According to another theory, the change is due to increased mobility of the ossicles and loosening of bands of connective tissue. The increase of power is only transient, and, after removal of the cause, the perceptive faculty relapses to its former state. The phenomenon occurs in persons with sound hearing, and in those who are more or less deaf. It is noticed that in proportion to the loss of power the noise required to excite the nerve must be of corresponding intensity.

This form of hyperacusis is apt to be manifested only under certain conditions, and is not observed when the sound which stimulates the perceptive faculty produces only a weak effect. It would seem that different tests are required for hyperacusis in different cases, and that a noise which raises the perceptive faculty of one deaf person, or for one ear, is too intense for another, and may, indeed, have quite a contrary effect. Thus it occasionally happens that a deaf person hears conversation during a noise better than another with full hearing-power; in the latter case, the louder sound masks the voice altogether.

Acoustic Anæsthesia is a condition in which the function of the auditory nerve is impaired or abolished. The cause of the alteration may be either in the peripheral parts of the auditory apparatus, in the trunk of the nerve, or in the nervous centres; the exact localisation of the mischief is often very difficult and sometimes impossible. There is, for example, often much doubt as to the origin of unilateral or bilateral nervous deafness (either partial or complete), which is apt to come on after injuries to the skull (severe concussion, fracture at the base or posterior part), and when associated with symptoms of organic cerebral disorder, or with meningeal disease, especially cerebro-spinal meningitis. The same may be said of nervous deafness after acute infectious diseases, though such a sequela may generally be referred to meningeal complications. In such cases the aural affection is generally bilateral, and the prognosis is unfavourable. Little is known as to the origination of deafness in cases of neurasthenia, or of the condition which underlies the impairment of hearing sometimes produced by lead and quinine. In the latter cases

the loss of function is seldom very marked; subjective auditory sensations are generally much more prominent symptoms.

In cases of neurasthenia, disorders of hearing may be associated with hemianæsthesia and other evidences of nervous derangement, or may constitute the only symptom of perversion or loss of sensation. The disorder generally takes the form of anæsthesia, which may be either complete or incomplete, and may exist on one or both sides; it is often accompanied by subjective sensations of various kinds and degrees of intensity. Giddiness is seldom complained of, and, in cases of hemianæsthesia, evidences of middle-ear disease are usually absent; but the entrance of air into the tympanum is not felt, and touching the membrane causes no sensation.

When the acoustic anæsthesia occurs alone and affects only one ear, there is sometimes hyperæsthesia on the opposite side. This latter condition may precede the impairment of hearing, as in a case recorded by Dr. Fulton.* The anæsthesia is not infrequently accompanied by some slight lesion of the middle ear, discoverable only on careful examination, and not of itself sufficient to account for the impairment of function. Bone-conduction is usually more or less interfered with, and sometimes altogether abolished. The anæsthesia is liable to vary from day to day, and may entirely disappear during longer or shorter periods. It may be that on one day loud shouts are almost inaudible; whereas a few days later the tick of a watch is distinctly heard. Some patients assert that they cannot hear whispers, though other sounds are clearly distinguished.

In girls auditory anæsthesia sometimes coincides with the first appearance of menstruation, and with disorders of this function. In a few cases of undoubted neurosis escape of blood from the auditory meatus has been declared to occur during the menstrual periods. In connection with the alleged occurrence of this phenomenon, the following case would seem to deserve mention:—In May, 1893, a girl, aged twenty, was brought from a Home for Fallen Women to the Aural Department of the London Hospital, with the statement that she was liable to hæmorrhage from the auditory meatus on both sides. The matron, who accompanied her, told me that the girl stated that she had been seduced and had left her child in the country. On subsequent examination,

* *Archives of Otolaryngology*, vol. xiv. p. 111.

it was found that she had a virgin *os uteri*, and presented no signs whatever of having been pregnant. The membrana tympani and the deeper parts were quite normal, and the hæmorrhage was represented by dried blood in the outer part of the meatus. As there was no visible cause for the alleged bleeding from the ears, the patient was admitted into the hospital, and carefully watched. No bleeding could be detected while the girl was thus under observation. There was no doubt as to the falsity of the statement regarding the pregnancy, and a similar explanation of the aural hæmorrhage was quite justifiable. Other cases may doubtless be explained in a like manner.

Anæsthesia of the auditory nerve is sometimes associated with loss or perversion of other special sensations—*e.g.*, of smell, taste, and vision, and with attacks of vertigo, headache, and epileptiform convulsions. Symptoms of this kind are not confined to females; they sometimes occur among boys and young men.

The diagnosis is for the most part easily made, inasmuch as other and more common symptoms of neurasthenia generally co-exist. The suddenness with which the deafness is apt to come on and pass off would disprove the existence of organic lesions. Excitement and fatigue usually aggravate the deafness, while the opposite effect is produced by rest and tonic treatment of various kinds.

General and severe debility, due to a great variety of causes, is sometimes attended by loss or impairment of hearing-power. Thus patients convalescing from pneumonia and intermittent fevers are sometimes more or less deaf until their strength has become established. Sexual excesses and the immoderate use of alcohol and tobacco are other causes of nervous deafness; and this symptom has been known to come on suddenly during great mental excitement and after severe hæmorrhage. Fatigue of the auditory nerves, as a consequence of long-continued exposure to monotonous sounds, is a not infrequent cause of impairment of hearing: instances of this character are sometimes seen in engine-drivers, smiths, coopers, and boiler-makers. In the case of engine-drivers, good hearing-power is almost as important as perfect vision. It is a mistake to suppose that so long as such men can hear a conversation in ordinary voice there can be no dangerous impairment of hearing. Other sounds besides those of a whistle and a fog-signal often give important warning to a driver. An

unusual sound may be the first intimation that some portion of the machinery has broken down or is out of order, and this might pass unnoticed by a man with a slight defect of hearing. So, too, the signal by which the guard can communicate with the driver might remain unheeded. Dr. Hartmann alludes to the fact that an engine-driver, who already hears badly, is liable to hear much worse after having made a long journey, and recovers the loss only after rest.

In these cases of defective hearing due to occupations both ears are usually affected; and in some a disorder of the middle ear is superadded to that of the labyrinth. As a general rule, however, the symptoms are due to changes in the internal ear. They consist in impairment of hearing, subjective sensations, and sometimes in disorder of equilibrium.

Habermann* examined thirty-one chain-workers, and found that all were more or less deaf. In a few cases there was some affection of the middle ear; and in these persons, the hearing-power was proportionately greater, the obstacle to conduction appeared to protect the labyrinth from the effects of loud sounds. Dr. Barr examined 100 chain-workers who had been thus occupied on an average for seventeen and a-half years. He found that fifty-nine could not hear whispers; thirty-three could hear them with both ears, and eight with one ear. Loud talking was inaudible to thirteen; ten could hear it only on one side, and seventeen on both sides at about a yard off. In these and similar cases the impairment increases as time goes on; and in some patients the complaint is observed to grow worse even after they have given up work. In several classes of sufferers various other circumstances assist in producing and aggravating the complaint. Among these the most important are: atmospheric changes, exposure to cold and damp, dust, and particles of various kinds which irritate the naso-pharynx. Engine-drivers and stokers are obviously exposed to the action of all these causes.† Few escape, after from five to ten years of service.

In all cases of nervous deafness loss of bone-conduction will be superadded to the impairment of hearing ordinary sonorous vibrations. The anæsthesia is sometimes partial, in so far as it

* *Archiv für Ohrenheilkunde*, vol. xxx, p. 1.

† See a Paper on "Railroad Accidents in connection with Bad Hearing of Engine-Drivers," by Dr. Moos, of Heidelberg.—*Archives of Otology*, vol. xi, p. 91.

relates to certain sounds or notes; thus a tune may be heard perfectly, while the patient is decidedly deaf to conversation and common noises. Sometimes an opposite condition is discoverable, and very curious differences of this kind are occasionally noticed in different patients and in the same patient at different times. Thus some hear speech far better than any other sound; while others who can detect some peculiar sound, such as the ticking of a watch, are comparatively deaf to all others. In connection with these cases, Urbantschitsch suggests that each root of the auditory nerve may possess a different functional importance. This hypothesis would serve to explain the fact that under certain pathological conditions, the hearing-power for articulate speech remains intact, whereas rhythmical sounds are imperfectly heard. Many persons decidedly deaf find that there is a marked improvement when the sound comes from a certain direction; some instances are described in which the patients heard fairly well only when words were uttered immediately behind them.

In one form of nervous deafness certain notes, or perhaps an entire octave, are lost; or it may happen that the want of perception extends to high and low notes at the ends of the scale. In elderly persons high notes are often lost, and the same symptom is not infrequent in connection with various labyrinthine disorders. Dr. Wollaston recorded a case in which the deafness involved four octaves; he also alludes to the frequency of deafness for high notes, such as the chirping of a cricket, and states that the loss of perceptive power is sometimes very sharply defined. These cases of deafness for certain sounds are explained by the hypothesis that separate portions of the membrana basilaris are adapted for the perception of certain notes; though the possibility of central lesions must be borne in mind. Similar effects may be produced by obstacles to sound-conduction; for these do not invariably affect all notes, but sometimes different notes in different degrees.

Closely allied to nervous deafness is the condition termed "paracusis loci," in which the faculty of distinguishing the direction whence sounds come is impaired or abolished. The anomaly is associated with deafness on one or both sides, and is due to the fact that sounds are referred to the side on which they are best heard. When the deafness is bilateral it is

necessary that the loss should be more marked on one side than on the other.

Subjective Auditory Sensations are those which occur in the absence of any demonstrable objective cause. They are due either to the existence of some pathological process in the sound-conducting apparatus, or to some affection of the auditory nerve or nerve-centres. Deafness is not an invariable accompaniment, but is present in many cases.

Subjective auditory sensations differ greatly in quality; and a large number of terms are used by patients in attempting to describe them. Thus they are spoken of as ringing, whistling, singing, whizzing, buzzing, roaring, bubbling, crackling, etc. Sometimes several sounds are heard, either together or consecutively, in the same ear. Their quality is no guide as to their source; the weaker they are the lower is the pitch, and the more they resemble a diffused dull noise. On the other hand, with increased loudness the higher is the pitch, and the sound more and more resembles a musical note. The sensations vary much in strength: sometimes they are very slight and not noticed when the patient's attention is in any way distracted; in other cases, they are so pronounced as to make the patient utterly miserable and unfit for the duties of life, and even to cause melancholia and suicide. A vast number of degrees exist between these extremes; many sufferers get accustomed to the sounds, and are but little incommoded by them.

The character and intensity of the sounds are apt to vary from time to time, sometimes without apparent cause, sometimes as a result of changes in the condition of the ear, or in external circumstances. Thus the noises are generally more troublesome when any existing catarrh of the tympanum or throat becomes exaggerated, in damp weather, after exposure to cold, after a sleepless night and as a result of indigestion. In some patients they are worse in the morning; in others, after the fatigues of the day.

There is a remarkable peculiarity connected with subjective auditory sensations, viz., that sometimes they appear to originate external to the ear and at various distances from it; in other cases, their source appears to be situated within the cranium. In the latter case, the sound may appear to proceed from every part of the head, or only from certain spots; in another class of

sufferers there is a continuous noise within the cranium, with the occasional or frequent addition of louder sounds, resembling explosions. It must be remembered that when the auditory nerve is physiologically excited, the resulting sensation of sound is referred to some external object. The same idea is formed when the excitement is due to some pathological cause; but the patient after a time discovers the mistake, and becomes conscious that the sound really originates in the ear or in some other part of the head.

The sound may be heard by one or both ears; in the latter case the source of the sensation appears to be in the head, either in the middle, fore, or back part of it, provided that both ears are equally affected. If the sensation be more acute on one side than on the other, the sound will seem to originate nearest to the ear which is most affected. When, as sometimes happens, the intensity of the sound varies from time to time, the idea as to its source of origin will likewise change. Very feeble sounds usually seem to originate within the ear.

Causes.—For the production of subjective auditory sensations, some pathological condition of the sound-conducting or sound-perceiving apparatus must necessarily exist. With regard to the former, subjective sensations are one of the most prominent symptoms of adhesive inflammation of the middle ear, the drawing inwards of the base of the stapes being the immediate cause. The same result ensues when the membrana tympani and the chain of ossicles are forced inwards, when the air in the middle ear is rarefied, and when there is increased action of the tensor tympani muscle, or retraction of the tendon of the stapedius.

Pathological changes in the cochlea and in the auditory nerve-centres are capable of giving rise to subjective sensations of hearing. Thus the latter often occur in cases of anæmia and chlorosis, after severe losses of blood, and in the opposite conditions of hyperæmia and cerebral congestion. Inflammation of the brain and cerebral tumours are often accompanied by marked subjective auditory sensations. Full doses of certain drugs—*e.g.*, quinine and salicine—are apt to affect the hearing and to excite subjective noises, as of bells ringing in the ears. The sense of hearing is sometimes decidedly impaired for several hours or days; but the effects usually pass off soon after the medicine has been discontinued. Galvanism applied so as to excite the auditory

nerve always causes a sensation of sound. In some cases the noises are heard only in certain positions of the head: they are often more distinct when the patient is lying down.

Noises in the ears are sometimes of reflex origin, and are excited by impressions made upon various parts of the body. In other cases, they are either increased or lessened by friction or irritation of other parts. Thus, Türk recorded a case in which pressure on the forehead and face generally, and likewise on the tongue and hard palate, resulted in considerable diminution of the intensity of the sounds. Some portion of the effect may have been due to the distraction of the patient's attention. On the other hand, Gruber mentions cases in which the noises could be increased by slight irritation of parts supplied by the fifth nerve—*e.g.*, by slightly rubbing the surface of the cheek. Moos mentions the case of a woman who was conscious of noises in her left ear whenever she attempted to wear a *pince-nez*. She was advised to try spectacles, and found that they did not produce any unpleasant effect. The cause is sometimes to be found in the nasal mucous membrane. Urbantschitsch has met with two cases in which subjective auditory sensations completely ceased after the application of caustic to the swollen mucous membrane covering the inferior and middle turbinate bones. Neuralgia of the fifth pair is sometimes accompanied by noises in the ears and deafness; and such symptoms are not necessarily of central origin, but may be due to reflex contraction of the tensor tympani muscle. In a case recorded by Weber-Liel, attacks of migraine were always associated with deafness and tinnitus; but these symptoms altogether ceased after division of the tendon of the tensor tympani. Cases due to impressions made upon nerves other than the fifth pair are very uncommon. It is, however, stated that exposure of the feet to cold and irritation of branches of the sciatic nerve have been known to cause or aggravate subjective aural sensations.

It is generally considered that a condition of excitement of the auditory nerve is the basis of these subjective sensations; but Urbantschitsch points out that in some instances these sensations must be connected with diminished function of the nerve, and that they are increased in proportion to such diminution. The fact that subjective auditory sensations may continue without change for months or years, without exhausting the

supposed stimulus which provokes them, makes the hypothesis of irritation somewhat doubtful. It is no doubt true that such a condition of the auditory nerve or centres is the general cause of the sensations; but other influences may co-operate in the production of the result. It is a well-ascertained fact that in some cases the noises may be made to cease by listening to external sounds; but this experience is not universal. On the other hand, in some instances the subjective sounds are intensified in the presence of other noises, and this result may be explained by supposing that fatigue of the nerve-centres has resulted from their excitement. Another variation is occasionally noticed, viz., the production of a subjective auditory sensation by an external sound. Some patients are free from any trouble of the kind so long as silence reigns around them; but the least noise provokes the peculiar sensations, which then continue indefinitely.

In some patients the sounds are only occasionally noticed; in others they are always present, though liable to variations in intensity. In the former class the sounds may trouble the patient either at definite or indefinite intervals, and sometimes the periodicity is maintained during months or years. The noises are sometimes associated with discharges from the ear and other symptoms of otitis, which likewise assumes an intermittent character. In another class of cases the auditory sensations are associated with severe coryza, of an intermittent character, and for which the inhalation of two or three drops of amyl nitrite proves a very efficient remedy.

The continuous subjective auditory sensations may be developed either gradually or suddenly; in some patients the noises are at first irregularly intermittent, and afterwards become continuous. Even when this latter stage has been reached, exacerbations are wont to occur, and the intensity of the sounds is generally influenced by such conditions as the general health of the patient, the state of the weather, etc. The noises are always more troublesome if the patient becomes weak and depressed from any cause, and especially from want of sleep. The state of the organs of digestion exercises a decided influence in many cases; in some patients the noises are made worse by a little alcohol; in others an opposite result is experienced. External noises are sometimes sufficient to mask the subjective sensations, which then become noticeable only at night.

It is necessary to distinguish between subjective sensations proper and the so-called "entotic" noises, which originate in the middle ear or adjacent parts, and are transmitted to the labyrinth. These noises are often caused by the condition of the blood-vessels, and anomalies in the circulation in the small arteries supplying the ear. In some cases murmurs originating in the internal jugular vein are transmitted in an upward direction, and become clearly audible: the sound ceases, however, when pressure is made upon the vein in the upper part of the neck. It has been suggested that an enlarged jugular fossa may be the source of origin of an entotic murmur; the opening of the lateral sinus into the fossa is often very narrow, and increased rapidity of the blood-current may cause a bellows-sound. Hyperæmia of the tympanic vessels, and especially of those of the malleus, may cause vibrations of the ossicles, and consequent sensations of sound; noises due to this cause ought, however, to cease when the jaws are firmly closed, inasmuch as the tympanic artery is thereby compressed as it enters the Glaserian fissure. Valvular diseases of the heart not infrequently give rise to entotic sounds. The latter sometimes originate in close proximity to the labyrinth; thus they may arise from contraction of the muscles, either the tensor tympani or stapedius, from collections of secretion in the tympanum, and from movements of the membrane or of the walls of the Eustachian tubes. The perception of these noises is favoured by increased sensitiveness of the auditory nerve, and by anything which increases the resonance within the ear, such as closure of the meatus. Sometimes these entotic noises are so loud that they can be distinctly heard by others, and they are then termed "objectively perceivable." Among such sounds may be mentioned a cracking noise in the maxillary articulation, produced by traction of the muscles on the Eustachian tube.

Subjective auditory sensations are often very important symptoms: they are liable to exercise a marked influence on the health and spirits of the patient, and are often associated with other symptoms of aural disease. More or less deafness is the usual accompaniment, and its development sometimes precedes and sometimes follows that of the tinnitus. There is, however, no necessary correspondence between the intensities of the two symptoms; severe deafness may be associated with slight tinnitus,

and indeed may exist without any trace of the latter. Moreover, in some cases in which the two are associated, the deafness eventually becomes complete, while the tinnitus altogether ceases, and this result may be attributed to decided anæsthesia of the auditory nerve. If, in such a case, the hearing be improved by treatment, the tinnitus may return, and the trouble it causes may outweigh the relief in the other direction.

It is not always possible to decide whether the sounds are subjective or entotic. If they are audible to a bystander there is, of course, no doubt as to their origin. In like manner, if the sounds can be made to cease by compressing the carotid artery or jugular vein, they belong to the category of entotic noises. Sounds which are due to disorders of the tympanum are apt to vary in intensity and quality from time to time, the changes depending upon improvements or exacerbations of the aural disease. Sounds depending on the presence of foreign bodies—*e.g.*, plugs of cerumen—generally subside after removal of the latter, unless various changes have been set up, and which require some time for their disappearance. Subjective sensations, coming on suddenly, and of a decided character, depend for the most part upon some affection of the labyrinth, and especially of the cochlea, or upon some central lesion; they may, however, be due to sudden effusion into the tympanum. When the subjective sensations occur in persons presenting signs of nervous or mental disorder, they are presumably referable to some central affection of the auditory nerve.

It must be remembered that in some cases the noises are due to movements which the persons have acquired the habit of making, and which in the course of time occur almost involuntarily. Thus some children amuse themselves by producing noises in the throat by rapidly contracting the muscles of the soft palate. Adults have been known to fall into the same habit from practising movements for the relief of disagreeable sensations in the upper part of the pharynx; and when this habit has been acquired, the muscles are apt to contract spontaneously. The diagnosis is not difficult, inasmuch as the contractions and accompanying noises cease when the patient makes an effort for that purpose.

In some cases the patients state that the sounds they hear are those of human voices or of the cries of animals, and sometimes

words or sentences are declared to be distinctly perceived. Such a symptom is not uncommon in insane patients, but it also occurs in persons in good mental condition. Prof. Huxley relates that "in reading books written by persons with whom I am acquainted, I am sometimes tormented by hearing words pronounced in the exact way in which these persons would utter them, any trick or peculiarity of voice or gesture being also very accurately reproduced." He goes on to say that he supposes "that everyone must have been startled, at times, by the extreme distinctness with which his thoughts have embodied themselves in apparent voices." In some of these and similar cases there is a delusion of the senses; in others, a delusion of the judgment. These mistakes are sometimes made by deaf persons, who are free from tinnitus, but misinterpret various sounds. Decided auditory hallucinations are sometimes associated with various pathological conditions of the auditory apparatus, and subside when these are removed. Thus a plug of wax in the ear may be the real cause of subjective sensations, in which cries resembling those of a human being are heard, and which cease at once on the removal of the foreign body. That hallucinations, however, may depend upon irritation of the cortical centres is proved by the fact that they are sometimes present in persons who are totally deaf to all ordinary sounds.

In still rarer cases than those hitherto mentioned, the subjective sensations are those of tunes or melodies, and these must be classed among hallucinations. Hartmann mentions the case of a musically trained lady, under his care for nervous dulness of hearing in a very advanced stage, and who heard for a long time the most exquisite melodies, mostly well known to her. After a time they were confused together, so that utter discord was created.

Prognosis.—The prognosis in cases of subjective auditory sensations depends upon the cause and upon the condition of the patient and the auditory apparatus. If there be chronic adhesive catarrh, in all probability the sounds will not be influenced by any form of treatment. On the other hand, if the case be one of anæmia or neurasthenia, much good may often be effected by appropriate measures. Continuous noises, and sounds of a definite character, are more likely to be permanent than intermittent and indefinite sounds. When, with obvious disease of the tympanum, sounds previously intermittent become continuous, there is reason

to believe that the aural complaint has increased in severity. As a general rule, the prognosis is unfavourable in proportion to the intensity of the sensations, and the time during which they have continued.

Treatment.—Our first effort should be to discover and to remove the cause; the patient should be carefully examined in order to detect any existing affection of the ear, nose or throat, any disorder of the nervous system, or any constitutional disease. Inquiries should be made into his habits of life, diet, use of alcohol, quantity of sleep, and other circumstances calculated to affect the nervous system. After attending to all these subjects, various special means may be tried. Relief is often afforded by inflating the middle ear through the catheter, and thus reducing the intra-labyrinthine pressure. Equally good results are sometimes obtained by rarefying the air in the meatus with the aid of Siegel's speculum or Delstanche's *rarefacteur*. The effects, though often marked, usually subside more or less rapidly.

Some authorities, notably Politzer and Gruber, recommend the introduction of the vapour of chloroform or of ether into the tympanum through the catheter. Solutions of these drugs may also be tried—*e.g.*, a few drops of such mixtures as ether, two to four parts; glycerine eight to twelve parts; or chloroform and glycerine in similar proportions. The hydrochlorate of cocaine is another remedy of this character; five to ten drops of a 6 per cent. solution may be injected at intervals of three or four days. Amyl nitrite proves very useful in some cases; the patient should inhale the vapour of two or three drops, poured into a cone of blotting paper.

Local applications to the meatus and neighbourhood of the ear are sometimes tried, but seldom prove efficacious. Morphine, iodide of potassium, cocaine, and camphor are thus used, either in the form of ointment or in solution. The local application of sulphuric ether sometimes does good; it should be mixed with olive oil (5 to 15—25), and either instilled into the meatus or introduced on a pledget of cotton-wool. It causes a pleasant sensation in the ear, and often lessens the tinnitus. If the sensations are very troublesome at night and prevent sleep, the subcutaneous injection of morphine is likely to prove useful.

Remedies administered internally often do more good than external applications of any kind. The bromide of potassium is

one of the best remedies for subjective auditory sensations occurring in nervous, restless persons ; it should be given in full doses of from fifteen to thirty grains, and in some cases a combination of chloral with the bromide acts very satisfactorily, and much better than either drug alone. Hydrobromic acid will relieve noises of a pulsating character; and in a similar class of cases, and for nervous subjects, camphor is often useful. The tincture may be given internally in ordinary doses. For pulsating sounds, connected with or independent of heart disease, Politzer recommends the tinctures of digitalis and of strophanthus, and states that he has often witnessed good results from both these remedies.

Various tonic and anti-spasmodic remedies will, in some cases, relieve or even cure subjective auditory sensations. Strychnine is likely to be useful whenever there are symptoms of nervous debility; it may be used subcutaneously or internally. Iron is, of course, indicated for weakly and anæmic subjects; any of the usual preparations may be given, proper attention being at the same time paid to the state of the bowels. Quinine, if specially indicated by any complication, must be given with great care; it often aggravates aural sensations. When used it should be combined with hydrobromic acid. Valerian is recommended by some writers; Gruber has obtained very good results from arnica in nervous cases; he gives the tincture, in doses of from five to fifteen drops, several times daily.

In scrofulous and syphilitic subjects various combinations of iodine are likely to be serviceable; weakly patients are to be treated by long courses of the syrup of the iodide of iron, and when the disease is traceable to syphilis, the iodide of potassium should be given in full doses, and continued for several weeks. Iodine ointment may at the same time be applied to the mastoid process, and warm baths will aid the other remedies. Arsenic has been known to relieve auditory sensations, and the late Mr. Hinton strongly recommended the chloride of ammonium in doses of twenty grains, three times a day.

When there are signs of cerebral congestion purgatives are indicated, and salines are most likely to be useful. In the same class of cases it is sometimes advisable to apply leeches from time to time to the mastoid process, or to take a few ounces of blood by cupping at the back of the neck. Blisters (*see* page 315) are likely to be advantageous when the symptoms are chronic and

of a milder character. Great care should be paid to the diet, mode of living, etc. Rest and change of air often do good, and materially assist the action of the various remedies already mentioned.

Electricity is sometimes useful in cases of tinnitus aurium; the manner of application will be described in a succeeding chapter. Only very mild continuous currents should be employed, and the sittings should occupy from ten to twenty minutes on alternate days.

CHAPTER XLVI.

ELECTRICITY IN THE TREATMENT OF DISEASES OF
THE EAR.

Physiological Action of Galvanism upon the Auditory Nerve—Sounds Produced—Other Effects, as Pain, Giddiness, &c.—Brenner's Experiments—Duchenne's Method—Benedikt's Views—Value of Electricity in the Treatment of Aural Diseases—Weber-Liel's Method—Instruments used by Author.

THE galvanic current is useful in some forms of diseases of the ear; the faradic current is serviceable in a much smaller number of cases. The physiological action of galvanism upon the auditory nerve has been carefully studied by Brenner and Erb, and our present knowledge of this subject is mainly due to these observers. The results of their investigations may be thus briefly summarised:—When the negative pole is applied to the tragus, and the positive to any other part of the body, such as the opposite side of the neck or the back of the hand, a distinct sound is heard when the circuit is closed; this continues for some time and finally ceases. When the circuit is opened, whether by removing the electrode, or by breaking the metallic continuity, no sound is heard. When the positive pole is placed on the tragus, and the negative on the back of the hand, no sound is perceived when the circuit is closed, and the result is the same while the electrodes remain in position; but on opening the circuit a faint sound is heard. The subjective sensations consist of humming or buzzing sounds when the current is of slight force; but when the latter is increased a louder sound is heard. Some authorities state that the loudness of the sound is not influenced by the strength of the current; but that the

sound produced always corresponds with the resonance-note of the sound-conducting apparatus.

According to Brenner, the sound, whatever may be its character, is caused by the galvanic stimulus applied to the auditory nerve, and is not due to reflex action through the trigeminus. In opposition to this view is the fact that when the cutaneous sensibility is diminished, a stronger galvanic current is required to produce the auditory sensations; on the other hand, when there is cutaneous hyperæsthesia, the auditory nerve reacts more powerfully. It has been supposed that the sensation might be caused by contraction of the internal muscles of the ear, but Urbantschitsch found that after tenotomy of the stapedius muscle, the stapes being quite isolated, sounds were still produced when galvanism was applied.

In order to test the condition of the auditory nerve, the negative pole is placed on the tragus, and the positive on the back of the hand; a weak current is then used, say of three elements, and if there be no reaction when the circuit is closed, the number is increased till a sound is heard; the number used expresses the condition of the nerve. It sometimes happens that a sound is heard in the opposite ear; the latter is under the influence of the other electrode.

Other sensations, besides those of sound, are not infrequently produced by galvanism applied to the ear. In some cases there is severe pain, especially when a pointed electrode is used, and on this account a somewhat broad instrument should be chosen. The positive pole causes a dull, heavy pain, or feeling of weight in the ear; the negative gives rise to a sharp pricking sensation, which assumes a burning character in a short time. Another effect is contraction of some of the facial muscles, and especially of the orbicularis palpebrarum, zygomatici, corrugator supercilii, occipitalis, and sometimes of the ear-muscles, and of those of the lower jaw. These symptoms are most distinct when the negative pole is applied to the ear and the circuit closed. In some patients flashes of light appear before the eyes; in others giddiness becomes very troublesome. This latter symptom is most marked when the electrodes are applied to the sides of the head, at points opposite to each other; but is less severe when the electrodes are so arranged that the current is parallel to the long axis of the body. The giddiness is often accompanied by

vomiting and nausea, and may last for many hours. Other symptoms less frequently noticed are—swallowing movements when the circuit is opened and closed; a flow of saliva; cough; gustatory sensations; and tingling or itching along the side of the tongue.

Brenner's experiments on aural patients proved that the condition of the external and middle ear decidedly influences the galvanic reaction. When the external meatus is closed, galvanism applied to the tragus produces little or no effect; but when perforation of the membrane exists, the results are often very marked. In cases in which the reaction is but slight, and is produced with difficulty, the cause is ordinarily to be found in some obstacle to conduction, and not in any peculiar condition of the auditory nerve itself; the latter is, indeed, under such circumstances more often in a state of increased irritability. Simple hyperæsthesia is evinced by the longer continuance of the sensation and the ease with which it is produced; in marked cases it is sufficient to apply the electrode at some little distance from the tragus. Diminished galvanic irritability is shown by the rapid passing away of the sensations, as well as by the difficulty in producing them. Irritability of the nerve may exist in association with absolute deafness and loss of bone-conduction.

The induced current is sometimes used in cases of nervous deafness, and Duchenne's method is probably the best way of employing it. The patient's head is so placed that the external auditory meatus is perpendicular. A little tepid water is poured into the canal so as to fill about half of it, and a metallic wire is then introduced, care being taken not to touch the walls of the meatus or the membrana tympani. It is best to use a special rheophore, in which the wire is isolated by an ivory covering, and is prevented from touching the membrane. Having waited till the buzzing caused by the pressure of the water has subsided, the ear-rheophore is connected with one of the conductors of an induction apparatus, and the circuit is closed by placing another moist rheophore on the mastoid process, and connecting it with the second conductor. The current, thus applied, produces the sensation of a dry sound; a tickling in the tongue and at the bottom of the ear; a peculiar taste, and a luminous sensation on the side stimulated. The flow of saliva is sometimes increased;

but this change is always preceded by a feeling of dryness on the side of the tongue affected.

With regard to the effects of the induced current, Duchenne states that it causes contraction of the small muscles, movements of the chain of bones, vibration of the membrane of the fenestra ovalis, and consequent agitation of the fluid of the labyrinth. He obtained good results in cases of "hysterical" deafness, in deafness from quinine, and in deafness following continued fevers. In very sensitive persons, and especially when the tissues of the meatus and membrane are much injected, it is best not to pass an electrode into the canal, but to place it on the mastoid process, while the other one is applied over the malar bone, or in front of the ear.

According to Benedikt, sounds are much more readily produced by the electric current in diseased ears than when all the structures are normal. He also believes that acoustic sensations can be produced through the sympathetic nerve by reflex action, and he applies the current to the latter for therapeutical purposes. Schulz explains the action of the galvanic current in a different manner; he supposes that the peripheral twigs of the sensory nerves at the spot where the electrode is applied are rendered electrotonic. This condition is propagated to the central extremities of the nerves, and thence to the sensorium, which becomes conscious of the change in the electro-motor condition.

There is considerable difference of opinion as to the value of electricity in the treatment of diseases of the ear, and no definite rules can be laid down for its employment. It is sometimes useful as an adjunct to other remedies. Thus, galvanism applied to the tragus may restore bone-conduction, increase hearing-power, and relieve subjective sensations. It must, however, be confessed that the result is sometimes negative, and sometimes even prejudicial, inasmuch as the symptoms are aggravated by the treatment.

The method of applying electricity to the ear, proposed by Weber-Liel, yields good results in certain cases. He introduces the current through the Eustachian tube by means of a silver wire passed through a catheter. The galvanism thus acts upon the muscular structures of the tube, and possibly upon the tensor tympani and stapedius. No effect is produced upon the auditory nerve; but this method of application sometimes causes sub-

jective sensations to cease, and improves the hearing. The remedy is, of course, applied to the middle ear, and it may be useful in cases of atrophy, or degeneration of the muscular structures. Weber-Liel states that after the tubal muscles have been thus galvanised, air passes more readily through the catheter into the tympanum, and that Valsalva's method succeeds where before it failed. As, however, improvement of a similar character is not infrequently obtained by means of the catheter alone, this instrument should be used before electricity is resorted to, or both methods of treatment may be employed. From the therapeutic

FIG. 121.

THE AUTHOR'S AURAL ELECTRODE.

FIG. 122.

THE AUTHOR'S PHARYNGEAL ELECTRODE.

point of view it is immaterial to which cause an improvement is to be attributed.

The instruments which I generally use are shown at Fig. 121 and Fig. 122. The former is moistened in salt and water and then inserted into the meatus; and the latter is placed against the soft palate and then lifted upwards and outwards, so that its extremity may be near the pharyngeal termination of the Eustachian tube. This method is less troublesome and is less disagreeable to the patient than most of the plans mentioned, and is, moreover, equally efficacious. I have by this means obtained results similar to those mentioned by Weber-Liel.

CHAPTER XLVII.

DEAF-MUTISM.

Classification of Deaf-Mutes—Statistics—Deaf and Dumb in Great Britain and other Countries—Influence of Sex—Causes of Congenital Deaf-Mutism—Hereditary Transmission and Consanguineous Marriages—Pathological Appearances—Acquired Deaf-Mutism—Age of the Sufferers—Additional Symptoms and Consequences—Diagnosis—Prognosis and Treatment—Importance of Early Instruction.

CHILDREN learn to speak by hearing words pronounced by others and endeavouring to reproduce the sounds. A child destitute of the sense of hearing remains dumb, and those children who lose their hearing-power during infancy or before they have thoroughly learnt to speak, lose the faculty they may have acquired. There are, therefore, three classes of deaf-mutes:—

1. Those who are congenitally deaf.
2. Those who have become deaf after birth and before acquiring speech.
3. Those who have become deaf after having acquired the faculty of speech to a greater or less extent.

Statistics carefully collected by Dr. A. Hartmann,* of Berlin, show that, taking countries with an aggregate population of 246,000,000, there is an average proportion of 7·77 deaf-mutes in every 10,000 individuals. The proportion is lowest in the Netherlands, being 3·35; and highest in Switzerland, viz., 24·5 in every 10,000 inhabitants. In Great Britain the proportion is 5·57.† The statistics prove that deaf-mutism is far more common in mountainous districts than in level countries, and that in Europe it is remarkably frequent in the Alps and Pyrenees.

* *Taubstummheit und Taubstummenbildung*, Stuttgart, 1880.

† *Report of the Royal Commission on the Blind, Deaf, and Dumb*.

With regard to the deaf and dumb in the United Kingdom, the census tables show that their proportions to the general population have decreased during the last two decades (1 in every 1,484 in 1861, and 1 in every 1,794 in 1881). The Commissioners, however, point out that the census in England and Wales is very incomplete; it is difficult to obtain an accurate return of the deaf in their early years, as the parents are naturally unwilling to return a child as deaf and dumb till he is at the least five years old; the deafness, therefore, of children under that age cannot be accurately known, and is probably understated. The statistical inquiries in Ireland are more complete and accurate. In the United States the proportion of deaf-mutes is considered to be 1 in 1,800.

Influence of Sex.—In all countries from which trustworthy statistics can be obtained, deaf-mutism is found to be more frequent among males than among females, and this preponderance of the male sex obtains in both congenital and acquired deaf-mutism. Dr. Hartmann states that in Prussia in 1871 the proportion of males to females was 100 to 103·4; but the proportion of deaf-mutes was 85 females to 100 males. With regard to the frequency of congenital as compared with acquired deaf-mutism, it would appear that the latter class is somewhat more numerous than the former.

The **Main Causes of Congenital Deaf-Mutism** are hereditary transmission and consanguineous marriages. Of 2,262 congenital deaf-mutes, recorded by Mr. Graham Bell, more than one-half, or 54·5 per cent., had other members of their families deaf and dumb. Direct transmission of deaf-mutism is not very frequently observed. Among fifty-one deaf and dumb children in the Asylum, Old Kent Road, examined by Dr. Francis Warner, who has kindly placed his report at my disposal, thirty-two were congenitally deaf. Of the remaining nineteen, the deafness in five was due to "fits or brain-disease;" for the rest, the causes assigned were: measles, whooping-cough, scarlet fever, sunstroke, falls, and dentition. In three cases, the children were the offspring of first cousins; and in five, the deafness (with the consequent mutism) was acquired between the ages of three and six years. In Dr. Hartmann's statistics there are 276 couples, of whom one—either the husband or the wife—was a deaf-mute. These had 419 children with perfect senses, and only eleven deaf

and dumb children. Mr. Bell states that with one parent who is a congenitally deaf-mute, one-tenth of the children are deaf; and with both parents, congenitally deaf-mutes, about one-third are born deaf.

Consanguineous marriages play an important part in respect to deaf-mutism; but the statistics are not kept with sufficient accuracy to admit of more than general conclusions. The frequency of the defect in Alpine districts is traceable, in a measure, to the marriages of relations, and according to good authorities in New York and elsewhere, one out of every ten congenitally deaf-mutes is the offspring of consanguineous parents. There is abundant proof that a marriage of this character occurring in a family in which there is already deafness, results in a marked tendency to the defect in the offspring; the family peculiarities, whatever they may be, are thus reinforced. Dr. Hartmann records a very remarkable example of the influence of consanguineous marriages. "A deaf-mute child had other five deaf-mute brothers and sisters; and, although no case of deaf-mutism had occurred in former generations of the family, it was found that the parents, as well as the grand-parents and great-grand-parents, had been cousins. Thus the pernicious effect of consanguinity did not show itself until after the third marriage."

Pathological Appearances.—Various pathological changes have been found in cases of congenital deafness, the most prominent being evidences of intra-uterine meningitis and of inflammatory processes in the middle ear and labyrinth; arrested development of parts of the ear and of the auditory nerve and centres; bilateral atresia of the external meatus and tympanum, and rachitic processes in the labyrinth. Syphilis and scrofula would appear to account for a small proportion of cases of congenital deafness. In two cases described by Moos,* there was a remarkable flattening of the occipital region and considerable atrophy of the posterior cerebral lobes. In one of these, a boy aged four, there was also distinct paresis of the right arm and leg, and marked congenital talipes on both sides.

The petrous bones from six deaf-mutes have been examined by Drs. Moos and Steinbrügge.† In two cases no nerves were discoverable in the lamina spiralis ossea in the first turns of the

* *Archives of Otolaryngology*, vol. xi. p. 307.

† *Ibid.*, vol. xi. pp. 236, 299; vol. xii. p. 304; vol. xiii. p. 247; vol. xv. p. 123.

cochlea; the ganglion cells within Rosenthal's canals were stunted or atrophied; the organs of Corti were imperfectly developed and in a state of fatty degeneration; the ductus cochlearis and scala vestibuli were filled up with caseous masses. In one case, the labyrinth was altogether absent on both sides, and the auditory nerves were for the most part atrophied. In another case, there were connective-tissue adhesions in the scala tympani, defects in Corti's organ, and of the nerves and ganglion cells in the first and second turns of the cochlea. The osseous parts of the ear presented various changes, some of a hyperplastic, others of a destructive character.

Acquired Deaf-Mutism is caused by various changes in the organ of hearing, which in their turn result from affections of the central nervous system, of the labyrinth, and the sound-conducting apparatus. Cerebro-spinal meningitis, inflammation of the labyrinth, scarlatina, diphtheria, typhoid fever, measles, acute hydrocephalus, syphilis, and mumps, are the diseases to which the majority of cases belonging to this class are traceable. The lesions found in the ear are: the remains of suppurative inflammation in the tympanum; exfoliation of the ossicles; caries and necrosis of the labyrinth; bands of connective tissue preventing movements of the ossicular chain; adhesions of the ossicles to the walls of the cavity; destructive changes and osseous formations in the labyrinth; inflammatory deposits in the meninges involving the auditory nerves on both sides, and in the floor of the fourth ventricle.

The **Age** of the patients at the time of becoming deaf is a point of much importance. Wilde's statistics of 503 cases show that 120 became deaf in the first two years; 109 in the third and fourth; 76 in the fourth; 38 in the fifth; 36, 32, and 21 in the sixth, seventh, and eighth years respectively; 11 and 15 in the ninth and tenth; 33 between the tenth and fifteenth, and 12 after the latter year.

In these cases of congenital and acquired deaf-mutism, the dumbness is, of course, the result of the defective hearing. The influence of hearing upon speech is shown by the alterations in the voice among deaf persons in general: it becomes harsh, loud, and inflexible. These features are especially marked in deaf-mutes. When the deafness has been acquired in early childhood there is no longer any great inducement to speak, and with loss

of practice the power disappears; the voice becomes harsher and less intelligible, and in the absence of proper care and attention, dumbness is superadded to the loss of hearing. The want of exercise of the lungs and throat is found to result in imperfect development of the thoracic muscles and flattening of the chest. Hence the deaf and dumb are predisposed to lung-disease and to chilblains. In other respects, however, the sufferers are well developed, and many of them exhibit a high degree of mental power. As a general rule they are capricious, obstinate, ill-disposed towards other children, and shy, though inquisitive; capacity for imitation is often a marked feature.

Diagnosis. — In early life it may be difficult to ascertain whether and to what extent the child is deaf. Absolute deafness is less frequent than loss of perception of speech. In order to test the condition of the hearing, the child's attention should be excited, by toys or other means, while sounds of various intensities are produced (by clapping the hands, ringing a bell, or whistling) behind his back. Perception will be demonstrated by the child's turning his head towards the source of the sound. It must be remembered that loud noises are always accompanied by more or less vibration of the walls and floor of the room, which can be *felt* by a person whose attention is thus attracted, although totally deaf. The perception of sound through the bones of the head is tested in the ordinary way by placing tuning-forks of varying pitch on the vertex or mastoid process. A child more than twelve months old will smile if he hears the sound. Low notes are usually heard better than high ones. If sound be perceived a further examination will determine whether speech of any kind is heard. Some deaf-mutes hear to such an extent that they are able to repeat vowel-sounds, especially *a*, *o*, and *u*, uttered close to the ear. Others are able to repeat consonants and even a few words. Dr. Hartmann's statistics show that 60·2 per cent. of the total number of deaf-mutes are entirely devoid of the sense of hearing. A fourth part are able to perceive sounds: 11·3 hear vowels and 4·3 hear words. "The chief point of distinction with regard to the hearing-power of those born deaf and those who have acquired deafness, is that of the latter the number of the totally deaf is far larger (68·4 per cent.) than that of the former (42·2 per cent)."

Prognosis and Treatment.—In a few congenital cases, the deaf-

ness not being absolute and due to changes in the middle ear, some improvement has been observed to take place in the course of time. Dr. Hartmann mentions the case of a girl, totally deaf since birth, in whom hearing was established spontaneously to such an extent that she was able to repeat words spoken close to the ear. Politzer also records a few similar cases. Practically, however, any child unable to hear ordinary voice at a distance of two or three feet from the ear is unable to acquire language by the ordinary method. In acquired deaf-mutism, resulting from destructive processes in the middle ear, or from disease of the brain or its membranes, no improvement can be expected. Attention should, however, be paid to the condition of the ears, and suitable treatment should be adopted for any purulent discharge, or chronic inflammatory processes. When the case is one of a child who has learnt in some measure to speak, every effort should be made to prevent loss of the faculty already possessed. To this end the child should be encouraged to speak, and made to read aloud regularly and distinctly. Too much stress cannot be laid on the importance of proper treatment of aural disease in early life. In not a few cases of deaf-mutism, the deafness and its result are due to neglect.

At the present day there are three systems whereby deaf-mutes are educated: these are (1) the sign and manual, (2) the pure oral, and (3) these two combined. The object of each is to enable the sufferers to converse with their fellow creatures, to acquire knowledge, and to earn their own livelihood.

The differences between the three systems are thus tersely stated in the Commissioners' Report:—The sign and manual system specially trains the deaf to communicate and associate with their fellow deaf.

The pure oral system specially trains the deaf to communicate and associate with the hearing and speaking world.

The combined system, as its name implies, endeavours to combine the two former, the result being that with few exceptions signs and the manual alphabet prevail, and cause the pupils to relinquish the use of speech, and to seek the society of deaf and dumb people.

The arguments which the advocates of the different systems advance to establish their case may be summed up in a few words. Starting with the assumption that a written language is common

to all, the advocates of the first system claim that the sign-language is the natural way in which the deaf and dumb express themselves. Those who maintain the superiority of the oral system allege that their aim is to make the deaf and dumb conversant with ordinary language and able to express themselves by speech. The advocates of the third plan assert that it is best to give the deaf and dumb the advantages of both systems.*

It would seem that the sign and manual system has nearly died out in the United Kingdom. The Commissioners recommend that every child who is deaf should have full opportunity of being educated on the pure oral system. The first step in this system is to teach the deaf-mute to learn what another person is saying to him by noticing the movement of the lips. This necessitates very careful articulation by the teacher, and very close observation by the deaf-mute, the perfection and speed with which it is learnt varying with the skill and intelligence of the teacher and pupil. The next step, to teach the dumb to articulate, involves more difficulty. The teacher writes a letter on a board, and then pronounces it. The pupil imitates the motion of the lips, and emits a sound which by practice comes to resemble that uttered by the teacher. Various combinations of letters are next taken, and the same process is adopted until words are learnt. When the pronunciation cannot be learnt from the movements of the lips, the teacher places the pupil's hand on his larynx while he utters the sound. These lessons require constant practice, under trained teachers, for six or eight years, in which period a large proportion of the children become enabled to make themselves well understood by this system of speech and to carry on long conversations. The result, in the main, depends on their intellectual capacity, upon the amount of hearing-power which may yet remain, and the manner and duration of the training. Dr. Hartmann states that about one-third can be trained with such success that they can converse with everybody. In a similar proportion, the speech is somewhat less distinct, so that it is not clearly understood by those unaccustomed to it. In the remaining third, the utterances are almost unintelligible.

Children should come under instruction as early as possible, before the vocal organs have lost power from disuse, and while

* *Report of the Royal Commission*, p. 62.

still supple enough to produce sounds free from that harshness which usually characterises their later development. Even if the results of the oral system prove very imperfect in any given case, yet a little power of speech enables the pupil to communicate with the rest of the world on terms more nearly equal than those afforded by the language of signs or the finger alphabet.

CHAPTER XLVIII.

ARTIFICIAL AIDS TO HEARING.

Ear-Trumpets and Tubes—Maloney's Otophone—Poltzer's Instruments—
Rhodes' Audiphone—Paladino's "Fonifero"—Desirability of Early
Use of Ear-Trumpet.

IN many cases of impaired hearing conversation is facilitated by the use of ear-trumpets and tubes, which collect vibrations and convey them to the auditory canal. Instruments of this kind are found to be most serviceable when the deafness is due to the results of chronic catarrhal processes in the middle ear, the membrana tympani and ossicles remaining in position. When the deafness is due to disease of the labyrinth, little if any benefit can be experienced from the use of such appliances.

An ordinary ear-trumpet consists of a conical tube with a wide mouth for the admission of vibrations; the other extremity is much narrowed and is fitted with an ear-piece, often placed at a right angle with the rest of the tube. The trumpet is made of metal, vulcanite, or horn; the large extremity is often cut off obliquely so as to increase the size of the opening. By the aid of such an instrument many deaf persons are enabled to hear the voice of a speaker at some distance. For conversation, when the speakers are near, a flexible tube is the most convenient appliance. This has a funnel-shaped mouth-piece at one extremity, and an olive-shaped ear-piece at the other. The mouth-piece is made of vulcanite or horn, and is from two to three inches in diameter; the tube is about three feet in length. When used the patient places the ear-piece in his meatus, and the speaker, holding the mouth-piece near his lips, pronounces the words clearly, but not with excessive loudness. Some persons hear

best when the voice of the speaker is scarcely more than a whisper. When tinnitus is present great care is necessary, as it is sometimes much aggravated by the use of the hearing-tube. When the external meatus is very irritable and will not admit of the introduction of the ear-piece, the latter should be shaped like a shell or small cup, so as to cover the auricle.

An instrument, termed an "otophone," has been invented by Mr. Maloney, of Washington, and is declared by Dr. C. H. Burnett* to be the most useful ear-trumpet presented to his notice. It succeeds where other forms fail. It does not fit into the meatus; the aural end is supplied with a disk, which is held to the ear, this arrangement preventing irritation of the canal. Besides the trumpet, Mr. Maloney has devised a disk, which "is fastened to the auricle by a locking device, kept in place by the tragus, antitragus, and concha." This instrument appears to act by enlarging the space between the helix and tragus.

A small instrument for insertion into the meatus has been constructed by Politzer,† who claims that it improves the hearing in a considerable number of deaf persons. Its principle is based upon the fact that a sound acting upon the ear is heard more loudly when the surface of the tragus is enlarged backwards by the application of a small firm plate. When the instrument is in position, an increased number of vibrations are conducted to the auditory meatus.

The instrument is shaped like a hunting-horn; its narrower inner extremity is inserted into the auditory meatus, the outer larger part lies on the auricle, with the opening directed backwards towards the concha. Three sizes are sufficient for all cases, and vulcanite, coloured red, is the best material. The inner portion of the tube is removed to the extent of about one-third of the circumference. The instrument is passed into the meatus with the wider opening pointing upwards; and then turned so that the same opening looks backwards towards the concha. According to Politzer's experiments, when this instrument is worn, the hearing-distance is, on an average, doubled; though in about one-fourth of the cases no change results, and in some the hearing-distance is lessened.

Another instrument, devised by the same authority, has for its

* *Archives of Otology*, vol. xvi. p. 177.

† *Lehrbuch der Ohrenheilkunde*, 2 Aufl. S. 554.

object the communication of the vibrations of the auricular cartilage to the membrana tympani by means of an elastic conductor. This consists of a piece of rubber-tubing, 4—5cm. (about 2 inches) long and 2mm. (about $\frac{1}{12}$ inch) thick, with its inner end cut obliquely, and resting against the membrana tympani. The outer end is curved, so as to fit into the concha: the effect is increased by passing it through a little round disk of vulcanite, which lies in the hollow.

An instrument termed the "audiphone," invented by Mr. Rhodes, of Chicago, is designed to conduct sounds through the bones of the head, and thereby improve the hearing. It consists of a flexible plate of vulcanite or well-lacquered pasteboard, 10 to 12 inches long and rather less in breadth, and somewhat resembling a fan in shape. There is a handle at the lower border, while the opposite edge has a small metal plate which is applied to the teeth or zygoma. In one modification, the audiphone is constructed of several pieces, jointed together, and made to assume the necessary curve by means of a silken cord. The instrument is applied to the upper incisor teeth, with its convexity directed forwards; sound-waves impinging upon it are conducted to the bones of the head and the labyrinth. The audiphone is easily held, and is less conspicuous than an ear-trumpet: it is, however, less useful than the latter in the majority of cases.

Paladino's instrument, the "fonifero," is designed to conduct sounds directly from the larynx of the speaker to the teeth or external meatus of the hearer. It consists of a straight rod 18 to 25 inches in length, having at one end a thin semi-circular metallic band and at the other a small metal plate. The former is applied to the skin over the larynx.

In some cases the best conversation tube is found to be a single piece of india-rubber tubing with a hollow piece of vulcanite at one end to fit into the meatus, and a small cup-shaped piece of vulcanite at the other end to collect the sound. If the meatus is irritable, a disk about one and a-half inches in diameter, and perforated in its centre, may be fixed on the aural end of the tube in the place of the vulcanite plug.

With regard to all these instruments, it would seem that the hearing-trumpets are more generally useful than any other contrivance. They must always be tested by the patient; it is impossible to predict the degree of assistance that will accrue

from any one of them. An instrument should be selected which improves the hearing as much as possible, without irritating the meatus or causing any unpleasant sensations. Patients are generally loth to have recourse to these artificial aids until the deafness has become very serious. They should, however, be advised not to wait until this stage has been reached, but to use a hearing-tube or trumpet as soon as ordinary conversation is not heard so as to be clearly understood.

CHAPTER XLIX.

LIFE-ASSURANCE AND DISEASES OF THE EAR—
SIMULATED DEAFNESS.

Diseases of the Ear Tending to Imperil or Shorten Life—Diseases of the Ear which may be Regarded as Unimportant with Reference to Life-Assurance—Decision in Cases of Suppurative Inflammation—Simulated Deafness—Means of Testing—Military Regulations in Austria and Prussia with Regard to Recruits Suffering from Aural Diseases.

CHRONIC suppuration of the middle ear is a possible source of danger to life; and though in the large majority of cases it is free from fatal consequences, yet it seldom exists for any length of time without impairing the health of the individual. It has been shown in previous chapters that cerebral abscess, pyæmia, caries and necrosis of the temporal bone, suppuration within the mastoid cells, and facial paralysis are some of the results of chronic suppuration in the tympanum; and on this account persons suffering from this ailment require to be very minutely examined when they present themselves for life-assurance. In all serious diseases of the ear, and particularly in that one just mentioned, the question for the medical examiner to determine is whether the life should be accepted or not, and if accepted, what addition should be made to the premiums.

It is not too much to say that cases of chronic suppurative inflammation of the tympanum should be unhesitatingly rejected if there be a large perforation in the membrane, with granulations or polypi in the cavity. The decision becomes, if possible, more easy, if there be at the same time evidences of caries of the

osseous walls, fistulous openings in the mastoid process, or signs of facial paralysis. The presence of exostoses in the meatus is to be considered as a decidedly unfavourable addition to chronic tympanic suppuration. As a matter of course any ulceration, presumably of a malignant character, affecting the auricle or meatus, will disqualify the applicant, and the same decision will be required when there is any history of attacks of giddiness and disorders of co-ordination in connection with some aural disease.

Certain other conditions of the ear, inasmuch as they do not affect the general health and are not prone to be attended by dangerous complications, are of no special importance as regards life-assurance. This category includes the various cutaneous affections of the auricle and meatus—*e.g.*, eczema and furuncles, and also exostoses in the canal, when unaccompanied by suppurative inflammation beyond. Chronic adhesive processes in the middle ear have no bearing upon the question of life-assurance, and persons with cicatrices in the tympanic membrane, whether adherent or not to the inner wall, may so far be regarded as “good lives.”

When a dry perforation remains, but no discharge is visible, some consideration will be required before deciding as to the eligibility of the applicant. The danger lies in a recurrence of the tympanic affection, and the risk will be considerably heightened if there be evidences of pharyngeal catarrh. Under such circumstances some addition should be made to the premium, the amount depending upon the general health and circumstances of the patient, the condition of the tympanum, so far as can be ascertained, and the state of the throat and chest.

In the case of recent suppurative inflammation within the tympanum, the decision may be postponed so as to allow time for suitable treatment to be adopted. If after the lapse of two or three months the inflammation subside, the discharge cease and the perforation become dry, the life may be accepted, subject to the conditions stated above. Should, however, the discharge continue and granulations form, it will be advisable in the interests of the office to decline to accept the proposal. All cases with discharge from the ear, or any history thereof, should be very carefully examined. The duration of life in such persons

is below the average. Some, indeed, die at a comparatively early age either from the direct consequences of the local affection, or from some wasting disease. It must be borne in mind that many years may elapse between the first appearance of a discharge from the ear and its fatal consequences in the brain.

SIMULATED DEAFNESS.

Dulness of hearing and complete deafness are not infrequently simulated in countries in which the inhabitants are liable to compulsory military service. The defect is sometimes pretended to exist under other circumstances, *e.g.*, when damages are claimed from a railway company for injuries alleged to have been sustained in a collision, etc.

In all cases of suspected simulation of deafness, the history and account given by the patient should be carefully noted down. The ears should next be examined, and the condition of the meatus, membrana tympani, and Eustachian tube on both sides accurately determined. Dulness of hearing is more frequently simulated than absolute deafness; and in some cases a pre-existing defect is exaggerated, and alleged to disqualify the patient from following his occupation.

For unilateral deafness, supposed to be simulated, the following tests should be applied:—

A plug of cotton-wool is inserted into the meatus of the normal ear and a vibrating tuning-fork is then placed on the vertex. An impostor will probably assert that he does not hear the sound at all, whereas perception must be decidedly increased in the occluded ear. He may, on the other hand, admit that he hears the sound, though very faintly, on the deaf side. A plug of cotton-wool should now be placed in that ear; the sound ought to be strengthened, and the assertion that it is no longer heard will be proof of the imposition.

The watch and speech may next be used as tests, and the following plan will serve to detect imposition:—The eyes are covered with a bandage, and the hearing distance for the sound ear is carefully determined. A plug of cotton-wool is then inserted into this ear, but not closely packed. When tested as before by means of the watch and speech, an impostor will

probably assert that he hears nothing, whereas the insertion of cotton-wool into the meatus affects but slightly the hearing-distance of a normal ear for speech. Words uttered with a moderate degree of loudness can still be heard at a distance of several yards.

This test may be modified as follows:—The examiner explains that he wishes to introduce an india-rubber plug into the sound ear; but he uses a piece of india-rubber tubing, which fits the meatus accurately, or a plug furnished with a stopper, which is withdrawn after insertion. Little, if any difference will thus be effected in the hearing-power; but an impostor is likely to assert that his hearing is greatly impaired, or perhaps quite abolished.

The voice may also be utilised as a test in this way: the distance is ascertained at which spoken words can be clearly heard. The person's eyes are then bandaged, and the examiner retires to a greater distance, and utters words with the same degree of intensity. He then tests the hearing at various distances, some within and others beyond the normal distance. An impostor will get confused, and will probably assert that he fails to hear words uttered close to his ear, while those spoken at a much greater distance are admitted to be audible. There is yet another plan: the examiner, remaining in the same spot, repeats a word several times, gradually lowering his voice.

A method devised by Teuber* is very efficacious, but requires a special form of apparatus. The wall of a room is perforated by two metallic tubes, each of which is prolonged by a piece of india-rubber tubing. The latter terminates in an ear-piece for each meatus. Each india-rubber tube has a lateral branch, which is inserted into the meatus of an assistant. The examiner, who is out of sight, speaks first into one and then into the other tube: the words or sentences are of course heard by one or other assistant. If he makes rapid changes from one tube to the other, an impostor will soon get confused, and will fail to distinguish words spoken in one ear from those spoken in the other. When told to repeat what he has heard, he will prove that the ear which he declares to be deaf is capable of discharging its functions.

There is another and a more simple method, based on the same

* *Berlin. Klin. Woch.*, 1869, Nr. 9.

principle. A tube is inserted into each ear; the examiner speaks through one, and his assistant through the other at the same time. In a genuine case the patient will repeat only what has been spoken into the normal ear; an impostor will become confused, and will repeat words heard on the side on which he asserts that he is deaf.

A binaural stethoscope may be utilised for detecting feigned unilateral deafness. In a case in which it was tried the patient asserted that he was deaf on the left side. A tightly-fitting wooden plug was inserted into the right caoutchouc tube, and both elastic tubes were placed in the metal ones. Testing the instrument on himself, the examiner found that speech was not heard by the right ear. When the patient was thus tested, he repeated without hesitation words spoken into the funnel-shaped end of the instrument, which served as the mouth-piece. The tube containing the plug was then withdrawn from the right meatus, which was firmly closed by pressure on the tragus. On again speaking into the stethoscope, which was still connected with the left ear, the patient positively asserted that he heard nothing. He was conscious that the tube through which he had (as he supposed) before heard was no longer connected with the right ear.

For the detection of simulated bilateral deafness a bandage should be placed over the eyes, and each ear tested separately by speech and the acoumeter. The patient's statements are carefully noted with a view to discover contradictions. For the detection of simulated total deafness, the person must be seen when asleep, and the amount of noise required to rouse him should then be noticed. If placed under chloroform, so as to become only partially insensible, an impostor may answer questions put to him, or show by some remark that he hears the conversation that is going on around him. It has been suggested that during the ordinary examination, a third person should make some disparaging or insulting observations with reference to the suspected impostor, while the examiner notices whether any effect is produced upon the features of the latter. Another suggestion of a similar character is that the examiner should tell the person that he may go, that he is unfit for work, etc. Such plans, however, would fail to detect a clever impostor, who would be quite prepared for any such attempts to throw him off his guard.

AUSTRIAN AND PRUSSIAN REGULATIONS WITH REGARD TO
THE HEARING OF RECRUITS.

The following regulations are in force in Austria and Prussia with regard to the fitness for service of recruits with any aural affection.

In Austria the following conditions do not constitute unfitness for service :—

(a) Reduction of hearing-power of both ears to a distance of 8 metres (26 feet). Clearly-uttered whispers, by a person of normal hearing, must be heard, so that the words can be repeated, at a distance of 2 metres ($6\frac{1}{2}$ feet), in a moderately still and quiet place.

(b) Reduction of hearing-power in one ear to a distance of 4 metres (13 feet), the hearing on the other side being normal.

(c) Partial loss of one auricle, malformations, and non-malignant growths of the external ear, with hearing-power as laid down under *a* and *b*.

(d) Congenital or acquired stenoses of the external meatus. the morbid process which was the cause thereof having come to a standstill, and the hearing-distance being not less than that described above.

(e) With a hearing-distance as above, the following affections of the external and middle ear and their consequences do not, *per se*, cause unfitness : plugs of cerumen, exostoses, constrictions, cicatrices, calcareous deposits, and retractions of the membrana tympani ; all forms of simple catarrhal inflammation, together with any resulting adhesive processes.

The following conditions render a man fit only for sanitary duties, care of the sick, and charge of clothing :—

(a) Deafness on both sides, with a hearing-distance up to 4 metres (13 feet).

(b) Deafness on one side, with a hearing-distance up to 2 metres ($6\frac{1}{2}$ feet), and perfect hearing on the other.

(c) Partial loss of one auricle, malformations, and non-malignant growths of the external ear, with the hearing-distance as above.

(d) Congenital or acquired stenoses of the meatus, with no signs of active disease, the hearing-distance being as above.

(e) Affections of the external and middle ear and their consequences, not *per se* causing unfitness, with a hearing-distance as above.

The following conditions unfit for active service, in some cases, after repeated testing; in others, at once and as a matter of course:—

(a) Deafness on both sides with a hearing-distance under 4 metres (13 feet).

(b) Deafness on one side, with a hearing-distance under 2 metres ($6\frac{1}{2}$ feet).

(c) Chronic perforation of the membrana tympani.

(d) All forms of chronic suppurative inflammation in the middle ear, with their complications.

(e) Loss of one auricle.

(f) Congenital or acquired total closure of the external meatus, even if unilateral.

For service in the Landsturm a man is still fit who has—

(a) Loss of one auricle.

(b) Chronic perforation of the membrane, with hearing-distance of about 2 metres ($6\frac{1}{2}$ feet).

The following conditions disqualify a man for active service, but not for mechanical work connected with warlike operations:—

(a) Deafness on both sides, with a hearing-distance below 4 metres (13 feet), but such as does not unfit for ordinary work.

(b) Congenital or acquired total closure of the external meatus on one side.

(c) A permanent opening in the membrane, the defect not preventing ordinary employment.

(d) All forms of chronic suppurative inflammation in the middle ear, with their complications, so long as they do not hinder ordinary work.

Congenital or acquired total closure of the meatus on both sides constitutes a complete disqualification.

In Prussia, temporary unfitness is caused by inflammation of the meatus.

Unfitness for active service is caused by the following conditions, when of a permanent character:—

(a) Chronic impairment of hearing, to a moderate extent, in both ears.

(b) Unilateral deafness, with no signs of active disease.

Permanent unfitness is caused by :—

(a) Absence of one auricle.

(b) Deafness or incurable severe impairment of hearing on both sides.

(c) Permanent perforation of the membrane and other incurable diseases of the ear, of a serious character.
