The operation of couching was once supposed to consist altogether in removing the opaque lens out of the axis of vision, by means of a needle, constructed for the purpose; but, it is well known to be frequently effectual on another principle, even when the nature and consistence of the cataract do not admit of the depression of the opaque body. In short, experience fully proves that the diseased lens, when broken and disturbed with the needle, and especially when freely exposed to the contact of the aqueous humour by a proper laceration of its capsule, is gradually dissolved and removed by the action of the absorbents.

However, when a surgeon speaks of *depression*, he always means the operation of pushing the cataract nearly perpendicularly, and to a sufficient depth below the pupil into the vitreous humour, so as to prevent the opaque substance from being an impediment to vision. Writers of the highest reputation and greatest experience differ so widely about the merits of this operation, that, I think it fair to conclude, that, on each side, strong prejudices and exaggerations have been suffered to enter the question. In general, it will be observed, that oculists, and others, who seek for a name in this branch of surgery, decry the operation of depression; and, if it were designed to make the use of the needle an exclusive practice, then I believe the results of modern experience would compel every impartial surgeon to enter a protest against the decision. In this respect, the doctrines of Pott, Callisen, Hey, and Scarpa, are undoubtedly wrong, though their sentiments are blended with many valuable

and important truths. Beer, who is by no means a great advocate for depression, admits its utility in particular cases. It is easily comprehensible, says he, that in this way, a firm and large cataract, either cannot be removed without injuring the retina, and the attachment of the corpus ciliare to the vitreous humour, or not far enough to prevent the opaque body from rising again at the first opportunity. Hence, the former complaints about the frequent return of the cataract, and other ill consequences, unappeasable vomiting, suddenly produced amaurosis, and severe inflammation, &c. But, while Beer acknowledges the frequency of these ill effects of depression, he condemns the universal rejection of it, attempted at the present day, and the unlimited substitution for it of *reclination*, which consists in applying the needle in a certain manner to the anterior surface of the cataract, and depressing the opaque body into the vitreous humour, in such a way, that the front surface of the cataract is now the upper one, its back surface the lower one, its upper edge backwards, and its lower edge forwards; a change, which Beer says, cannot be made without an extensive destruction of the cells of the vitreous humour. Hence, with few exceptions, this author thinks the common mode of depression should be preferred. (*Lehre von den Augenkr. B. 2, p. 352.*) And, in this sentiment, he is joined by Mr. Travers, who remarks, that the real objection to couching is the breaking up of the fine texture of the globe of the eye, by the forcible depression of the lens. "Whether it be depressed edgeways or breadthways, makes no difference in the result; it must still occupy a breach in the cells of the vitreous humour, and must derange and disorder that delicate texture, and those connected with it. A slow insidious inflammation marked by a gradual development of the symptoms of disorganization, viz. congestion of vessels, turbid humours, flaccid tunics, and palsied iris, is too often the consequence. The sight, instead of improving, when the immediate effects of the injury are passed away, remains habitually weak and dim, or declines and fades altogether. The advocates for *reclination* seem to forget, that the principle, which is the same in both operations, is the real ground of objection. As to the position of the lens, I suspect less mischief is done by the old method of depression, as less force is required to break a space for the vertical, than the horizontal lens, provided the depression be carried to no greater extent, than is necessary to clear the inferior border of the pupil." (*Synopsis of the Diseases of the Eye, p. 318.*)

Beer divides both the operations of couching and *reclination* into three stages: the first is that in which the needle is introduced into the eye; the second that, in which it is passed into the posterior chamber and placed across the anterior surface of the cataract; the third is that, in which the operator accomplishes the act of depression, or *reclination*.

There are two couching needles, which now seem to be generally preferred; namely, that which was used by the late Mr. Hey; and that recommended by Scarpa.

The length of Mr. Hey's needle is somewhat less than an inch. It would be sufficiently long if it did not exceed seven-eighths of an inch. It is round, except near the point, where it is made flat by grinding two opposite sides. The flat part is ground gradually thinner to the extremity of the needle, which is semi-circular, and ought to be made as sharp as a lancet. The flat part extends in length, about an eighth of an inch, and its sides are parallel. From the part where the needle ceases to be flat, its diameter gradually increases towards the handle. The flat part is one-fortieth of an inch in diameter. The part which is nearest the handle, is one-twentieth of an inch. The handle, which is three inches and a half in length, is made of light wood, stained black. It is octagonal, and has a little ivory inlaid in the two sides, which correspond with the edge of the needle.

Mr. Hey describes the recommendations of this instrument in the following terms:

1. "It is only half the length of the common needle; and this gives the operator a greater command over the motions of its point, in removing the crystalline from its bed, and tearing its capsule. It is also of some consequence, that the operator should know how far the point of his needle has penetrated the globe of the eye, before he has an opportunity of seeing it through the pupil; as it ought to be brought forwards when it has reached the axis of the pupil. Now he may undoubtedly form a better judgment respecting this circumstance, when the length of his needle does not much exceed the diameter of the eye, than when he uses one of the ordinary length, which is nearly two inches. The shortness of the needle is peculiarly useful, when the capsule is so opaque that the point cannot be seen through the pupil.

2. "As this needle becomes gradually thicker towards the handle, it will remain fixed in that part of the sclerotic, to which the operator has pushed it, while he employs its point in depressing and removing the cataract. But the spear-shaped needle, by making a wound larger in diameter, than that part of the instrument, which remains in the sclerotic, becomes unsteady, and is with difficulty prevented from sliding forwards against the ciliary processes, while the operator is giving it those motions which are necessary for depressing the cataract.

"On the same account the common spear-shaped needle may suffer some of the vitreous humour to escape during the operation, whereby the iris and ciliary processes would be somewhat displaced, and rendered flaccid; whereas the needle which I use, making but a small aperture in the sclerotic, and filling up that aperture completely during the operation, no portion of the vitreous humour can flow out so as to render the iris and ciliary processes flaccid.

3. "This needle has no projecting edges; but the spear-shaped needle, having two sharp edges, which grow gradually broader to a certain distance from its point, will be liable to wound the iris, if it be introduced too near the ciliary ligament, with its edges in a horizontal position. I have been informed, that, in an operation performed by one of the most eminent surgeons in the metropolis, now deceased, the iris was divided as far as the pupil. If the operator, in order to avoid this danger, introduces his needle with its edges in a vertical position, he will divide the fibres of the sclerotic transversely, and, by thus enlarging the wound, will increase the unsteadiness of the instrument. Besides, however the needle be introduced, one of its sharp edges must be turned toward the iris in the act of depressing the cataract; and, in the various motions which are often necessary in this operation, the ciliary processes are certainly exposed to more danger than when a needle is used which has no projecting edge.

4. "It has no projecting point. In the use of the spear-shaped needle, the operator's intention is to bring its broadest part over the centre of the crystalline. In attempting to do this, there is great danger of carrying the point beyond the circumference of the crystalline, and catching hold of the ciliary processes, or their investing membrane, the *membrana nigra*. This accident is the more probable, as the point of the needle must unavoidably be directed obliquely forwards, and this motion, if carried too far, brings the point into contact with the ciliary processes, as they surround the capsule of the crystalline.

"A needle, (recommended by Mr. Hey,) will pass through the sclerotic with ease. It will depress a firm cataract readily, and break down the texture of one that is soft. If the operator finds it of use to bring the point of the needle into the anterior chamber of the eye, (which is often the case,) he may do this with the greatest safety, for the edges of the needle will not wound the iris. In short, if the operator, in the use of this needle, does but attend properly to the motion of its point, he will do no avoidable injury to the eye, and this caution becomes the less embarrassing, as the point does not project beyond that part of the needle by which the depression is made, the extreme part of the needle being used for this purpose." (Hey.)

Scarpa employs a very slender needle, possessing a sufficient firmness to enter the eye without hazard of breaking, and having a point, which is slightly curved. The curved extremity of the needle is flat upon its dorsum, or convexity, sharp at its edges, and has a concavity, constructed with two oblique surfaces, forming in the middle a gentle eminence, that is continued along to the very point of the instrument; there is a mark on the side of the handle, which corresponds to the convexity of the point. The surgeons of the Leeds Infirmary have had one advantage in the needle, which they

have used in imitation of Baron Hilmer; I mean, having it made of no greater length, than the purposes of the operation demand. A couching needle is sufficiently long when it does not exceed, at most, an inch in length: this affords the operator a greater command over the motions of the point, and enables him to judge more accurately, how far it has penetrated the globe of the eye, before he has an opportunity of seeing it through the pupil. To the needle, therefore, so much recommended by Scarpa, and so successfully used by him, and Dr. Morigi, principal surgeon of the hospital at Piacenza, and one of the most expert operators of the present day in Italy, it seems proper to unite the improvement of having it made no longer than is necessary. The needle, here described, will penetrate the sclerotic coat as readily as any straight one, of the same diameter, and, by reason of its slenderness, will impair the internal structure of the eye less in its movements, than common couching needles. When cautiously pushed in a transverse direction, till its point has reached the upper part of the opaque lens, it becomes situated with its convexity towards the iris, and its point in an opposite direction; and, upon the least pressure being made by its convex surface, it removes the cataract a little downward, by which a space is afforded at the upper part of the pupil, between the cataract and the ciliary processes, through which the instrument may be safely conveyed in front of the opaque body and its capsule, which it is prudent to lacerate in the operation. In cases of caseous, milky, and membranous cataracts, the soft pulp of the crystalline may be most readily divided, and broken peice-meal by the edges of its curved extremity; and the front layer of the capsule lacerated into numerous membranous flakes, which, by turning the point of the instrument towards the pupil, may be as easily pushed through this aperture into the anterior chamber, where Scarpa finds absorption takes place more quickly, than behind the pupil.

I ought to mention, however, that Beer, and a few other skilful operators, still give the preference to a straight spear-pointed needle; and, if such an instrument be selected, I do not think a better one can be devised, than that described by Scarpa, but made quite straight.

As Mr. Travers has observed, in all cases of operation with the needle, the employment of a solution of the extract of belladonna in an equal part of distilled water, is a point of the first importance. "The space, included between the eyebrow and lash, should be thickly painted with the solution once, or oftener, in the twenty-four hours, and this varnish should be preserved moist for a period of half an hour, in order to admit of its absorption. The frequency of the application must be determined by its effect upon the pupil. The preternatural dilatation should not be permanently maintained; for, if it be, the pupil will in all probability be mis-shapen," when the use of the

belladonna is suspended, and the iris recovers its power. (*Synopsis of the Diseases of the Eye*, p. 322.)

The couching needle (if the curved one be used) is to be held with its convexity forward; its point backward; and its handle parallel to the patient's temple. The surgeon, having directed the patient to turn the eye towards the nose, is to introduce the instrument boldly through the sclerotic coat, at the distance of at least one line and a half from the margin of the cornea, for fear of injuring the ciliary processes. Most authors advise the puncture to be made at about one line, and some even at the minute distance of 1-16th of an inch (*Hey*) from the union of the cornea with the sclerotica; but, as the ciliary processes ought invariably to be avoided, and there is no real cause to dread wounding the aponeurosis of the abductor muscle, as some have conceived, the propriety of puncturing the globe of the eye, at the distance of one line and a half, or two, from the margin of the cornea, as advised by Petit, Platner, Bertrandi, Beer, &c. must be sufficiently manifest.

Nor is it a matter of indifference, at what height the needle is introduced, if it be desirable to avoid, as much as possible, effusion of blood in the operation. Anatomy reveals to us, that the long ciliary artery pursues its course to the iris, along the middle of the external convexity of the eye-ball, between the sclerotic and choroid coats; and hence, in order to avoid this vessel, it is prudent to introduce the instrument a full line below the transverse diameter of the pupil, as Dudell, Guntz, Bertrandi, Beer, Scarpa, &c. have directed. If the couching needle were introduced higher than the track of the long ciliary artery, it would be inconvenient for the depression of the cataract.

The exact place, where the point of the needle should next be guided, is, no doubt, between the cataract and ciliary processes, in front of the opaque lens, and its capsule: but, as I conceive, the attempt to hit this delicate invisible mark, borders upon impossibility, and, with a straight pointed needle, might even endanger the iris, I cannot refrain from expressing my dissent to the common method of passing a couching needle at once in front of the cataract. On the contrary, it seems safer to direct the extremity of the instrument immediately over the opaque lens, and, in the first instance, to depress it a little downward, by means of the convex flat surface of the end of the needle, in order to make room for the safe conveyance of the instrument, between the cataract, and corpus ciliare, in front of the diseased crystalline and its capsule; taking care, in this latter step of the operation, to keep the marked side of the handle forward, by which means the point of the needle will be in an opposite direction to the iris, and will come into contact with the diseased body, and the membrane binding it down in the fossula of

the vitreous humour. When this has been done, and the case is a firm cataract, the instrument will be visible through the pupil; and now we are to push its point transversely, as near as possible the margin of the lens, on the side next the internal angle of the eye, taking strict care to keep it continually turned backward. The operator is then to incline the handle of the instrument towards himself, whereby its point will be directed through the capsule, into the substance of the opaque lens; and, on making a movement of the needle, describing the segment of a circle, at the same instant inclining it downward and backward, he will lacerate the former, and convey it, in the generality of cases, with the latter, deeply into the vitreous humour.

Beer, as I have explained, gives the preference to a spear-pointed straight needle, one flat surface of which, at the period of its first introduction into the eye, is turned upwards; the other, downwards; one edge, directed towards the nasal, the other, towards the temporal canthus; and the point towards the centre of the eyeball. Beer prefers this mode of proceeding, in order to avoid moving the lens too soon out of its natural situation, whereby the subsequent manœuvres of depression or reclination, he thinks would be rendered very uncertain and incomplete. He also recommends the surgeon to support his hand in some measure on the patient's cheek by means of the little finger, so as to have it in his power to check the too sudden and deep entrance of the instrument into the eye, liable to happen when the broadest part of the spear-point has passed through the sclerotica. (*Lehre*, &c. B. 2, p. 354.)

It happened, unfortunately for the credit of the operation of depression, that Petit admonished surgeons to beware of wounding the anterior layer of the crystalline capsule: he had an idea, that, when this caution was observed, the vitreous humour would afterward fill up the space, previously occupied by the lens, and that thus the refracting powers of the eye might become as strong as in the natural state, and the necessity for using spectacles be considerably obviated. But, we are now apprized, that leaving this very membrane, from which Petit anticipated such great utility, even were it practicable to leave it constantly uninjured in its natural situation, would be one of the worst inculcations that could possibly be established; for, in many cases, where extraction proves fruitless, in some, where depression fails, the want of success is owing to a subsequent opacity of the crystalline capsule; in short, blindness is reproduced by the secondary membranous cataract. It seems more than probable, that, in some of the instances, where the opaque lens has been said to have risen again, nothing more has happened, than the disease in question. Therefore, notwithstanding the whole capsule in the majority of cases may be depressed with the lens out of the axis of vision, as it is not a constant occur-

rence, I cannot too strongly enforce the propriety of extirpating, as it were, every source and seat of the cataract in the same operation, and, in imitation of the celebrated Scarpa, who is entitled to the honour of having first pointed out the great importance, of this practice, I shall presume to recommend, as a general rule in couching, always to lacerate the front layer of the capsule, whether in an opaque or transparent state.

The capsule of the crystalline lens may retain its usual transparency, while the lens itself is in an opaque state. In this case, an inexperienced operator might, from the blackness of the pupil, suppose, not only that he had removed the lens, but also the capsule from the axis of sight; and, having depressed the cataract, he might unintentionally leave this membrane entire in its natural situation. Therefore, if there should be any reason for suspecting, that the anterior layer of the capsule has escaped laceration; if, in other words, the resistance made to moving the convexity of the instrument forward, towards the pupil, should give rise to such a suspicion; for the sake of removing all doubt, it is proper to communicate to the needle a gentle rotatory motion, by which its point will be turned forward, and disengaged, through the transparent capsule, opposite the pupil: then, by repeating a few movements downward and backward, it will be so freely rent with the needle, as to occasion no future trouble.

If a straight, slender, spear-pointed needle be used, like that of Beer, and the second stage of the operation be completed by the introduction of the extremity of the instrument into the posterior chamber, then, according to the directions given by the same writer, when depression is indicated, the needle is to be immediately carried to the uppermost part of the cataract, with its point directed somewhat obliquely downwards; and with that surface, which in the first instance, was applied to the front of the lens, now placed upon its superior edge; then the opaque body is to be pushed rather obliquely, downwards and outwards, so far below the pupil, that it can no longer be distinguished. After this has been done, the needle is to be gently raised, in order to see whether the cataract will continue depressed, and if it be found to do so, the needle is to be withdrawn in the same direction, in which it was introduced.

On the other hand, says Beer, when re-clination is to be practised, the needle after being applied to the front surface of the cataract, is not to be moved further out of the position of the second stage of the operation, but its handle is merely to be raised diagonally forwards, whereby the cataract will be pressed downwards and outwards to the bottom of the vitreous humour, and turned in the manner already specified. Beer has delivered what appears to me one valuable piece of advice for operators on the eye with the needle: whether depres-

sion, or re-clination, is to be done, says he, a surgeon can only use this instrument without injurious consequences on the principle of a lever; and every attempt to press with the whole length of the instrument is not only ineffectual, with respect to the progress of the operation, but so hurtful to the eye, that bad effects must follow, as may be readily conceived, when it is recollected how violently the ciliary nerves must be stretched.

As for the modifications of the manœuvres, rendered necessary by the varieties of cataracts, they are (says Beer) so unimportant in all cases of depression, that a young operator will easily understand them himself. But, things are far otherwise in the practice of re-clination; for, when the case is a completely formed *capsular-lenticular cataract*, and the opaque capsule is so thin, as to be torn during the turning of the lens, the latter body will indeed be placed in the intended position at the bottom of the eye, but the capsule itself, which has merely been lacerated, must form a secondary cataract, unless the surgeon, with a sharp double-edged needle, immediately divide it in every direction, and remove it as far as possible from the pupil. When, during re-clination, a *softish lens*, or one which is *pulpy* to its very nucleus, breaks into several pieces, it is necessary, in order not to have afterwards a considerable secondary lenticular cataract, to put the larger fragments separately in a state of re-clination, while the smaller ones may either be depressed, or (if the pupil be not too much contracted) they may be pushed into the anterior chamber, where they will soon be absorbed. When the cataract is partially adherent to the uvea, Beer recommends an endeavour to be first made, with the edge of the needle, (which is to be introduced flat between the cataract and the uvea, above or below the adhesion) to separate the adherent parts before the attempt at re-clination is made. Should it be a cataract, which always rises again as soon as the needle is taken from it, though the instrument has not pierced it at all, the case is termed the *elastic cataract*, in which the lens is not only firmly adherent to its own capsule, but this also to the *membrana hyaloidea*. Here Beer thinks, that the best plan is first to carry the needle to the uppermost point of the posterior surface of the lens, and by means of perpendicular movements of the cutting part of the instrument, to endeavour completely to loosen this preternatural adhesion of the cataract to the vitreous humour, when re-clination may be tried again, and will perhaps succeed. But, says Beer, when the continual rising of the cataract is caused by the operator's running the needle into it, the instrument must either be withdrawn far enough out of the eye to let it be again properly brought into the posterior chamber, when re-clination may be effectually repeated; or, if the cataract be firmly fixed on the needle at the bottom of the eye, the instrument should not be raised again, but previously to being withdrawn, it should be rotated a couple of

times on its axis, whereby the pierced lens will be more easily disengaged from the needle, and at last continue depressed. (*Lehre von den Augenkr. B. 2, p. 356—358.*)

In addition to Beer's directions for couching and reclinatio, the following observations seem to me to merit attention.

When the case is a *fluid or milky* cataract, the operator frequently finds, that, on passing the point of the couching needle through the anterior layer of the capsule, its white milky contents instantly flow out, and, spreading like a cloud over the two chambers of the aqueous humour, completely conceal the pupil, the iris, and the instrument, from his view; who, however, ought never to be discouraged at this event. Although it seems to me most prudent, to postpone the completion of operations with the needle, in the example of blood concealing the pupil, in the first step of couching, and not to renew any attempt before the aqueous humour has recovered its transparency; I am inclined to adopt this sentiment, chiefly because the species of cataract is, in this circumstance, generally unknown to the operator, consequently he must be absolutely incapable of employing that method of couching, which the peculiarities of the case may demand. Speaking of this case, however, Beer says, "the surgeon must hasten the completion of extraction, or reclinatio, though possibly the operation may not always admit of being continued, or, if gone on with, it must be done, as it were blindfold." (*Lehre, &c. B. 2. p. 361.*) When a milky fluid blends itself with the aqueous humour, and prevents the surgeon from seeing the iris and pupil: this event itself is a source of information to him, inasmuch as it gives him a perfect insight into the nature of the cataract, which he is treating; and instructs him what method of operating it is his duty to adopt. The surgeon, guided by his anatomical knowledge of the eye, should make the curved point of the needle describe the segment of a circle, from the inner, toward the outer canthus, and in a direction backward, as if he had to depress a firm cataract. (*Scarpa.*) Thus he will succeed in lacerating, as much as is necessary, the anterior layer of the capsule, upon which, in a great measure, the perfect success of the operation depends; and, not only in the milky, but almost every other species of cataract.

In regard to the extravasation of the milky fluid in the chambers of the aqueous humour, numerous observations, from the most creditable authorities, prove, that it spontaneously disappears very soon after the operation, and leaves the pupil of its accustomed transparency. "In twelve cases of a dissolved lens, on which I have operated," says Latta, "the dissolution was so complete, that, on entering the needle into the capsule of the lens, the whole was mixed with the aqueous humour, and all that could be done, was to destroy the capsule as completely as possible, that all the milky matter might be evacuated. In ten of these

cases, vision was almost completely restored in four weeks from the operation. Mr. Pott, in treating of this circumstance, viz. the effusion of the fluid contents of the capsule into the aqueous humour, observes, that so far from being an unlucky one, and preventive of success, it proves, on the contrary, productive of all the benefit which can be derived from the most successful depression or extraction, as he has often and often seen.

When the cataract is of a *soft, or caseous* description, the particles of which it is composed will frequently elude all efforts made with the needle to depress them, and will continue behind the pupil in the axis of vision. This has been adduced as one instance that baffles the efficacy of couching, and may really seem to the inexperienced, an unfortunate circumstance. It often happens in the operation of extraction, that fragments of opaque matter are unavoidably overlooked and left behind; yet Richter confesses, that such matter is frequently removed by the absorbents. Supposing a caseous cataract were not sufficiently broken, and disturbed in the first operation, and that, consequently, the absorbents did not completely remove it, such a state might possibly require a reapplication of the instrument; but this does not generally occur, and is the worst that can happen. It is quite impossible to determine *a priori*, what effect will result from the most trivial disturbance of a cataract; its entire absorption may, in some instances, follow, while in others, a repetition of the operation becomes necessary for the restoration of sight. Even where the whole firm lens has reascended behind the pupil, as Latta and Hey confirm, the absorbents have superseded the necessity for couching again. The disappearance of the opaque particles of cataracts was, in all times, and in all ages, a fact of such conspicuousness, that, as appears from the authority of Barbette and others, it was recorded, even previous to the discovery of the system of lymphatic vessels in the body. Indeed the modern observations of Scarpa and others, so strongly corroborate the account which I have given of the vigorous action of the absorbents, in the two chambers of the aqueous humour; and particularly, in the anterior one, that, from the moment the case is discovered to be a soft, or caseous cataract, it seems quite unnecessary to make any further attempt to depress it into the vitreous humour. Mr. Pott sometimes, in this circumstance, made no attempt of this kind, but contented himself with a free laceration of the capsule, and, after turning the needle round and round, between his finger and thumb, within the body of the crystalline, left all the parts in their natural situation, where he hardly ever knew them fail of dissolving so entirely, as not to leave the smallest vestige of a cataract. This eminent surgeon even practised occasionally what Beer sanctions, and Scarpa so strongly recommends at this day; for he sometimes pushed the firm part of such

cataracts through the pupil into the anterior chamber, where it always disappeared, without producing the least inconvenience; we must, at the same time add, that he thought this method wrong, not on account of its inefficacy, but an apprehension that it would be apt to produce an irregularity of the pupil, one of the worst inconveniences attending the operation of extraction. But the deformity of the pupil, after extraction, seems to proceed either from an actual laceration of the iris, or a forcible distention of the pupil, by the passage of large cataracts through it, a kind of cause that would not be present in pushing the broken portions of a caseous lens into the anterior chamber. Hence, it does not seem warrantable to reject this very efficacious plan of treatment. It is well deserving of notice, that Mr. Hey, who has several times seen the whole opaque nucleus and very frequently small opaque portions fall into the anterior chamber, makes this remark: "Indeed, if the cataract could, in all cases, be brought into the anterior chamber of the eye, without injury to the iris, it would be the best method of performing the operation." What the same author also observes in the subsequent part of his work, is strikingly corroborative of the efficacy of Scarpa's practice. The practice of the Italian professor consists in lacerating the anterior portion of the crystalline capsule, to the extent of the diameter of the pupil in a moderately dilated state: in breaking the pappy substance of the diseased lens piecemeal; and in pushing the fragments through the pupil into the anterior chamber, where they are gradually absorbed.

One great advantage of couching, insisted upon by Scarpa, depends upon its generally removing the capsule, at the same time with the lens, from the passage of the rays of light to the retina. Sometimes, however, this desirable event, by which the patient is extricated from the danger of a *secondary membranous cataract*, does not take place even in the operation of depression; and, when the lens included in its capsule is extracted from the eye, by the other method, it may always be considered as rather an uncommon circumstance. What most frequently constitutes the secondary membranous cataract, is the anterior half of the capsule, which not having been removed, or sufficiently broken, in a previous operation, continues more or less entire in its natural situation, afterwards becomes opaque, and thus impedes the free transmission of the rays of light to the seat of vision. Sometimes the secondary membranous cataract presents itself beyond the pupil, in the form of membranous flakes, apparently floating in the aqueous humour, and shutting up the pupil: at other times it appears in the form of triangular membranes, with their bases affixed to the *Membrana Hyaloidea*, and their points directed towards the centre of the pupil. When there is only a minute membranous flake suspended in the posterior chamber, Scarpa thinks it by no means necessary for the patient to submit to another

operation; vision is tolerably perfect, and the small particle of opaque matter will, in time, spontaneously disappear. But when the secondary membranous cataract consists of a collection of opaque fragments of the capsule, accumulated so as either in a great degree or entirely to close the pupil; or when the disease consists of the whole anterior half of the opaque capsule, neglected in a prior operation, and continuing adherent in its natural situation, it is indispensable to operate again; for, although in the first case, there may be good reason to hope, that the collection of membranous fragments might, in time, disappear, yet it would be unjustifiable to detain the patient for weeks and months in a state of anxiety and blindness, when a safe and simple operation would restore him, in a very short space of time, to the enjoyment of this most useful of the senses. In the second case, says Scarpa, it is absolutely indispensable: for while the capsule remains adherent to its natural connexions, the opacity seldom disappears, and may even expand itself over a larger portion of the pupil. He advises the operation to be performed as follows: when the aperture in the iris is obstructed by a collection of membranous flakes, detached from the *membrana hyaloidea*, the curved needle should be introduced, with the usual precaution of keeping its convexity forward, its point backward, until arrived behind the mass of opaque matter; the surgeon is then to turn the point of the needle towards the pupil, and is to push through this opening, regularly one after another, all the opaque particles into the anterior chamber, where, as we have before noticed, absorption seems to be carried on more vigorously than behind the pupil. All endeavours to depress them into the vitreous humour, Scarpa has found it to be in vain; for scarcely is the couching needle withdrawn when they all reappear at the pupil, as if, (to use his own phrase) carried thither by a current: but when forced into the anterior chamber besides, being incapable of blocking up the pupil, they lie without inconvenience, at the bottom of that cavity, and in a few weeks are entirely absorbed.

When the *secondary membranous cataract* consists of the whole anterior layer of the crystalline capsule, or of several portions of it connected with the *membrana hyaloidea*, Scarpa, after cautiously turning the point of the needle towards the pupil, pierces the opaque capsule: or, if there be any interspace, he passes the point of the instrument through it; then, having turned it again backward, he conveys it, as near as possible, to the attachment of the membranous cataract, and after piercing the capsule, or each portion of it successively, and sometimes carefully rolling the handle of the instrument between his finger and thumb, so as to twist the capsule round its extremity, he thus breaks the cataract, as far as it is practicable, at every point of its circumference. The portions of membrane, by this means separated from their adhesions, are next cautiously pushed, with the point of the

couching needle turned forward, through the pupil, into the anterior chamber. In these manœuvres the operator must use the utmost caution not to injure the iris, and ciliary processes, for upon this circumstance depends the avoidance of bad symptoms after the operation, notwithstanding its duration may be long, and the necessary movements of the needle frequently repeated. If a part of the membranous cataract be found adherent to the iris, (a complication, that will be indicated when, upon moving it backward, or downward with the needle, the pupil alters its shape, and from being circular becomes of an oval, or irregular figure,) even more caution is required than in the foregoing case, so as to make repeated, but delicate movements of the needle, to separate the membranous opacity, without injuring the iris. Beer's mode of proceeding in such a case, I have already described.

Scarpa does not deem it necessary to vary the plan of operating above explained, if occasionally the cataract be formed of the posterior layer of the capsule. And according to this author, the same plan also succeeds in those rare instances where the substance itself of the crystalline wastes, and is almost completely absorbed, leaving the capsule opaque, and including, at most, only a small nucleus, not larger than a pin's head. Scarpa terms it the *Primary Membranous Cataract*, and describes it as being met with in children, or young people under the age of twenty; as being characterized by a certain transparency, and similitude to a cobweb; by a whitish opaque point, either at its centre or circumference; and, by a streaked and reticulated appearance: he adds, that whosoever attempts to depress such a cataract is baffled, as it reappears behind the pupil, soon after the operation: he recommends breaking it freely with the curved extremity of the couching needle, and pushing its fragments into the anterior chamber, where they are gradually absorbed in the course of about three weeks.

No other topical application is generally requisite, after the operation, but a small compress of fine linen; and the patient ought to be kept in a quiet, moderately darkened room. On the following morning, a dose of some mild purgative salt, such as the sulphate of soda, or magnesia, may usually be administered, with advantage. I shall not enlarge upon the method of treatment, when the inflammation, subsequent to couching, exceeds the ordinary bounds; in hypochondriacal, hysterical, and irritable constitutions, this is more frequently met with, and I have already touched upon the propriety of some preparatory measures before operating upon these unfavourable subjects.

Beer remarks, that, although after extraction, very cautious trials of the sight are indispensable, they are by no means proper after the depression or reclinatio of a cataract; for, the action of the muscles of

the eye in the inspection of objects at various distances, is very liable to make the opaque body rise again. Hence, as soon as the pupil is clear, Beer recommends covering both eyes (even when one only has been operated upon) with a plaster, and simple linen compress, which last is to be fastened on the forehead with a common bandage. The same experienced operator also enjoins perfect quietude of the body and head for some days. The patient, he says, may either lie in bed, or sit in an arm-chair, as may be most agreeable, care being taken to avoid all sudden motions. The most proper food for the patient is such as is easily digested, not too nutritious, and does not require much mastication. Every thing must be avoided which has a tendency to excite inflammation in the eye. On the third or fourth day the eye should be opened, and afterwards be merely protected by a green silk eye screen, which should also be gradually dispensed with. The patient should be careful to do whatever is agreeable to the eye which has been operated upon, and as carefully avoid every thing which irritates it, or causes a disagreeable sensation in it, a difficulty of opening the eyelids, or keeping them open, a discharge of tears, or a redness of the white of the eye, &c.

Of the thrombus under the conjunctiva, sometimes caused by the prick of the needle, and of the readily bleeding granulations which occasionally shoot up at the puncture, I need not here particularly speak.—For relieving the obstinate vomiting, sometimes excited by injury of the ciliary nerves, or that of the retina, Beer recommends castor, musk, and opium, except when the eye is in a state of inflammation, in which circumstance, the antiphlogistic treatment is preferable. Such vomiting, Beer joins other writers in believing, is often produced by a firm lens being depressed too far, so as to injure the retina; a case, however, which is usually combined with a suddenly produced, complete, or incomplete amaurosis. Here, unless the position of the lens can be changed by a sudden movement of the head, the above class of medicines will be of no use. This kind of amaurosis may also take place without any vomiting, and, as Beer has had opportunities of remarking, it will not always subside, even though the cataract be made to rise again. The same amaurotic affection may also result from the surgeon hurting the retina by pushing the needle too deeply against this membrane. According to Beer, the ophthalmia, liable to happen in these cases, as well as after extraction and kexatonyxis, is always most severe in the iris and neighbouring textures. (*Von den Augenkr. B. 2, p. 361—63.*)

I cannot help remarking how judicious it is never to attempt too much at one time in any mode of couching. It happens in this, as in most other branches of operative surgery, that celerity is too often mistaken for skill; the operator should not only be

slow and deliberate in achieving his purpose; he should be taught to consider that a repetition of couching may, like the puncture of a vein, be safely and advantageously put in practice again and again; and with far greater security, than if, for the sake of appearing expeditious, or avoiding the temporary semblance of failure, a bolder use of the couching needle should be made, than the delicate structure of the eye warrants. We read, in Mr. Hey's *Practical Observations on Surgery*, that he couched one eye seven times, before perfect success was obtained; had he been less patient, and endeavoured to effect by one or two rough applications of the instrument, what he achieved by seven efforts of a gentler description, it is highly probable, that the structure of the eye would have been so impaired, as well as the consequent ophthalmia so violent, as to have utterly prevented the restoration of sight.

All the various methods of couching having now been described, I subjoin the sentiments of Beer, respecting the circumstances by which the choice of depression or reclinacion ought to be regulated. According to this author, when the cataract is very firm, or moderately so, with a scabrous surface, or the case is what has been already described under the name of *encysted cataract*, or when the cataract consists of any tough membrane, both depression and reclinacion can only be a palliative remedy, for, says he, none of these cataracts after the operation can be dissolved and absorbed, but must remain in the eye, as a foreign unorganized body, ready at every opportunity to rise again, and partially or completely blind the patient anew. Beer assures us, that he has carefully examined the eyes of persons after death, on whom depression or reclinacion had been practised, in some instances, twenty or more years previously; but, in almost all the examples, the lens was found firm and undissolved, or at most only diminished, with, or without its capsule. Membranous cataracts were very trivially lessened; though they had quite lost their tough consistence, and were changed into a firmish white mass. In a living person, Beer says he saw an instance, in which a cataract rose again after it had been depressed by Hilmer thirty years previously: it was small, angular, and, when the pupil was dilated, it floated from one chamber of the eye into the other. When extracted, which was done with complete success, it was found to be almost ossified. In 1805, Beer extracted from a woman, forty years of age, a very large, hard, yellowish, white lenticular-cataract, which had been in the anterior chamber twenty-six years. The lens had been thus displaced by a blow received on the eye from the branch of a tree. Nor has Beer ever yet seen a case, in which a cataract of a semi-firm consistence was dissolved and absorbed. (*Von den Augenkr.* B. 2, p. 363.) Had Beer confined his statements to what happens to certain cataracts, on which depression, or reclinacion, strictly

so called, had been practised, I should have been disposed to accede to the general assertion, respecting the great length of time, which a firm or tough capsular cataract remains in the vitreous humour undissolved and unabsorbed. But, if he mean that the same thing is generally the case with cataracts broken piecemeal, and placed in the aqueous humour, we know, that such a representation is contradicted by the experience of an infinite number of the highest authorities in surgery. Nay, notwithstanding the case adduced of a bony lens having remained in the aqueous humour twenty-six years, I am disposed to think, that Beer himself does not intend to question the absorption of the fragments of cataracts in the aqueous humour, particularly as at p. 357, B. 2, he sanctions pushing the fragments of semi-firm cataracts through the pupil into the anterior chamber, where, he confesses, that *they are soon absorbed*.

Beer thinks that, in general, depression and reclinacion are indicated only in cases, in which extraction is absolutely impracticable, or attended with too great difficulty; as will be better understood when this operation is considered. As examples of this kind, Beer specifies an extensive adhesion of the iris to the cornea; a very flat cornea, and, of course, so small an anterior chamber, that an incision of proper size in the cornea cannot be made; a broad arcus senilis; an habitually contracted pupil (incapable of being artificially dilated); an eye much sunk in the orbit, with a small fissure between the eyelids; eyes affected with incessant convulsive motions; a partial adhesion of the cataract to the uvea; unappeasable timidity in the patient; and an impossibility of managing him during and after the operation, in consequence of his childhood or stupidity.

With regard to the question, whether depression or reclinacion should be preferred, Beer is of opinion, that the first method is indicated only when the dimensions of the cataract are small, and consequently, when there is room enough for it to be placed below the pupil, without the ciliary processes being torn from the annulus ciliaris. Such cases are the *dry-husked, capsulo-lenticular cataract*, (the *primary membranous cataract*, of Scarpa,) when perfectly free from adhesions to the uvea; the true *lenticular secondary cataract*, produced by the small but firm fragments of the lens having been left, or risen again; and the genuine *secondary membranous, or capsular cataract*. On the other hand, reclinacion is to be preferred when, together with the above objections to extraction, the surgeon has to deal with a fully formed, very *hard lenticular, or capsulo-lenticular cataract*; or with a case of the latter kind, complicated with partial adhesions to the uvea; or when the case is a *secondary capsular cataract*, similarly circumstanced; a *secondary cataract of lymph*; a *gypsum-cataract*; or there is reason to apprehend a considerable tendency in the blood-vessels of the interior of the eye to

become varicose. (*Lehre von den Augenkr. B. 2, p. 365.*)

The manner of operating with the needle upon the congenital cataracts of children, will be hereafter explained.

EXTRACTION OF THE CATARACT.

As soon as it was fully proved that the true cataract was an opacity of the crystalline lens; that the loss of sight would not be occasioned by the removal of this body; that the cornea might be divided without danger; and that when the aqueous humour had been discharged, it would be quickly regenerated; the mode of cure, by extracting the cataract out of the eye, naturally presented itself. (*Wenzel.*)

Freytag first made an attempt to extract the cataract, about the close of the 17th century. After him, Lotterius of Turin performed this operation, a good description of which was first given by Daviel; and the ingenuity and industry of Wenzel afterwards brought this mode of operating considerably nearer to perfection. (*Brambilla, Instrumentarium Chir. Austriacum, 1782, p. 71.*)

With the valuable instructions which Ware and Beer have still more recently furnished, the extraction of the cataract may now be regarded as brought to the highest state of improvement. According to Beer, the extraction of the cataract usually admits of division into three stages, the first of which, as in depression and reclinatio, is the most important, because, unless it be performed exactly as it ought to be, the operation will be very liable to fail, and it is exceedingly difficult to make amends for any fault committed in this early part of the proceedings. The first stage consists in making an effectual opening in the cornea with a suitable knife. The second, in dividing the anterior layer of the capsule, which, says Beer, should not be merely punctured, or torn with a bluntish instrument, but cut with a sharp two-edged lance-pointed needle, and, as much as possible, annihilated. In the third stage, the expulsion of the cataract from the eye is effected either by the well-regulated action of the eye-ball itself, or by the assistance of art. But, as Beer remarks, they who have learned the manner of effectually and skilfully cutting the cornea, will frequently have the pleasure to find the two last stages beneficially converted into one, and the operation in general soon and expeditiously completed. (*Von den Augenkr. B. 2, p. 366.*)

The knives, used by Richter, Wenzel, Ware, and Beer, are all of them more or less different; but, they agree in the common quality of completely filling up the wound, as it is extended, so that none of the vitreous humour can escape before the division of the cornea is finished.

Wenzel's knife resembles the common lancet employed in bleeding, excepting that its blade is a little longer, and not quite so broad. Its edges are straight, and the blade

is an inch and a half (eighteen lines) long, and a quarter of an inch (three lines) broad, in the widest part of it, which is at the base. From this part it gradually becomes narrower towards the point; so that this breadth of a quarter of an inch extends only to the space of about one-third of an inch from the base; and, for the space of half an inch from the point, it is no more than one-eighth of an inch broad.

The knife, employed by the late Mr. Ware, is, in regard to its dimensions, not unlike the instrument employed by Wenzel. The principal difference is, that Mr. Ware's knife is less spear-pointed; in consequence of which, when this latter instrument has pierced through the cornea, its lower, or cutting edge will sooner pass below the inferior margin of the pupil, than the knife used by Wenzel. On this account, Mr. Ware believed that the iris would be less likely to be entangled under the knife, which he recommended, than under Wenzel's, when the instrument begins to cut its way downwards, and the aqueous humour is discharged. Mr. Ware particularly advises great care to be taken to let the knife increase gradually in thickness from the point to the handle; by which means, if it be conducted steadily through the cornea, it will be next to an impossibility, that any part of the aqueous humour can escape, before the section is begun downwards; and, consequently, during this time, the cornea will preserve its true convexity.—But, if the blade should not increase in thickness from the point; or if it be incurvated much in its back, or edge, the aqueous humour will unavoidably escape, before the puncture is completed; and the iris, being brought under the edge of the knife, will be in great danger of being wounded by it. But, a better knife than any other which has yet been proposed, is that employed by Beer, a representation of which I have given in Vol. 1, of the *First Lines of Surgery*, plate 7, fig. 3. The sentiments of Richter, Scarpa, Beer, and others, about the position of the patient in the operation, and the mode of fixing the eye, have been already noticed in a foregoing section.

Baron Wenzel determined to run no risk of bad consequences from undue pressure on the eye, made no endeavour to fix this organ at all at the period of cutting the cornea.

The late Mr. Ware did not approve of this plan of leaving the eye unfixed. The danger likely to arise from undue pressure, he observes, can only take place, after the instrument has made an opening into the eye: but the pressure which Mr. Ware advises, in order to fix the eye, is to be removed the instant the knife is carried through the cornea, and before any attempt is made to divide this tunic downwards. To understand this subject better, however, the reader should know, that Mr. Ware divided the incision of the cornea into two distinct processes; the first of which may be called

punctuation, and the second section. So long, says Mr. Ware, as the knife fills up the aperture in which it is inserted, that is, until it has passed through both sides of the cornea, and its extremity has advanced some way beyond this tunic, the aqueous humour cannot be discharged, and pressure may be continued with safety. The punctuation of the cornea being completed, the purpose of pressure is fully answered; and, if such pressure be continued, when the section of the cornea begins, instead of being useful, it will be hurtful. To avoid all bad effects, Mr. Ware recommends the cornea to be cut in the following way.

The operator is to place the fore and middle finger of the left hand, upon the tunica conjunctiva, just below, and a little on the inside of the cornea. At the same time, the assistant, who supports the head, is to apply one, or, if the eye projects sufficiently, two of his fingers, upon the conjunctiva, a little on the inside and above the cornea. The fingers of the operator and assistant, thus opposed to each other, will fix the eye, and prevent the lids from closing. The point of the knife is to enter the outside of the cornea, a little above its transverse diameter, and just before its connexion with the sclerotica. Thus introduced, it is to be pushed on slowly, but steadily, without the least intermission, and in a straight direction, with its blade parallel to the iris, so as to pierce the cornea towards the inner angle of the eye, on the side opposite to that which it first entered, and till about one-third part of it is seen to emerge beyond the inner margin of the cornea. When the knife has reached so far, the punctuation is completed. The broad part of the blade is now between the cornea and the iris, and its cutting edge below the pupil, which of course is out of all danger of being wounded. As every degree of pressure must now be taken off the eyeball, the fingers, both of the operator and his assistant, are instantly to be removed from this part, and shifted to the eyelids. These are to be kept asunder by gently pressing them against the edges of the orbit; and the eye is to be left entirely to the guidance of the knife, by which, says Mr. Ware, it may be raised, depressed, or drawn to either side, as may be found necessary. The aqueous humour being now partly, if not entirely evacuated, and the cornea of course rendered flaccid, the edge of the blade is to be pressed slowly downward, till it has cut its way out, and separated a little more than half the cornea from the sclerotica, following the semi-circular direction, marked out by the attachment of the one to the other. (Ware.)

As soon as the point of the knife had arrived opposite the pupil, Wenzel used to incline it gently backward, and thus puncture the capsule of the crystalline. But, Mr. Ware very properly objects to this method of opening the capsule with the instrument used for cutting the cornea, and at the same time. The plan may exhibit dexterity; but is of no use, and is often at-

tended with considerable danger of wounding the iris.

In the eyes of some persons, the iris is convex, and it is almost impossible to complete the section of the cornea, without entangling the iris under the edge of the knife, unless a particular artifice be adopted. Wenzel, in this circumstance, recommends gently rubbing the cornea downward with the finger; one of the most important directions, according to Mr. Ware, in the Baron's whole book.

Wenzel imputed several advantages to the oblique manner in which he used to divide the cornea. The best modern oculists, however, do not imitate this method.

If the edge of the knife should incline too much forward, and its direction be not altered, the incision in the cornea will be too small, and terminate almost opposite the pupil. In this case, there will be great difficulty in extracting the cataract, and the cicatrix afterwards will often obstruct sight. If, on the contrary, the edge of the instrument be inclined too much backward, and its direction be not changed, the incision will approach too near the part where the iris and sclerotica unite, and, there will be great danger of wounding them. These accidents may be prevented by gently rolling the instrument between the fingers, until the blade takes the proper direction.—(Wenzel.)

Mr. Ware has seen operators, through a fear of wounding the iris, introduce and bring out the instrument at a considerable distance before the union of the cornea and sclerotica; in consequence of which, the incision from one side of the cornea to the other has been made too small to allow the easy extraction of the cataract, although from above downward, it was fully large enough for this purpose. Mr. Ware has also sometimes observed, that though the punctuation of the cornea from side to side has been properly conducted, and its section afterwards, to all appearance, effectually completed, yet, on account of the frictions, employed to disengage the iris from the edge of the instrument, the knife, in cutting downward, has been carried between the layers of the cornea, and, consequently, though the incision has appeared externally, to be of its proper size; internally, it has been much too small for allowing the cataract to be easily extracted. In this case, the incision must be enlarged, by means of a pair of curved blunt-pointed scissors, which should be introduced at the part where the knife first entered the cornea. (Ware.)

Beers subdivides the first stage of this operation into four, each of which, he says, claims the utmost attention, if it be wished to make the incision in the cornea in every respect proper: the first is the introduction of the knife through the cornea into the anterior chamber; the second is directing the knife towards the place where its point is to be brought out again; the third is bringing out the point, and guiding the

knife in continuing the incision in the cornea; and the fourth is the finishing of that incision. As Beer states, a completely well-made incision in the cornea, must, in the first place, be of sufficient size to let the cataract escape from the eye without the slightest impediment; and it will be large enough, if care be taken to open one half of the cornea near its edge. Secondly, it must be of a proper shape, its margin not being triangular, nor notched, but evenly rounded. In general, says Beer, no greater disadvantage can happen than that of having too small an incision in the cornea; for, even when the cataract is pressed out of such an opening, portions of it are always left behind, which afterwards cannot be extracted without trouble; and though the sight may be at the moment restored, it will be fortunate if the eye be not afterwards spoiled by the effects of inflammation. When the incision is triangular, or notched, its edges cannot be put smoothly together so as to be healed by the first intention, which, however, is highly necessary, and the consequence is a white ugly scar, which is slowly produced with inflammation, and forms a greater or lesser permanent impediment to vision downwards, though the patient be capable of seeing the smallest objects, which are straight before him.

According to Beer, when the knife is to be introduced, its point should enter the cornea, about one-eighth of a line from its edge, and one-fourth of a line above its transverse diameter, directed obliquely towards the iris, with its edge turned downwards, by which means, the point will pass immediately into the anterior chamber. As soon as it has arrived there, which is indicated partly by the bright extremity of the knife being seen within the space in question, and partly by the *tactus eruditus*, such a direction is to be given to the instrument, that its point may project from the place of its entrance nearly in a direct line towards the intended place of its exit out of the cornea, but a little higher; while the posterior surface of the blade is to be conveyed across the anterior chamber exactly parallel to the iris. The knife is to be cautiously pushed on, neither too quickly nor too slowly, with its point continually directed somewhat upwards above the part, where it is to pass out again, until the point arrives near the inner edge of the cornea; but, in the transverse passage of the knife, its edge should not be suffered either to go nearer to, or further from, the iris, as every turn of the blade backwards or forwards, opens the upper angle of the wound, when the aqueous humour immediately escapes, and the iris not only falls close against the posterior surface of the blade, but, sometimes even under the edge, so as to throw the young operator into the greatest embarrassment. If the point of the knife has now been favourably brought out, the surgeon is to continue to push it on, without pressing it downwards, or making a sawing motion

with it, until the last stage of the operation, viz. that in which the incision is finished. However, as soon as the point of the knife has passed out of the cornea, and reached the inner canthus, attention must be paid, first, to that part of the blade which is yet in the anterior chamber, so that the iris may not fall under its edge, and the knife may not take an erroneous direction; secondly, to the point of the knife, which continually projects more and more, so that the inner canthus may not be wounded, which accident, though trivial in itself, would make the unprepared patient suddenly and involuntarily draw back his head. The only way of preventing this injury, says Beer, is regularly to incline the handle more backwards and downwards, in proportion as the point passes further out of the anterior chamber. Thirdly, at the period, when the last piece of the cornea is to be cut, the knife should be pushed on very slowly, for otherwise the lens, and with it a part of the vitreous humour may be discharged, as now the muscles of the eye are acting, and compressing this organ with the greatest force, and in old persons especially, the loose conjunctiva, after the cornea is cut through, comes against the knife, and is apt to be wounded. At the time, when the operator finishes the incision in the cornea, the assistant is to let the upper eyelid cover the eye, and a few seconds are to be allowed for the patient to recover from his fright.

In the second stage of the operation, Beer directs the assistant again steadily to hold the patient's head in the same manner, as during the cutting of the cornea; but, the upper eyelid, he says, must be carefully and effectually raised, without touching the eyeball in the least, or letting the ends of the fingers project beyond the edge of the tarsus. The operator is to depress the lower eyelid with his forefinger, which is not to be removed away from the eye, but gently applied to the lower part of it with the intervention of the eyelid, by which means, the cataract-lance, or capsule-needle, may be more readily and easily introduced under the flap of the cornea into the pupil, while the gentle pressure, and the projection of the cataract thereby produced, considerably enlarge the pupil, and facilitate the proper division of the capsule. In order to complete the latter object, the surgeon introduces one of the sharp edges of the capsule-needle, with the point directed towards the inner canthus, between the cornea and the iris, the wound in the former of these membranes being opened as little as possible, lest the atmospheric air enter the eye, a circumstance, of which Beer entertains great apprehension. After the capsule needle has been cautiously passed to the inferior margin of the pupil, its lower sharp edge is to be applied to the capsule of the lens with its point directly upwards, and one of its flat surfaces towards the inner; and the other, towards the outer canthus. The operator is now strictly to cut through the capsule, by making at small distances from

one another repeated perpendicular strokes with the edge of the needle. Then the handle of the instrument is to be half turned round on its axis, and similar strokes are to be made with its edge in a somewhat oblique direction, by which means, the anterior layer of the capsule will be cut into many squarish fragments, some of which, in the third stage of the operation, are taken out of the eye together with the cataract, and the risk of a secondary cataract of the anterior layer of the capsule is in a great measure removed. When the capsule-needle has done its business, it is to be withdrawn from the eye in the same position in which it was introduced, and the second stage of the operation is thus finished. (*Beer, B. 2, p. 369.*)

I believe no better instructions, than the foregoing, can be delivered, respecting the most advantageous method of dividing the capsule. They are infinitely better than those given by Wenzel and Ware. As soon as the point of the cornea knife had arrived opposite the pupil, Wenzel used to incline it gently backward, and thus puncture the capsule; but, Mr. Ware very properly objected to this plan, which, however it might serve to exhibit the dexterity of the operator, was attended with no advantage to the patient, and could not be so efficient and safe as the mode of making the division of the capsule a distinct part of the operation.

Indeed, Wenzel himself did not recommend opening the capsule of the crystalline, in every instance, at the time of cutting the cornea. In cases, where the pupil is much contracted, and where the muscles of the eye and eyelids are easily thrown into convulsions, it is improper, says he, to puncture the capsule when the section of the cornea is making. This is also improper when the space, between the crystalline, and the iris, termed the posterior chamber, is large. In all such cases, Wenzel acknowledged, that it is better simply to divide the cornea in the first instance, and then to puncture the capsule with a different instrument.

Wenzel and his father used to employ, for this purpose, a flat needle, one line, that is, one-twelfth part of an inch in diameter, having its cutting extremity a little incurvated. This needle, which they advised to be made of nealed gold, in order that its pliability may allow the operator to bend it in different directions, as occasion requires, is fixed in a handle, two inches and a half in length, and similar to that of the cornea knife. At the other extremity of the same handle, a small curette, or scoop is fixed, made also of nealed gold, which is of use for extracting the cataract.

The late Mr. Ware's method of opening the capsule will be hereafter noticed.

When the incision in the cornea has been completed, and the capsule effectually divided, the cataract, as Beer observes, advances into the pupil immediately behind the capsule-needle, and, if there be the least action in the eye itself, it is generally at once

discharged. Under these very favourable circumstances, however, it sometimes happens, that a portion of the gelatinous or scabrous surface of the cataract is detached at the margin of the pupil, as the opaque body is passing out, and, therefore, in the second stage of the operation, Beer recommends having Daviel's scoop always ready, which is to be substituted for the capsule-needle, and employed for preventing the loose fragments from falling back into the posterior chamber in the following manner: as soon as the operator remarks, that, in the passage of the cataract out of the pupil, a portion of it will be scraped off by the edge of that opening, he should introduce the scoop at the lower and outer edge, of the cataract upwards, between the cornea and the iris, so as to be able to keep the part of the cataract, which is ready to break off, close up behind the rest of it, and bring the whole out of the eye.

But, says Beer, when the third stage of the operation, viz. the removal of the cataract from the eye, cannot be so readily accomplished, a circumstance, not always owing to an imperfection in the incision in the cornea, or in the division of the capsule, but sometimes proceeding from a want of proper action in the eye itself; the operator, if he feels convinced that the fault does not lie in the first or second stage of the operation, (in which case, it would be necessary to endeavour to rectify what is wrong,) should assist in promoting the discharge of the cataract. There are two manners of doing this, and it is not a matter of indifference which is selected; for, the second should be adopted only, when the first will not answer. Hence, says Beer, the operator, like a skilful accoucheur, must first trust to the action of the organ itself, which he should in a certain degree excite, and not proceed immediately to the use of a scoop, hook, or forceps. The eye is to be suffered to turn quickly a few times upwards, and in general, during these movements, the surgeon will perceive, that the lower edge of the cataract advances further through the pupil, and at length, slips out of the eye, without the aid of instruments. If at this period, a portion of the cataract were found to be likely to break off, the employment of Daviel's scoop, in the way already explained, would be proper. On the other hand, if, during the protracted movements of the eye upwards, this organ evince little energy of its own, the cataract will not enter the pupil, or scarcely do so, much less pass out of the eye, and the operator is under the necessity of resorting to manual assistance, and with the end of the finger used for keeping the lower eyelid depressed, he is gently to press the lid against the lower part of the eyeball. Such pressure should be gradually increased, until the greatest diameter of the cataract has passed into the pupil, at which moment, the pressure must not be discontinued, before the cataract is completely out of the eye, which object may be promoted by supporting the lower part

of the lens with Daviel's scoop, and then the pressure is to be diminished in the same gradual way, in which it has been previously augmented. Immediately the cataract is completely out of the eye, and the surgeon has paid due attention to the removal of any fragments left behind, the assistant is to let the upper eyelid descend. the patient is to be desired to keep both his eyes shut and perfectly still, and his head and eyes are to be covered with a clean white piece of linen, so that the effect of the light may be moderated.

When the patient has recovered from the alarm, which, according to Beer, the passage of the cataract outwards, especially when it is large and firm, always produces in a greater or lesser degree, he is to be placed with his back towards the window, and the linen is to be raised a little from the eye, which is to be very slowly opened, while the other eye, which has not been operated upon, is to be kept well covered. Beer says, that the patient should then be shown some objects, not of a shining, or very bright description, at different distances; and, if he is able to see them plainly, the surgeon may proceed to apply the dressings without delay.

Beer confesses, that, if possible, it would be better to dispense altogether with making any trials of the power of the eye, which has just been operated upon, because such attempts must tend to increase the subsequent inflammation in the organ; yet, he is of opinion, that these trials of the eyesight are necessary after extraction of the cataract. First, because the capability of seeing immediately, is a thing always expected by the patient and his friends, and leaving them in ignorance on this point, would keep up an anxiety, likely to have a bad effect in rendering the ophthalmia more severe. Secondly, Beer urges, as a stronger motive for the custom, the circumstance of the patient seeing, when his eye is first opened, all, even the smallest objects, though he suddenly loses the faculty of distinguishing them at all, or sees them very obscurely; and, now, if he be half turned with his face towards the window, one will find in the pupil, which directly after the passage of the cataract was perfectly clear, some soft or firm fragments of the lens, which are first dislodged from within the capsule by the variations in the eye, produced by the inspection of different objects at different distances, and which, without these trials of vision, would be long in being loosened by the aqueous humour, and might form a secondary lenticular cataract; which will not now be the case, as the surgeon can and ought at once to remove them. (*Lehre von den Augenkr.* 2 B. p. 373.)

The preceding mode of operating, as Beer observes, will not answer for every case of cataract, adapted to extraction; but, the plan sometimes requires to be modified according to circumstances. Thus, according to the same writer, when the eye is very prominent, and particularly when at the

same time the fissure of the eyelids is extremely narrow, the incision in the cornea must not be made horizontally, but obliquely outwards; for otherwise the edge of the lower eyelid will retard the healing of the wound, and an ugly cicatrix, more or less injurious to the eyesight, be the consequence.

When the cataract is of middling consistence, neither very hard, nor soft, Beer assures us, that the attempt ought to be made to extract the cataract and the capsule together at the same time, as formerly recommended by him. (*Methode den grauen Staahr sammt der Kapsel auszuziehen*, &c. *Wien*. 1799.) In such a case, he says, the experiment will mostly succeed, if properly conducted, and, if it should not, it causes not the slightest detriment to the eye, nor the least obstacle to the effectual completion of the operation. In order to accomplish what is desired, the capsule-needle is to be introduced into the pupil, as in the second stage of the operation, and its point is then to be slowly pushed, as far as its greatest diameter, into the centre of the lens, so that one surface of the needle may be upwards, the other downwards; one of its cutting edges turned towards the inner canthus, the other towards the outer one. And now the needle, with the impaled cataract, is to have sudden, but short perpendicular jerks communicated to it, by which means, the upper and lower connexions of the capsule with the neighbouring textures will be in part loosened. The needle is next to be suddenly rotated, without withdrawing it from the cataract, so that one of its flat surfaces may face the inner canthus, the other, the outer one; and one of its edges may be turned upwards, the other, downwards; and then the short sudden jerks of the needle in the horizontal direction may be repeated, for the purpose of breaking, as much as possible, the lateral connexions of the capsule. Lastly, the capsule-needle is to be quickly withdrawn from the eye, when it is mostly followed by the lens and the capsule, or the cataract comes away fixed on the point of the instrument, at which moment the pupil becomes perfectly clear and black. When the cataract does not follow the withdrawing of the needle, the surgeon is to proceed with the usual cautions to the third stage of the operation. Great as the advantage would always be of extracting the cataract, together with its capsule, it is plain, that the attempt is not practicable when the case is a very hard lenticular cataract, because the capsule-needle cannot be effectually introduced into the body of such a lens, situated upon the yielding vitreous humour. Nor would the plan answer, if the cataract were very soft, as the movements of the needle in it could have no effect in breaking the connexions of the capsule.

In the case described by Beer under the name of *encysted cataract*, the capsule must not be opened; but after properly opening the cornea, if the cataract does not escape of itself at this moment from the eye, the

operator must immediately introduce the small cataract-tenaculum, with its point turned downwards, between the cornea and the iris, into the pupil. The cataract should then be firmly taken hold of with the hook, and slowly and steadily drawn out of the eye with its thick, tough capsule. Beer says, that extraction should be performed in the same way in the dry-husked capsulo-lenticular cataract of children and adults, except that, in all these cases, a fine, elastic, sharp, silver, or golden spatula, fixed at the lower part of Daviel's curette or scoop, should be ready at hand to assist in separating the cataract from the vitreous humour, immediately the opaque substance is disposed to pass out of the eye. Also in the completely fluid cataract, when the capsule is partially opaque and thickened, a circumstance easily known by appearances, the same mode of extraction must be attempted. But, if the hook should tear its way out, and the capsule empty itself, the extraction must be performed altogether with the forceps. The latter instrument is to be cautiously introduced in the same manner as the capsule-needle into the pupil, one of the largest and thickest portions of the capsule are then to be taken hold of, and suddenly drawn out towards the opposite side, by which means, generally the whole anterior layer, and sometimes also the posterior layer of the capsule will be detached, and the pupil immediately cleared. On the contrary, in what Beer has called the *bar cataract*, which, he says, is seldom fit for an operation, as soon as the cornea has been opened, the bar must first be separated, by means of the capsule-needle, from the uvea, in whatever way is found most practicable, and then it is to be extracted with the small cataract-tenaculum, or teeth forceps; when this has been done, the cataract itself must be taken out of the eye in the same manner as the encysted cataract. (*B. 2, p. 377.*)

When extraction has been completed, the next object is to dress the eye; while the patient turns his eye upwards, the lower eyelid is to be drawn downwards from the eye with the fore-finger, and steadily held so, until the patient has shut his eye as much as possible. At this moment, Beer applies a small strip of adhesive plaster, perpendicularly over the fissure of the eyelid, a practice very properly not imitated in this country; and then a doubled piece of fine linen, which is fastened on the forehead with a common bandage. Both eyes he dresses in the same manner, even when only one has been operated upon.

Mr. Ware found, that a dossil of lint, steeped in plain water, or brandy and water, and covered with the spermaceti, or saturnine cerate, and removed once every day, is the most easy and convenient dressing, that can be applied after the operation. The cerate over the lint prevents the latter, when impregnated with the discharge, from becoming stiff, and irritating the lids. Mr. Ware thought the mode of applying the compress and bandage over the eye, a circumstance

of no small importance, because, if too loose, the dressings are very apt to slip off, and, consequently, to press unequally and injuriously on the eye; and, if too tight, the undue pressure will excite pain and inflammation, and even force out some of the vitreous humour. Mr. Ware's compress is made of soft linen, folded, two or three times, wide enough to cover both eyes, and sufficiently long to extend from the upper part of the forehead to the lower part of the nose. This he pins at the top of the patient's night-cap; and its lower part, which is divided in the middle, to allow the nose to come through it, he lays loosely over the eyes. The bandage, also made of old linen, and as broad as six fingers, he carries round the head over the compress, and pins to the side of the night-cap moderately tight. A slip of linen is afterwards carried under the chin, and pinned at each end to the side of the bandage, so as to prevent it from slipping upwards. (*Ware.*) Beer recommends the patient to lie upon his back, with his head not too low, and in a chamber which is not too light, and to remain in this way at least until the wound in the cornea is closed. As, during the first two days after the operation, the doubled piece of linen, which Beer places over the eye, is repeatedly wet through with the discharged aqueous humour, it is to be changed several times a day, care being taken to let the fresh pieces of linen be well aired and warmed. With respect to the after treatment, Beer also enjoins the observance of every thing, which has been already pointed out as proper after depression and reclination; and, in particular, while the wound in the cornea is not firmly healed, and the eye cannot be kept open, the patient must refrain from taking snuff and smoking tobacco. According to the same author, no thoughts should be entertained of opening the eye again, till two or three days after the discharge of the aqueous humour has completely ceased; a circumstance always indicated by slight prickings in the eye itself, by a burning, though not very severe, pain, attending the escape of that fluid from the inner canthus, and in irritable, nervous, debilitated subjects, even by the sensation of transient luminous appearances. Therefore, Beer says, the eye should seldom be opened before the 5th, or 6th day. When this is first done, the light should be very moderate, and the patient placed with his back towards it, all unnecessary lateral light being kept from the eye by the linen attached to the forehead, while the daily trials of the newly recovered powers of the eye should be made with the utmost precaution. On the 8th, 9th, or at latest, on the 10th day, Beer recommends leaving the eye open, but screened above by a green eye-shade, in a half darkened chamber; and he is afterwards to be treated, until his eye is perfectly well, according to the rules already laid down as proper to be observed after couching. And, especially when the patient has had cataracts in both eyes, Beer thinks it as well to apprize him, in order to prevent un-

necessary alarm, that, upon first going out into the open air particularly in the evening, he will be for some moments almost blinded, and then begin to see again, but every object will now appear covered with a white, shining circle, which at length goes off; though, in the open air, it will sometimes continue for several days. (B. 2. p. 380.)

The late Mr. Ware published an inquiry into the causes preventing the success of extraction of the cataract.

The first, which he considers, is making the incision through the cornea too small. In this circumstance a degree of violence will be required to bring the cataract through the wound: and, if the cataract be not altered in its figure, the wound will be forcibly dilated, and the edge of the iris compressed between the cornea and the cataract. In this way, either some of its fibres may be ruptured, or it may be otherwise so much injured, as to excite a considerable degree of inflammation, and even induce, in the end, a closure of the pupil.

This accident may arise from the operator's cutting the cornea, without being able to see exactly the position of this membrane, in consequence of the eye having turned inward, owing to its not being properly fixed. The fault may also proceed from the incision having been begun below the transverse diameter of the cornea. In this manner, nine-sixteenths, or rather more than half of the circumference of this membrane, will not be divided; which extent the incision ought always to occupy, in order to allow the cataract to be extracted with facility.

When however the cornea is remarkably flat, and the iris projects unusually forward in the anterior chamber, Mr. Ware recommends including only one-third of the cornea in the first incision, and afterwards enlarging the aperture, on the outer side, by means of curved scissors.

Taking care to fix the eye in Mr. Ware's way, is represented by this author as being of great consequence in hindering the wound in the cornea from being made too small.

Whenever the wound in the cornea is made too small, it should always be enlarged before proceeding further in the operation; and, according to Mr. Ware, this can be best accomplished with a pair of curved blunt-pointed scissors, on the outer side of the cornea, where the knife first made its entrance.

For doing this, Beer recommends the use of Daviel's scissors, which are to be introduced with their concavity towards the operator, and their point directed towards the pupil. Beer also introduces the point of the inner blade into the middle of the wound of the cornea, under the flap already made, and passes it somewhat higher than the place to which it is necessary to enlarge the incision. Then he first conveys the instrument to the inner or outer angle of the wound, where the dilatation is to be made, keeping the blade which is within the cor-

nea, not parallel to the iris, but in an oblique position with respect to it, for otherwise the best scissors will fail to make a clear division. The scissors also must not be opened more, than is absolutely necessary, and they should be very quickly shut, and in such a manner, that the outer blade ought only to move towards that within the cornea, lest the eye suffer injury. Beer says, that it is hardly ever necessary to enlarge the incision in the cornea at both its angles; and, in these cases, he confesses, that all idea of shaping the wound altogether as it ought to be, must be renounced. (*Lehre von den Augenkr. R. 2, p. 282.*)

Wounding the iris with the cornea-knife, is the second accident, which Mr. Ware considers. The principal cause seems to him to be a discharge of the aqueous humour, before the knife has passed through the cornea low enough to hinder the lower part of the iris, which forms the inferior rim of the pupil, from getting beneath the edge of the instrument. According to Mr. Ware, the escape of the aqueous humour may be owing to some inaccuracy in the shape of the knife, or unsteadiness in introducing it. The falling of the lower part of the iris under the edge of the knife, Mr. Ware believes, cannot always be prevented by the utmost skill, or precaution of the operator. Happily, however, says he, we have been taught, that the iris may be reinstated, after it has been thus displaced, and without suffering any injury, by making gentle frictions on the cornea, with the point of the finger.

By unsteadiness in passing the knife, Mr. Ware means, that the knife may not only be suffered to make a punctuation through this tunic, but, that its edge may, at the same time, be unintentionally pressed downward, so as to make an incision likewise; in consequence of which downward motion of the knife, an aperture must unavoidably be left in the cornea, through which the aqueous humour will escape. If the cornea knife increase through its whole length, both in width and thickness, and if it be merely pushed through the cornea, no space will be left, through which any fluid can escape.

According to Beer, the escape of the aqueous humour, as the knife passes across the anterior chamber, may happen with, or without any fault on the part of the operator, and the iris fall not merely against the posterior surface of the knife, but even project under its edge, and over its back. When this happens, Beer joins Ware in recommending the end of the middle finger, situated at the inner canthus, to be gently pressed without delay upon that part of the cornea, which is in front of the knife, and, at the moment, when this is done, the iris will recede from the edge of the instrument, and the operator, by being very quick, may proceed again without any risk of injuring that part of the eye. But, if the iris should be found to project again above and below the knife immediately the point of the finger is removed from the cornea, such removal should not be made, and the knife be

boldly pushed on until its point pierces the other side of the cornea; or, if the point has already passed some way out of the cornea towards the inner canthus, the blade is to be pushed on so far, that no protrusion of the iris is possible. For, says Beer, while the finger continues to make gentle pressure upon the cornea, the iris will not fall under the knife. Should the eye chance to withdraw itself from the knife, after this has penetrated the anterior chamber; a circumstance, which may easily happen in restless timid patients, the greater part or the whole of the aqueous humour is immediately discharged, and the iris comes in contact with the empty cornea. In this case, Beer says, that the operator should find out the wound with another knife, and with a wriggling motion of the instrument, conduct it between the iris and the cornea, twisting and turning the point about until it has successfully passed beyond the external, then beyond the inner pupillary margin of the iris, and has finally come out of the cornea again. Now the incision in the cornea may be properly finished, in doing which, it is always necessary to keep the middle finger applied to this membrane, in consequence of the disposition of the iris to fall against the knife. Beer mentions it as a curious fact, that most of the patients, who are restless and unmanageable at the first introduction of the knife, and who themselves cause that disagreeable occurrence now spoken of, are, on the contrary, very quiet during the foregoing manœuvres. (*Lehre von den Augenkr. B. 2, p. 381.*)

The third accident, noticed by Mr. Ware, is the escape of the vitreous humour. The common occasion of this occurrence is the undue application of pressure. It may take place, either when the incision is made through the cornea, or at the time of extracting the cataract. Some eyes are subject to spasm, which renders them much more liable to this accident. To prevent it, Mr. Ware recommends every kind and degree of pressure to be taken from the eye, before the knife has completely cut its way through the cornea. And, as soon as the knife has proceeded sufficiently low to secure the iris from being wounded, the operator should not only take heed, that his own fingers do not touch the eye, but should also direct the assistant, who supports the upper lid, to remove his fingers entirely from this part. The assistant seldom need make any pressure on the globe of the eye: however, when there is room for one of his fingers to be placed on the inner and upper part of the globe, without interfering with those of the operator, the method may be followed, in order to make the eye still more fixed. But immediately the *punctation* of the cornea is completed, the assistant's finger should always be entirely removed both from the eyelids and eye itself.

Notwithstanding the upper lid is left thus free, there will be sufficient space between it and the lower lid, to allow the progress of the knife to be seen; and, in finishing the

wound, the operator should depress the lower lid with great gentleness.

The vitreous humour may also be lost, in consequence of opening the capsule of the lens nearer the circumference, than the centre of the pupil. As the crystalline is both thinner and softer at that part, the instrument will be liable to pass through both sides of the capsule, and enter the vitreous humour. This humour having no longer any barrier to its escape, is liable to be forced out by the action of the eyelids alone; and, when pressure is afterwards made, to bring the cataract through, a much greater quantity will be lost, and the cataract, instead of coming forward, will recede from the pupil. The only way to extract it now, is, by letting the upper lid be gently raised by an assistant, (a rare instance, in which this is necessary after cutting the cornea) while the operator, either with the fore-finger of the left-hand, or with the blunt end of the curette, applied beneath the incision in the cornea, prevents the cataract from sinking further. Then, with his right-hand, let him introduce a hook under the flap of the cornea, and with its point carefully entangle the cataract, and bring it away.

To prevent, however, such difficulties, Mr. Ware never attempted to puncture the capsule, until the whole pupil was in view. He was in the habit of opening the capsule with a gold-pointed needle, arched towards its extremity. Wenzel's needle, for this purpose, was flat in its extremity: Mr. Ware's pointed; and this is their only difference. The latter introduced his instrument under the flap of the cornea, with its arched part uppermost, until its point was on a level with the centre of the pupil. The end of the instrument was then turned inward, and gently rubbed on the capsule of the crystalline, until it pierced it. In a few instances, Mr. Ware found the capsule so tough, that the point of the gold needle would not enter it, and he was obliged to use a sharp steel instrument, of the same shape as that with a gold point. As already explained, Beer was much bolder with the capsule than Ware, and there can be little doubt, that both his capsule-needle and mode of using it are better, than those of Wenzel and Ware.

The vitreous humour may also be lost, at the time of extracting the cataract, and the usual cause is an undue application of pressure. All violent pressure is quite unnecessary for forcing out the cataract, when the wound in the cornea is sufficiently large. When the wound is too small, it should be enlarged as above directed. If pressure be continued at all after the cataract is extracted, the capsule of the vitreous humour will certainly be ruptured, and some of this part of the eye protrude. Pressure may even rupture the capsule of the vitreous humour, before the cataract is brought through the incision in the cornea; the same consequences will ensue; and the same practice be necessary, as in the case, in which the operator has unskillfully opened the capsule

of the vitreous humour with the needle, in attempting to open that of the lens.

In taking away fragments of opaque matter from the pupil, by means of the curette, great care is requisite to avoid wounding the posterior part of the capsule of the crystalline with the end of the instrument, so as to open a way for the escape of the vitreous humour.

The vitreous humour may, indeed, be forced out, after the extraction of the cataract, merely by a spasmodic action of the eyelids. On this subject, Mr. Ware, after hinting his suspicion, that, in a case of this kind, which he saw, the assistant's keeping up the lid contributed to the event, repeats his advice, "that the upper eyelid should be raised solely by the fingers of the left-hand of the operator," after cutting the cornea.

Mr. Ware seems to think, that more evil has resulted from the operator's being deterred, by the readiness, with which the vitreous humour continues to start out, from ascertaining, that all the fragments of the cataract are removed, and that the whole of the iris has resumed its position, than from the mere loss of the vitreous humour, which is quickly regenerated.

When a portion of the vitreous humour protrudes, Beer thinks, that the safest practice is not to meddle with it, though he owns, that, in this circumstance, the wound heals slowly, and is always followed by a more or less perceptible, whitish scar, the pupil being generally drawn towards it, and deformed, while the iris and the partly emptied membrana hyaloidea become adherent to the edges of the incision in the cornea. But, says Beer, the eyesight will be but little, or not at all impaired, notwithstanding one-eighth or one-fourth of the vitreous humour may be lost. However, he observes, that when one-third or half of it has escaped, a good degree of vision afterward cannot be expected; and when more than half has been lost, the operation will have a still less successful result. He states also, that, when two-thirds have been lost, though the eye may recover its natural form, the pupillary edge of the iris will remain contracted round the empty, light-gray membrana hyaloidea, which projects into the anterior chamber, consequently, the pupil will be closed, and that state of the iris ensue, which is aptly termed a *sinking of the pupil*, *subsidentia pupillæ* or *synicesis*.

Mr. Ware notices the accident of extracting only a part of the cataract, and leaving the remainder behind. He is an advocate for removing all opaque substances from the pupil, except an extreme degree of irritability, to which some eyes are subject, should render the introduction of every sort of instrument, after the cataract is extracted, difficult and dangerous. Mr. Ware usually removed opaque portions of the cataract by means of a curette; and, occasionally, when the opaque substance was large, and adherent to the capsule, he was obliged to extract it with small forceps. Before finishing the operation, Mr. Ware approves of always

rubbing the end of the finger gently on the forepart of the eye, over the eyelids; which proceeding tends to bring into view any opaque matter, which may previously lie behind the iris. Mr. Ware relates a case, proving, that such opacities, as cannot be removed in the operation, are capable of being absorbed.

When, notwithstanding the observance of the directions laid down by Beer, as explained in the previous columns, some of the pul-taceous, or scabrous surface of the cataract is detached, and continues behind in the posterior chamber, Beer says, that it ought to be immediately removed, lest the patient be left with a secondary lenticular cataract, which, he observes, is not always so certain of being dissolved and absorbed, as some imagine. The fragments may be removed in two ways; and, first, the experiment of rubbing the upper eyelid over the eye should be made, because it not unfrequently brings the remains, especially when they are gelatinous, completely through the pupil, and out of the incision in the cornea. But, if such manoeuvre should not be effectual, Beer recommends cautiously introducing Daviel's curette to the outer pupillary edge of the iris, with its concavity towards the inner surface of the flap of the cornea, without raising this flap unnecessarily high, and then the operator is to endeavour to scoop out at once as much of the opaque matter as he can, and bring it to the inner surface of the cornea. He says, that it will rarely be necessary frequently to repeat the introduction of the curette. (*B. 2, p. 387.*)

According to Mr. Ware, an opacity of the capsule can be the only reason for removing it. The anterior part, he says, can alone become the object of the operator's attention: its posterior part is necessarily hidden, while the cataract remains in the eye, and afterward, if discovered to be opaque, it is so closely connected with the capsule of the vitreous humour, that Mr. Ware believes it cannot be removed by any instrument, without hazarding a destructive effusion of this humour.

When, however, the opaque lens is accompanied with an opacity in the front part of the capsule, Mr. Ware recommends the following plan. After cutting the cornea, as usual, a fine pointed instrument, somewhat smaller in size than a round couching-needle, and a little bent towards the point, should be introduced under the flap of the cornea, with its bent part upward, until its point is parallel with the aperture of the pupil. The point should then be turned toward the opaque capsule, which is to be punctured by it, in a circular direction, as near to the rim of the pupil as the instrument can be applied, without hurting the iris. Sometimes, the part included within the punctures, may be extracted on the point of the instrument; and, if this cannot be done, it should be removed with a small pair of forceps. The lens, whether opaque or transparent, should next be extracted, by making a slight pressure with

the curette, either above, or below, the circumference of the cornea.

On the preceding subject, Beer remarks, that when none of the lens itself is left behind, but there is a slight degree of opacity in the anterior layer of the capsule, easily distinguishable from the cut flakes, and producing the least obstacle to vision, the opaque membrane should be taken away with the forceps, in the manner described in the preceding pages; for, otherwise a secondary capsular cataract will follow, which will become of a snow-white colour, and if only a trivial degree of iritis take place after the operation, it will become adherent to the iris, and the pupil become contracted and disfigured. (*B. 2, p. 388.*)

Beer does not agree with Ware in condemning all attempts to remove the posterior layer of the capsule, when found opaque, after the extraction of the lens. The case, he says, is indicated by the light gray speckled appearance of the whole pupil, and by the patient seeing nothing at all, or objects only indistinctly in a thick mist. Beer advises a cataract-tenaculum to be passed into the pupil, in the same way as the capsule-needle is introduced in the second stage of extraction, directing its point downwards as it enters, and upwards when it is brought out again. After it has entered the pupil, it is to be made to divide and annihilate, by repeated turns of the tenaculum, the back layer of the capsule, and also the membrana hyaloidea, directly behind it, which, in such a case, is always adherent, and opaque. Of these membranes a considerable part, closely wound round the hook, may be taken out of the eye, though never without some slight loss of the vitreous humour. In cases of this kind, the patient ought to be informed, that, though his sight will be restored, a part of the cataract must be left, and will be visible behind the pupil, particularly when it is dilated; for, otherwise, suspicions may arise, that the operation has been badly done, and a relapse apprehended. (*B. 2, p. 388.*)

Mr. Ware has considered the bad consequences of allowing foreign bodies of any kind, after the operation, to press unequally on the globe of the eye; comprehending, under this head, the intervention of the edge of the lower eyelid between the sides of the divided cornea; the inversion of the edge of the lower eyelid; and the lodgment of one, or more, loose eyelashes on the globe of the eye.

To prevent the first accident, every operator, before applying the dressings, should carefully depress the lower eyelid; and, before he suffers the lid to rise, should take care that the flap of the cornea be accurately adjusted in its proper position; and, that the upper lid be dropped, so as completely to cover it. After this, the eyelids should not be opened again, for three or four days, that is, until there is a good reason to suppose the wound in the cornea closed. (*Ware.*)

The inversion of the lower eyelid is hurt-

ful, in consequence of its making the eyelashes rub against the eye. These should be extracted the day before the operation. For the mode of effecting a permanent cure, see *Trichiasis*.

Besides the danger, to which the eye is exposed, from the inversion of the edge of the lid, the eye may receive injury from the improper position of the eyelashes alone; one or more of which, during the operation, may happen to bend inwards; or, becoming loose, may afterward insinuate themselves between the inside of the lid and the eye. An eyelash bent inward, should be rectified; if broken off and loose, it should be removed.

Mr. Ware lastly considers prematurely exposing the eye to a strong light. He censures the plan of opening the eyelids, within the first two or three days after the operation, because the stimulus of the light increases the ophthalmia, and the method is apt to disturb the wound in the cornea, before it is closed. Mr. Ware, however, wishes it not to be inferred, that he is an advocate for long confinement after the operation. His mode is to keep the patient wholly in bed, and to direct him to move his head as little as possible for the first three days after the operation. During this time, a dossil of wet lint is kept on his eyes, covered with a saturnine plaster, compress, and bandage, as already described. The dressing is renewed once every day, and the outsides of the eyelids washed with warm water in winter, and cold in summer. At each time of dressing, the skin of the lower lid is drawn gently down, to prevent any tendency to an inversion. Animal food is prohibited, and the patient enjoined not to talk much. On the fourth day, he is permitted to sit up for two or three hours, and, if he has had no stool since the operation, a mild opening medicine is now administered. On the fifth, the time of his sitting up is lengthened, and, presuming that the wound in the cornea is now closed, Mr. Ware usually examines the state of the eye. After this, no dressings need be applied in the daytime, care being taken to defend it from a strong light, by a pasteboard hood, or shade, and by darkening the room, so that no inconvenience is felt. The patient may now also look, for a short time, at large objects. The following part of the treatment need interfere very little with the wishes of the patient, unless unexpected accidents should occur. (*Ware.*)

As Beer, observes, if the patient be very restless, make frequent attempts to open his eye in the least, and partly lie upon the eye, or if in changing the compresses the greatest caution be not used, the eye will perhaps be roughly pressed upon, and the iris protrude between the displaced and half-opened edges of the incision in the cornea, to which it will become adherent during a slow and very seldom violent inflammation. From the moment when the iris thus interposes itself between the sides of the wound, the aqueous humour begins to collect, and at length pushes the iris considerably for-

wards. In this case, Beer recommends carefully opening the eye in a very moderate light, and adopting the expedients formerly mentioned, for the purpose of making the iris recede. The dressings should be reapplied, and the eye kept closed and very quiet for at least eight or ten days, so as to hinder a recurrence of this disagreeable accident. But if the iris should be already adherent to the edges of the wound in the cornea, the eye incapable of bearing light, and the aqueous humour more or less accumulated in the anterior chamber, Beer says, every thing must be left to time, while the eye is kept lightly covered for about a fortnight, and the existing inflammation properly treated. Then, if the protrusion or staphyloma of the iris should not be diminished, by the means calculated for lessening the inflammation, caustic, or the knife must be employed. (*Beer, B. 2, p. 391.*) The same causes which have been above specified as conducive to a protrusion of the iris, may also produce a discharge of the vitreous humour.

The following observations by Beer are interesting: when the dressings have been unskilfully applied; when the incision in the cornea has been made horizontally upon a large prominent eye; when the fissure of the eyelids is exceedingly narrow; or the patient is restless; a proper cicatrization of the wound in the cornea may not follow. Though the aqueous humour may collect in the anterior chamber, the partially united lamellæ of the cornea may be incapable of duly resisting the distention of that fluid, and consequently protrude in the form of a light-gray, semi-transparent, oval vesicle, extending nearly the whole length of the wound in the cornea, and being most prominent in the centre. The patient complains of an annoying sense of pressure in the eye, as in cases of protrusion of the iris; but the discharge of the aqueous humour has completely stopped, and therefore the anterior chamber presents its natural appearance, and the pupil its regular round shape, though the edges of the wound in the cornea are whitish and swollen. This case was formerly regarded as a prolapsus of the membrane of the aqueous humour; but Beer considers it as a sort of hernia of the cornea, termed *ceratocèle*. Merely puncturing, or cutting away the cyst is of no service; for, though the aqueous humour immediately flows out, the wound soon closes again, and the tumour reappears, attended also with some risk of the iris falling into the cyst, and becoming adherent to it. Effectual relief cannot be obtained, unless the tumour be removed with Daviel's scissors, as close as possible to the wound; the dressings skilfully arranged; and the eye kept closed and quiet for eight days, or a fortnight. In such a case, a whitish scar is always permanently left. (*Beer, B. 2, p. 393.*)

Beer observes, that when the pupil contracts very considerably after the incision in the cornea is made, and the cataract at

the same time remains at some distance from the uvea, too small an opening has generally been made, and it ought to be enlarged. But if the cataract cannot be forced through the pupil, without making pressure on the lower part of the eyeball, and the closure of the pupil should still continue, the circumstance proceeds from the loss of the aqueous humour, and the second stage of extraction must be deferred a little while until the pupil dilates again, and the operation must then be finished in a very moderate light.

When, in the second stage of the operation, the anterior layer of the capsule has been properly divided, and yet the cataract will not pass into the pupil, though the eye itself acts with energy, Beer says, that it is indispensably necessary to make pressure upon the lower part of the eyeball, as already advised, and to continue it either until the cataract with its lowermost edge effectually projects through the pupil and out of the eye, or until it is moved so far directly upwards, (without entering the pupil,) that its lower margin is brought into view, and quite a black semilunar interspace is seen between it and the inferior pupillary edge of the iris. At this moment the operator, without increasing the pressure of the finger on the eyeball, lest the vitreous humour burst, and a great part of it be lost, and without lessening the pressure, lest the cataract sink back into the eye, should introduce Daviel's curette into the above interspace, with its hollow surface applied against the back surface of the cataract, which is to be gently pushed out of the eye. In doing this, Beer owns that a small part of the vitreous humour is almost always lost, but the quantity is not at all comparable to what is lost when the hyaloid membrane gives way before Daviel's curette is introduced, which can then only be passed into the eye through the protruded vitreous humour for the purpose of pushing out the cataract.

Beer notices the occasional protrusion of the iris, in the third stage of the operation, more or less between the edges of the incision in the cornea, immediately after the exit of the cataract. Here, says Beer, the iris should be reduced without the least delay, and the pupil, which is completely oval, made round again; a thing which the operator may easily perform, by applying his hand flat upon the patient's forehead, letting the latter shut his eye, rubbing the upper eyelid quickly, yet gently with the thumb, and then suddenly opening the eye, by which means a moderate light will all at once strike it, and induce an expansion of the iris.

In all patients who have been operated upon for cataracts, the edges of the eyelids become glued together with mucus on the first night after the operation; yet, according to Beer, in individuals particularly subject to copious secretions of mucus, it is not unusual for the puncta lachrymalia and lachrymal ducts to be blocked up with thick-

ened mucus, whereby the tears are prevented from duly passing down into the nose, so that from time to time they are discharged from the inner angle of the eye, and collect under the eyelids. In this case the patient soon begins to complain of a violent, continual, and increasing sense of pressure on the eye, and the upper eyelid swells, unattended with any redness. Irritable persons also experience a stupefying dull headach. These inconveniences may be immediately removed by clearing away the mucus with a little lukewarm milk from the inner canthus, and letting a stream of clean water fall over the cheek. Care must also be taken to hinder a recurrence of the circumstance again, and to remove it if it should happen.

The inflammation, consequent to extraction, chiefly affects the iris and neighbouring textures. Beer refers its origin principally to the entrance of air into the interior of the eye; which, owing to the size of the wound, he says, is not entirely to be prevented. But another cause is the introduction of different instruments into the eye, and hence the inflammation is generally severe, when it has been necessary to remove fragments of the cataract with Daviel's curette, or to take away the capsule with forceps, or destroy it with the tenaculum-needle. However, Beer is of opinion, that a surgeon, who knows how to operate well in every mode, will not find the inflammation, under these circumstances, more violent after extraction, than other methods, and therefore, he thinks, that when no considerable impediment exists, it should be preferred. Beer, who considers extraction as a radical mode of removing a cataract, thinks, that when there are no great and insurmountable obstacles to its performance, and the operator can execute it as well as all other methods, and with the requisite skill, it ought to be preferred. But when he is deficient in skill, he is himself the greatest impediment to the success of the operation. The particular cases, in which the methods of depression and reclinatio are indicated, have been already specified, and in these, of course, extraction is not advantageous. There are also some examples, as Beer remarks, in which the latter operation must be hazardous for a beginner, and therefore, in respect to such an operator, by no means eligible, as in cases of *bar-ataract*, and *capsulo-lenticular cataracts with a cyst of purulent matter*. (Beer, B. 2, p. 396.)

OF KERATONYXIS.

The etymology and meaning of this term will be found in its place in this dictionary. This operation requires the pupil to be first artificially dilated. It admits of being divided into two stages; first, the introduction of the needle through the cornea and pupil as far as the cataract; and, secondly, the breaking of the lens to pieces, and the division and laceration of its capsule. For these purposes, Beer prefers a common,

straight, spear-shaped, sharp-edged couching-needle to any curved-one, however fine it may be made; first, because it pierces the cornea, with greater facility; secondly, because both a soft cataract and the capsule can be more effectually cut with it, a larger opening being made, through which the aqueous humour may flow over the fragments of the lens, and the dissolution of the cataract be thus rendered more certain; whereas, with a curved needle, Beer says, the lens can only be disturbed, and the capsule torn, under which circumstances, inflammation and a secondary capsular cataract is likely to be produced. He directs the instrument to be introduced either at the lower, or at the external part of the cornea, one line and a half from its margin, the point being directed obliquely towards the pupil, and the capsule is to be effectually cut by moving the extremity of the needle laterally in various ways; and, above all things it is necessary at the time of breaking the lens piecemeal, not to let the instrument continue always within this body, but, at every stroke, to lift it completely out of the lens and capsule, and then introduce it into them again in different directions.

As Beer observes, this method of operating must soon have been found as little adapted to all cataracts, as any other mode; for, otherwise, the suggestion would not have been made to practise *reclination* through the cornea. To this form of reclination, however, Beer adduces great objections; for, he says, that, in this manner, either the cataract cannot be properly turned, if the iris be duly spared; but it will continue to lie obliquely, being always quite evident below the pupil, and very apt to rise again from the slightest cause; or it is indeed depressed far enough towards the bottom of the eye, but, however much the pupil may be artificially dilated, the pupillary edge of the iris is more or less injured, especially with the convexity of a curved needle. In addition to these considerations, Beer urges against this method all the objections, which apply to the practice of reclination through the sclerotica.

After the lens and capsule have been effectually cut in pieces, the same light mode of dressing and the same after-treatment are proper, which are adopted in cases of depression and reclination. Beer also particularly objects to any trials being immediately made of the eyesight. At the same time, he assures us, that he has not met with any of the instances, so frequently mentioned in books, of persons, on whom keratonyxis has been done, seeing perfectly well, and having quite a clear pupil in a few days: under the most favourable circumstances, several weeks, and sometimes as many months, elapsed, before the pupil became quite transparent.

According to Beer, keratonyxis is not liable to many accidents. Sometimes, says he, the artificially dilated pupil contracts, as soon as the needle has pierced the cornea, and reached the cataract: in this circumstance,

the operator must wait quietly, until the pupil gradually expands again, a change, which may be promoted by screening the eye with the hand. If the operation were to be continued without delay, either the pupillary edge of the iris would be seriously and dangerously hurt by the needle, or the cataract could not be effectually divided. When, contrary to expectation, the nucleus of the cataract is too hard to be broken piecemeal, reclinacion and depression should be done through the cornea, as well as circumstances will allow, and these objects can be more easily effected with a part, than with the whole, of the lens. When the lens is found completely fluid, but the capsule opaque only at some points, Beer, with a view of preventing a secondary capsular cataract, recommends cutting the membrane in all directions, and annihilating it as much as possible. Keratonyxis may be followed by the same evils, which occasionally take place after depression and reclinacion, and which will require similar treatment. But, according to Beer's experience, one of the most frequent consequences is a secondary capsular cataract, which often ensues even though the pupil was quite clear at the time of the operation, and though it may not quite blind the patient, it considerably lessens his power of vision, and renders the operation very incomplete.

When the sole object of keratonyxis is to break and cut the cataract and its capsule piecemeal, and the fragments are to be left to dissolve and to be absorbed, the operation can be indicated only where this division, breaking, dissolution, and absorption of the cataract, can be successfully wrought. Hence, Beer sets down the method as not calculated for firm, hard, lenticular cataracts; nor for those which are softish and scabrous only upon their surface; and, he says, that it is not suited for capsulo-lenticular cataracts, nor for any cases, termed false cataracts, which are of a membranous nature. Keratonyxis, he observes, may be expected to answer only in fluid or gelatinous cataracts, when the capsule is either little or not at all opaque and thickened, and of course can be easily opened and cut to pieces, as in the case described under the name of encysted cataract. For the above reasons, the method is well adapted for children and young subjects, in whom the origin and general complications of a cataract involve the case in suspicious circumstances.

Langenbeck, who has practised keratonyxis to a considerable extent, thinks extraction preferable to it only when the whole cataract can be brought out at once, by means of gentle pressure on the eye, and with the aid of Daviel's curette, as in the case of a firm cataract; while he represents keratonyxis as most advantageous, where, by the manœuvre of opening the capsule, the mass of the cataract would be so divided by the instrument as not to admit of being extracted altogether; but, would require the use of a scoop, forceps, or hook for bringing out the fragments, as in examples of soft,

milky, and capsular cataracts. Langenbeck also urges, as a reason against extracting soft cataracts, their greater size, whereby in their passage through the pupil in an entire state, they may injure the iris. (*Neue Bibliothek für die Chir.* 1. B. p. 461.) Valuable information on keratonyxis has been published by the same author in the 4th vol. of his first Bibliothek, in the 1st vol. of his new Bibl. p. 1, &c. 1815; and in a tract entitled, "*Prüfung der Keratonyxis einer Methode den grauen Staar durch die Hornhaut zu reclinieren, oder zu zerstückeln nebst erläuternden Operations geschichten.*" Gottengen. 1811. See also G. H. Buchorn's *Diss. de Keratonyxide*; Halæ.

OF THE CONGENITAL CATARACT, AND OPERATING UPON CHILDREN.

I shall not stop here to inquire, whether the expression *congenital cataract* is generally used with strict propriety; but, it is worth noticing, that the term is reprobated by Beer, as being in general incorrectly applied.

So much has been already said in a preceding section of this article, concerning the propriety and striking advantages of operating for the cataracts of children, that to expatiate further upon this point would be a mere waste of time.

We have noticed the case, which Scarpa terms the *primary membranous cataract*, and which is mentioned by that distinguished professor, as being met with in children, or young people, under the age of twenty, the substance of the crystalline itself being almost entirely absorbed, while the capsule is left in an opaque state, including, at most, only a small nucleus, not larger than a pin's head. This disease is described by Scarpa as being exceedingly rare, and characterized by a certain transparency, and similitude to a cobweb; by a whitish opaque point, either at its centre, or circumference; and by a streaked and reticulated appearance. Now, this example, which is represented by Scarpa as being rare, appears, from the experience of Mr. Saunders, to be by no means uncommon, since, at the London Infirmary for curing diseases of the eye, it has been found, that the majority of congenital cataracts are capsular, or membranous. This last statement is also at variance with that of the late Mr. Gibson, who has asserted, that, in infants, the cataract is generally fluid. (*Edinb. Med. and Surgical Journal*, Vol. 7, p. 397.) Mr. Ware also asserts, that, in children, born with cataracts, the crystalline humour has generally, if not always, been found either in a soft, or fluid state. (*Obs. on the Cataract, and Gutta Serena*, Vol. 2, p. 380.) However, as Mr. Saunders must have had the most experience in these particular cases, I believe, we must consider his account as the most accurate. We learn from this last gentleman's publication, that, in the congenital cataract, after the crystalline lens is converted into an opaque substance, it is gradually absorbed; and, in proportion to the progress of absorption,

the anterior lamella of the capsule approaches the posterior, until they form one membrane, which is white, opaque, and very elastic. This process is commonly completed long before the eighth year, and the operator will now find a substance, which he will in vain endeavour either to extract or depress. But, there is one form of the congenital cataract, in which the absorption of the lens does not proceed, viz. when the centre of the crystalline is opaque, and its circumference is perfectly transparent. Should the capsule and lens be penetrated, however, with any instrument, the

opacity soon becomes complete, and from this moment, the substance of the lens begins to be absorbed.

The experience of Mr. Saunders proves, that, in the congenital cataract, the lens may be either solid, soft, or fluid, but, that more frequently it is partially, or completely absorbed, and the cataract is capsular.

The following table of forty-four cases is given in Mr. Saunders's work, for the purpose of showing in what proportion each species of cataract has been found to prevail in congenital cases.

Solid opaque lens, with or without opacity of the capsule. Three single, two double cataracts	5
Solid lens, opaque in the centre, transparent in the circumference, with capsule in the same state. Five double	5
Soft opaque lens, with, or without opacity of the capsule. Two single, two double	4
Soft opaque lens, with solid nucleus. One single, two double	3
Soft opaque lens, with dotted capsule, the spots white, the spaces transparent. Two double	2
Fluid cataract, with opacity of the capsule. Two single	2
Fluid cataract, with opacity of the capsule, and closed pupil. Two double	2
Opaque and thickened capsule, the lens being completely absorbed, or the remains of it being thin and squamose. Six single, twelve double	18
Opaque and thickened capsule, with only a very small nucleus of the lens unabsorbed in the centre. Two single	2
Opaque and thickened capsule in the centre, remains of the lens in the circumference. One double	1

Here the corresponding character of congenital cataracts in the eyes of each individual is exhibited by the number of double cases, and we are informed, that the same character was preserved in the cataracts of several children of the same family. (*Saunders on Diseases of the Eye, edit. by Dr. Farre, p. 135, 136*)

The congenital cataract appears frequently to afflict several children of the same parents. In the course of the present article, I have already had occasion to advert to two striking examples of this fact. The first is related by Mr. Lucas, who attended five children of a clergyman at Leaven, near Beverley, all born with cataracts. (See *Med. Obs. and Inquiries, Vol. 6.*) The second is mentioned by Mr. Gibson, who some years ago, saw five or six children, the families of two sisters, who were all totally blind, and in an idiotic state, having cataracts accompanied with amaurosis. (*Edinb. Med. and Surgical Journal, Vol. 8, p. 398.*) Several instances occurred to the late Mr. Saunders. In one family, two brothers were thus afflicted. In a second family, two brothers, twins, became blind with cataracts at the age of twenty-one months, each within a few days of the other. It is re-

markable, that the four cataracts had precisely the same character. In a third family, a brother and two sisters were born with this disease. The eldest sister was affected with it only in one eye, the brother and youngest sister in both eyes. In a fourth family, three brothers and a sister had all congenital cataracts. (*Saunders on the Diseases of the Eye, p. 134, 135.*)

Children with congenital cataracts possess various degrees of vision; but, when they are totally blind, their eyes not being attracted by external objects, volition is not exercised over the muscles of these organs, which roll about with an irregular, rapid, and trembling motion.

I shall now proceed to speak of the manner of operating upon children. Until the time of Mr. Pott, the intention of surgeons, in couching, or depressing the cataract, (as indeed the expression itself implies,) was to push the opaque crystalline downward, away from the pupil. Mr. Pott, conscious that the cataract often existed in a fluid, or soft state, was aware that it could not then be depressed; and, therefore, in such cases, he recommended using the couching needle for the express purpose of breaking down the cataract, and of making a large

aperture in the capsule, so that the aqueous humour, which he believed to be a solvent for the opaque crystalline, might come into immediate contact with this body. This operation, subsequently to Mr. Pott, has been strongly and ably recommended by Mr. Hey, of Leeds, and Professor Scarpa, of Pavia. In the cases of children, it even received the approbation of the late Mr. Ware, who informs us, that he and his son had performed a similar operation on a considerable number of infants and young persons with uniform success. (*On the Operation of Puncturing the Capsule of the Crystalline Humour*, p. 9.)

But, notwithstanding the utility and efficacy of lacerating the front layer of the crystalline capsule had been so much insisted upon by Scarpa and others, their observations were confined to the cataract in the adult subject, and, before the example set by the late Mr. Saunders, no one (excepting, perhaps, Mr. Gibson of Manchester) ventured to apply, as a regular and successful practice, such an operation to the eyes of infants and children. Indeed, it seems highly probable, that even Mr. Gibson himself would have remained silent upon the subject, had not his attention been roused by the reports of the London Institution for curing diseases of the eye, which reports, he says, were dispersed and exhibited in the public news rooms of Manchester. For the creation and perfection of this beneficial practice, therefore, I am disposed to give the memory of Mr. Saunders great honour. The propriety of operating for the cataracts of children had long ago been insisted upon by a few writers, and the attempt even now and then made; but, the method never gained any ground, until Mr. Saunders led the way.

It only remains for me to describe the plans of operating, as executed by Mr. Saunders, Mr. Gibson, and Mr. Ware.

The principle, on which Mr. Saunders proceeded in his operations on the congenital cataract, was founded on the opinion, that the only obstacle to the absorption of the opaque lens is the capsule; and that as the latter also is most generally opaque, "the business of art is to effect a permanent aperture in the centre of this membrane. This applies to every case of congenital cataract, which can occur." Mr. Saunders used to overcome the difficulty of operating upon children, by fixing the eyeball with Pellier's elevator, having the patient held by four or five assistants, dilating the pupil with belladonna, and employing a very slender needle, armed with a cutting edge from its shoulders to its point, and furnished with a very sharp point, calculated to penetrate with the utmost facility.

Before the operation, the extract of belladonna, diluted with water to the consistence of cream, is to be dropped into the eye, or, to avoid irritation, the extract itself may be smeared in considerable quantity, over the eyelid and brow. In less than an hour, if there be no adhesions, it produces a full dilata-

tion of the pupil, exposing to view nearly the whole anterior surface of the cataract. The application should then be washed from the appendages of the eye.

In using the needle, Mr. Saunders most carefully abstained from doing any injury to the vitreous humour, or its capsule, and it was an essential point with him to avoid displacing the lens. In directing the extremity of the instrument to the centre of the capsule, he passed it either through the cornea, near the edge of this membrane, (the operation now called *keratonyxis*), or through the sclerotica a little way behind the iris. By the first, which is called the *anterior* operation, Mr. Saunders conceived, that less injury would be inflicted, and less irritation excited, than by introducing the needle behind the iris, through all the tunics of the eye. In every case, the first thing aimed at was the permanent destruction of the central portion of the capsule to an extent equal to that of the natural size of the pupil. If the capsule contained an opaque lens, Mr. Saunders used next to sink the needle gently into the body of the crystalline, and moderately open its texture; cautiously observing not to move the lens at all out of its natural situation.

When the case was a fluid cataract, Mr. Saunders was content in the first operation with simply lacerating the centre of the capsule, being desirous of avoiding to increase the irritation following the diffusion of the matter of the cataract in the aqueous humour.

When the cataract was entirely capsular, Mr. Saunders acted with rather more freedom, as he entertained in this case less fear of inflammation: but, in other respects, he proceeded with the same objects in view, which have been already related, and of which the principal consisted in effecting a permanent aperture in the centre of the capsule, without detaching this membrane at its circumference; for then the pupil would have been more or less covered by it, and the operation imperfect, "because this thickened capsule is never absorbed, and the pendulous flap is incapable of presenting a sufficient resistance to the needle to admit of being removed by a second operation." (P. 145.)

I have already explained, that Mr. Saunders found, that the greatest success attended the operation between the ages of eighteen months and four years. One operation frequently accomplished a cure; as many as five were seldom requisite.

The only particularity, in Mr. Saunders's treatment of the eye after the operation, was that of applying the belladonna externally for the purpose of making the pupil remain dilated, till the inflammation had ceased, so as to keep the edge of the iris from contracting adhesions with the margin of the torn capsule. In leaving this part of the subject, I must advise every surgeon to read the interesting account of Mr. Saunders's practice, published by his friend and colleague, Dr. Farre. Many minute particulars will be

found in this work, highly worthy of the practitioner's attention and imitation.

Mr. Gibson appears to have been unacquainted with the usefulness of the extract of belladonna in preparing the eye for the operation. A few hours before operating, he was in the habit of ordering an opiate, sufficient to produce a considerable degree of drowsiness, so that the infant generally allowed its eyelids to be opened, and properly secured without resistance, and was little inclined to offer any impediment to the introduction of the couching needle; but, on the contrary, presented the sclerotica to view, naturally turning up the white of its eye. If the infant was more than a year old, and whenever it was necessary, Mr. Gibson used to introduce its body and arms into a kind of sack, open at both ends, and furnished with strings to draw round the neck, and tie sufficiently tight round the legs, so that its hands were effectually secured, and the assistants had only to steady its body, and fix its head, whilst the child was laid on a table, upon a pillow. Mr. Gibson never found it necessary to use a speculum, having uniformly experienced, that, after the couching needle was introduced, he had no difficulty in commanding the eye, aided by a slight degree of pressure upon the eyeball with the index and middle fingers of his left-hand, which were employed in depressing the lower eyelid. He admits, however, that the speculum can easily be applied, if an operator prefer it. He generally used Scarpa's needle, because, in infants, the free rupture of the capsule of the lens ought commonly to be aimed at, in order that the milky cataract may escape, and mix with the aqueous humour; or, if the cataract be soft, that the aqueous humour may be freely admitted to its pulpy substance which has been previously broken down with the needle. He thinks that no peculiarity is necessary in depressing the hard cataract of infants. Before Scarpa's needle was known in this country, Mr. Gibson used Mr. Hey's, which was generally effectual, and, as he conceives, possesses the recommendation of being less liable to have its point entangled in the iris. He says, that, when a milky cataract has been thus evacuated, it renders the aqueous humour turbid; but, that, within the space of two days, the eye generally acquires its natural transparency, and vision commences. When the capsule and substance of the soft cataract have been broken down, and the aqueous humour has come into contact with the lens, the solution and disappearance of the cataract, in all the cases, upon which Mr. Gibson has operated, have uniformly taken place in a short time. The experience of Mr. Gibson curiously differs from that of Mr. Saunders in one respect: he assures us, that although he has met with cataracts in infants hard enough to bear depression, yet that *he has never met with a simple membranous cataract*; though this is no uncommon occurrence in patients at the age of eight, or ten, as well as in adults, who have been blind from

birth. (See *Edinb. Med. and Surgical Journal*, Vol. 8, p. 398, 399.)

For the purpose of fixing the eye, Mr. Ware considered Pellier's elevator requisite in operating upon infants. When the patient, however, had advanced beyond the age of infancy, Mr. Ware sometimes fixed the eye by means of the fingers alone. For the purpose of puncturing the capsule, and breaking down the cataract, this gentleman gave the preference to an instrument, which resembles one recommended by Cheselden, for the purpose of making an artificial pupil; but it is somewhat narrower. Its blade indeed is so narrow, that it nearly resembles a needle. Its extremity is pointed, and it cuts on one side for the space of about the eighth of an inch, the other side being blunt. It is perfectly straight; is an inch long in the blade; and forms a complete wedge through its whole length. Upon one side of the handle is a coloured spot, by attending to which, the operator may always ascertain the position of the instrument in the eye.

Mr. Ware dilated the pupil with the extractum belladonnæ, softened with a little water, and applied about half an hour before the time of operating. This gentleman believed, that in operating upon infants, the surgeon might perform the operation with more composure, if the patient were laid upon a table, with the head properly raised on a pillow. The bent end of Pellier's elevator should be introduced under the upper eyelid, and the instrument committed to the care of an assistant. If the right eye is to undergo the operation, and the surgeon operate with his right hand, he must of course sit or stand behind the patient; and, in this case, he will himself manage the speculum with his left-hand. The eye being thus fixed, Mr. Ware passed the point of the narrowed-bladed knife above mentioned through the sclerotica, on the side next to the temple, about the eighth of an inch from the union of that membrane to the cornea, the blunt edge being turned downwards. The instrument was pushed forwards in the same direction, until its point had nearly reached the centre of the crystalline. The point was then brought forwards, until it had passed through the opaque crystalline and its capsule, and was plainly visible in the anterior chamber. If the cataract was fluid, and the anterior chamber became immediately filled with the opaque matter, Mr. Ware deemed it advisable to withdraw the instrument and defer further measures until the matter was absorbed, which absorption usually took place in the course of a few days, and sometimes of a few hours. If no visible change were produced in the pupil, the point and cutting edge of the instrument were applied in different directions, so as to divide both the opaque crystalline and its capsule into small portions, and, if possible, bring them forwards into the anterior chamber. This may require the instrument to be kept in the eye for a minute or two; but, if the operator preserve his steadiness, he may continue it there a much

longer time without doing the least injury to the iris, or to any other part. If the cataract be found of a firm consistence, (though this rarely happens in young persons,) it may be advisable to depress it below the pupil; and in such a case particular care should be taken to perforate largely the posterior part of the capsule, and to withdraw the instrument immediately after the cataract has been depressed in order to hinder it from rising again. If the opacity be in the capsule the instrument will not act so easily upon it as it does on the opaque crystalline; but, notwithstanding this, the capsule as well as the crystalline, may be divided by it into larger or smaller portions, which, when thus divided, will be softened by the action of the aqueous humour; and though in the first operation on such case, says Mr. Ware, it may not be possible to remove the opacity, yet, on the second or third attempt, the divided portions may be brought forwards into the anterior chamber, in which place, they will then be gradually absorbed, and soon disappear. After the operation, Mr. Ware seldom found it necessary to take away blood from children, or persons under the age of twenty. He continued a cooling antiphlogistic treatment a few days. After this, if any opaque matter remained, he expedited its absorption by dropping a small portion of powdered sugar into the eye once or twice a day. When, at the end of a week or ten days, the inflammation was over, and the pupil obstructed with opaque matter, Mr. Ware advised a repetition of the operation. After a similar interval, the operation, he says, may be requisite again. In most cases, Mr. Ware was obliged to operate twice; in a few instances, once proved sufficient; and only in three, out of the last twenty, did he find it necessary to operate a fourth time. (*On the Operation of Puncturing the Capsule of the Crystalline Humour.*)

I think any impartial man, who considers the practice of the three preceding operators, will find great cause to admire the superior gentleness and skill, which predominate in the operations of the late Mr. Saunders. For my own part, I am so fully convinced of the mischief, which has been done to the eyes, by the rash boldness, awkwardness, and unsteadiness of numerous operators, that, it appears to me, the inculcation of gentleness and forbearance in all operations for the cataract, is the bounden duty of every man, who has occasion to write upon the subject. Great manual skill, and invariable gentleness, indeed, seem to me to have had more share in rendering Mr. Saunders's operations successful, than any particularity either in his method or his instrument. I have no hesitation in declaring my own partiality to the principles, on which his practice was founded, and my belief, that they are well calculated to improve most materially this interesting branch of surgery. CATHETER. (from καθύμι, to thrust into.) A tube which is introduced through the urethra into the bladder, for the purpose of drawing off the urine. (See *Urine, Retention of*.) Of course, there are two kinds of catheters; one, intended for the male, the other, for the female urethra. With respect to catheters, three things are to be considered: 1st, the instrument itself; 2d, the manner of introducing it; and 3d, the conduct to be pursued after its introduction.

Catheters were anciently composed of copper: Celsus knew of no other kind. As these, however, had the inconvenience of becoming incrustated with verdigris, they at length fell into disuse, and others, made of silver, were substituted for them. This change, which was made as early as the time of the Arabian practitioners, still receives the approbation of the best modern surgeons. The common catheter is a silver tube, of such a diameter as will allow it to be introduced with ease into the urethra, and of various figures and lengths, according as it is intended for the young or adult, the male or female, subject. For an adult female subject, it should be about six inches long; and, for young girls, four or five. For men, the length ought to be from ten inches and a half to eleven inches. But, as

the instrument need not enter far into the bladder, Mr. John Bell's advice to avoid too great a length, merits observance. (*Principles of Surgery*, Vol. 2, p. 193.) As the urethra in some instances is narrow, and, in others wide, surgeons should be furnished with catheters of different diameters. The choice of the instrument, in respect to its width, is likewise determined very much by the nature of the disease of the urethra. (Langenbeck, *Bibl. B. 1*, p. 1177.) For a woman, the diameter ought to be at least two lines; and, for girls, a line and a half. For male adult subjects, Desault recommends the thickness of two lines and one-third; and, for boys, that of a line and a half. In general, whenever the urethra is pervious, it is better to follow the advice of Desault, and employ a largish catheter, which will enter the passage more easily, and not be entangled in the folds of the membranous lining of the canal, while it will afford a more ready outlet for the urine. On the other hand, small catheters should be preferred, when there are obstructions in the passage. Catheters also differ in shape: those which Desault used for male subjects, had only a slight curvature of one-third of their length; a curvature, which began insensibly from their straight part, and was continued to the very end of their beaks. The curvature was also regular, so as to form the segment of a circle six French inches in diameter. As the course of the urethra in the male subject is regular, the caprice evinced by surgeons in the different curvatures of their catheters, cannot be founded on any correct anatomical principles, and the bend of the instrument, (at least for subjects of the same age and stature,) should generally not vary at all, but be strictly adapted, as Langenbeck remarks, to the natural track of the urethra. (*Bibl. 1*, p. 1177.) The female catheter, however, has only a slight curvature towards its beak; a shape adapted to the direction of the meatus urinarius. Desault also improved silver catheters, by causing them to be made with elliptical openings, or eyes, at the sides of the beak, with rounded edges, instead of the longitudinal slits previously in use, in which the lining of the urethra was frequently entangled, pinched, and lacerated, so that acute pain and profuse hemorrhage were the consequences. With the view of preventing these evils, he also filled up the openings with lard. (See *Œuvres Chir. de Desault*, T. 3, p. 118.)

Besides silver, or inflexible catheters, surgeons now frequently employ flexible ones, made of elastic gum. These last, indeed, are of so much importance, that they may be said to constitute one of the greatest improvements in modern surgery. I shall not here inquire, whether they were first invented by Theden, Pickel of Wurzburg, or Bernard of Paris; this is a point, which the Germans and French must settle themselves. Imperfect attempts had been made by others at earlier periods to invent catheters, possessing the property of flexibility. Van

Helmont proposed the use of catheters, made of horn; but, this substance was found to be too stiff, and to be very quickly coated with depositions from the urine. Fabricius ab Aquapendente employed leather catheters, which were objectionable, inasmuch as they were soon softened by the urine and mucus of the urethra, when they shrivelled, and became impervious. Other flexible catheters were also formerly tried, composed of spiral springs of silver-wire, covered with the skins of particular animals. These last, however, were very quickly spoiled by putrefaction; and when left in the urethra any considerable time, the beak sometimes entirely separated from the rest of the instrument, and was left behind in the bladder.

The elastic gum-catheters, now in use, are liable to none of the preceding inconveniences: they are formed of silk tubes, woven for the purpose, and covered with a coat of elastic gum; they are sufficiently flexible to accommodate themselves to the different curvatures of the urethra; they are not softened by the urine; and they constantly remain with their cavity unobliterated. Their smooth and polished surface makes them continue a long while free from incrustations deposited from the urine. Sometimes, they are introduced with a stilet, or wire, which is passed into their canal, in order to give them a certain curvature, and a greater degree of firmness; but, in general, it is withdrawn as soon as the tube is in the bladder.

Elastic catheters are less irritating to the urethra, and less apt to become covered with calculous incrustations, than silver tubes: they can also be frequently introduced, when a metallic one will not pass.

The selection of good bougies and catheters, especially in operations upon the male subject, is a business of the first-rate importance, for, by employing such as are disposed to break, "many a practitioner has doomed his patient to years of dreadful, and, perhaps, hopeless suffering, and brought down irreparable disgrace upon his own head." (*Med. Chir. Journ.* Vol. 5, p. 75.) M. Nicod, in performing the operation of lithotomy upon a male found the stone, which was very brittle, one inch and a half long, and eight or nine lines thick, traversed in the direction of its greater diameter, by a piece of elastic gum catheter, which had acted as a nucleus for the deposition of calcareous matter. (See *Obs. sur le danger d'employer de mauvaises sondes de gomme elastique*; *Journ. de Médecine*, par Leroux, Oct. 1816.)

The best elastic catheters used to be fabricated at Paris, by Bernard. At the present time, the best maker in France is Feburier, orfèvre, in the Rue du Bac No. 51, at Paris; but the elastic gum catheters now made in London are in some respects better than French, being generally much smoother and more regular, though I believe our smallest size is not yet so small, as what Feburier makes. The gum catheters are made at Paris of twelve different sizes, which corres-

pond to twelve holes in a plate of brass.

"Each catheter, therefore, (says a late intelligent visitor to that capital) has its size designated by its number, which greatly facilitates the ascertaining of the progress of the case towards a cure. Numbers 1 and 2 are smaller than can be procured in England, and are so slender, that I thought there might be danger of their breaking, until I was convinced by seeing the method of making them, that there is no reason for fearing any such thing. A firm tissue of silk is woven upon a brass stilet, of the size of the cavity of the instrument to be made. In weaving this tissue, the orifice or eye is left, and the whole therefore consists of one entire thread. The successive layers of varnish are deposited on the outer surface of the silken tissue, their number depending on the size of the instrument; and each coating of varnishing undergoes a long process of scouring before the next is put on, for which purpose women are employed by Feburier." (See *Sketches of the Medical Schools of Paris* by J. Cross, 1815, p. 122, 123.)

According to this gentleman, however, the English gum-catheters possess advantages: "they retain their curve better without the stilet, are less liable to crack, and have eyes more smooth and better formed." (P. 124.) Bernstein, in his Dictionary of Surgery, gives the following account of this instrument, as it is fabricated in Germany: One of the most useful inventions which have been made, with respect to these instruments, is to construct them of elastic gum, and the merit of this invention is to be ascribed, without doubt, to Theden. (*Neue Bemerkungen u. Erfahrungen*, &c. Th. 2. Berlin, 1782, p. 143.) They were afterward improved by a silversmith at Paris, of the name of Bernard, who did not apply the dissolved elastic gum to a wire cylinder, as Theden had done, but to one made of knitted silk; and these catheters certainly deserve to be recommended in preference to all others. But, with respect to their price, the elastic catheters formerly prepared by Pickel, of Wurzburg, (*Richter's Chir. Bibliothek*, B. 6. p. 512,) deserve particular recommendation. These consist of silk cylinders, plaited or worked upon a probe, and afterwards covered with the following varnish: three parts of white-lead, minium, or sugar of lead, with boiled linseed oil, which is the common varnish used by cabinet-makers, mixed with one part of melted amber, and the same quantity of oil of turpentine. With this varnish the silk cylinders are covered, and the same thing is repeated three times, as soon as each coating has been dried in the open air. The catheters are then put in a baker's oven twenty-four hours, when bread has been baked in it the last time, and when it retains the temp. of 60. 70. Reaum. Here they are to remain ten or twelve hours. When the catheter has been taken out of the oven, the inequalities are to be rubbed off with a little pumice-stone;

the end is to be sewed up; the oblong lateral aperture is cut in it; and it is to be coated twelve or fifteen times more with varnish. The catheter must be always well dried in the open air, before the varnish is spread upon it again, and after every third coating which it has received, it must be put in the oven again, so that it must in all have received from fifteen to eighteen coatings with varnish, and have been laid five or six times in the oven. The end is smoothed off with oil. (*Cyclopædia by Rees, Art. Catheter.*)

When the object of passing a catheter is merely to empty the bladder, without any design of leaving the instrument afterwards in the passage, Langenbeck always prefers an inflexible one, made of silver. (*Bibl. für die Chir. B. 1, p. 1176.*)

Sometimes spasm about the perinæum renders the introduction of a catheter difficult. In this case, a dose of opium should be administered, before a second attempt is made. When inflammation prevails in the passage, the introduction may often be facilitated by a previous bleeding.

The operation of introducing the catheter may be performed, either when the patient is standing up, sitting, or lying down, which last posture is the most favourable. In order to pass a catheter with ease and dexterity, the following circumstances must be observed: the instrument must be of suitable shape and size; a just idea of the perineum and curvature of the urethra must be entertained; the catheter must be introduced with the greatest care and delicacy; and the relaxation of the abdominal muscles has been insisted upon, (*Langenbeck, Bibl. 1, p. 1177.*) though, I confess, that it does not appear to me, how this circumstance is of importance.

One of the most important maxims is, never to force forward the instrument, when it is stopped by any obstacle. If there are no strictures, the stoppage of the catheter is always owing to one of the following circumstances. Its beak may be pushed against the os pubis. This chiefly occurs when the handle of the instrument is prematurely depressed. Here the employment of force can obviously do no good, and may be productive of serious mischief. The beak of the catheter may take a wrong direction, and push against the side of the urethra, especially at its membranous part, which it may dilate into a kind of pouch. In this circumstance, if force were exerted, it would certainly lacerate the urethra, and occasion a false passage. The end of the catheter may be entangled in a fold of the lining of the urethra, and here force would be equally wrong. Lastly, the point of the instrument may be stopped by the prostate gland, in which case force can be of no service, and may do great harm. Hence, it is always proper to withdraw the instrument a little, and then push it on gently in a different position.

There are two methods of introducing a male catheter, viz. with the concavity turned

towards the abdomen; or with the concavity directed downwards in the first stage of the operation. Of course, the latter plan requires the instrument to be turned, so as to place its concavity upwards, as soon as the beak has arrived in the perineum; and hence, the French surgeons call this method the "tour de maître."

The operation may be divided into three stages. In the first, the catheter passes, in the male subject, that portion of the urethra which is surrounded by the corpus spongiosum; in the second, it passes the membranous part of the canal, situated between the bulb and the prostate gland; and in the third, it enters this gland, and the neck of the bladder.

In the first stage, little trouble is usually experienced; for the canal is here so supported by the surrounding corpus spongiosum, that it cannot easily be pushed into the form of a pouch, in which the end of the instrument can be entangled.

When the catheter is to be introduced with its concavity towards the abdomen, and the patient is in the recumbent posture, the thighs are to be separated, and the legs moderately bent. The surgeon is to draw back the prepuce, and to hold the penis between the thumb and fore-finger of his left-hand, which are to be applied on each side of the corona glandis, and not at all to the under surface of the penis, so as to avoid pressing upon the commencement of the urethra. After the catheter has been well oiled, its handle is to be held between the thumb and fore-finger of the right-hand, and to rest with the back of the little finger upon the patient's abdomen, in the vicinity of the navel. Now, while the handle is parallel to the axis of the body, the beak is to be introduced into the urethra; the penis being extended, and drawn forwards, as it were, over the instrument, while the latter is gently pushed on, until its beak has reached the arch of the pubes. When the penis cannot be drawn further over the catheter, the beak has arrived in this situation, where it stops in front of the arch, and is pressing against the posterior side of the urethra. At this particular moment, the handle is to be depressed towards the patient's thighs, and the manœuvre, well managed, generally directs the end of the catheter, at once through the prostatic portion of the urethra into the cavity of the bladder. In short, as soon as the beak of the instrument has passed under the arch of the pubes, and the surgeon very slowly brings the handle forwards, or downwards, the beak is elevated, and glides into the bladder. In this stage of the operation, the penis must be allowed to sink down, and not be kept tense, as this would only render the passage of the instrument more difficult.

The operation, however, is not always successfully accomplished in this manner. The beak of the catheter may be stopped by the os pubis; it may take a wrong direction, so as to push the membranous part of the urethra to one side or the other; or it may be

stopped by a fold of the lining of the passage.

The first kind of impediment is best avoided, by not depressing the handle of the catheter, too soon; that is, before the point has passed beyond the arch of the pubes. When the membranous part of the urethra is pushed to one side or the other, the instrument ought to be withdrawn a little, and then pushed gently on in a different direction; but, if this expedient is unavailing, the index finger of the left-hand may be introduced into the rectum, for the purpose of supporting the membranous part of the urethra, and guiding the extremity of the catheter. The passage of the catheter through the membranous part of the urethra, and especially the attempt to hit the entrance of the prostate, are the most difficult things in the operation, and also the only ones attended with risk of mischief, which is frequently produced by rough, unskilful surgeons, when they use violence, and rupture this yielding weak portion of the canal.

When the prostate gland is enlarged, the urethra makes a more sudden turn upwards, just as it approaches the bladder, than is natural. The end of the catheter, therefore, should be more bent upward, than in other cases.

In the third stage of the operation, the beak of the instrument has to pass the prostate gland and neck of the bladder. The principal obstacles to its passage, in this situation, arise from spasm of the neck of the bladder, and muscles in the perineum, and from the instrument being pushed against the prostate gland, instead of into the continuation of the urethra through it. The first impediment may generally be obviated by waiting a few moments, and gently rubbing the perineum, before attempting to push the catheter further into the passage. The hinderance, caused by the prostate, is best eluded by using an instrument the point of which is more curved, than its other part. Sometimes the surgeon himself presses the prostate towards the os pubis, by means of his finger in the rectum, and thus prevents the passage of the catheter, by increasing the sudden curvature at this part of the urethra. Hence, as Richter observes, it is a very important maxim, never to introduce the finger so far into the rectum, as to press on the prostate gland itself.

When the catheter has turned round the pubes, and is just about to enter the neck of the bladder, is the critical moment, in which may be seen, whether a surgeon can or cannot manage the operation with skill; for, if he knows how to pass the instrument, he suddenly, but not violently changes its direction. He depresses the handle with a particular kind of address, and raises the point, which, as if it had suddenly surmounted some obstacle, starts into the neck of the bladder, and the urine bursts out in a jet from the mouth of the catheter.

They, who are unskilful, press the tube forward, and persist, as they had begun, in

drawing up the penis, on the supposition that by stretching this part they lengthen the urethra, and make it straight, whereas they elongate only that part of the canal, along which the catheter has already passed. (*John Bell's Principles of Surgery, Vol. 2. p. 213.*)

When the catheter is to be introduced with its concavity downwards, or by the "tour de maitre," the beak is to be passed into the urethra, and the penis drawn over it, as it were, as in the foregoing method. In other words, the instrument well oiled, is to be introduced, with its convexity uppermost, as far as it can be, without using force. As soon, however, as the end of the catheter has reached the point, at which the canal begins to form a curve under the pubes, the surgeon is to make the penis and the instrument perform a semicircular movement, by inclining them towards the right groin, and then towards the abdomen. In the execution of this manœuvre, care is to be taken to keep the beak of the catheter stationary, so that it may be the centre of the movement, and simply revolve upon itself. This part of the operation, the object of which is to turn the concavity of the catheter upwards, ought to be done very slowly, a large sweep being made with the handle, while particular care is taken not to retract, nor move the beak from its position. The handle is then to be depressed, and the operation finished exactly in the same manner, as when the first plan is pursued. As Desault properly observes, the only circumstance, in which the two methods differ, is, that, in one, the same thing is performed by two movements, which is done in the other by one; so that the operation is rendered more difficult and painful. Hence, many judicious modern surgeons never practise the "tour de maitre," except when their patients are very corpulent or placed in the position usually chosen for lithotomy, when other modes of introducing the catheter would be less convenient.

The depth to which the catheter has entered, the cessation of any feeling of resistance to the motions of the beak, when revolved upon its axis, and the issue of the urine, are the circumstances, by which the surgeon knows, that the instrument has passed into the bladder.

According to the experience of Desault, the practice of gradually letting out a part of the urine, after the catheter has been introduced, is by no means advantageous.—He also disapproves of running into the opposite extreme, that is to say, of letting the urine flow out of the catheter, as fast as it is secreted; for, then, the bladder is kept constantly relaxed, and the detrusor muscle will not be likely to recover its tone. When the bladder is continually empty, it is liable to come into contact with the end of the catheter; a circumstance which has sometimes caused considerable irritation, pain, and even ulceration of that viscus. Besides these inconveniences, there are some others; the catheter is sooner obstructed with mu-

cus, and covered with incrustations, than when it is closed with the stilet. The patients are likewise obliged to remain in bed, where they are either wet with their urine, or compelled to have incessantly a pot for its reception. The best practice, therefore, seems to be that of letting out all the urine, as soon as the catheter is introduced, and then closing the instrument until the bladder has become moderately distended again; for experience proves, that such moderate distention and relaxation of the muscular fibres of the bladder, alternately kept up, have the same good effects upon that organ, as moderate exercise has upon other parts of the body. When a catheter is to be left in the urethra, it should always be properly fixed with a narrow piece of tape, or else it is apt to slip out, or even pass too far into the passage. For this purpose, some surgeons use cotton-thread, which they fasten to the rings, or round the external end of the catheter. The two extremities of the thread are then carried some way along the dorsum of the penis, when they are tied together, and afterwards conveyed in opposite directions round the part, till they meet underneath it, where they are tied in a bow. When a silver catheter is employed, a tape, or narrow riband is passed through each of the rings, and conveyed to each side of the pelvis, where it is fastened to a circular bandage. Mr. Hunter remarks, that the common bag-truss for the scrotum answers extremely well, when two or three rings are fixed on each side of it along the side of the scrotum, and the ring of the cannula is fastened to any of them with a piece of tape. (*On the Venereal Disease*, Ed. 2, p. 159.)—He also notices another method: when the catheter (says he) is fairly in the bladder, the outer end is rather inclined downwards, nearly in a line with the body. To keep it in this position, we may take the common strap, or belt part of a bag-truss, with two thigh straps, either fixed to it, or hooked to it, and coming round each thigh forwards by the side of the scrotum, to be fastened to the belt, where the ears of the bag are usually fixed. A small ring, or two, may be fixed to each strap just where it passes the scrotum or root of the penis; and with a piece of small tape, the ends of the catheter may be fixed to those rings, which will keep it in the bladder. It seems Mr. Hunter did not, like Desault, disapprove of leaving the catheter unclosed, and he adds, therefore, "a bit of rag, about four or five inches long, with a hole at the end of it, passed over the exterior end of the catheter, and the loose end allowed to hang in a basin placed between the thighs, will catch the water, which cannot disengage itself from the catheter, and keep the patient dry; or, if another pipe is introduced into the catheter, it will answer the same purpose. (*Op. cit.* p. 191.) But, there are numerous modes of fixing a catheter, which need not be specified; for, although they are of importance, the principles which should be observed in adopting them, are the main things to be

understood. These are, first, never to fix a catheter in such a way, that too much of the instrument projects into the cavity of the bladder; and, secondly, to be careful that the thread or tape, which is applied, will not chafe and irritate the parts.

Mr. Hey has offered some good practical remarks on the introduction of the catheter. If, says he, the point of the catheter be less turned than the urethra, the point will be pushed against the posterior part of the passage, instead of following the course of the canal. The posterior part of the urethra has nothing contiguous to it which can support it; and no considerable degree of force will push the point of the catheter through that part between the bladder and the rectum. If this accident is avoided, still the point will be pushed against the prostate, and cannot enter the bladder. Mr. Hey tells us, that the truth of this is illustrated by the assistance which is derived, whenever the catheter stops at the prostate, from elevating the point of the instrument with a finger introduced in the rectum.

Mr. Hey takes notice of the impropriety of pushing forwards the point of the catheter, before its handle is sufficiently depressed, as the point would move in a horizontal direction, and be likely to rupture the posterior side of the urethra.

The difficulty arising from the inflamed and dry state of the passage, (which difficulties I should conceive can never be great,) Mr. Hey says, may be obviated by the previous introduction of a bougie, well covered with lard.

In order to pass the catheter, Mr. Hey places his patient on a bed, in a recumbent posture, his breech advancing to, or projecting a little beyond the edge of the bed. If the patient's feet cannot rest upon the floor, Mr. Hey supports the right leg by a stool, or by the hand of an assistant. The patient's head and shoulders are elevated by pillows; but the lower part of the abdomen is left in a horizontal position. Mr. Hey commonly introduces the catheter with its convexity towards the abdomen, and having gently pushed down the point of the instrument, till it becomes stopped by the curvature of the urethra, under the symphysis pubis, he turns the handle towards the navel, pressing at the same time its point. In making the turn, he sometimes keeps the handle at the same distance from the patient's abdomen, and sometimes makes it gradually recede; but, in either method, he avoids pushing forwards the point of the catheter any farther than is necessary to carry it just beyond the angle of the symphysis pubis. When he feels that the point is beyond that part, he pulls the catheter gently towards him hooking, as it were, the point of the instrument upon the pubes. He then depresses the handle, making it describe a portion of a circle, the centre of which is the angle of the pubis. When the handle of the catheter is brought into a horizontal position, with the concave side of the instrument upwards, he pushes forwards the point, keep-

ing it close to the interior surface of the symphysis pubis; for when passing in this direction, it will not hitch upon the prostate gland, nor injure the membranous part of the urethra.

If the surgeon uses a flexible catheter, covered with elastic gum, it is of great consequence to have the stilet made of some firm metallic substance, and of a proper thickness. Mr. Hey always makes use of brass wire for the purpose. If the stilet is too slender, the catheter will not preserve the same curvature during the operation; and it will be difficult to make the point pass upwards behind the symphysis pubis in a proper direction. If the stilet is too thick, it is withdrawn with difficulty.

When the stilet is of a proper thickness, this instrument has one advantage over the silver catheter, which is, that its curvature may be increased while it is in the urethra, which is often of great use when the point approaches the prostate gland. In all cases, where an elastic gum catheter is preferred, care must be taken that it does not pass unnecessarily far into the bladder; and, if it be too long, a part of it ought to be cut off, or a shorter one employed.

When the proper manœuvres with a silver catheter do not succeed, the surgeon must change it, taking a bigger or more slender one, with a greater or less curve, according to such observations as he may have made in his first attempt. But, if the catheter has been of a good form or commodious size, yet has not passed easily, he should, instead of choosing a rigid catheter of another size or form, take a flexible one for his second attempt. The flexible catheter is generally slender, and of sufficient length, and its shape may be accommodated to all occasions, and to all forms of the urethra; for, having a stiff wire, we can give that wire either before or after it has passed into the catheter, whatever shape we please; and what is still of greater importance, we can introduce the instrument without, or with the wire, as circumstances may require; or what is more advantageous, we can introduce the wire particularly so as not quite to reach the point of the catheter, but only to within two inches or a little more of this part, by which contrivance the point, if previously warmed, and wrought in the hand, has so much elasticity, that it follows the precise curve of the urethra, and yet has sufficient rigidity to surmount any slight resistance. If this too fail, and especially, if there be the slightest reason to suspect, that the resistance is not merely spasmodic, but arises from stricture near the neck of the bladder in a young man, or swelling of the prostate in an old one, we may take a small bougie, turn up the extremity of it with the finger and thumb, so as to make it incline towards the pubes, and allowing no time for the wax to be softened, pass it quickly down to the obstruction, turn it with a vertical or twisting motion, and make it enter the constricted part. On withdrawing it in about ten minutes or a quarter of

an hour, the urine generally escapes, or the catheter may now be introduced. (*John Bell's Principles of Surgery, Vol. 2, p. 215.*)

Mr. Hey has found, that, in withdrawing the stilet of an elastic gum catheter, the instrument becomes more curved; and he has availed himself of this information by withdrawing the stilet, as he is introducing the catheter beyond the arch of the pubes, by which artifice the point is raised in the due direction.

Mr. Hey says you may sometimes, though not always, succeed in introducing an elastic gum catheter by using one which has acquired a considerable degree of curvature and firmness, by having had a curved stilet kept in it a long while. Introduce this without the stilet, with its concavity towards the abdomen, taking care not to push on the point of the instrument, after it has reached the symphysis pubis, until its handle is depressed into a horizontal position.

When it is necessary to draw off the urine frequently, and the surgeon cannot attend often enough for this purpose, a catheter must be left in the urethra, till an attendant, or the patient himself, has learnt the mode of introducing the instrument. (*Hey.*)

Mr. Hey imputes the formation of a false passage, or the rupture of the membranous part of the urethra, generally to the method of pushing forwards the catheter, before its handle has been depressed. In this manner, the course of the instrument crosses that of the urethra, and the point of the catheter pressing against the posterior side of the membranous part of the urethra, is easily forced through the coats of that canal. The want of due curvature in the catheter, and of sufficient bluntness in its point, greatly contribute to facilitate this injury. In this case, the point of the instrument passes more readily into the wound, than onward along the urethra against the symphysis pubis. Without this pressure, the point is apt to recede, and not readily enter the membranous part of the urethra.

Mr. Hey surmounted a difficulty of this kind, by bending upwards the point of a silver catheter, so as to keep it more closely in contact with the anterior part of the urethra, and thereby pass over the wound made in the posterior side of the canal. In the instance alluded to, as it was necessary to leave an elastic gum catheter in the urethra, Mr. Hey procured some brass wire of a proper thickness, with which he made a stilet, and, having given it the same curvature as that of the silver catheter, he introduced it about four hours after the preceding operation, and fixed it by tying it to a bag truss. Mr. Hey sometimes succeeded by partly withdrawing the stilet, at the moment when he wished to increase the curvature of the catheter.

In an instance, in which the urethra had suffered a violent contusion, Mr. Hey drew off the urine with a silver catheter of unusual thickness, after he had failed with instruments of a smaller bore. He suspected that the urethra was ruptured, and was obli-

ged to raise the point of the catheter by a finger introduced into the rectum, and to use bleeding, purgatives, the warm bath, and opium, before it could be made to pass. The elastic gum catheter was afterwards employed. It is an unsettled point, whether it is best to leave the catheter in the urethra, until the power of expelling the urine is regained, or to draw off the urine twice a day, and withdraw the catheter after each operation. Mr. Hey thinks that no general rule can be laid down; some patients cannot bear the catheter to remain introduced; others seem to suffer no inconvenience from it. On the whole, however, Mr. Hey commonly prefers removing the catheter. In this manner, he is of opinion, that the power of expelling the urine again is soonest acquired.

The preceding question is often determined by the nature of the disease, and, as Mr. Hunter observes, in cases of debility of the bladder, and where a catheter passes with difficulty, or with great uncertainty, as well as in other instances, in which it must be used frequently, and for a length of time, it will be necessary to keep it introduced, so as to allow the water to pass freely through it. (*On the Venereal Disease*, Edit. 2, p. 191.)

In France, a conical silver catheter (*sonde conique*) is frequently employed in difficult cases by Boyer, Roux, &c. This instrument has a very slight curvature, and an extremity almost pointed. By force, regularly applied, it is introduced into the bladder, in spite of all opposition. Care is taken to keep it in the centre of the passage, and the direction of its point is judged of by the position of the lateral rings. The rule mentioned by Roux, for commencing the great depression of the outer extremity of the instrument, is, when, by the finger in the rectum, the point can be felt to have reached the apex of the prostate. (See *Sketches of the Medical Schools of Paris*, by J. Cross, p. 112.) In bad cases, the conical catheter is usually allowed to remain introduced three or four days, and on being withdrawn, a small flexible gum catheter generally admits of being used.

The forcible manner in which the French surgeons employ the conical silver catheter, must often do great and dangerous mischief. Thus, in two examples, which were witnessed and examined by Roux himself after the decease of the patients, a false passage had been made, no flexible gum catheter could be passed, the urine was effused in the cellular membrane, and the parts were gangrenous. (See p. 116 of the above work.) According to the observation of Mr. Cross, the French surgeons employ the conical silver catheter with too little discrimination, and "in their practice they seem to make no nice distinctions between impediments to the flow of urine from spasm, irritable and inflamed state of the canal, disease of the prostate gland, and cartilaginous stricture of long duration. If the conical catheter be admissible at all, it is in the last of these cases, particularly, when combined with

fistula in perinæo; and here all surgeons, who are familiar with the treatment of diseases of the urethra, occasionally use means, which approach very closely to the forcing method of the French. I have heard of instances, in which John Hunter employed great force with the silver catheter, and overcame the obstruction. I have seen Mr. Pearson, (who generally treats strictures as mildly, and, I need hardly say, as successfully as any man) take a steel sound, and pass it gradually and forcibly on into the bladder, at the same time feeling his way, as it were, by keeping one finger in the rectum: the relief of the patient, and the ultimate cure of the disease, were the results of this practice." (P. 118.) It appears further, that the conical silver catheter has been used by Mr. A. Cooper. Without altogether condemning the occasional employment of this instrument, I perfectly coincide with Mr. Cross, that it is one, with which young men, of little caution and no experience, may do more harm in the first few cases they meet with, than the rest of their life will afford them opportunities of doing good.

Mr. Hunter refers to instances, in which the common catheter had been pushed through the projecting part of the prostate gland into the bladder, and the water then drawn off; but, "in one patient, the blood from the wound passed into the bladder, and increased the quantity of matter in it. The use of the catheter was attempted a second time; but, not succeeding, I was sent for. I passed the catheter till it came to the stop, and then suspecting, that this part of the prostate projected forwards, I introduced my finger into the anus, and found that gland very much enlarged. By depressing the handle of the catheter, which of course raised the point, it passed over the projection; but, unfortunately the blood had coagulated in the bladder, which filled up the holes in the catheter, so that I was obliged to withdraw it, and clear it repeatedly. This I practised several days; but, suspecting that the coagulum must in the end kill, I proposed cutting him (the patient) for the stone; but he died before it could be conveniently done, and the dissection, after death, explained the case, &c." (*On the Venereal Disease*, Ed. 2, p. 172.)

To one acquainted with anatomy, the introduction of the female catheter is exceedingly simple. From motives of delicacy to the sex, the instrument should always be passed without any exposure. The surgeon should hold the catheter in his right hand, while he introduces the fore-finger of his left-hand between the nymphæ so as to feel upon the upper surface of the passage the little papilla, which surrounds, and denotes to the touch, the precise situation of the orifice of the meatus urinarius. Holding the concavity of the catheter forward, the surgeon, guided by the fore-finger of his left-hand, is then to introduce the instrument upward into the bladder. A female catheter should always be furnished with some contrivance for preventing its slipping com-

pletely into the bladder: the following case, mentioned in a respectable periodical work, fully proves the truth of this remark.

Some years ago, a surgeon, practising in the country, was required to introduce the catheter for a lady labouring under retention of urine. During the operation, he was observed to exhibit signs of confusion, and to quit his patient in considerable embarrassment. The same day, he abruptly left his home, and was never seen afterward. The lady passed several years of dreadful suffering, attributed by herself and the professional gentleman, on whom the treatment of the case devolved, to aggravation of the original complaint. At length, an abscess presented itself in the sacral region, and the surgeon punctured it, when his instrument came in contact with some unusually hard substance imbedded in the centre of the abscess. With a pair of forceps, he now extracted to his utter astonishment a blackened female catheter. From this period, the lady's sufferings all terminated. A similar accident nearly happened in the practice of another gentleman. (See *Medico-Chir. Journ.* Vol. 5, p. 75, Lond. 1818.) (See *Urine, Retention of*.) J. Hunter, *Treatise on the Venereal Disease*, Ed. 2, in various places. Hey's *Practical Observations in Surgery*, Ed. 3. John Bell's *Principles*, Vol. 2. Ware on the Catheter. *Sketches of the Medical Schools of Paris*, by J. Cross, p. 111, &c. Jos. M'Sweeney, *Observations on the Catheter*, Edinb. Med. and Surgical Journ. No. 58, p. 52. Richter's *Anfangsgr. der Wundarzneykunst*. Rees's *Cyclopædia*, Art. Catheter. Langenbeck, 1 *Bibl. für die Chir.* B. 1, p. 1175, 12mo. Gott. 1806. Desault, *Œuvres Chir.* T. 3. The *Observations on the Catheter*, by Desault, Richter, J. Hunter, and Hey, are the best, with which I am acquainted.

CATLING, often spelt in surgical books, *catlin*, is a long, narrow, double-edged, sharp-pointed, straight knife, which is chiefly used in amputations of the leg and fore-arm, for dividing the interosseous ligaments and the muscles, &c. situated between the two bones. The catling is frequently made too wide and large, so that it cannot execute its office with the right degree of ease.

CAUSTICS. (from *καίω*, to burn.) Medicines, which destroy parts by burning, or chymically decomposing them.

The potassa fusa (kali purum,) the potassa cum calce (calx cum kali puro,) the antimonium muriatum, the argenti nitras, the hydrargyri nitrico-oxydum, the acidum sulphuricum, and the cupri sulphas, are the caustics in most frequent use among surgeons.

CAUTERIZATION. (from *καυτηρίζω*, to cauterize.) The act of burning any part with a cautery.

CAUTERY. (from *καίω*, to burn.) Cauteries are of two kinds, viz. *actual* and *potential*. By the first term, is implied a heated iron; by the second, surgeons understand any caustic application.

The high opinion which the ancients entertained of the efficacy of the actual cautery, may be well conceived from the follow-

ing passage. "Quoscumque morbus medicamenta non sanant, ferrum sanat; quos ferrum non sanat ignis sanat; quos vero ignis non sanat, insanabiles existimare oportet." (*Hipp. Sect. 8, Aph. 6.*) The actual cautery has been employed for the stoppage of bleeding, where the vessels could neither be tied, nor compressed. It has been also employed for the destruction of carcinomatous tumours and ulcers; fistulæ; polypi, and a variety of fungous diseases. Whoever looks over the writings of Hippocrates, will discover that the actual cautery was a principal means of relief in several chronic affections, as dropsies, diseased joints, &c.

In modern times, the actual cautery has been more and more relinquished, in proportion as surgery has attained a higher state of improvement. On the continent, however, it still retains advocates. In France, all the professors recommend and employ it in particular cases. The hospital gangrene, a peculiar disorder, which is much more frequently seen in foreign hospitals, is said to be little affected by any internal remedies. "Vegetable and diluted mineral acids are the local means employed with effect in mild cases. I have, (says Mr. Cross,) already alluded to a case of Pelletan's, where carbon was applied, and the progress of the disease impeded. But, the actual cautery is the only means, that has been found effectual, in stopping the fatal progress of bad cases of hospital ulcer, and the iron is applied red-hot, so as to produce an eschar on every point of the surface of the sore." (See *Sketches of the Medical Schools of Paris*, by J. Cross, p. 84.)

Desault often employed the actual cautery to destroy fungous tumours of the antrum. (See *Antrum*.) The same practice is still followed by Pelletan and other eminent surgeons in France. Mr. Cross saw it adopted in one such case with good effect. (P. 86.) That part of the fungus, which can be cut away, is to be so removed, and the deeper portion, out of the reach of the knife, is to be cauterized. If there be any case in surgery, justifying the use of a red-hot iron, it is a fungus of the antrum. But, even in this instance, I should prefer any other certain mode of destroying the root of the disease.

CERATOTOME. (from *κεράς*, a horn, and *τομή*, to cut.) The name given by Wenzel to the knife, with which he divided the cornea, or horny coat of the eye.

CERATUM CALAMINÆ. (L.) A good simple dressing.

CERATUM CETACEI. (L.) The spermaceti cerate. A mild, unirritating salve, for common purposes.

CERATUM CONII. R. Unguenti Conii lbj. (See *Unguentum*.) Cetacei ℥ij. Cera Albæ, ℥iij. M. One of the formulæ at St. Bartholomew's Hospital, occasionally applied to cancerous, scrofulous, phagedenic, herpetic, and other inveterate sores.

CERATUM HYDRARGYRI SUBMURIATIS. R. Hydrarg. Submuriatis, ℥i. Cerali Lapid. Calamin. ℥ss. M. Some practitioners are partial to this as a dressing for chancres.

CERATUM LYTTE. (L.) This, which was lately called the cerate of cantharides, was once much used for stimulating blistered surfaces, in order to maintain a discharge. The ceratum sabinæ, however, which answers much better, and is not attended with danger of bringing on strangury, inflammation of the bladder, &c., has almost superseded the ceratum lyttæ.

CERATUM PLUMBI SUPERACETATIS. (L.) An eligible, mildly astringent, unirritating salve.

CERATUM PLUMBI COMPOSITUM. (L.) An excellent, unirritating, gently astringent salve, for common purposes.

CERATUM SABINÆ. *R.* *Sabinæ Recentis Contusæ*, *Ceræ Flavæ*, sing. lbj. *Adipis Suillæ*, lbiv. Mix the savin with the melted wax and hog's lard, and strain the composition.

This is the common application for keeping open blisters, on the plan recommended by Mr. Crowther. (See *Blisters*.)

CERATUM SAPONIS. (L.) *R.* *Plumbi oxydi semivitrei* lib. j. *Aceti* cong. j. *Saponis unc.* viij. *Olei olivæ*, *Ceræ flavæ*, sing. lib. j.

This is the soap cerate of St. Bartholomew's Hospital. In preparing it, the utmost caution must be used. The three first ingredients are to be mixed together and boiled gently till all the moisture is evaporated; after which, the wax and oil, previously melted together, must be added. The whole composition, from first to last, must be incessantly and effectually stirred, without which the whole will be spoiled. This formula was introduced into practice by Mr. Pott, and is found to be a very convenient application for fractures, and also as an external dressing for ulcers; being of a convenient degree of adhesiveness, and at the same time possessing the usual properties of a saturnine remedy.

In applying this cerate, spread on linen, in fractures of the leg or arm, one caution is necessary to be observed, namely, that it be in two distinct pieces; for if, in one piece, the limb be encircled by it, and the ends overlap each other, it will form a very inconvenient and partial constriction of the fractured part, in consequence of the subsequent tumefaction. (*Pharm. Chirurg.*)

CERUMEN AURIS. A degree of deafness is frequently produced by the lodgment of hard dry pellets of this substance in the meatus auditorius. The best plan, in such cases, is to syringe the ear with warm water, which should be injected with moderate force.

In some instances, deafness seems to depend on a defective secretion of the cerumen, and a consequent dryness of the meatus. Here, a drop or two of sweet oil may now and then be introduced into the ear, and fomentations applied.

CERUSSA ACETATA. Sugar of lead. Acetite of lead. This preparation, which is now named by the college *plumbi superacetatis*, is well known as an ingredient in a variety of lotions and collyria. It has the qualities of preparations of lead in general,

being highly useful for diminishing inflammation.

CHALAZIUM. (from *χалаζα*, a hailstone.) A little tubercle on the eyelid which has been whimsically supposed to resemble a hailstone. It is the same as the hordeolum or sty. (See *Hordeolum*.)

CHAMOMILE. The flowers, which are bitter and aromatic, are used in surgery, for making fomentations.

CHANCER. (from *καγνισος*, cancer venereus.) A sore which arises from the direct application of the venereal poison to any part of the body. Of course it almost always occurs on the genitals. Such venereal sores, as break out from a general contamination of the system, in consequence of absorption, never have the term *chancre* applied to them. (For an account of the nature and treatment of chancres, see *Venereal Disease*.)

CHEMOSIS. (from *χαμα*, to gape.) When ophthalmia or inflammation of the eye, is exceedingly violent, it frequently happens, that one or more vessels become ruptured on the side next the eyeball, and a quantity of blood is infused into the cellular membrane, which connects the conjunctiva with the anterior hemisphere of the eye. Hence, the conjunctiva becomes gradually elevated upon the eyeball, and projects towards the eyelids, so as to conceal within it the cornea, which appears as if it were depressed. (*Scarpa*.) In this way, the middle of the eye assumes the appearance of a gap, or aperture.

According to the late Mr. Ware, when blood is extravasated under the tunica conjunctiva, there cannot be an easier or more effectual remedy than æther. A few drops are to be poured into the palm of the hand, and diffused over it, which may be immediately done by pressing the other hand against it. The hand is then to be applied to the eye, and kept close to it, while the spirit is evaporating. By this means, the action of the absorbent vessels for the dispersion of the blood is excited, and quickened.

In a few instances of chemosis, in which the swelling and inflammation of the conjunctiva have been great, the same author found the following application particularly beneficial, after free evacuations: *R. Interiorium foliorum recentium Lactucæ Sissilis*, ℥ij. *Coque cum Aq. Pur.* ℥ss. *In balneo mariæ pro semihora; tunc exprimatur succus, et applicetur paululum ad oculos et ad palpebras, sæpe in die.* (*Ware*.)

Ophthalmia, attended with chemosis, demands the most rigorous employment of the antiphlogistic treatment. Both general and topical bleeding should be speedily and copiously put in practice, with due regard, however, to the age and strength of the patient. Leeches should be applied to the vicinity of the eyelids, or, what is preferable, the temporal artery should be opened. When chemosis is very considerable, the distention of the conjunctiva may be relieved by making an incision in it, near its junction with the cornea. (See *Ophthalmia*.)

CHEVASTER or **CHEVA'STRE**. A double-headed roller, the middle of which was applied to the chin; the bandage then crossed at the top of the head, and passed on each side to the nape of the neck, where it crossed again. It was next carried up to the top of the head, and so on, till all the roller was exhausted.

CHIA'STRE. A bandage for stopping hemorrhage from the temporal artery. It is double-headed, about an inch and a half wide, and four ells long. The middle of the roller is applied to the unwounded side of the head; the bandage is carried round to the bleeding temple, and there made to cross over a compress on the wound. The roller is then continued over the coronal suture, and under the chin, care being taken to make the bandage cross upon the compress. In this way, the roller is applied round the head, till the whole is spent.

CHILBLAINS are the effect of inflammation, arising from cold. A chilblain in its mildest form, is attended with a moderate redness of the skin, a sensation of heat and itching, and more or less swelling, which symptoms, after a time, spontaneously disappear. The intolerable itching and sense of tingling, accompanying the inflammation of the milder description of chilblains, are observed to be seriously aggravated by exposure to heat. In a more violent degree, the swelling is larger, redder, and sometimes of a dark blue colour; and the heat, itching, and pain, are so excessive, that the patient cannot use the part. In the third degree, small vesicles arise upon the tumour, which burst and leave excoriations. These often change into ill-conditioned sores, which sometimes penetrate even as deeply as the bone, discharge a thin ichorous matter, and generally prove very obstinate. As Dr. John Thomson has remarked, "when the serum contained in the vesications is let out by a small opening, a portion of new cuticle is usually formed to supply the place of that, which has been separated; but, when the inflammation is severe, and the affection neglected, or improperly treated, the parts, which are the seat of vesication, are liable to pass into the state of viated ulcers. In this state, they yield a thin, ichorous, or sanious discharge, and are in general brought, only after a long time, and with much difficulty, to a healthy suppuration. In neglected cases, these ulcers not unfrequently become covered with foul sloughs. Ulceration often supervenes, and the soft parts covering the bones, are destroyed." (*On Inflammation*, p. 638.) The worst stage of chilblains is attended with sloughing.

Chilblains are particularly apt to occur in persons, who are in the habit of going immediately to the fire, when they come home in winter with their fingers and toes very cold; they are also frequent in persons, who often go suddenly into the cold, while very warm. Hence, the disease most commonly affects parts of the body, which are peculiarly exposed to these sudden transitions; for instance, the nose, ears, lips, toes,

heels, and fingers. Richter remarks, that they are still more frequently occasioned, when the part, suddenly exposed to cold, is in a moist perspiring state, as well as warm. Young subjects are much more liable to this troublesome complaint than adults; and females brought up in a delicate manner, are generally more afflicted, than the other sex.

The most likely plan of preventing chilblains is to accustom the skin to moderate friction; to avoid hot rooms and making the parts too warm; to adapt the quantity and kind of clothing to the state of the constitution, so as to avoid extremes, both in summer and winter; to wash the parts frequently with cold water; to take regular exercise in the open air in all weathers, and to take particular care not to go suddenly into a warm room, or very near the fire, out of the cold air.

Although chilblains of the milder kinds are only local inflammations, yet they have some peculiarity in them; for they are not most benefited by the same antiphlogistic applications, which are most effectual in the relief of inflammation in general.

One of the best modes of curing chilblains of the milder kind is to rub them with snow, or ice cold water, or to bathe them in the latter, several times a day, keeping them immersed each time, till the pain and itching abate. After the parts have been rubbed or bathed in this way, they should be well dried with a towel, and covered with flannel or leather socks.

This plan is perhaps as good a one as any; but it is not that which is always congenial to the feelings and caprice of patients; and with the constitutions of some it may even disagree. In such cases, the parts affected may be rubbed with spirit of wine, linimentum saponis, tinctura myrrhæ, or a strong solution of alum, or vinegar. A mixture of oleum terebinthinæ and balsamum copaivæ, in equal parts, is a celebrated application. A mixture of two parts of camphorated spirit of wine, and one of the liquor plumbi subacetatis has also been praised. Mr. Wardrop speaks highly of one part of the tincture of lyttæ, with six of the soap liniment. (*Medico-Chir. Trans. Vol. 5. p. 142.*)

With respect to vesications, "their occurrence is always hastened, and the inflammation, upon which they depend, greatly aggravated by the action of external heat; and, hence, the propriety of continuing cold applications to frost-bitten parts, so long as their temperature continues above the natural standard, or the inflammation excited seems to retain an acute character. From the tendency, which the inflammation excited, has to pass into gangrene, the more stimulating applications, such as spirit of wine, diluted ammonia, or oil of turpentine may be required. But, should these applications prove too stimulating, their strength may be weakened by additions of greater or less portions of the linimentum

ex-aqua calcis." (*Thomson on Inflammation*, p. 648.)

When chilblains have suppurated and ulcerated, the sores require stimulating dressings, such as lint dipped in a mixture of the liquor plumbi, subacetatis dilutus, and liquor calcis; tinctura myrrhæ, or warm vinegar. If a salve be employed, one which contains the hydrargyri nitrico-oxydum is best. Ulcers of this kind frequently require to be touched with the nitrate of silver, or dressed with a solution of it.

Chilblains, attended with sloughing, should be poulticed, till the dead parts are detached. The sores should then be first dressed with some mildly stimulating ointment, such as the unguentum resinæ flavæ. With this, in a day or two, a little of the hydrargyri nitrico-oxydum may be mixed; but the surgeon should not venture on the employment of very irritating applications, till he sees what the parts will bear, and whether such will be requisite at all; for, were he too bold, immediately he leaves off the poultices, he might bring on sloughing again.

The reader may find a long list of applications for chilblains in *Rees's Cyclopædia*, article Chilblains. See also *Richter's Anfangsgr. der Wundarzn.* Band. 1. *Thomson's Lectures on Inflammation*; p. 637, &c. *Lassus, Pathologie Chirurg.* T. 2. p. 388, &c. *Léveillé Nouvelle Doctrine Chir.* T. 4, p. 352, &c. *Callisen's Systema Chirurgiæ Hodiernæ*, Vol. 1. p. 304, &c. Edit. 1798. *Pearson's Principles of Surgery*, p. 153, &c. Edit. 1808.

CHIMNEY-SWEEPER'S CANCER.—See Scrotum.

CHORDEE. (French, from *χρῆδν*, a cord.) When inflammation is not confined merely to the surface of the urethra, but affects the corpus spongiosum, it produces in it an extravasation of coagulable lymph, as in the adhesive inflammation, which uniting the cells together, destroys the power of distention of the corpus spongiosum urethræ, and makes it unequal in this respect to the corpora cavernosa penis, and therefore a curvature takes place at the time of an erection, which is called a *chordee*. The curvature is generally in the lower part of the penis. When the *chordee* is violent, the inner membrane of the urethra is so much upon the stretch, that it may be torn, and a profuse bleeding from the urethra excited, that often relieves the patient, and even sometimes proves a cure.

This is the *inflammatory chordee*; there is another kind, which has been named *spasmodic*.

In the beginning of the inflammatory *chordee*, bleeding from the arm is often of service; but it is more immediately useful to take blood from the part itself by leeches; for, we often find, that when a vessel gives way, and bleeds a good deal, the patient is greatly relieved. Exposing the penis to the steam of hot water frequently gives great relief. Poultices have also beneficial effects; and both fomentations and poultices will often do most good when they contain camphor. Opium, given internally, is of singu-

lar service; and if it be joined with camphor, the effect will be still greater.

When the *chordee* continues after all inflammation has terminated, no evacuations are required; for, the consequences of the inflammation will cease gradually by the absorption of the extravasated coagulating lymph. Mercurial ointment, rubbed on the part, will considerably promote this event. When the common methods of cure are unavailing, hemlock is sometimes very useful. Electricity may be of service. A *chordee* is often longer in going off, than any other consequence of a gonorrhœa, but, in the end, it disappears.

For bringing about the removal of the extravasated lymph, camphorated mercurial ointment is better, than the simple unguentum hydrargyri. According to Mr. Hunter, the *spasmodic chordee* is much benefited by bark. (See his *Treatise on the Venereal Disease*, Ed. 2.)

CICATRIX. A scar: the mark left after the healing of a wound, or ulcer.

CICATRIZATION. The process by which wounds and sores heal. Granulations having been formed, the next object of nature is to cover them with skin. The parts which had receded by their natural elasticity, in consequence of the breach made in them, now begin to be brought together by the contraction of the granulations. The contraction takes place at every point, but principally from edge to edge, which brings the circumference of the sore towards the centre, so that the sore becomes smaller and smaller, even although little, or no new skin is formed.

The contracting tendency is in some degree proportioned to the general healing disposition of the sore, and looseness of the parts. When granulations are formed upon a fixed surface, their contraction is mechanically impeded; as, for instance, on the skull, the skin, &c. Hence, in all operations on such parts, as much skin should be saved as possible.

When there has been a loss of substance, making a hollow sore, and the contraction of the granulations has begun, and made a good deal of progress, before they have had time to rise as high as the skin, then the edges of the skin are generally drawn down, and tucked in by it, in the hollow direction of the surface of the sore.

The contraction of the granulations continues, till the healing is complete; but, it is greatest at first. That there is a mechanical resistance to such contraction, is proved by the assistance, which may be given to the process by the application of a bandage.

Besides the contractile power of the granulations, there is also a similar power in the surrounding edge of the cicatrizing skin, which assists the contraction of the granulations, and is generally more considerable than that of the granulations themselves, drawing the mouth of the wound together, like a purse. The contractile power of the skin is confined principally to the very edge, where it is cicatrizing, and, as Hunter be-

lieved, to those very granulations, which have already cicatrized; for, the natural or original skin, surrounding this edge, does not contract, or at least not nearly so much, as appears by its having been thrown into folds and plaits, while the new skin is smooth and shining.

The uses of the contraction of granulations are various. It facilitates the healing of a sore, as there are two operations going on at the same time, viz. contraction and skinning.

It avoids the formation of much new skin, the advantage of which is evident; for it is with the skin as with all other parts of the body, viz. that such as are originally formed are much fitter for the purposes of life, than those which are newly formed, and not nearly so liable to ulceration.

When the whole surface of a sore has skinned over, the substance, the remains of the granulations, on which the new skin is formed, still continues to contract, till hardly any thing more is left than what the new skin stands upon. This is a very small part, in comparison with the first formed granulations, and it in time loses most of its apparent vessels, becoming white and ligamentous. All newly healed sores are at first redder than the common skin, but in time, they become much whiter.

As the granulations contract, the surrounding old skin is stretched to cover the part, which had been deprived of skin.

When a sore begins to heal, the surrounding old skin, close to the granulations, becomes smooth, and rounded with a whitish cast, as if covered with something white. This, Mr. Hunter supposed to be a beginning cuticle, and it is as early and sure a symptom of healing as any. While the sore retains its red edge all round, for perhaps a quarter, or half an inch in breadth, we may be certain, that it is not in a healing state.

Skin is a very different substance, with respect to texture, from the granulations upon which it is formed; but it is not known, whether it is a new substance formed by the granulations, or a change in the surface of the granulations themselves.

The new skin most commonly takes its rise from the surrounding old skin, as if elongated from it; but not always. In very large sores, but principally old ulcers, in which the edges of the surrounding skin have but little tendency to contract, and the cellular membrane underneath to yield, or the old skin to become drawn over the ulcerated surface, the nearest granulations do not acquire a cicatrizing disposition. In such cases, new skin forms in different parts of the ulcer, standing on the surface of the granulations, like little islands.

Whatever change the granulations undergo to form new skin, they are generally guided to it by the surrounding skin, which gives this disposition to the surface of the adjoining granulations.

The new-formed skin is never so large as the sore was, on which it is formed, owing to the contraction of the granulations, and

the yielding of the surrounding old skin. If the sore is situated where the adjoining skin is loose, as in the scrotum, then the contractile power of the granulations being quite free from obstruction, a very little new skin is formed; but, if the sore is situated where the skin is fixed or tense, the new skin is nearly as large as the sore.

The new skin is at first commonly on the same level with the old. This, however, is not the case with scalds and burns, which frequently heal with a cicatrix, higher than the skin, although the granulations may have been kept from rising higher than this part.

The new-formed cutis is neither so yielding nor so elastic as the original is; it is also less moveable. It gradually becomes, however, more flexible and loose. At first, it is very thin and tender, but it afterwards becomes firmer and thicker. It is a smooth continued skin, not formed with those insensible indentations, which are observed in the natural or original skin, and by which the latter admits of any distention, which the cellular membrane itself will allow of.

This new cutis, and indeed all the substance which had formerly been granulations, is not nearly so strong, nor endowed with such lasting and proper actions, as the originally formed parts. The living principle itself is less active; for when an old sore breaks out, it continues to yield, till almost the whole of the new-formed matter has been absorbed, or has mortified.

The young cutis is extremely full of vessels; but these afterwards disappear, and the part becomes white.

The surrounding old skin, being drawn toward the centre by the contraction of the granulations, is thrown into loose folds, while the new skin itself seems to be upon the stretch, having a smooth shining appearance.

The new cuticle is more easily formed from the cutis, than the cutis itself from granulations. Every point of the surface of the cutis is concerned in forming cuticle, so that this is forming equally every where at once; but the formation of the cutis is principally progressive from the adjoining skin.

The new cuticle is at first very thin, and rather pulpy than horny. As it becomes stronger, it looks smooth and shining, and is more transparent than the old cuticle.

The rete mucosum is later in forming than the cuticle, and in some cases never forms at all. In blacks who have been wounded, or blistered, the cicatrix is a considerable time before it becomes dark; and in one black, whom Mr. Hunter saw, the scar of a sore, which had been upon his leg when young, remained white when he was old. Many cicatrices of blacks, however, are even darker than any other parts of the skin. (*Hunter on the Blood, Inflammation, &c. The reader may also consult Thomson's Lectures on Inflammation, p. 399, &c.*)

CICUTA. See *Conium Maculatum*.

CINCHONA. As one of the designs of this dictionary is to embrace the subjects

of a surgical pharmacopœia, peruvian bark, which is administered in a multiplicity of surgical cases, cannot be passed over in silence.

Its great repute for its virtues in stopping mortifications, and accelerating the separation of the sloughs, every person, whether of the medical profession or not, has frequently heard of. Indeed, so high is the character of the medicine, that many practitioners order it in some stage, or another, of almost every distemper, often prescribe it when it is totally useless, give it when it actually does harm, and make their patients swallow such quantities as operate perniciously, when smaller doses would effect striking benefit. Some men are credulous enough to think, that from the peruvian bark vigour and strength are directly extricated, and infused into the constitution, in exact proportion to the quantity of the medicine, which the stomach will keep down and digest.

While a doctrine of this sort prevails, we must expect to see indiscriminate and erroneous practice. The generality of diseases will always be attended with an appearance of languor and weakness, and, certainly, while there exists a supposition that a drug is at hand, possessing the quality of evolving and communicating strength, it would be absurd to fancy, that so important an article will not be largely exhibited in a multiplicity of surgical cases. I shall not presume to hazard an idea of the powers of the peruvian bark in the practice of physic; but, I have not the least doubt, that they have been unwarrantably exaggerated in surgery, so as to blind and prejudice many a practitioner of good abilities, and lead him to adopt injudicious and hurtful methods of treatment.

Under particular circumstances, bark has undoubtedly the quality of increasing the tone of the digestive organs; and, of course, whenever the indication is to strengthen the system by nourishing food, and the appetite fails, this medicine may prove of the highest utility, provided it is given in moderate doses, and it appears to agree with the stomach and bowels. But, the plan of making the patient swallow as much of the medicine as can be got into his stomach, must, in my opinion, be invariably followed by bad, instead of good effects. How can it be reasonably expected, that the stomach, which is already out of order, can be set right by having an immoderate quantity of any drug whatever forced into it? In fact, if the alimentary canal were in a healthy state, must not such practice be likely to throw it into a disordered condition?

Bark is an excellent medicine, when judiciously administered; but, like every other good medicine, in bad hands, it may be the means of producing the worst consequences. How much good does mercury effect in an infinite number of surgical diseases, when prescribed by a surgeon of understanding; what a poison it becomes under the direction of an ignorant practitioner!

With respect to cases of mortification, bark is often most strongly indicated, when the sloughing is not surrounded with active inflammation, when the patient is debilitated, and his stomach cannot take nutritious food. I have always regarded the notion of giving bark, as a specific for gangrene, as totally unfounded and absurd. I have watched its effects in these cases, and could never discern that it had the least peculiar power of operating directly upon the parts, which are distempered. Whatever good it does, is by its improving the tone of the digestive organs, and making them more capable of conveying nourishment, and, of course, strength into the constitution.

I should feel myself guilty of a degree of presumption in speaking thus freely upon this subject, were not my sentiments in some measure supported by those of certain surgical writers, the remembrance of whom will always be hailed with unfeigned veneration and esteem. Mr. Samuel Sharp was not bigoted to bark, and, while he allowed it to possess a share of efficacy, he would not admit that it was capable of miraculously accomplishing every thing, which the ignorant or prejudiced alleged. "I know," says he, "it will be looked upon by many as a kind of scepticism to doubt the efficacy of a remedy so well attested by such an infinity of cases, and yet, I shall frankly own, I have never clearly to my satisfaction, met with any evident proofs of its preference to the cordial medicines usually prescribed; though I have a long time made experiment of it with a view to search into the truth."

Perhaps it may seem strange, thus to dispute a doctrine established on what is called matter of fact; but, I shall here observe, that in the practice of physic and surgery, it is often exceedingly difficult to ascertain a fact. Prejudice, or want of abilities, sometimes misleads us in our judgment, where there is evidently a right and a wrong; but, in certain cases, to distinguish how far the remedy, and how far nature operate, is probably above our discernment. In gangrenes, particularly, there is frequently such a complication of unknown circumstances, as cannot but tend to deceive an unwary observer. Mortifications arising from mere cold, compression, or stricture, generally cease upon removing the cause, and are, therefore, seldom proper cases for proving the power of the bark. However, there are two kinds of gangrene, where internals have a fairer trial; those are a spreading gangrene from an internal cause, and a spreading gangrene from violent external accidents, such as gunshot wounds, compound fractures, &c. Yet, even here we cannot judge of their effect with absolute certainty; for, sometimes, a mortification from internal causes is a kind of critical disorder. There seems to be a certain portion of the body destined to perish, and no more; of this we have an infinity of examples brought into our hospitals, where the gangrene stops at a particular point;

without the least assistance from art. The same thing happens in the other species of gangrene from violent accidents, where the injury appears to be communicated to a certain distance, and no farther; though by the way, I shall remark in this place, contrary to the received opinion, that gangrenes from these accidents, (where there has been no previous straitness of bandage,) are as often fatal, as those from internal causes.

"As I have here stated the fact, we see how difficult it is to ascertain the real efficacy of this medicine; but, had bark in any degree those wonderful effects in gangrenes, which it has in periodical complaints, its pre-eminence would no more be doubted in the one case, than in the other. What, in my judgment, seems to have raised its character so high, are the great numbers of single observations published on this subject, the authors of which not having frequent opportunities of seeing the issue of this disorder, under the use of cordials, &c. and some of them, perhaps, prejudiced with the common supposition, that every gangrene is of itself mortal, have therefore ascribed a marvellous influence to the bark, when the event has proved successful.—(*Sharp's Crit. Inq. chap. 8, on Amputation.*)

Some further remarks on this subject will be reserved for the article *Mortification*.

According to Mr. Bromfield, bark is a specific for old ulcers, where the inflammation seems circumscribed at the distance of an inch round the sore, the surface of the ulcer looks glossy, and the discharge is extremely thin and very offensive, with little or no sleep, from the violence of the pain. He further observes, that the addition of opium, as circumstances may require, will often be found necessary. (*Chirurgical Observations and Cases, Vol. 1, p. 132.*)

Bark is given so extensively in the practice of surgery, that there are few important cases, in which, in certain circumstances, and at some period or another, it is not indicated. When persons have been weakened by a course of mercury, or by the effects of any disease whatsoever, moderate doses of bark will frequently be found of great service. But, it only becomes so on the principles above suggested, and, as far as my judgment extends, this medicine should never be prescribed in any surgical cases in excessive and unreasonable quantities.

The yellow bark, or the cortex cinchonæ cordifoliæ of the new pharmacopœia, is said to possess more efficacy, than the other kinds.

CINNABAR ARTIFICIAL. (*Hydrargyri Sulphuretum rubrum.*) Is chiefly employed by surgeons for fumigating venereal ulcers. An apparatus is sold in the shops for this purpose. The powder is thrown upon a heated iron, and the smoke is conducted by means of a tube to the part affected.

CIRCUMCISION. (from *circumcideo*, to cut round.) The operation of cutting off a circular piece of the prepuce, sometimes

practised in cases of phymosis. (See *Phymosis*.)

CIRSOCELE. (from *κίρσοις*, a varix, and *κύημα*, a tumour.) Cirsocele is a varicose distention and enlargement of the spermatic vein; and whether considered on account of the pain, which it sometimes occasions, or on account of a wasting of the testicle, which now and then follows, it may truly be called a disease. It is frequently mistaken for a descent of a small portion of omentum. The uneasiness which it occasions, is a dull kind of pain in the back, generally relieved by suspension of the scrotum. It has been resembled to a collection of earth-worms; but whoever has an idea of a varicose vessel, will not stand in need of an illustration by comparison. It is most frequently confined to that part of the spermatic process, which is below the opening in the abdominal tendon; and the vessels generally become rather larger, as they approach the testis. Mr. Pott never knew any good effect from external applications of any kind.

In general the testicle is perfectly unconcerned in, and unaffected by, this disease; but it sometimes happens that it makes its appearance very suddenly, and with acute pain, requiring rest and ease; and sometimes after such symptoms have been removed, Mr. Pott has seen the testicle so wasted as hardly to be discernible. He has also observed the same effect from the injudicious application of a truss to a true cirsocele; the vessels, by means of the pressure, became enlarged to a prodigious size, but the testicle shrunk to almost nothing. (*Pott's Works, Vol. 2.*)

Morgagni has remarked, that the disease is more frequent in the left, than the right spermatic cord; a circumstance which he refers to the left spermatic vein terminating in the renal. (*De Sedibus et Caus. Morb. Epist. 43, art. 34.*)

Cirsocele is more frequently than any other disorder, mistaken for an omental hernia. As Mr. Astley Cooper remarks, when large, it dilates upon coughing; and it swells in an erect, and retires in a recumbent posture of the body. There is only one sure method of distinguishing the two complaints; place the patient in a horizontal posture, and empty the swelling by pressure upon the scrotum; then put the fingers firmly upon the upper part of the abdominal ring, and desire the patient to rise; if it is a hernia, the tumour cannot reappear, as long as the pressure is continued at the ring; but if a cirsocele, the swelling returns with increased size, on account of the return of blood into the abdomen being prevented by the pressure. (*A. Cooper on Inguinal Hernia.*)

Cirsocele can for the most part only be palliated, and seldom radically cured. When the complaint is attended with pain, cold saturnine, and alum, lotions may be applied to the testicle and spermatic cord. At the same time, blood should be repeatedly taken away by means of leeches; the bowels

should be kept gently open; the patient should be placed in a horizontal posture; and the testicle should be supported in a bag-truss.

In general, the patient only finds it necessary to keep up the testicle by this kind of suspensory bandage.

Gooch, and other writers, have related cases of cirsocele, in which the pain was so intolerable and incurable, that nothing but castration could afford the patient any relief. (*J. A. Murray de Cirsocele, Upsal, 1784. Pott on Hydrocele, &c. Richter in Nov. Comment. Goett. No. 4, and in Obs. Chir. Fasc. 2, p. 22. Gooch Chir. Works. Most, Diss. de Cirsocele, Halæ, 1796.*)

CIRSOPHTHALMIA (from *χίρς*, a varix, and *ὀφθαλμός*, the eye.) A general varicose affection of the blood-vessels of the eye.

CLAP. (See *Gonorrhœa*.)

COLLYRIUM ACIDI ACETICI. *R.* Aceti Distillati ℥j. Spiritus Vini tenuioris ℥ss. Aq. Rosæ ℥viij. Misce. The strength to be diminished or increased, as circumstances may require. This collyrium is recommended for weak watery eyes, and sometimes for the scrofulous ophthalmia.—(See *Wilson's Pharm. Chir. p. 66.*)

COLLYRIUM ALUMINIS. *R.* Aluminis purif. ℥j. Aq. rosæ ℥vj. This is a good astringent collyrium, employed at Guy's Hospital.

COLLYRIUM AMMONIÆ ACETATÆ. *R.* Liq. ammon. acet. Aq. rosæ. sing. ℥j. M.

COLLYRIUM AMMONIÆ ACETATÆ CAMPHORATUM. *R.* Collyrii ammon. acet. Misturæ camphoratæ sing. ℥ij. M.

COLLYRIUM AMMONIÆ ACETATÆ OPIATUM. *R.* Collyrii ammon. acet. ℥iv. Tinct. opii. gutt. xl. M.

COLLYRIUM CUPRI SULPHATIS CAMPHORATUM. *R.* Aq. Cupri sulphatis camphoratæ ℥ij. Aq. distillatæ ℥iv. M. Recommended by Mr. Ware, for the purulent ophthalmia of children.

COLLYRIUM HYDRARGYRI OXYMURIATIS. *R.* Hydrarg. oxy-muriatis gr. ss. Aq. distillat. ℥iv. M. This collyrium is fit to be employed, after the acute stage of the ophthalmia has for some time subsided, and it will disperse many superficial opacities of the cornea.

COLLYRIUM OPIATUM. *R.* Opii Extracti gr. x. Camphoræ gr. vj. Aquæ distillatæ ferventis ℥xii. Beat the two first ingredients together in a mortar, and mix the hot water gradually, and strain the fluid.

This collyrium is recommended in some ophthalmies, attended with great pain and swelling. (See *Wilson's Pharm. Chir. p. 10.*)

COLLYRIUM PLUMBI ACETATIS. *R.* Aquæ rosæ ℥vj. Plumbi acetatis. ℥ss. Misce. or, *R.* Aq. distillatæ ℥iv. Liq. plumbi acetatis. gutt. x. M. This is a good application to the eyes, when one of a gently astringent, cooling quality is indicated.

COLLYRIUM ZINCI JUPHATIS.—Zinci sulphatis gr. v. Aq. distillatæ ℥iv. M. This is the most common collyrium of all: it may be made gradually stronger.

COLLYRIUM ZINCI SULPHATIS CUM MUCILAGINE SEMINIS CYDONII MALI. *R.* Aq. plantaginis ℥iv. zinci sulphatis gr. v. et mucil. sem. cydon. mal. ℥ss. M.

In order to check the morbid secretion from the eyelids, in cases of fistula lachrymalis, or what Scarpa calls *il flusso palpebrale puriforme*, this celebrated Professor recommends a few drops of the above collyrium to be insinuated between the eyelids and the eye.

COLPOCELE. (from *κολπος*, the vagina, and *κλῆμα*, a tumour.) A tumour, or hernia, situated in the vagina.

COLPOPTOSIS. (from *κολπος*, the vagina, and *πτωσις*, to fall down.) A bearing or falling down of the vagina. (See *Vagina, Prolapsus of*.)

COMA. (from *κα*, or *κατα*, to lie down.)—Anciently any total suppression of the powers of sense; but now it means a lethargic drowsiness. It is a symptom of several surgical disorders.

COMMUNUTED. (from *comminuo*, to break in pieces.) A fracture is termed *communuted*, when the bone is broken into several pieces.

COMPRESS. (from *comprimo*, to press upon.) Folded linen, lint, or other materials, making a sort of pad, which surgeons place over those parts of the body on which they wish to make particular pressure, and for this purpose a bandage is usually applied over the compress. Compresses are also frequently applied to prevent the ill effects, which the pressure of hard bodies, or tight bandages, would otherwise occasion.

COMPRESSION OF THE BRAIN. (See *Head, Injuries of*.)

CONCUSSION OF THE BRAIN. (See *Head, Injuries of*.)

CONDUCTOR. (from *conduco*, to guide.) A surgical instrument for directing the knife in certain operations. It is more commonly called a *director*.

CONDYLOMA. (from *κονδυλος*, a tubercle, or knot.) A small, very hard tumour. The term is generally applied to excrescences of this description about the anus. The practitioner may either destroy them with the lapis infernalis, tie their base with a ligature, so as to kill them, or remove them at once, with a knife: the first is generally the worst; the last the best and most speedy method.

CONIUM MACULATUM. Hemlock.—*Cicuta.* This is a medicine to which my observations in practice incline me to impute considerable efficacy in several surgical diseases. However, there is no doubt that, when it is represented as a certain cure for cancer and scrofula, exaggeration is employed. It is an excellent remedy for irritable painful sores of the scrofulous kind, and it will complete the cure of many ulcers, in which the venereal action has been destroyed by mercury, though the healing does not proceed in a favourable way. Hemlock is likewise beneficial to sp-

veral inveterate malignant sores, particularly some, which are every now and then met with upon the tongue. It is an eligible alterative in cases of noli me tangere, porrigo, and various herpetic affections. I have seen several enlargements of the female breast give way to hemlock conjoined with calomel. Some swellings of the testes also yield to the same medicines. Hemlock certainly has not the power of curing cancer; but, its narcotic and anodyne qualities tend to lessen the pain of that distemper, so as to render it by no means a contemptible remedy in that intractable kind of case.

Respecting hemlock, Mr. Pearson observes, that the extract and powder may be sometimes given with evidently good effect in spreading irritable sores; whether they are connected with the active state of the venereal virus, or whether they remain after the completion of the mercurial course; and it would seem, that the benefit conferred by this drug, ought not to be ascribed solely to its anodyne qualities, since the same advantages cannot always be obtained by the liberal exhibition of opium, even where it does not disagree with the stomach. He states that cicuta is almost a specific for the venereal ulcers, which attack the toes at their line of junction with the foot, and which frequently become gangrenous. Also, in spreading sores, which are accompanied with great pain, and no appearance of remarkable debility, hemlock will often do more than bark, vitriol, or cordials. The common mode of exhibiting hemlock is in the form of pills, made of the extractum conii, five grains to each. However, I have always thought three grains sufficient to begin with, the dose being afterwards gradually augmented. It is curious how large a quantity may at last be taken in this manner. Mr. J. Wilson, in his *Pharmacopœia Chirurgica*, informs us of a remarkable case of cancerous ulcer, for which the patient took a hundred and twenty pills, each consisting of five grains of the extractum conii, in twenty-four hours, and this without any benefit being produced, or any inconvenience to the patient.

The stomach being a little disordered, and the head somewhat giddy, is a sign of the dose being sufficiently strong.

"According to some writers, but more particularly Dr. Withering, there are several ways, in which the views of a medical practitioner, in prescribing this remedy, may be frustrated. The plant chosen for preparing the extract may not be the true *conium maculatum*, which is distinguished by red spots along the stalk. It may not be gathered when in perfection, namely, when beginning to flower. The inspissation of the juice may not have been performed in a water-bath, but, for the sake of despatch, over a common fire. The leaves, of which the powder is made, may not have been cautiously dried and preserved in a well stopped bottle; or, if so, may still not have been guarded from the ill effects of exposure to light. Or, lastly, the whole medi-

cine may have suffered from the mere effects of long keeping. From any of these causes, it is evident, the powers of cicuta may have suffered; and it happens, no doubt, very frequently, that the failure of it ought, in fact, to be attributed to one or other of them." (*Pharmacopœia Chirurgica*, published in 1802; p. 174.)

I have sometimes prescribed as an alterative with manifest benefit in several surgical diseases, a pill containing three grains of extractum conii, one of hydrargyri submuriæ (calomel,) and one of antimoniæ sulphuretum præcipitatum. (*F. Hoffman, of Hemlock. 8vo. Lond. 1763. A. Storck, Libellus, quo demonstratur cicutam non solum usu interno tutissimè exhiberi, sed et esse simul remedium valdè utile, &c.; Editio altera, 8vo. Vindob. 1761. Also Supplementum Necessarium de Cicuta, 8vo. Vindob. 1761. J. Pearson, On various Articles of the Materia Medica, &c. 2d Edit. 8vo. Lond. 1807.*)

CONTUSED WOUNDS. (See Wounds.)

CONTUSION. (from *contundo*, to bruise.)

A bruise.

Slight bruises seldom meet with much attention; but, when they are severe, very bad consequences may ensue, and these are the more likely to occur, when such cases are not taken proper care of.

In all severe bruises, besides the inflammation which the violence necessarily occasions, there is an instantaneous extravasation, in consequence of the rupture of many of the small vessels of the part. In no other way can we account for those very considerable tumours which often rise immediately after injuries of this nature. The black and blue appearance instantly following many bruises, can only be explained by there being an actual effusion of blood from the small arteries and veins, which have been ruptured. Even largish vessels are frequently burst in this manner, and considerable collections of blood are the consequence. Blows on the head very often cause a large effusion of blood under the scalp. I have seen many ounces thus extravasated.

Besides the rupture of an infinite number of small vessels and extravasation, which attend all bruises in a greater or less degree, the tone of the fibres and vessels, which have suffered contusion, is considerably disordered. Nay, the violence may have been so great, that the parts are from the first deprived of vitality, and must slough.

Parts at some distance from such as are actually struck, may suffer greatly from the violence of the contusion. This effect is what the French have named a *contrecoup*.

The bad consequences of bruises are not invariably proportioned to the force which has operated; much depends on the nature and situation of the part. When a contusion takes place on a bone, which is thinly covered with soft parts, the latter always suffer very severely in consequence of being pressed, at the time of the accident, between two hard bodies. Hence, bruises of the shin so frequently cause sloughing and

troublesome sores. Contusions affecting the large joints, are always serious cases; the inflammation occasioned is generally obstinate, and abscesses and other diseases, which may follow, are proper grounds for serious alarm.

In the treatment of bruises, the practitioner has three indications, which ought successively to claim his attention.

The first is to prevent and diminish inflammation, which, from the violence done, must be expected to arise. The bruised parts should be kept perfectly at rest, and be covered with linen, constantly wet with the liquor plumbi acetatis dilutus. When muscles are bruised, they are to be kept in a relaxed position, and never used.

If the bruise should have been very violent, it will be proper to apply leeches, and this repeatedly, and even in some cases, particularly when the joints are contused, to take blood from the arm. In every instance, the bowels should be kept well open with saline purgatives.

A second object in the cure of contusions, is to promote the absorption of the extravasated fluid by discutient applications.—These may at once be employed in all ordinary contusions, not attended with too much violence; for then nothing is so beneficial as maintaining a continual evaporation from the bruised part, by means of the cold saturnine lotion, and, at the same time, repeatedly applying leeches. In common bruises, however, the *Lotio ammonia muricata* (see this article.) is an excellent discutient application; but most surgeons are in the habit of ordering liniments for all ordinary contusions, and certainly they do so much good in accelerating the absorption of the extravasated blood, that the practice is highly praiseworthy. The *linimentum saponis*, or the *linimentum camphoræ*, are as good as any that can be employed. (See *Linimentum*.)

In many cases, unattended by any threatening appearances of inflammation, but in which there is a good deal of blood and fluid extravasated, bandages act very beneficially, by the remarkable power which they have of exciting the action of the lymphatics, by means of the pressure which they produce.

A third object in the treatment of contusions, is to restore the tone of the parts.—Rubbing the parts with liniments has a good deal of effect in this way. But, notwithstanding such applications, it is often observed, that bruised parts continue for a long while weak, and even swell, and become oedematous, when the patient takes exercise, or allows them to hang down, as their functions in life may require. Pumping cold water two or three times a day, on a part thus circumstanced, is the very best measure which can be adopted. A bandage should also be worn, if the situation of the part will permit. These steps, together with perseverance in the use of liniments, and in exercise gradually increased, will soon bring every thing into its natural state again.

CORNEA TUNICA. (from *cornu*, a horn.) The anterior transparent convex part of the eye, which in texture is tough like horn. It has a structure peculiar to itself, being composed of a number of concentric cellular lamellæ, in the cells of which is deposited a particular sort of fluid. It is covered externally by a continuation of the conjunctiva, which belongs to the class of mucous membranes; and it is lined by a membrane, the tunica humoris aquei, which seems to belong to the serous class.

FLESHY EXCRESCENCES OF THE CORNEA.

Mr. Wardrop, in his *Essays on the Morbid Anatomy of the Human Eye*, has published an excellent chapter on this subject. Besides pterygia, which are treated of in another part of this dictionary, Mr. Wardrop states that the cornea is subject to two kinds of caruncles, or fleshy excrescences. One appears at birth, or soon after it, and resembles the *navi materni* so frequent on the skin of various parts of the body. The second is described as having a greater analogy to the fungi, which grow from mucous surfaces, and being in general preceded by ulceration.

Of the congenital excrescence of the cornea, Mr. Wardrop has seen two remarkable instances. The first was in a girl, eight or ten years of age, on whose left eye there was a conical mass, the base of which grew from about two-thirds of the cornea, and a small portion of the adjoining sclerotic coat.

The second example occurred in a patient upwards of fifty years old. The tumour had been observed from birth, was about as large as a horse-bean, and only a small portion of it seemed to grow from the cornea. The other part was situated on the white of the eye, next the temporal angle of the orbit. From the middle of the excrescence, upwards of twelve long firm hairs grew, and hung over the cheek.

Mr. Wardrop acquaints us, that a similar tumour, with two hairs growing out of it, was seen at Lisbon by Dr. Barron, of St. Andrews. Mr. Crampton also mentions, that he once saw a "tuft of very strong hairs proceeding from the sclerotica." (*Essay on the Entropion*, p. 7.) And De Gazeilles met with an instance in which a single hair grew from the cornea. (*Journ. de Médecine*, Tom. 24.) According to Mr. Wardrop, this species of excrescence of the cornea greatly resembles the spots, covered with hair, which are frequent on various parts of the surface of the body.

With regard to the second kind of tumour growing from the cornea, a fungus, proceeding from an ulcer of this part of the eye, is stated to be very uncommon. However, it is said, that, when a portion of the iris protrudes through an ulcer of the cornea, the growth of a large excrescence from the projecting part is not so unusual. Of such a disease, Mr. Wardrop has cited examples from *Maitre Jean's Traité des Maladies des*

yeaux, Voigtel, Beer, and Plaichner. Excrescences, growing from the cornea, are also quoted from the following works; *Handbuch der Pathologischen Anatomie, Von F. G. Voigtel, Halle, 1804. Praktische Beobachtungen über den grauen Staar und die Krankheiten der Hornhaut, von Joseph Beer, Wien, 1791. Plaichner's Dissertatio, de Fungo Oculi.* (See Wardrop's *Essays on the Morbid Anatomy of the Human Eye, Vol. 1, chap. 4.*) Others are likewise described by Mery, in *Mém. de l'Acad. des Sciences, 1783*; by Dupré in *Phil. Trans. Vol. 19*; and Home in the same work, Vol. 81.

The only treatment which excrescences of the cornea admit of, is to remove them with a scalpel and a pair of forceps, or to destroy them with caustic.

ABSCESSSES OF THE CORNEA.

The following description of abscesses of the cornea, is taken from Mr. Wardrop's valuable work on the Morbid Anatomy of the Eye.

When the matter is collected between the lamellæ of the cornea, it first appears like a small spot; and, instead of resembling a small speck in colour, it is of the yellow hue of common pus. As the quantity of the matter increases, this spot becomes broader, and it does not alter its situation from the position of the head. If it be situated among the external layers of the cornea, or immediately below the corneal conjunctiva, a tumour is formed anteriorly, and, if touched with the point of a probe, the contained fluid can be felt fluctuating within. or if the eye be looked at sideways, an alteration in the form of the cornea may be readily perceived.

When the matter collects between the interior lamellæ, it does not produce any evident alteration, in the external form of the cornea; but, if it be touched with the point of a probe, a fluctuation can be more or less distinctly perceived, and the spot alters its form, and becomes somewhat broader.

Such collections of matter appear on every part of the cornea. Sometimes they alter their situation by degrees, and sink downwards; and sometimes they change both their situation and form. They very seldom cover more than one-fourth or one-third of the cornea.

When the quantity of matter is small, it is often completely absorbed during the abatement of the inflammatory symptoms, and it generally leaves no vestige behind it. In other cases, the cornea is eroded externally, producing an ulcer, and subsequently opacity. In some few instances, the internal lamellæ of the cornea gives way, and the matter escapes into the anterior chamber. When an artificial opening is made, the matter often does not readily flow out; and it is sometimes so tenacious, and contained in a cavity so irregular, that it neither escapes spontaneously, nor can it be evacuated by art.

It is particularly to the cases, in which

matter collects between the layers of the cornea, that the terms *unguis*, and *onyx*, are applied. (See Wardrop's *Essays on the Morbid Anatomy of the Human Eye, Vol. 1, chap. 6.*) According to a late writer, these words should be restricted to what he names "crescentic interlamellar depositions."—(Travers's *Synopsis of the Diseases of the Eye, p. 115.*) Where the cornea is affected with onyx, this gentleman commends antiphlogistic treatment. (P. 278.) And with respect to a large collection of matter in the cornea, whether the puriform onyx, or central abscess, he observes that it requires "a supporting constitutional treatment, mild cathartics, and the application of blisters;" calomel should be avoided, and the cornea can seldom be punctured to advantage. (P. 280.)

OPACITIES OF THE CORNEA.

Opacity of the cornea is one of the worst consequences of obstinate chronic ophthalmia. The term *opacity* is used, when the loss of transparency extends over the whole, or the greater part of the cornea; while other cases of a more limited kind are named *specks*. The distinction, as Beer observes, is chiefly important in respect to the prognosis. (*Lehre von den Augenkr. B. 2, p. 77.*)

Scarpa distinguishes the superficial and recent species of opacity from the *albugo* and *leucoma*, (see these words,) which are not in general attended with inflammation, assume a clear pearl colour, affect the very substance of the cornea, and form a dense speck upon this coat of the eye. The *nebula*, or slight opacity, here to be treated of, is preceded and accompanied by chronic ophthalmia; it allows the iris and pupil to be discerned through a kind of cloudiness, and consequently does not entirely bereave the patient of vision, but permits him to distinguish objects, as it were, through a mist. The *nebula* is an effect of protracted or ill treated chronic ophthalmia. The veins of the conjunctiva, much relaxed by the long continuance of the inflammation, become preternaturally turgid and prominent; afterwards they begin to appear irregular and knotty, first in their trunks, then in their ramifications, near the union of the cornea with the sclerotica, and lastly, in their most minute ramifications, returning from the delicate layer of the conjunctiva, spread over the cornea. It is only, however, in extreme relaxation of the veins of the conjunctiva, that these very small branches of the cornea become enlarged.

When this happens, some reddish streaks begin to be perceptible, in the interspace of which, very soon afterwards, a thin milky albuminous fluid is effused, which dims the diaphanous state of the cornea. The whitish, delicate, superficial speck, thence resulting, forms precisely what is termed, *nebula*, or the kind of opacity here to be considered. And since this extravasation may happen only at one point of the cornea, or in more places, the opacity may be in one speck, or

in several distinct ones, but which altogether diminish, more or less, the transparency of this membrane.

The cloudiness of the cornea, which sometimes takes place in the inflammatory stage of violent acute ophthalmia, especially differs from the species of opacity expressed by the term *nebula*. The first is a deep extravasation of coagulating lymph in the internal cellular texture of the cornea, or else the opacity proceeds from an abscess between the layers of this membrane about to end in ulceration. On the other hand, the *nebula* forms slowly upon superficies of the cornea, in long protracted chronic ophthalmia; is preceded first by a varicose enlargement of the veins in the conjunctiva, next of those in the delicate lamina of this tunic, continued over the front of the cornea; and finally it is followed by an effusion of albuminous lymph in the texture of this thin layer, expanded over the transparent part of the eye. This effusion never elevates itself in the shape of a pustule. Wherever the cornea is affected with *nebula*, the part of the conjunctiva, corresponding to it, is constantly occupied by a net-work of varicose veins, more knotty and prominent than other vessels of the same description, and though the cornea be clouded at more points than one, there are distinct corresponding fasciculi of varicose veins in the white of the eye. Scarpa injected an eye affected with chronic ophthalmia, and *nebula*, and he found that the wax easily passed, both into the enlarged veins of the conjunctiva, and those of that part of the surface of the cornea where the opacity existed; the inosculation all round the margin of the cornea were beautifully variegated, without trespassing that line, which bounds the sclerotica, except on that side, where the cornea was affected with the species of opacity.

Mr. Travers does not adopt precisely the same definition of *nebula*, as Scarpa; for, he describes it as a thickening of the conjunctiva, and an effusion of adhesive matter between it and the cornea, or *between the lamellæ of the latter*, commonly the product of acute strumous ophthalmia. (*Synopsis*, &c. p. 118.)

According to Scarpa, the superficial opacity, which alone he calls *nebula*, demands, from its very origin, active treatment; for, though at first it may only occupy a small portion of the cornea, when left to itself, it advances towards the centre of this membrane, and the ramifications of the dilated veins upon this coat, growing still larger, at length convert the delicate continuation of the conjunctiva upon the surface of the cornea, into a dense opaque membrane, obstructing vision.

The curative indication in this disease is to make the varicose vessels resume their natural diameters, or if that be impracticable, to cut off all communication between the trunk of the most prominent varicose veins of the conjunctiva, and the ramifications coming from the surface of the cornea, the seat of the opacity. The first

mode of treatment is executed by means of topical astringents and corroborants, especially Janin's ophthalmic ointment, and *success attends it, when the opacity is in an early state, and not extensive*. But when advanced to the centre of the cornea, the most infallible treatment is the excision of the fasciculus of varicose veins near their ramifications, that is, near the seat of the opacity. By means of this excision, the blood retarded in the dilated veins of the cornea is voided; the varicose veins of the conjunctiva have an opportunity to contract and regain their tone, no longer having blood impelled into them; and the turbid secretion effused in the texture of the layer of the conjunctiva continued over the cornea, or in the cellular substance, connecting these two membranes, becomes absorbed. The celebrity, with which the *nebula* disappears, after this operation, is surprising, commonly in twenty-four hours. The extent, to which the excision of the varicose veins of the conjunctiva must be performed, depends upon the extent of the opacity of the cornea. Thus, should there be only one set of varicose vessels, corresponding to an opacity of moderate extent, it is sufficient to cut a portion of them away. Should there appear several dim specks upon the cornea, with as many distinct sets of varicose vessels, arranged round upon the white of the eye, the surgeon must make a circular incision into the conjunctiva, near the margin of the cornea, by which he will certainly divide every plexus of varicose vessels. But let it be observed, that a simple incision through the varicose vessels is not permanently effectual in destroying all direct communication between the trunks and ramifications of these vessels upon the cornea, after such an incision made, for instance, with a lancet; though it be true that a separation of the mouths of the divided vessels follows in opposite directions, it is no less true, that in the course of a few days after the incision, the mouths of the same vessels approximate each other, and inosculate, so as to resume their former continuity. Hence, to derive from this operation all possible advantage, it is essential to extirpate with the knife a small portion of the varicose plexus, together with the adherent particle of the tunica conjunctiva.

The eyelids are to be separated from the affected eye by a skilful assistant, who is, at the same moment, to support the patient's head upon his breast. The surgeon is then to take hold of the varicose vessels, with a pair of small forceps, near the edge of the cornea, and to lift them a little up, which the lax state of the conjunctiva renders easy; then, with a pair of small curved scissors, he is to cut away the plexus of varicose vessels, together with a small piece of the conjunctiva, making the wound of a semilunar form, and as near as possible to the cornea. If it should be necessary to operate upon more than one plexus of varicose vessels situated at some distance apart, the surgeon must elevate them one after the other with the forceps and remove them. But, when

they are very close together, and occupy every side of the eye, he must make an uninterrupted circular incision in the conjunctiva, guiding it closely to the margin of the cornea all round, so as to divide with the conjunctiva, all the varicose vessels.

This being done, he may allow the cut vessels to bleed freely; even promoting the hemorrhage by fomenting the eyelids, until the blood discontinues to flow. Scarpa then covers the eye with an oval piece of the emplastrum saponis, and a retentive bandage. The eye ought not to be opened till twenty-four hours after the operation, when, usually, the opacity of the cornea will be found completely dispersed; and, during the ensuing days, the patient is to be enjoined to keep the eye shut, and covered with a bit of fine rag. A collyrium of milk and rose-water warm, may be applied two or three times a day. When the inflammation of the conjunctiva happens, about the second or third day after the operation, particularly in cases in which the incision is made all round, while the greater part of the sphere of the eye reddens, a whitish circle, in the place of the incision, forms a line of boundary to the redness which does not extend further upon the cornea. This inflammation of the conjunctiva, with the aid of internal antiphlogistic remedies, and topical emollients, abates in a few days, and then pus is secreted along the track of the incision in the conjunctiva. The wound contracts, and growing smaller and smaller, soon cicatrizes. Bathing the eye with warm milk and rose-water is the only local treatment necessary in this stage of the complaint.

Thus, not only the transparency of the cornea is revived, but also the preternatural laxity of the conjunctiva is diminished, or even removed. When the conjunctiva subsequently appears yellowish and wrinkled, the use of topical astringents and corroborants, and of Janin's ophthalmic ointment, may be highly beneficial, in preventing the recurrence of the varicose state of the vessels. (*Scarpa sulle malattie degli occhi, c. 8.*)

According to the experience of Dr. Vetch, Scarpa's plan of removing the plexus of varicose vessels, together with a portion of the conjunctiva, produces no good effect, "except in cases of great relaxation of the membrane covering the eye." He asserts, that new vessels immediately appear in the room of those removed, and the good derived from the bleeding does not compensate for the irritation produced by the operation. (*A Practical Treatise on the Diseases of the Eye, p. 86.*) However, when it is reflected, that Scarpa advises this practice only for advanced cases, and particularly recommends topical astringents for the more recent stages of the disease, he nearly agrees with Dr. Vetch, as far as this point is concerned. But, Scarpa's account of the disease and its treatment is left imperfect by the omission of any notice of the connexion frequently existing between opacity of the cornea, and a rough scabrous granulated

state of the lining of the eyelids. Yet perhaps, Scarpa was not to be expected to treat of this combination in his chapter on nebula, because his definition of this superficial opacity will not altogether suit the affection of the same membrane, referred to in the following observations. It is remarked by Dr. Vetch, that, after the complete cessation of conjunctival ophthalmia, as far as regards that portion of the membrane, which covers the eye, the villous elongation of the vessels of the lining of the eyelids, instead of recovering their natural state, acquire a further increase of size, so as to produce a rough, scabrous or granulated surface, with a secretion of puriform matter. The irritation of this unequal surface gradually induces an inflammatory state of the sclerotic vessels, and, consequently, a greater flow of blood towards the cornea: the superficial vessels become varicose; the conjunctiva assumes a dusky and loaded appearance; and the cornea becomes opaque, not partially, but throughout the whole extent of its structure. This affection, says Dr. Vetch, is essentially different from those nebulous, or partial opacities, which take place in primary sclerotic inflammation, and which consist in slight extravasations, accompanied by intolerance of light, and in which any affection of the palpebral linings is a secondary, instead of a primary circumstance. The cornea is of the green colour, presented by a broken gun-flint; and while it is sufficiently diaphanous to permit the perception of light, it is yet too opaque to allow the patient to discern external objects, except by their shades. Nor can the colour of the iris, and limits of the pupil be seen. Dr. Vetch also describes the conjunctiva as being sometimes so much relaxed, and its vessels so generally loaded, as to give it a dusky appearance similar to that of the cornea; and, in other instances, without much alteration of its thickness, or transparency, it is said to lose for a considerable extent its close attachment to the subjacent lamina of the cornea. Along with the opaque state of the cornea, there is more generally an enlargement of individual vessels, which penetrate almost to its centre, increase as they come outwards, and terminate in trunks, which run to the duplicature of the conjunctiva. Dr. Vetch represents this disease of the palpebræ as consisting at first in a highly villous state of their membranous lining. This state, if not rectified by proper treatment, gives birth to granulations, which, in time, become more deeply sulcated, hard, or warty, accompanied by an oozing of purulent matter. Dr. Vetch has explained, that the use of the actual cautery, excision, and friction, for the purpose of curing the diseased state of the eyelids, may be traced back to Hippocrates, who prefers escharotics. Dr. Vetch ascribes their first employment in these cases to St. Ives. Mr. Saunders, he observes, took an early and a just view of the relations, existing between the diseased conditions of the palpebral linings, and the opaque state of the cornea; and he

succeeded in establishing the cure of the latter by the removal of the former. In short, Dr. Vetch admits, that, in the case, which more especially formed the claim of Mr. Saunders to the discovery of the nature of the disease, the practice of excision was attended with complete success. Dr. Vetch contends, however, that this method is for the most part inadequate to the cure of the disease; and that there are very few cases, in which the more certain and consistent process of gradually repressing the diseased surface by escharotic substances will not produce a more complete and permanent cure. After giving a fair trial to a great variety of escharotics, made into ointments, and applied to the inside of the upper eyelid, Dr. Vetch found the direct application of the escharotic substances themselves was preferable. When there is too much increased action in the vessels of the sclerotic coat, Dr. Vetch recommends the use of escharotics to be preceded by cupping the temples: or, where there is any risk of a slough, the application of a leech to the inside of the lower eyelid. Whatever will bring on a determination of blood to the head is to be avoided, and a low regimen observed.

The escharotics, preferred by Dr. Vetch, are the sulphate of copper and nitrate of silver, scraped in the form of a pencil, and fixed in a portcrayon. In this way, Dr. Vetch says, they should be applied, not as some have conceived, with the view of producing a slough over the whole surface, but, with great delicacy, and in so many points only, as will produce a gradual change in the condition and disposition of the part. As long as there is any secretion of pus, the above application may be materially assisted by the daily use of the undiluted liquor plumbi acetatis. When the disease resists these remedies, and its surface is hard and warty, Dr. Vetch applies to the everted surface powder of verdigris, or burnt alum, finely levigated; or even lightly touches the diseased surface with the kali purum. In employing these remedies, he enjoins confining their operation to the point of contact, so as to prevent them from hurting the eye. Hence, they are to be applied in very minute quantities with a fine camel's hair pencil, and to be washed off with an elastic gum syringe, before the eyelid is returned. Of the employment of astringent collyria, in conjunction with escharotics, Dr. Vetch disapproves. (See *A Practical Treatise on the Diseases of the Eye*, p. 67, &c.) With respect to the treatment by excision as first practised by Mr. Saunders with scissors, and afterwards by Sir W. Adams with a knife, the principle of cure does not appear to me different from that aimed at with escharotics, unless these latter be supposed not always to destroy, but sometimes to cause an absorption of the fungous granulations. For the purpose of cutting away the redundant diseased membrane, the eyelids should be everted over a probe.

For the form of disease, termed by Mr. Vol. I.

Travers "strumous nebula, with vessels overshooting the cornea," this gentleman recommends ptyalism. He says, that "the hydrargyrus cum creta, or oxy-muriate, in small, but frequent doses, will sometimes succeed better in this case, than the other forms of mercury, and the combination of calomel with antimony, better than that with opium." When the internal exhibition of mercury either disorders the bowels, or has no effect on the constitution, frictions are to be preferred. (*Synopsis of the Diseases of the Eye*, p. 282.) In the particular form of opacity, to which he alludes, he disapproves of dividing the vessels of the conjunctiva, before the inflammation has declined. (P. 285.)

From some observations, published by Mr. Wardrop, it would appear, that certain opacities of the cornea are produced by an increase in the quantity of the contents of the eyeball, and not by the deposition of an albuminous fluid in the texture of the cornea, as takes place in the common speck. He considers this fact proved by cases, in which the cornea regained its transparency the instant the aqueous humour was evacuated. Some cases are detailed by this gentleman, with the view of recommending the practice of puncturing the cornea, and discharging the aqueous humour, for the relief of the kind of opacity to which we have here alluded. (See *Med. Chir. Trans. Vol. 4*, p. 180, &c.)

For other opacities of the cornea, refer to *Albugo*, *Leucoma*, and *Staphyloma*.

ULCERS OF THE CORNEA.

An ulcer is a common consequence of the bursting of a small abscess, which not unfrequently forms beneath the delicate layer of the conjunctiva continued over the cornea, or in the very substance of the cornea itself, after violent ophthalmia. At other times, the ulcer is produced by the contact of corroding matter, or sharp-pointed bodies insinuated into the eyes, such as quicklime, pieces of glass, or iron, thorns, &c. As Dr. Vetch has observed, ulceration of the cornea is a very frequent consequence of purulent ophthalmia. The little abscess of the cornea is attended with the same symptoms, as the severe acute ophthalmia; especially with a troublesome sensation of tension in the eye, eyebrow, and nape of the neck; with ardent heat; copious secretion of tears; aversion to light; intense redness of the conjunctiva, particularly near the point of suppuration. The inflammatory pustule, compared with similar ones, in any other part of the body, is slow in bursting after matter is formed. Scarpa deems it improper, however, to puncture the small abscess; for, though it assumes the appearance of being perfectly matured, the matter contained in it is so tenacious, and adherent to the substance of the cornea, that not a particle issues out of the artificial aperture, and the wound exasperates the disease, increases the opacity of the cornea, and often occasions another small abscess to form in the

vicinity of the first. Indeed, if the observations of Mr. Travers be correct, "the ulcer of the cornea begins, not in abscess, but, in a circumscribed deposit of lymph, or in pure ulcerative absorption without pus." (*Synopsis of the Diseases of the Eye*, p. 106.) And Dr. Vetch takes notice, that the observation, with respect to fluid matter never forming in the cornea, he invariably found true in several cases, where the whole of the eyeball had been destroyed by inflammation. (*Pract. Treatise on the Diseases of the Eye*, p. 52.) This author differs from Scarpa, however, respecting the question of opening pustules, or abscesses of the cornea; for he remarks, that, whenever the matter, or slough is removed, the ulcer, however deep and extensive, will fill up without leucoma being the consequence. By a little address, he says, it may, in most instances, be removed in a mass upon the point of a lancet, or couching needle. (*Op. cit.* p. 50.) This remark applies both to cases where lymph, or tenacious matter more or less protrudes, and to instances, in which it is quite confined between the lamellæ of the cornea. Scarpa thinks that the safest plan is to temporize, until the pustule spontaneously bursts, promoting it by means of frequent fomentations, bathing the eye with warm milk and water, and applying emollient poultices. The spontaneous bursting of the little abscess is usually denoted by a sudden increase of all the symptoms of ophthalmia; particularly by an intolerable burning pain at the point of the cornea, where the abscess first began, greatly increased by motion of the eye, or eyelid. The event is confirmed by ocular inspection, and at the spot where the white pustule existed, a cavity appears, as may best be seen, when the eye is viewed in the profile. Extraneous bodies in the eye, which have simply divided a part of the cornea, or lodged in it, when soon extracted, do not in general cause ulceration, as the injured part heals by the first intention. Those which destroy or burn the surface of this membrane, or which, when lodged, are not soon extracted, excite acute ophthalmia, suppuration at the injured part, and at length ulceration.

As Dr. Vetch has observed, the appearance of ulceration varies according to the degree of apostematation, or tendency towards it, in the surrounding cornea: when this part is clear, the case is doing well, but when opacity comes on, the ulcer is increasing. The soft middle lamina, he says, is destroyed with great rapidity, when the inflammation is violent, but as soon as the ulcer reaches the internal coat, its progress often proceeds no further. (*Practical Treatise on Diseases of the Eye*, p. 52.)

The ulcer of the cornea, as Scarpa remarks, has this in common with all solutions of continuity in the skin, where this is delicate, tense, and endowed with exquisite sensibility, that, at its first appearance, it is of a pale ash-colour; has its edges high and irregular; creates sharp pain; discharges, instead of pus, an acrid serum, and tends to

spread widely and deeply. Such is the precise character of ulcers upon the cornea, and such is the nature of those upon the nipple of the mamma; the glans penis; lips; apex of the tongue; the tarsi; the entrance of the meatus auditorius externus; nostrils; &c. Ulcers of this description, neglected, or ill-treated, speedily enlarge, make their way deeply, and destroy the parts in which they are situated. If they spread superficially upon the cornea, the transparency of this membrane is destroyed; if they proceed deeply, and penetrate the anterior chamber of the aqueous humour, this fluid escapes, and a fistula of the cornea may ensue; and if it should form a larger opening in it, besides the exit of the aqueous humour, it occasions another more grievous malady than the ulcer itself, namely, a prolapsus of a portion of the iris; an escape of the crystalline lens and vitreous humour; in short, a total destruction of the whole organ of sight. It is therefore of the highest importance, as soon as an ulcer appears upon the cornea, to impede its growing larger, as much as the nature of it will permit; the morbid process should be converted into a healing one, and the surgeon must exert his skill with more attention, the more extensive and deep the ulceration has proceeded. According to Scarpa, the cicatrix of a larger ulcer impairs the texture of the cornea so much, that the injury is irreparable. Yet, Dr. Vetch assures us, that when a slough covers an ulcer of considerable extent, and is taken off with great caution, so as not to wound the inner tunic of the cornea; or when it cannot be removed, if it be slightly scarified, and divided; the cornea may recover its transparency after two-thirds of it have been in this state. (*Pract. Treatise on the Diseases of the Eye*, p. 51.)

They who inculcate, that no external application can be adopted with benefit, for the cure of this disease, before the acute ophthalmia has been subdued, or, at least, diminished, are, in Scarpa's opinion, deceived. Experience teaches, that local remedies ought, in the very first instance, to be applied to the ulcer, such as are appropriate to lessen the increased morbid irritability, and stop the destructive process going on; afterwards such means should be taken, as will cure the ophthalmia, if it does not subside gradually, as the ulcer heals. It is a fact, confirmed by repeated observation, that it is the ulcer which keeps up the ophthalmia, not the ophthalmia the ulcer. The case, however, is to be excepted, in which the ulcer makes its appearance in the height of a severe ophthalmia. Here the first indication is to abate inflammation, before attempting to heal the sore.

It is true, that when the little abscess of the cornea breaks, the symptoms of acute ophthalmia are aggravated; the redness of the conjunctiva is increased, as well as the turgid state of its vessels; but it is equally certain, that it happens from no other cause, than an increased inflammation in the part, in consequence of the augmented sensibility

in the ulcerated spot of the cornea. As soon as this increase of sensibility in the ulcer of the cornea ceases, or abates in violence, the ophthalmia retreats with equal speed, and finally, when the ulcer heals, the inflammation disappears gradually, or, at most, requires only the use of an astringent, and corroborant collyrium, for a few days. Analogous examples every day occur in practice, in ulcers of other parts, besides the cornea; particularly in little foul ulcers on the inside of the lips, on the apex of the tongue, on the nipples, on the glans penis, which, as was described above, at their first appearance, assume an ash-coloured surface, excite inflammation of the part in which they are seated, and cause a very troublesome itching and ardent heat in the part affected. To subdue this inflammation, we do nothing more, and the vulgar do the same, than repel the excessive irritability in these ulcers, and convert the ulcerative process into cicatrization: this done, the surrounding inflammation immediately disappears of itself.

Such speedy and good effects may be obtained by caustic. It immediately destroys the naked extremities of the nerves in the ulcerated part, and soon removes the diseased irritability in the part affected; it converts the ash-coloured surface of the ulcer, and the serous discharge upon it, into an eschar and scab, which, as a kind of epidermis, moderates the contact of the neighbouring parts upon the ulcer, and at length converts the process of ulceration into that of granulation and cicatrization.

For cauterizing the ulcer of the cornea, the caustic, to which Scarpa gives the preference, is the argentum nitratum. It must be scraped to a point like a crayon pencil, and the eyelids being opened perfectly, and the upper eyelid suspended, by means of Pellier's elevator, the ulcer of the cornea is to be touched with the apex sufficiently to form an eschar. Should any of the caustic dissolve in the tears, the eye must be copiously bathed with warm milk. At the instant the caustic is applied, the patient complains of a most acute pain; but this aggravation is amply compensated, by the ease experienced a few minutes after the operation; the burning heat in the eye ceases, as it were by a charm; the eye and eyelids become capable of motion without pain; the flux of tears and the turgidity of the vessels of the conjunctiva decrease; the patient can bear a moderate light, and enjoys repose. These advantages last while the eschar adheres to the cornea.

On the separation of the eschar, sometimes at the end of two, three, or four days after the application of the caustic, the primary symptoms of the disease recur, especially the smarting and burning pain at the ulcerated part of the cornea; the effusion of tears; the restraint in moving the eye and eyelids; and the aversion to light; but all these inconveniences are less in degree than before. At their recurrence, the surgeon, without delay, must renew the application of the argentum nitratum, making a

good eschar, as at first, upon the whole surface of the ulcer, which will, as before, be followed by perfect ease in the eye. The application of the caustic is, if required, to be repeated a third time, that is, if upon the separation of the eschar, the extreme irritability in the ulcer is not exhausted, and its progressive mischief checked. When the case goes on favourably, it is a constant phenomenon in the cure of this disease, that, at every separation of the eschar, the diseased sensibility of the eye is decreased; the ulcer also, abandoning its pale ash-colour, assumes a delicate fleshy tint, a certain sign that the destructive process which prevailed is turned into a healing one. The turgid state of the vessels of the conjunctiva, and the degree of ophthalmia, disappear, in proportion as the ulcer draws near to a cure. At this epoch, when the formation of granulations has begun, the surgeon would act very wrongly, were he to continue the use of the argentum nitratum; it would now reproduce pain, effusion of tears, and inflammation in the eye; and the ulcer would take on that foul ash-coloured aspect, with swelled and irregular edges, which it had in the beginning. Platner has noticed this fact. *Necesse est, ut hoc temperatâ manu, nec crebrius fiat, ne nova inflammatio, novaque lachryma hic acrioribus concitetur. Inst. Chirurg. § 314.* As soon as ease is felt in the eye, and granulations begin to rise, whether after the first, second, or third application of the caustic, the surgeon must refrain from the use of every strong caustic, and use only the following collyrium. *R. Zinci Sulphatis gr. iv. Aq. Rosæ ʒiv. mucil. Sem. Cydon. mali ʒss M.* This to be used every two hours, the eye, in the intervals, being defended from the air and light, by means of a slight compress, and retentive bandage. When, besides the ulcer of the cornea, a slight relaxation of the conjunctiva remains, Janin's ointment, towards the end of the treatment, introduced between the eye and eyelids, morning and evening, proves serviceable. It must be adapted in strength and quantity to the particular sensibility of the patient.

To cure those superficial excoriations of the cornea, which make no excavation in the substance of this membrane, and which, in reality, are only a detachment of the cuticle, covering the layer of the conjunctiva continued over the cornea, the use of caustic is not requisite. The same collyrium, combined with mucilage, is sufficient. The symptoms which accompany such slight excoriations, or detachments of the cuticle, are unimportant, and when the patient takes care to bathe his eye, every two or three hours, with the solution of sulphate of zinc, and to avoid too much light, and exposure to the air, they soon get well.

According to Dr. Vetch, when the ulcerative process is likely to destroy the membrane, which lines the cornea, it can only be checked by measures, calculated to subdue the inflammation, upon which it depends. "As long, therefore, as there is an appear-

ance of activity in the disease, or recurrence of pain, local blood-letting by cupping, or leeches, must be steadily adhered to. The indication of the ulcer healing is easily seen in the diminished activity of the inflammation, relief from pain, and the clean aspect of the ulcerated part. The injection of vegetable, tepid astringent infusions may be used, or milk and water only. When called upon in extreme cases, where the immediate perforation of the inner membrane is threatened, we may, with great propriety, resort to the operation of puncturing the cornea at a place as remote as possible from the ulcer. Next in importance to a diminution of the action, on which the ulcer depends, is the removal by scarification of any slough thrown out from its surface, or imbedded in the adjoining part of the cornea. Sometimes, but always subordinate to these indications, we may add some topical applications to the ulcer; a solution of nitrate of silver, the infusion of tobacco, or calomel, in powder, applied with a camel's hair pencil." (*Practical Treatise on Diseases of the Eye*, p. 57.) In incipient protrusions of the inner membrane of the cornea, this author decidedly condemns the use of the *argentum nitratum* in the free manner proposed by Scarpa; observing, that, "if the caustic touches by accident the edge of the ulcer, or any part but the apex of the projecting vesicle, it will often produce much mischief."

Thus far of ulcers of the cornea, and the best mode of curing them in ordinary cases. However, sometimes, says Scarpa, in consequence of ill-treatment, the ulcer, already very extensive, assumes the form of a fungous excrescence upon the cornea, appearing to derive its nourishment from a band of blood-vessels of the conjunctiva; and, on this account, it occasions, not unfrequently, a serious mistake in being taken for a real pterygium. Left to itself, or treated with slight astringents, it produces, in general, a loss of the whole eye. It requires the speedy adoption of some active and efficacious plan, to destroy all the fungus upon the cornea, to annihilate the vessels of the conjunctiva tending to it, and to impede the progress of ulceration. This consists first in cutting away the fungus, with a pair of small scissors, to a level with the cornea, continuing the incision far enough upon the conjunctiva, to remove, with the excrescence, that string of blood-vessels, from which it seems to derive its supply. Having effected this, and allowed the blood to flow freely, Scarpa applies the *argentum nitratum* to all the space of the cornea, which appears to have been the seat of the fungus, so as to make a complete eschar; and if, upon its separation, the whole morbid surface should not be destroyed, he repeats the caustic until the ulcerative process changes into a healing one. To execute commodiously such a full application of the caustic, it is not in general enough to have the upper eyelid raised by an assistant, and the lower one depressed; it is also further

requisite, that the operator, by means of a spatula, introduced between the upper eyelid and the eyeball, should hold the same elevated with his own left-hand, while, with the right, he applies the caustic, so as to form a strong deep eschar.

The action of the caustic cannot always be calculated with precision, and therefore a portion of the whole thickness of the cornea may be destroyed with the fungus, which never fails to be followed by a prolapsus of part of the iris, through the aperture made in the cornea. This accident may seem grievous, yet it is not irreparable, as will be shown in the article *Iris, Prolapsus of*; and when the surgeon can produce a firm cicatrix at the point, where the excrescence was situated, which prevents a reproduction of the fungus, and a total destruction of the eye, he has fulfilled the indications required. (*Scarpa sulle Malattie degli Occhi*.)

In a late publication, two cases of ulcer of the cornea are recorded, which were benefited by Mr. Wardrop's operation of puncturing the cornea and discharging the aqueous humour. In the first example, there was an ulcer on the central part of the cornea, and a cluster of blood-vessels passing towards it. The whole eyeball was also much inflamed. The puncture was made at the place where the vessels passed. The patient's severe headach was relieved, and under the use of fomentations, and the vinous tincture of opium, all the other symptoms rapidly subsided. In the second case, there were two or three erosions, with a good deal of muddiness of the cornea, headach, &c. The obscurity of this membrane instantly disappeared, and the headach subsided, upon the aqueous humour being discharged. With the help of bleeding and fomentations, the symptoms abated, the ulcer healed in a few days, and the eye recovered. (*See Med. Chir. Trans. Vol. 4, p. 186—187.*)

In superficial ulcers of the cornea, attended with much inflammation of the conjunctiva, Mr. Travers recommends opium, combined so as to operate upon the skin, and keeping the bowels well open. Here he differs from Scarpa, in specifying the use of the nitrate of silver, as the best local treatment. Warm fomentations, he says, afford temporary relief, and where the inflammation of the sclerotica is intense, he advises the exhibition of mercury. (*Synopsis of the Diseases of the Eye*, p. 278.)

With regard to the treatment of indolent, and deep sloughing ulcers of the cornea, Mr. Travers praises, in addition to the employment of the nitrate of silver, the occasional use of leeches, and the administration of tonics and sedatives.

The same author has also noticed chronic interstitial ulcers, where the cornea is transparent, "but indented, like a bonce, when struck upon a marble hearth, or pitted, according as the ulcers are diffused, or circumscribed." These are said to succeed acute inflammation, when large quantities of blood

have been lost, and to occur frequently in children imperfectly nourished, or in adults, who are very debilitated. With the aid of good diet, tonics, and moderate topical stimulants, like the *vinum opii*, or the zinc collyrium, they become hazy, which denotes the commencement of the adhesive inflammation. (*Op. cit.* p. 117.)

OSSIFICATION OF THE CORNEA.

Mr. Wardrop has seen only one instance of ossification of the cornea; and, in that case, the whole eye was changed in its form, and the cornea had become opaque. On macerating the latter part, a piece of bone, weighing two grains, oval-shaped, hard, and with a smooth surface, was found between its lamellæ. A piece of bone was also found between the choroid coat and retina.

The same gentleman informs us, that Walter had, in his museum, a piece of cornea, taken from a man sixty years of age, containing a bony mass, which was three lines long, two broad, and weighed two grains.

In Mr. Wardrop's publication, there is also recorded a curious case, in which a portion of bone was formed, either in the substance of the cornea, or immediately behind it, and which was extracted from the eye by Mr. Anderson, surgeon at Inverary. The patient was a woman thirty-one years of age, and the formation of the bony substance, which was about half as large as a sixpence, is said to have been occasioned by a fall against the root of a tree, fifteen years before the operation, by which accident the eye was struck, though not cut. (See *Wardrop's Essays on the Morbid Anatomy of the Human Eye*, Vol. 1, chap. 10.)

ALTERATION IN THE FORM OF THE CORNEA.

This is the last subject which I shall take notice of in the present article. It is well known, that the convexity of the cornea varies in different persons, and in the same individual at different periods of life, this part of the eye being naturally most convex in young subjects. It appears, also, from the experiments of the late Mr. Ramsden, and those of Sir E. Home, that the sphericity of the cornea is altered according to the distance at which objects are viewed.

Sometimes the cornea projects, or collapses so considerably, without its transparency being affected, that sight is much impaired, or quite destroyed. The first case has been called by some authors, the *Staphyloma pellucidum*; the second *Rhytidosis*. Leveillé, the French translator of Scarpa's book on the diseases of the eye, has described a case, in which the cornea of both eyes became of a conical form: Mr. Wardrop met with two examples of a similar disease; but only one eye was affected in each of them. In both cases, the conical figure of the cornea was very remarkable, and the apex in the cone was in the centre of the cornea. When the eye was viewed

laterally, the apex resembled a piece of solid crystal, and when looked at directly opposite, it had a transparent sparkling appearance, which prevented the pupil and iris from being distinctly seen.

One of these cases occurred in a lady upwards of thirty years of age, and the changes produced in her vision were very remarkable. At the distance of an inch, or an inch and a half, she could plainly distinguish small objects, when held towards the temporal angle of the eye, although it required considerable exertion; but the sphere of vision was very limited.

On looking through a small hole in a card, she could distinguish objects held very close to the eye, and could even read a book.

At any distance greater than two inches, vision was very indistinct; and, at a few feet, she could neither judge of the distance, nor the form of the object.

When she looked at a distant luminous body, such as a candle, it was multiplied five or six times, and all the images were more or less indistinct. She could never find any glass sufficiently concave to assist her vision. She did not remark this complaint in her eye, until she was about sixteen years of age, and she does not think it has undergone any change since that time.

In Mr. Wardrop's publication may be read a letter from Dr. Brewster, giving an explanation of the phenomena of the foregoing case.

It appears, that Mr. Phipps has had opportunities of watching the progress of several cases, in which the cornea had become conical, and that he never saw the disease in persons under the age of fourteen or sixteen. The same gentleman also observes, that when the cone is once complete, the disease seldom makes any further progress, except that the apex sometimes becomes opaque.

Burgman saw a remarkable case, where the cornea of both the eyes of a person, who had been hanged, were so prodigiously extended, that they reached down to the mouth, like two horns. (*Haller, Disputationes Chirurg. Tom. 2.*) The chapter by Mr. Wardrop on the preceding subject will be found highly interesting to such as are desirous of further information concerning this curious disease of the eye. (See *Wardrop's Essays on the Morbid Anatomy of the Eye*, Vol. 1, chap. 13.) For information, relative to diseases of the cornea, see *M. Geiger, De Fistula Corneæ, Tub. 1742. C. F. Giffheil, De Ulceribus Corneæ, Tub. 1744. J. W. Baur, De Maculis Corneæ, &c. Tub. 1743. G. H. Volger, De Maculis Corneæ, 4to. Gott. 1778. A. G. Richter, Anfangsgr. der Wundarzn. B. 3, Kap. 4, Svo. Gott. 1795. Ant. Scarpa, Trattato delle Malattie degli occhi, 2 Ed. Svo. Pavia, 1816, chap. 8, 10. J. Beer, Praktische Beobacht. über den grauen Staar, und die Krankheiten, Der Hornhaut, Wien. 1799, und Lehre von den Augenkr. 2 B. Wien. 1817. M. J. Chelius, Ueber die durchsichtige Hornhaut des Auges,*

ihre Function, und ihre Krankhaften Veränderungen. Svo. Karlsruhe, 1818. A. Clemens, *Diss. sistens Tunica Corneae et Humoris Aquei Monographiam Physiologico-pathologicam*, 4to. Gott, 1816. J. Wardrop's *Essays on the Morbid Anatomy of the Human Eye*, Vol. 1, 8vo. Edit. 1808. B. Travers, *Synopsis of the Diseases of the Eye*, Svo. Lond. 1820. J. Vetch, *a Practical Treatise on the Diseases of the Eye*, Svo. Lond. 1820. The sections of this work on opaque cornea, and ulceration of the cornea, are highly interesting.

CORNS. (*Clavi, Spinæ Pedum, Calli, Condylomata, &c.*) A corn, technically called *clavus*, from its fancied resemblance to the head of a nail, is a brawn-like hardness of the skin, with a kind of root sometimes extending deeply into the subjacent cellular substance. When this is the case, the indurated part is fixed; but while the hardness is more superficial, it is quite moveable. Some corns rise up above the level of the skin, in the manner of a flat wart. They are hard, dry, and insensible, just like the thickened cuticle, which forms on the soles of the feet, or on the hands of labouring people.

Corns are entirely owing to repeated and long-continued pressure. Hence, they are most frequently in such situations as are most exposed to pressure, and where the skin is near bones, as on the toes, soles of the feet, &c. However, corns have occasionally been seen over the crista of the ilium, from the pressure of stays, and even on the ears, from the pressure of heavy ear-rings.

Corns of the feet are usually owing to tight shoes, and, consequently, they are more common in the higher classes, and in women, than other subjects. In females, indeed, the ridiculous fashion of wearing high-heeled shoes, was very conducive to this affliction; for, certainly, it merits the appellation. In shoes thus made, the whole weight of the body falls principally on the toes, which become quite wedged, and dreadfully compressed in the end of the shoe.

Though some persons, who have corns, suffer very little, others occasionally endure such torture from them, that they are quite incapable of standing or walking. Doubtless the great pain proceeds from the irritation of the hard corn on the tender cutis beneath, which is frequently very much inflamed, in consequence of the pressure. It is observed, that every thing which accelerates the motion of the blood, which heats the feet, which increases the pressure of the corn on the subjacent parts, or the determination of blood to the feet, or which promotes its accumulation in them, exasperates the pain. Hence, the bad effects of warm stockings, tight shoes, exercise, long standing, drinking, &c. The pain in warm weather is always much more annoying, than in winter.

If a person merely seeks temporary relief, it may be obtained by pulling off his tight shoes, sitting down, placing his feet in a horizontal posture, and becoming a little cool; the prominent portion of the corn

should be cut off, as far as it can be done, without exciting pain, or bleeding, and the feet should be bathed in warm water.

The radical cure essentially requires the avoidance of all the above causes, and, particularly, of much walking, or standing. Wide, soft shoes, should be worn. Such means are not only requisite for a radical cure, but they alone very often effect it. How many women become spontaneously free from corns in childbed, and other confinements! Though the radical cure is so easy, few obtain it, because their perseverance ceases as soon as they experience the wished-for relief.

When business, or other circumstances, prevent the patient from adopting this plan, and oblige him to walk or stand a good deal, still, it is possible to remove all pressure from the corn. For this purpose, from eight to twelve pieces of linen, smeared with an emollient ointment, and having an aperture cut in the middle, exactly adapted to the size of the corn, are to be laid over each other, and so applied to the foot, that the corn is to lie in the opening, in such a manner that it cannot be touched by the shoe, or stocking. When the plaster has been applied some weeks, the corn commonly disappears, without any other means. Should the corn be in the sole of the foot, it is only necessary to put in the shoe a felt-sole, wherein a hole has been cut, corresponding to the situation, size, and figure, of the induration.

A corn may also be certainly, permanently, and speedily eradicated, by the following method, especially when the plaster, and felt-sole with a hole in it, are employed at the same time. The corn is to be rubbed twice a day with an emollient ointment, such as that of marshmallows, or with the volatile liniment, which is still better; and, in the interim, is to be covered with a softening plaster. Every morning and evening, the foot is to be put for half an hour in warm water, and, whilst there, the corn is to be well rubbed with soap. Afterward, all the soft, white, pulpy outside of the corn, is to be scraped off with a blunt knife; but, the scraping is to be left off, the moment the patient begins to complain of pain from it. The same treatment is to be persisted in, without interruption, until the corn is totally extirpated, which is generally effected in eight or twelve days. If left off sooner, the corn grows again.

A multitude of other remedies for curing corns are recommended. They all possess, more or less, an emollient and discutient property. The principal are green wax, soap, mercurial, and hemlock plasters, a piece of green oil-skin, &c. They are to be applied to the corn, and renewed as often as necessary. An infallible composition consists of two ounces of gum ammoniacum, the same quantity of yellow wax, and six drams of verdigris. In a fortnight, if the corn yet remain, a fresh plaster is to be applied.

It is frequently difficult, and hazardous to

cut out a corn. The whole must be completely taken away, or else it grows again; and the more frequently it is partially cut away, the quicker is its growth rendered. When the skin is moveable, and, consequently, the corn not adherent to the subjacent parts, its excision may be performed with facility and safety, but not without pain. But, in the opposite case, either leaving a piece of the corn behind, or wounding the parts beneath, can seldom be avoided. The latter circumstance may excite serious mischief.

A person, entirely cured of corns, is sure to be affected with them again, unless the above-mentioned causes be carefully avoided. Some subjects are, indeed, particularly disposed to have the complaint. There are persons, who for life wear tight shoes, and take no care of their feet, and yet are never incommoded with corns. On the contrary, others are constantly troubled with them, though they pay attention to themselves. Many are for a time vexed with corns, and then become quite free from them, though they continue to wear the same kind of shoes and stockings.

Mr. Wardrop recommends cutting, or tearing away as much of the corn as can be done with safety; then keeping the toe for some time in warm water; and, after the adjacent skin has been well dried, rubbing the exposed surface of the corn with the argenti nitratum, or wetting it, by the means of a camel-hair pencil, with a solution of the oxy-muriate of mercury in spirit of wine. Either of these applications, two or three times repeated, he says, will mostly effect a cure. (See *Med. Chir. Trans.* Vol. 5, p. 140.) However, the use of caustic for the cure of corns is not a new proposal. (See *Callisen's Syst. Chir. Hodiernæ*, Part. 2, 200.)

The above account is chiefly taken from *Richter's Anfangsgrunde der Wundarzneykunst*, B. 1.

COUCHING. The depression of the cataract, or the introducing of an instrument into the eye, for the purpose of pressing the opaque crystalline lens downward, out of the axis of sight. (See *Cataract*.)

COUVRE CHEF. The name of a bandage. (See *Bandage*.)

CRANIUM. For an account of its fractures, see *Head, Injuries of*.

CREMOR LITHARGYRI ACETATI. R. Cremoris lactis ℥j. Liq. Plumbi. acet.

℥j. M. Employed by Kirkland in ophthalmies, and other inflammations.

CREPITATION. The crackling noise made in cases of emphysema, when the air is passing from one part of the cellular membrane into another.

CREPITUS. (from *crepo*, to make a noise.) This term is applied by surgeons to the grating sensation, occasioned by the ends of a fracture, when they are moved, and rubbed against each other. A crepitus is one of the most positive symptoms of the existence of such an accident.

CUBEBAE. (*Cubabah*, Arab.) *Piper caudatum.* *Cumamus.* *Cubebs.* The dried berries of the *Piper Cubeba* of Linnæus:—*foliis oblique ovatis, seu oblongis venosis acutis, spica solitaria pedunculata oppositifolia fructibus pedicellatis.* They are of an ash brown colour, generally wrinkled, and resembling pepper, but furnished each with a slender stalk. They are a warm spice, of a pleasant smell, and moderately pungent taste, imported from Java; and may be exhibited in all cases where warm spicy medicines are indicated. Great encomium has been passed upon this article as a remedy in gonorrhœa, and is considered under that head in the Appendix.

CUPPING. (See *Bleeding*.)

CUPRI SULPHAS. (*Sulphate of Copper*.) Is an escharotic, and an ingredient in several astringent fluid applications, lotions for ulcers, collyria for the eyes, and injections for the urethra.

CURETTE. (French.) An instrument, shaped like a minute spoon, or scoop, invented by Daviel, and used in the extraction of the cataract, for taking away any opaque matter, which may remain behind the pupil, immediately after the crystalline has been taken out.

CURVATURE OF THE SPINE. (See *Verlebræ, Disease of*.)

CYSTITOME. (from *κυστις*, and *τομή*, to cut.) An instrument made on the same principle as the pharyngotomus, and invented by M. de la Faye, for opening the capsule of the crystalline lens.

CYSTOCELE. (from *κυστις*, the bladder, and *κέλη*, a tumour.) A hernia, formed by a protrusion of the bladder. (See *Hernia*.)

CYSTOTOMIA. (from *κυστις*, the bladder, and *τομή*, to cut.) Making an opening into the bladder for the extraction of a stone or calculus. (See *Lithotomy*.)

D.

DACRYOMA. (from *δακρῦμα*, to weep.) An impervious state of one, or both the puncta lachrymalia, preventing the tears from passing into the lachrymal sac.

DAUCUS. The carrot, when boiled, and beaten to a pulp, is used in surgery as a poultice, which is often applied to malignant

and phagedenic ulcers. (See *Cataplasma Dauci*.)

DECOCTUM CHAMÆMELI. R. Florum Chamæmeli ℥ss. Aquæ Distillatæ lbj. Boil ten minutes, and strain the liquor. A common decoction for fomentations. (See *Fomentum*.)

DECOCTUM DULCAMARÆ. R. Dul-

camaræ Caulis Concisæ unciam, Aquæ Octarium cum Semisse. Decoque ad octarium, et cola.

The decoction of bittersweet, or woody nightshade, is recommended for some cutaneous diseases, proceeding from scrofula, lepra, and lues venerea. The dose is one or two table spoonfuls, three times a day. An aromatic tincture should be added.

DECOCTUM HELLEBORI ALBI.—(Now the *Decoctum Veratri*.) *R.* Pulveris Radicis Hellebori Albi ℥j. Aquæ Distillatæ lbij. Spiritus Vinosi Rectificati ℥ij. Boil the water and powder, till only one half the fluid remains, and when cold, add the spirit.

This is used as a lotion for curing psora, porrigo, and some herpetic affections.

DECOCTUM LOBELIÆ. (*Blue Cardinal Flower of Virginia*.) *R.* Radicis Lobeliæ Syphiliticæ Siccæ Manip. j. Aquæ Distillatæ lb. xii. This is to be boiled till only four quarts remain. The lobelia once gained repute as an antivenereal, though little reliance is now put in it. The patient is at first to take half a pint twice, and afterwards four times a day. It operates, however, as a purgative, and the doses must be regulated according as the bowels appear to bear them.

DECOCTUM MEZEREI. *R.* Corticis Radicis Mezerei Recentis ℥ij. Radicis Glycyrrhizæ Contusæ ℥j. Aquæ Distillatæ lbij. Boil the mezereon in the water, till only two pints remain; and, when the boiling is nearly finished, add the liquorice root.

The decoction of mezereon has been much prescribed for venereal nodes and nocturnal pains in the bones, in doses of from four to eight ounces, three times a day.

DECOCTUM PAPAVERIS. *R.* Papaveris Somniferi Capsularum Concisarum ℥iv. Aquæ lbiv. Boil for a quarter of an hour, and strain. In cases attended with great pain and inflammation, this decoction is used as a fomenting fluid.

DECOCTUM QUERCUS. *R.* Quercus Corticis ℥j. Aqua lbij. Boil down to a pint, and strain the fluid.

This decoction forms a very astringent injection, which is sometimes used for stopping gleet from the vagina. It also makes a lotion, which is of considerable use in cases of prolapsus ani. It may be applied to some slight rheumatic white swellings, which it will sometimes cure, particularly, when a little alum is put into it.

DECOCTUM SARSAPARILLÆ. *R.* Sarsaparilla Radicis Concisæ ℥iv. Aquæ Ferventis, lbiv. The sarsaparilla is to be macerated for four hours, near the fire, in a vessel lightly closed. The root is then to be taken out, bruised, and put into the fluid again. The maceration is to be continued two hours longer, after which the liquor is to be boiled till only two pints remain. Lastly, it is to be strained.

DECOCTUM SARSAPARILLÆ COMPOSITUM. *R.* Decocti Sarsaparillæ ferventis lbiv. Sassafras Radicis Concisæ, Guaiaci Ligni Rasi, Glycyrrhizæ Radicis

Contusæ, Singulorum ℥j. Mezerei Radicis Corticis ℥ij. These are to be boiled together for a quarter of an hour, and then strained.

This, and the preceding decoction of sarsaparilla, are much prescribed by surgeons in cases of venereal nodes and pains; but, while some surgeons hold them in high repute, in such cases, others entertain an opposite opinion of them. They are also commonly given in several cutaneous diseases, and in scrofula.

The simple decoction is frequently directed for the restoration of the constitution after a course of mercury, sometimes mixed with an equal quantity of milk.

The common dose of both the decoctions is from four to eight ounces, three times a day.

The compound one possesses similar qualities to those of the famous Lisbon diet drink, for which it is now generally prescribed.

DECOCTUM ULMI. *R.* Ulmi Corticis Recentis Contus. ℥iv. Aquæ lbiv. Boil to two pints, and then strain the liquor.

The decoction of elm bark is often prescribed in cutaneous diseases. Its operation is frequently promoted by giving with it the hydrargyri-submurias.

DECOCTUM VERATRI. (See *Decoctum Hellebori Albi*.)

DEPRESSION OF THE SKULL. (See *Head, Injuries of*.)

DEPRESSION OF THE CATARACT. (See *Cataract*.)

DETERMINATION. When the blood flows into a part more rapidly and copiously than is natural, it is said, in the language of surgery, that there is a *determination* of blood to it.

DIÆRESIS. (from *διαίρεσις*, to divide.) A division of substance; a solution of continuity. This was formerly a sort of generic term, applied to every part of surgery, by which the continuity of parts was divided.

DIGESTION. (from *digero*, to dissolve.) By the *digestion* of a wound, or ulcer, the old surgeons meant bringing it into a state, in which it formed healthy pus.

DIGESTIVES. Applications which promote this object.

DIORTHROSIS. (from *διορθωσις*, to direct.) One of the ancient divisions of surgery: it signifies the restoration of parts to their proper situations.

DIPLOPIA. (from *διπλῆς*, double, and *ὤψ*, the eye, or *ὀφθαλμοί*, to see.) *Visus duplicatus.* This is one of the most unusual diseases of the eyes, and it is of two kinds. For instance, the patient either sees an object double, treble, &c. only when he is looking at it with both his eyes, and no sooner is one eye shut, than the object is seen single and right; or else, he sees every object double, whether he surveys it with one, or both his eyes. The disorder is observed to affect persons in different degrees. Patients seldom see the two appearances, which objects present with equal distinctness; but generally, discern one much more plainly and perfectly, than the other. The first distinct shape, which

strikes the eye, is commonly that of the real object, while the second is indistinct, false, and visionary. Therefore, patients labouring under this affection, seldom make a mistake, but almost always know which is the true and real object. However, there are cases in which the patient sees with equal clearness, the two appearances which things assume, so that he is incapable of distinguishing the real object from what is false and only imaginary.

The disorder is sometimes transitory and of short duration, and may be brought on in a healthy eye by some accidental cause, generally an irritation affecting the organ. Sometimes, the complaint is continual; sometimes periodical. In particular instances, the patient only sees objects double, when he has been straining his sight for a considerable time, as for example, when he has been reading a small print for a long while by candlelight. In this case, the disorder becomes lessened by shutting the eyes for a few moments. There are also instances, in which the objects only have a double appearance at a particular distance, and not, either when they are nearer or further off. Sometimes the patient sees objects, double only upon one side, as, for example, when he turns his eyes to the right hand, while nothing of this sort is experienced in looking in any other direction. In certain cases, objects appear double, in whatever way the eyes are turned and directed.

The causes of double vision may be divided into four classes. Namely, the object which the patient looks at, may be represented double upon the retina, which is the effect of the first class of causes. Or, the object may be depicted in one eye differently from what it is in the other, in regard to size, position, distance, clearness, &c.; this is the effect of the second class of causes. Or, the object may appear to one eye to be in a different place from that which it seems to the other to occupy: the effect of the third class of causes. Or, lastly, the sensibility of the optic nerves is defective, so that the image of an object, though it may appear single to one eye as well as the other, yet in one identical situation will seem double to both of them. When the complaint originates from causes of the first and fourth class, the patient sees things double, whether he is using only one, or both eyes; but, when it proceeds from the second and third class of causes, the patient sees objects double only when he is looking at them with both eyes, and, no sooner does he shut one, than objects put on their natural, single appearance.

The following are the chief causes of the first class of a single object being depicted upon the retina as if double. 1. An unevenness of the cornea, which is divided into two, or more convex surfaces. There are cases, which show, that such an uneven shape may actually be the cause of double vision. (*Haller Element. Physiol. Tom. 5, p. 85.*) According to Beer, this conformation of the cornea is mostly a result of several preceding ulcers of that membrane, in which cir-

cumstance the patient sees with the affected eye not merely double, but treble, and quadruple, of which facts Beer has met with some examples. (*Lehre von den Augenkr. B. 2, p. 31.*) However, it must not be dissembled, that in a far greater number of instances, such unevenness of the cornea, though equally considerable, does not occasion this defect of sight. We have principally an opportunity of observing cases of this sort after the operation of extracting the cataract. Hence, it would seem, that the inequalities must be of very particular shape to produce double vision. The diagnosis of this cause is easy enough; but, the removal of it is impracticable: for, how is it possible to restore the original shape of the cornea? On this case, however, Beer delivers a more favourable prognosis than Richter, for he states, that when the patient is not decrepit, the double vision, from altered shape of the cornea, will gradually disappear of itself when proper care is taken of the constitution, and in particular of the eye. (*B. 2, p. 32.*) 2. An inequality of the anterior surface of the crystalline lens, whereby the same is divided into several distinct surfaces, it is suggested, may also be the occasion of diplopia. Such an inequality may possibly produce the disorder; but, it is exceedingly doubtful whether any case of this sort has ever been met with, and, as Richter properly remarks, the investigation is not worth undertaking, as the diagnosis and cure would be equally impracticable. The only possible method of cure would be the extraction, or depression, of the crystalline lens; yet, with the uncertainty respecting the nature of the cause, what man would be justified in performing an operation, in which the patient is not wholly exempt from the danger of losing his sight altogether? A double aperture in the iris, or as the case is termed, a double pupil, and a deviation of the pupil from its natural position, have been enumerated as causes of diplopia. (*Baumer in Act. Soc. Hassiac. 1, No. 27.*) However, Richter deems the reality of the first of these causes doubtful; for, cases have been noticed, where double vision was not the effect of there being two openings in the iris. (*Janin Mém. sur l'Oeil.*) But, were the disorder actually to originate in this way, it would not admit of a cure.

The causes of the second class, by the effect of which the object is represented, in regard to its size, position, distance, &c. differently in one eye from what it is in the other, are for the most part rather possible, than such as have been actually observed. The causes, which make objects assume an appearance contrary to the real one, may sometimes be confined to one eye, to which, things are depicted diversely from what they are to the other healthy eye, so that the patient sees, as it were double. Thus, for example, there may be a stronger refraction of the rays of light in one eye than the other; the patient may be a *myops* with one eye, and a *presbyops* with the other; and then the object will seem to one eye large,

to the other small, to one eye distant, to the other plainly near. This state of the sight, indeed, is said to have occurred after operating upon a cataract in one eye. (*Heuermann.*) However, that this is not a common consequence of operating upon a cataract in one eye, while the other is perfect, is sufficiently clear, from what has been said upon the subject, in a foregoing part of this work. (See *Cataract.*) In particular examples, objects which are perpendicular seem to the patient to have a sloping posture. When it is considered, that only one eye is thus affected, and that to it things will appear sloping, and to the other straight, double vision must be the effect. A few remarks connected with this subject will be introduced hereafter. (See *Sight, Defects of.*)

When both eyes are so directed to an object, that it becomes situated in the axis of vision of each of these organs, such object is represented in both at the same place, that is, it is depicted upon that part of the retina, on which the axis of sight falls. Thus the object seems to both eyes to be in the same place, and, though the two organs discern the thing, it only communicates a single appearance. But, when one eye is turned to any object in a different direction from that of the other; that is to say, when one eye is turned to an object in such a way, that the object is situated in the axis of vision of this eye, while the opposite eye is so turned, that the same object is placed on one side of its axis of vision; in other words, when a person squints; the object is depicted in one eye upon a different part of the retina from what it is in the other; consequently, the object appears to the two respective organs to be differently situated, and the patient is affected with diplopia. This is the third species of this disorder, which arises from strabismus as a third kind of occasional cause. Such patients naturally see objects double only when they behold them with both eyes.

A person, who squints, usually has one eye stronger than the other, and the weakness of one of these organs is the common cause of the strabismus. Such a person does not see objects double, because he only sees with one eye well, and with the other so faintly and imperfectly, that scarcely any impression is made. Hence, every case of strabismus is not necessarily combined with diplopia; indeed, the common kind of squinting is not joined with it. A person, affected with strabismus, only sees double, when the sight of each eye is equally strong, and when the squinting does not depend upon any weakness of one of the eyes, but upon some other occasional causes. The principal causes of the latter sort are of a spasmodic nature, viz.: an irritation affects some muscle of the eye in such a manner, that the patient is incapacitated from moving both his eyes according to his will, and from directing them to any object, so that such object may be at once in the axis of vision of both. On this case, the observations of Sir E. Home are interesting, who has made many

accurate reflections on the effect of an irregular action of the straight muscles of the eye in producing double vision. (*Phil. Trans.* 1797.)

Richter states, that, in the majority of cases, the irritation alluded to is seated in the gastric organs, though he thinks, that, any other species of irritation may operate upon the eyes in a similar manner. This kind of diplopia is frequently attendant on other spasmodic diseases as a symptom. It often accompanies hypochondriasis. Sometimes, it is the consequence of violent pain. Richter informs us of a man, who saw double and squinted, during a severe headach. He states, that another was affected in the same way during a toothach. Sometimes, the diplopia is owing to a paralysis of one of the muscles of the eye; (*Morgagni de Sedibus et Causis Morborum, Epist. 13, art. 20*; a paralysis of the abductor muscle) sometimes, to a tumour in the orbit. The diagnosis of this kind of diplopia is free from difficulty; the patient having been affected with squinting ever since things appeared double to him.

The views which Sir E. Home took of diplopia from irregular action, spasm, or weakness, of any particular muscle of the eye, led him to propose a plan of treatment, the principle of which is to keep the muscle affected for a time, perfectly at rest, which is easily done, by covering the eye with a bandage, and not allowing the organ to be at all employed.

The fourth class of causes are such irritations as act upon the optic nerves, changing their sensibility in such a way, that objects do not make that sort of impression upon them, which they ought to do. Thus, things sometimes have the appearance of being coloured, when they are really not so; immoveable objects seem in motion, straight objects appear oblique, and in the cases, which we are now treating of, single things seem to the eye double, treble, &c. This faulty kind of sensibility may also be produced by irritation in eyes, which are perfectly sound; but it is most readily occasioned in eyes, which are preternaturally weak and irritable. In these very trivial and inconsiderable irritations will often excite it. In the treatment, the common indication is to discover and remove whatever irritation conduces to this effect; but, the attempt frequently fails. In irritable eyes, the disorder is often brought on by very slight irritations, which cannot always be diminished, or removed. Here, the grand indication is to cure the weakness and irritability of the organs.

According to Richter, the fourth class of causes of diplopia is the most frequent. The irritations are of various kinds, and generally seated in the abdominal viscera. Diplopia is sometimes the consequence of inebriety, foulness of the stomach, intermitting fevers, hypochondriasis, worms, &c. However, the complaint is occasionally excited by other sorts of irritation. It has frequently followed a violent fright. It may be con-

connected with spasmodic and painful diseases of several kinds. Severe headaches and toothachs are sometimes joined with this affection of the sight. Richter mentions a boy, who, being in the woods, was struck by the bough of a tree over the eye, and, in consequence of the accident became affected with diplopia. He informs us of a man, who rode a journey on horseback, along a snowy road on a very sun-shiny day, and was affected in the same manner. This affection of the eyes is sometimes the effect of injuries of the head. (See *Hill's Cases in Surgery*, p. 108. *Schmucker, Med Chir. Bemerk.*, I. B. No. 26. *Hennen's Principles of Military Surgery*, p. 345, Ed. 2.) Persons who have weak eyes, are apt to become double-sighted, whenever they look attentively for a long while at any light shining objects. Patients in fevers are also sometimes double-sighted. (*Gooch's Cases, &c. Vol. 2.*)

The irritation, productive of diplopia, may lead to other serious complaints of the eye, when it operates with great violence. Indeed, it frequently happens, that diplopia terminates in some other disorder of the eyes, and is often the forerunner of the worst diseases of these organs, particularly the gutta serena. The difficulty, or ease of the cure, partly depends upon the nature of the remote cause, and partly upon the condition of the eye. Some of the causes are easy, others difficult of removal. When the eye is very weak and irritable, the disorder frequently continues, notwithstanding the irritation has been removed. Also, when the complaint is relieved, it is exceedingly difficult to prevent a relapse, for on very irritable eyes, slight irritations, which cannot be hindered, are apt to produce a return of the affection. Therefore, the indication is to remove the existing defect of sight, and take means for the prevention of its return, or the commencement of any other. The weakness and preternatural irritability of the eye should be removed, as well as every sort of irritation, things which are often difficult of accomplishment.

The chief business of the surgeon in the treatment of this kind of diplopia, consists in endeavouring to find out and remove the irritation occasioning the disorder. The majority of such irritations are of the same nature as those, which give rise to the gutta serena. (See *Amaurosis*.) Indeed, both the complaints are often only different effects of the same cause, and of course require a similar mode of treatment. The boy whom Richter has mentioned, as having become double-sighted in consequence of being struck over the eye with the bough of a tree, was cured by the external use of the infusum radices valerianæ and spiritus vini crocatus, with which the eyelids and adjacent parts were rubbed several times a day. A diplopia, which followed a violent fright, was cured by valerian, preceded by a few doses of cream of tartar. The case reported by Dr. Hennen, as proceeding from a gunshot wound of the soft parts, covering the root of the nose and right eyebrow,

yielded to abstinence, occasional emetics, and cold collyria. (*Principles of Mil. Surgery*, Ed. 2, p. 345.) A hypochondriacal patient got rid of the disorder by means of the warm bath. A diplopia, supposed to arise from disorder of the biliary secretion, was cured by means of pills made of gum-galbanum, gumiacum, rhubarb, and Venice soap, assisted with emetics and purgatives.

When the irritation, exciting the disorder, is only of temporary duration, as for instance, looking at shining objects; when the disorder continues after the removal of the irritation; or, lastly, when the irritation cannot be well detected; the surgeon is to endeavour, by means of nervous and soothing medicines either to remove the impression which the irritation has left upon the nerves; or to render the nerves insensible to the continuing irritation. According to Richter the following remedies have proved useful in cases of diplopia: hartshorn, dropped into the hand, and held before the eyes; the external use of the spiritus vini crocatus; warm bathing of the eye, particularly in a decoction of white poppy heads; bathing the eye in cold collyria; the internal administration of bark, valerian, small doses of ipecacuanha, flowers of zinc, and oleum cajeput. In one instance, in which it was impossible to detect the cause, Richter states, that soluble tartar with ox's gall and castoreum was found of service; that, in another similar case, rhubarb, ox's gall, and assafœtida; and, in a third, liquor ammoniæ acetatæ with ox's gall, proved useful. This author further observes, that, in all cases, in which the particular cause of the disorder cannot be precisely determined, we may conjecture that such cause has its seat in the abdominal viscera; and that much benefit may often be derived from mild resolvents, evacuants, and anodyne medicines. (*Richter's Anfangsgr. der Wundarzn.* B. 3. Kap. 15.)

According to Beer, the diplopia, which is not an effect of the continuance of another disease after inflammation of the eye, but probably depends upon injury of the retina, caused by such inflammation, usually diminishes, without the assistance of art, if the eye be not abused. (*Lehre von den Augenkr.* B. 2, p. 32.) For the foregoing account of diplopia I am chiefly indebted to Richter. See also A. Vater et J. C. DIRECTOR. (from *dirigo*, to direct.)—One of the most common instruments of surgery; it is long, narrow, grooved, and made of silver, in order that it may be bent into any desirable shape. Its use is to direct the knife, and protect the parts underneath from the edge or point of the latter instrument. The surgeon introduces the director under the parts, which he means to divide, and then either cuts down, along the groove of the instrument with a common bistoury, or cuts upward with a narrow, curved, pointed bistoury, the point of which is turned upwards, which he carefully introduces along the groove. This instrument and the crooked bistoury are commonly employed for opening sinuses, for cutting fistula in ano, and fistulæ in other situations, and for dilating the stricture in cases of hernia.

DISLOCATION. (from *disloce*, to put out of place.) *A Luxation.* When the articular surfaces of the bones are forced out of their proper situation, the accident is termed a *dislocation* or *luxation*.

Mr. Astley Cooper has justly remarked, that, of the various accidents which happen to the body, there are few which require more prompt assistance, or in which the reputation of the surgeon is more at stake, than cases of luxation; for, if much time be lost prior to the attempt at reduction, there is great additional difficulty in accomplishing it, and it is often entirely incapable of being effected. If it remains unknown, and consequently unreduced, the patient becomes a living memorial of the surgeon's ignorance or inattention. Hence, this experienced surgeon forcibly inculcates the careful study of anatomy; the want of an accurate knowledge of the structure of the joints being the chief cause of the many errors, which happen in the diagnosis and treatment of dislocated bones. The following passage cannot be too deeply impressed upon the surgeon's mind: "A considerable share of anatomical knowledge is required to detect the nature of these accidents, as well as to suggest the best means of reduction; and, it is much to be lamented, that our students neglect to inform themselves sufficiently of the structure of the joints. They often dissect the muscles of a limb with great neatness and minuteness, and then throw it away, without any examination of the ligaments, the knowledge of which, in a surgical point of view, is of infinitely greater importance; and from hence arise the numerous errors of which they are guilty, when they embark in the practice of their profession; for, the injuries of the hip, elbow, and shoulder, are scarcely to be detected, but by those who possess accurate anatomical information. Even our hospital surgeons, who have neglected anatomy, mistake these accidents; for, I have known the pulleys applied to an hospital patient, in case of a fracture of the neck of the thigh-

bone, which had been mistaken for a dislocation, and the patient cruelly exposed, through the surgeon's ignorance, to a violent and protracted extension. It is therefore proper, that the form of the ends of the bones, their mode of articulation, the ligaments by which they are connected, and the direction in which the larger muscles act, should be well understood." (*Surgical Essays, Part 1, p. 2*)

The most important differences of luxations are,—1. With respect to the articulation, in which these accidents take place;—2. The extent of the dislocation;—3. The direction in which the bone is displaced;—4. The length of time the displacement has continued;—5. The circumstances which accompany it, and which make the injury simple or compound;—6. And lastly, with respect to the causes of the accident.

1. Every kind of joint is not equally liable to dislocations. Experience proves, indeed, that, in the greater part of the vertebral column, luxations are absolutely impossible, the pieces of bone being articulated by extensive, numerous surfaces, varying in their form and direction, and so tied together by many powerful, elastic means, that very little motion is allowed. Experience proves, also, that the strength of the articulations of the pelvic bones can scarcely be affected by enormous efforts, unless these bones be simultaneously fractured. Boyer has therefore set down luxations of joints with continuous surfaces as impossible. (*Traité des Maladies, Chirurg. T. 4, p. 17.*) And, Mr. A. Cooper observes, that, in the spine, the motion between any two bones is so small, that dislocations hardly ever occur, except between the first and second vertebræ, although the bones are often displaced by fracture. (*Surgical Essays, p. 14.*)

In the articulations with contiguous surfaces, the facility with which dislocations happen, depends upon the extent and variety of motion in such joints. Thus, in the short bones of the carpus, and particularly of the tarsus, and at the carpal and tarsal extremities of the metacarpal and metatarsal bones, where flat broad surfaces are held together by ligaments, strong, numerous, and partly interarticular, and where only an obscure degree of motion can take place; dislocations are very unfrequent, and can only be produced by uncommon violence.

The loose joints, which admit of motion in every direction, are those in which dislocations most frequently occur; such is that of the humerus with the scapula. On the contrary, the ginglymoid joints, which allow motion only in two directions, are, comparatively speaking, seldom dislocated.—The articular surfaces of the latter are of great extent, and, consequently, the heads of the bones must be pushed a great way in order to be completely dislocated; and the ligaments are numerous and strong.

2. With respect to the extent of the dislocation, luxations are either *complete* or *incomplete*. The latter term is applied when

the articular surfaces still remain partially in contact. Incomplete dislocations only occur in ginglymoid articulations, as those of the foot, knee, and elbow. In these, the luxation is almost always incomplete; and very great violence must have operated, when they are completely dislocated. In the elbow, the dislocation is partial, with respect both to the ulna and radius. In the orbicular articulations, the luxations are almost invariably complete. However, "the os humeri sometimes rests upon the edge of the glenoid cavity, and readily returns into its socket."—(A. Cooper, *Essays Part 1*, p. 14.) The lower jaw is sometimes partially dislocated in a manner different from what is commonly meant by this expression, viz. one of its condyles is luxated, while the other remains in its natural situation.

As Mr. A. Cooper has explained, a partial dislocation sometimes occurs at the ankle joint. "An ankle (says he) was dissected at Guy's, and given to the collection of St. Thomas's, which was partially dislocated: the end of the tibia rested still in part upon the astragalus, but a large portion of its surface was seated on the os naviculare, and the tibia, altered by this change of place, had formed two new articular surfaces, with their faces turned in opposite directions towards the two bones. The dislocation had not been reduced."

3. In the orbicular joints, the head of the bone may be dislocated at any point of their circumference; and the luxations are named accordingly *upward, downward, forward, and backward*. In the ginglymoid articulations, the bones may either be dislocated laterally, or forward or backward.

4. The length of time a dislocation has existed, makes a material difference. In general, recent dislocations may be easily reduced; but, when the heads of the bones have been out of their places, for several days, the reduction becomes exceedingly difficult, and in other cases, very often impossible. The soft parts, and the bone itself, have acquired a certain position; the muscles have adapted themselves in length to the altered situation of the bone, to which they are attached, and sometimes, cannot be lengthened sufficiently to allow the bone to be reduced. Desault and Boyer believe, that frequently the opening in the capsular ligament soon becomes closed, and binds the return of the head of the bone into its original situation; a statement, which does not coincide with the sentiments of Mr. A. Cooper. (*Surgical Essays, Part 1*, p. 18.) Lastly, the luxated bone may become adherent to the parts on which it has been forced.

5. The difference is immense, in regard to the danger of the case, arising from the circumstance of a dislocation being attended, or unattended, with a wound, communicating internally with the joint, and externally with the air. When there is no wound of this kind, the danger is generally trivial, and the dislocation is termed a *simple one*: when there is such a wound, together with the

dislocation, the case is denominated *compound*, and is frequently accompanied with the most imminent peril. Indeed, the latter kind of accident often renders amputation proper.

6. The causes of dislocations are external and internal. A predisposition to such accidents may depend on circumstances natural, or accidental. The great latitude of motion, which the joint admits of; the little extent of the articular surfaces; the looseness and fewness of the ligaments; the lowness of one side of the articular cavity, as, at the interior and inferior part of the acetabulum; and the shallowness of the cavity, as of that of the capsula; are natural predisposing causes of luxations.

A paralytic affection of the muscles of a joint, and a looseness of its ligaments, are also predisposing causes. When the deltoid muscle is paralytic, the mere weight of the arm has been known to cause such a lengthening of the capsular ligament of the shoulder joint, that the head of the os brachii descended two or three inches from the glenoid cavity.

Two cases, strikingly illustrative of the tendency to dislocation from a weakened, or paralytic state of the muscles, are recorded by Mr. A. Cooper. The first is that of a junior officer of an India ship, who, for some trifling offence, had been placed with his foot upon a small projection on the deck, while his arm was kept forcibly drawn up to the yard-arm for an hour. "When he returned to England, he had the power of readily throwing that arm from its socket, merely by raising it towards his head; but, a very slight extension reduced it. The muscles were wasted, also, as in a case of paralysis." The other example happened in a young gentleman, troubled with a paralytic affection of his right side from dentition. "The muscles of the shoulder were wasted, and he had the power of throwing his os humeri over the posterior edge of the glenoid cavity of the scapula, from whence it became easily reduced." In these cases, Mr. A. Cooper observes, that no laceration of the ligaments could have occurred, and they show the influence of the muscles in preventing dislocation, and in impeding reduction. (*Surgical Essays, Part 1*, p. 10.)

The looseness of the ligaments sometimes makes the occurrence of dislocations so easy, that the slightest causes produce them. Some persons cannot yawn or laugh, without running the risk of having their lower jaw luxated. On this account, collections of fluid within the knee, causing a relaxation of the ligament of the patella, are often followed by a dislocation of that bone. And, whenever a bone has been once dislocated, it ever afterwards has a tendency to be displaced again by a slighter cause, than what was first necessary to produce the accident. This tendency, indeed, increases with every new displacement.

Such diseases, as destroy the cartilages, ligaments, and articular cavities of the

bones, may give rise to a dislocation. The knee is sometimes, but not frequently, partially luxated in consequence of a white swelling; the thigh is often dislocated in consequence of the acetabulum and ligaments being destroyed by what is commonly named the disease of the hip-joint. Such dislocations are termed *spontaneous*.

In the anatomical collection at St. Thomas's Hospital, there is a preparation of a knee, dislocated in consequence of ulceration, and ankylosed, the leg forming a right angle with the femur directly forwards. (See *A. Cooper's Surg. Essays, Part 1, p. 11.*)

An enarthrosis joint can only be dislocated by external violence, a blow, a fall, or the action of the muscles, when the axis of the bone is in a direction, more or less oblique, with respect to the surface with which it is articulated.

Any external force may occasion a dislocation (generally incomplete) in the ginglymoid joints; but, in the ball and socket articulations, the action of the muscles constantly has a share in producing the accident. So, when a person falls on his elbow, while his arm is raised outwards from his side, the force, thus applied, will undoubtedly contribute very much to push the head of the os brachii out of the glenoid cavity, at the lower and internal part. Still, the sudden action of the pectoralis major, latissimus dorsi, and teres major, which always takes place from the alarm, will also aid in pulling downward and inward the head of the bone. Under certain circumstances, the violent action of the muscles alone may produce a dislocation, without the conjoint operation of any outward force. But, when the patient is aware in time of the violence, which is about to operate, and his muscles are prepared for resistance, a dislocation cannot be produced without the greatest difficulty, (*A. Cooper, op. cit. p. 15.*) unless the posture of the member at the moment be such as to render the action of the strongest muscles conducive to the displacement, instead of preventive of it, as is frequently the case in luxations of the shoulder.

Dislocations are constantly attended with more or less laceration or elongation of the ligaments: and, in the shoulder and hip, the capsules are always torn, when the accident has been produced by violence. Some instances, in which the ligaments are only lengthened and relaxed, I have already quoted.

SYMPTOMS OF DISLOCATIONS.

As Boyer justly observes, there is not any dislocation, which does not produce pain and incapacity in the limb; but, these symptoms are only equivocal, and cannot distinguish the case from a fracture; nor even from a simple contusion. He divides the symptoms of dislocations into those which may be collected from the circumstances attending the occurrence of the accident; and into others, which he calls present, or positive.

In order that a dislocation may happen, there must be a particular attitude of the limb during the action of the external violence. Indeed the displacement can hardly occur from the direct action of the cause on the articulation itself. The action of the luxating cause is the more efficient, the further it is from the joint, and the longer the lever is, which it affects. Thus, in a fall on the side, when the arm, raised considerably from the trunk, has had to sustain all the weight of the body on a point at its inner side, the probability of a dislocation is evident, and even that the head of the bone has been forced through the lower portion of the capsular ligament.

But, the symptoms, which Boyer terms positive, or actually present, are numerous and clear:

1. In dislocations of orbicular joints, and complete luxations of ginglymoid joints, the articular surfaces are not at all in contact, and the point, where the dislocated bone is lodged, cannot be upon the same level with the centre of the cavity, from which it has been forced. Hence, a change in the length of the limb. In the ginglymoid joints, such alteration can only be a shortening proportioned to the extent of the displacement; for there is then an overlapping of the bones, similar to that of the fragments of a fracture, longitudinally displaced. But in the orbicular joints, the bone may be displaced and carried above, or below, the articular cavity, so that, in the first event, a shortening, in the second, an elongation of the limb, will be produced. But, as the direction of the member is at the same time altered, it is not always practicable to place the limbs parallel together, nor to bring them near the trunk, for the purpose of judging whether they are lengthened or shortened. A comparison, however, made without this advantage, will generally enable the surgeon to form a correct opinion. The proper length of a dislocated limb cannot be restored, except by putting the bone back into the cavity, from which it has slipped. In general, this cannot be accomplished without considerable efforts, while a slight exertion is usually sufficient to obtain the same effect in cases, where the shortening of the limb depends upon a fracture. It is also particularly worthy of notice, that, when once the natural length of the limb has been restored in dislocations, it remains, while there are a great many fractures, in which the shortening of the member recurs after it has been made to disappear. The surgeon must also recollect, that an elongation of the limb can never happen in cases of fracture, as it does in certain dislocations.

2. In almost all complete luxations, the direction of the axis of the limb is unavoidably altered. This circumstance arises from the resistance of that portion of the articular ligaments, which has not been ruptured, as well as from the action of the muscles. In complete lateral dislocations of ginglymoid joints, the direction of the axis of the

limb is not altered, on account of the total rupture of the ligaments, and even of a part of the surrounding muscles. Neither is this observable in incomplete dislocations of such articulations, on account of the extent of the articular surfaces. But, it is strongly marked in complete luxations of these joints, where the displacement has happened in the direction of the articular movements, although in cases of this description the ligaments must be totally ruptured. The muscles, which have suffered less, are in a state of extreme tension, and must necessarily alter the axis of the limb. The tension of certain muscles, and the preservation of some of the ligaments, especially in the orbicular joints, are also a cause of a rotatory movement of the dislocated limb at the moment of the displacement, and which it afterwards retains. Thus, in luxations of the thigh, the toes and knee are turned outward, or inward, according as the head of the thigh bone happens to be situated at the inside, or outside of the joint. These two kinds of alteration in the direction of the limb are permanent when they depend upon a dislocation; a circumstance quite different from what is observable in fractures, where the same changes occur, but can be made to cease at once without any particular effort.

3. The absolute immobility of a limb, or, at least, the inability of performing certain motions, is among the most characteristic symptoms of a dislocation. In some complete luxations of particular ginglymoid joints, the dislocated limb is absolutely, or very nearly incapable of any motion. Thus, in the dislocation of the fore-arm backwards, the particular disposition of the bones, and the extreme tension of the extensor and flexor muscles, confine the limb in the half-bent state, and at the same time resist every spontaneous motion, and likewise almost every motion which is communicated. In the orbicular joints, the painful tension of the muscles, which surround the luxated bone, nearly impedes all spontaneous movements, but, in general, analogous motions to that, by which the displacement was produced, can be communicated to the limb, though not without exciting pain. Thus, in the dislocation of the humerus downward, the elbow hardly admits of being put near the side, nor of being carried forward, and backward; but it can be raised up with ease. In the dislocation of the acromial end of the clavicle, the patient can bring the arm towards the trunk, separate it a little from the side, or carry it forward or backward; for he cannot raise it in a direct way. Lastly, in complete lateral dislocations of such joints, as have alternate motions, the patient has the power of performing no motion of the part; but, the complete destruction of all the means of union allows the limb to obey every species of extraneous impulse, and this symptom, which is besides never single, makes the nature of the case sufficiently manifest.

Sometimes, as Mr. A. Cooper has re-

marked, a considerable degree of motion continues for a short time after a dislocation: thus, in a man brought into Guy's Hospital, whose thigh bone had just been dislocated into the foramen ovale, a great mobility of the femur still remained; but, "in less than three hours it became firmly fixed in its new situation by the contraction of the muscles." (*Surgical Essays, Part 1, p. 3.*)

4. In dislocations with elongation of the displaced limb, the general and uniform tension of all the muscles arranged along it, gives to these organs an appearance as if they lay nearer the circumference of the bone, and the limb were smaller than its fellow. The muscles, however, which belong to the side, from which the dislocated bone has become more distant, appear more tense than the others, and form externally a prominent line. This is very manifestly the case with the deltoid muscle, when the arm is luxated downward. On the contrary, in dislocations where the limb is shortened, the muscles are relaxed; but, being irritated, they contract and accommodate themselves to the shortened state of the limb.—Hence, the extraordinary swelling of their fleshy part, and the manifest tumefaction of the portion of the member, to which they belong. We have a striking example of this in the dislocation of the thigh upward and outward, where the muscles at the inside of the limb form a distinct oblong tumour.

The parts, which surround the affected joint, also experience alterations in their form, whenever muscles, connected with the dislocated bone, occupy that situation. Thus, in dislocations of the thigh, the buttock on the same side is flattened, if the bone is carried inward; but, it is more prominent, when the thigh bone is carried outward; and its lower edge is situated higher, or lower, than in the natural state, according as the luxation may have taken place upward or downward. In the complete luxation of the fore-arm backward, the triceps is tense, and forms a cylindrical prominence, owing to the displacement of the olecranon backward, in which displacement it is obliged to participate.

5. The circumference of the joint itself presents alterations of shape well deserving attention, and, in order to judge rightly of this symptom, correct anatomical knowledge is of high importance.

The form of the joints principally depends upon the shape of the heads of the bones. Hence, the natural relation of the bones to each other cannot be altered without a change being immediately produced in the external form of the joint. The changes, which the muscles, passing over the luxated joint, at the same time undergo in their situation and direction, contribute likewise to the difference of shape, by destroying the harmony of what may be called the outlines of the limb.

When the head of a bone, articulated by enarthrosis, has slipped out of the cavity, instead of the plumpness, which previously

indicated the natural relation of parts, the head of the dislocated bone may be distinguished at some surrounding point of the articulation, while at the articulation itself may be remarked a flatness, caused by one of the neighbouring muscles stretched over the articular cavity, and more deeply may be perceived the outline and depression produced by this cavity itself. The bony eminences, situated near the joint, and whose outlines were gradually effaced in the general form of the member, are rendered much more apparent by the displacement, and project, in a stronger degree, than in the natural state. On this part of the subject, Mr. A. Cooper is particularly correct, when he observes, that the head of the bone can generally be felt in its new situation, excepting in some of the dislocations of the hip, and its rotation is often the best criterion of the accident. *The natural prominences of bone near the joint, either disappear, or become less conspicuous, as the trochanter at the hip-joint. Sometimes the reverse occurs; for in dislocations of the shoulder, the acromion projects more than usual.* (*Surg. Essays, Part 1, p. 4.*)

The lines, made by the contour of the limb and the natural relation of the bones, are so manifestly broken in dislocations of ginglymoid joints, that, when there is no inflammatory swelling, the case is intelligible in an instant. More certain knowledge, however, and more correct information, respecting the kind of displacement, are to be obtained by attentively examining the changes of position, which the bony prominences, forming the termination of the bones articulated together, have undergone, and which are the more obvious in these joints, inasmuch as they give attachment to the principal muscles. The natural relations of these processes being known, the least error of situation ought to strike the well-informed attentive practitioner. Thus, in the elbow joint, a considerable difference in the respective height, and in the distances between the olecranon and internal and external condyles, can be easily distinguished. But, the thing is less easy when the surrounding parts are so swelled and tense, as to make the bony projections deeper from the surface, and less obvious to examination. Even then, however, a good surgeon will at least find something to make him suspect the dislocation, and the suspicion will be confirmed when he again examines the part on the swelling beginning to subside. It is of the utmost consequence to make out what the case is as early as possible; for, the unnatural state, in which the soft parts are placed, keeps up the swelling a long while; and if the surgeon wait till this has entirely subsided, before he ascertains that the bones are luxated, he will have waited till it is too late to think of reducing them, and the patient must remain for ever afterward deprived of the free use of his limb. (*Boyer, Traité des Maladies Chir. T. 4, p. 45, &c.*) It is not only the inflammatory swelling, which may tend to conceal the

state of the ends of the bone; sometimes a quicker tumour arises from the effusion of blood in the cellular membrane, and causes an equal difficulty of feeling the exact position of the heads of the bones.

Dislocations are also, sometimes, attended with particular symptoms, arising altogether from the pressure caused by the head of the luxated bone on certain parts. The sternal end of the clavicle has been known to compress the trachea, and impede respiration: the head of the humerus may press upon the axillary plexus of nerves, and produce a paralytic affection of the whole arm. In one instance, cited by Mr. A. Cooper, a dislocated clavicle pressed upon the œsophagus, and endangered life. (*Surg. Essays, Part 1, p. 4.*)

As Kirkland has observed, there are some luxations, which are far worse injuries than fractures: of this description, are dislocations of the vertebræ, cases which, indeed, can hardly happen without fracture, and are almost always fatal; dislocations of the long bones, with protrusion of their ends through the muscles and skin, and severe inflammation, extensive abscesses, attended with great risk of being followed by large and tedious exfoliations, and not unfrequently gangrene.

According to Mr. A. Cooper, young subjects rarely experience dislocations; their bones break, or their epiphyses give way much more frequently than the articular surfaces are displaced. (*Surg. Essays, Part 1, p. 16.*) Suspected luxations of the hip in children commonly turn out to be disease of the joint, one instance of which is given by the preceding author, and an example of which I was lately consulted about myself. Also, when a dislocation of the elbow is suspected in a child, because the bone appears readily to return into its place, but directly to slip out of it again, Mr. A. Cooper says, that the case is an oblique fracture of the condyles of the humerus.

PROGNOSIS.

In general, every unreduced dislocation, must deprive the patient more or less completely of the use of the limb; for, nature cannot in any of these cases re-establish the natural relations which are lost. There is indeed an effort made to restore some of the motions, and the use of the limb in a certain degree: but, it is always very imperfectly accomplished, and in the best cases, only a confined degree of motion is re-established. Nature cannot in any way alter the lengthened or shortened state of the limb; and she can only correct in a very imperfect manner its faulty direction.—There are even some cases, in which nature can effect no amendment whatsoever; as, for instance, complete dislocations of ginglymoid joints in the direction of the articular movements: here so great an alteration would be requisite in the surfaces in contact, and so extensive an elongation of the muscles, that the dislocated part must continue nearly motionless.

There are, however, a few exceptions to this general rule. The arthrodia joints are seldom extensively displaced; and as, in the natural state, their motions are very limited, the loss of these motions, in consequence of the natural relations not having been restored, is of less importance.—Thus, the bones of the carpus, those of the tarsus, and the acromial end of the clavicle, may be dislocated, and be reduced either imperfectly, or not at all, without the functions of the limb, to which they belong, being materially impaired. (*Boyer, Traité des Maladies Chir. T. 4, p. 54.*)

Dislocations of enarthrosis are generally much less dangerous, than those of ginglymoid joints; for, the action of the muscles has a great share in producing the former; the violence done to the external parts is less; and the laceration of the soft parts is not so considerable. Even in the same kind of joints, the seriousness of the case depends on the largeness of the articular surfaces, and the number and strength of the muscles and ligaments.

Dislocations of the ginglymoid joints, however, are more easily reduced than those of enarthrosis articulations, the muscles of which are frequently very powerful, and capable of making great resistance to the efforts of the surgeon. This is frequently seen in luxations of the shoulder and thigh.

It may be said, however, of the luxations of enarthrosis joints, that, if they happen the most easily, they are attended with less injury; and that, although their reduction may require considerable efforts, yet it can be accomplished, and the accident leaves no ill effects. On the contrary, in dislocations of ginglymoid joints, the same reason which renders them more unfrequent, makes them also more serious. The solidity of these joints prevents the uniting means from being destroyed, except by great violence; and the extent of the articular surfaces does not permit a considerable displacement, especially a complete one, without extensive injury of the ligaments, and surrounding soft parts. It is for these reasons, no doubt, that compound luxations and protrusions of the heads of the bones, are most commonly seen in the ginglymoid articulations.

Still it must be allowed, that the incomplete dislocations of these joints, unattended with much displacement, are not at all serious accidents.

The more recent a luxation is, the more easy it is to reduce, and therefore, *ceteris paribus*, the less grave is the injury. In this point of view, dislocations of ginglymoid joints are the most serious, because they soon become irreducible.

Simple dislocations are much less dangerous, than those which are complicated with contusion, the injury of a large nerve, or blood-vessel, inflammatory swelling, fracture, wound, and, especially, a protrusion of one of the articular surfaces. (*Boyer, Traité des Maladies Chir. T. 4, p. 55, 56.*)

Dislocations from ulceration and suppuration in joints, termed *spontaneous luxations*, cannot admit of reduction: when they arise from the hip-disease, it is not merely in consequence of the ligaments being destroyed, the brim of the acetabulum itself is often annihilated. However, there are other *spontaneous* dislocations from preternatural looseness of the ligaments, where reduction may be accomplished with the greatest facility; though in these instances, the displacement generally recurs from the slightest causes.

TREATMENT OF DISLOCATIONS IN GENERAL.

Mr. Pott observes:—By what our forefathers have said on the subject of luxations, and by the descriptions and figures which they have left us of the means they used, of what they call their organs and machinements, it is plain, that force was their object, and that whatever purposes were aimed at or executed by these instruments or machines, were aimed at and executed principally by violence. Many, or most of them, are much more calculated to pull a man's joints asunder, than to set them to rights.—Hardly any of them are so contrived as to execute the purpose for which they should be used, in a manner most adapted to the nature or mechanism of the parts on which they are to operate. The force or power of some of the instruments is not always determinable as to degree, by the operator, and consequently may do too little or too much, according to different circumstances in the case, or more or less caution or rashness in the surgeon. If in the diagnosis of these accidents, an exact knowledge of the ligaments is of the highest importance, a familiar acquaintance with the muscles is not less essential in the treatment.

In dislocations, as in fractures, says Pott, our great attention ought to be paid to the muscles belonging to the part affected. These are the moving powers, and by these the joints, as well as other moveable parts, are put into action; while the parts to be moved are in right order and disposition, their actions will be regular and just, and generally determinable by the will of the agent, (at least in what are called voluntary motions,) but when the said parts are disturbed from that order and disposition, the action or power of the muscles does not therefore cease; far from it, they still continue to exert themselves occasionally, but instead of producing regular motions, at the will of the agent, they pull and distort the parts they are attached to, and which by being displaced, cannot perform the functions for which they were designed.

“Hence principally arise the trouble and difficulty which attend the reduction of luxated joints. The mere bones composing the articulations, or the mere connecting ligaments, would in general afford very little opposition; and the replacing the dislocation would require very little trouble or force, was it not for the resistance of the muscles and tendons attached to and con-

nected with them: for by examining the fresh joints of the human body, we shall find, that they not only are all moved by muscles and tendons, but also, that although what are called the ligaments of the joints do really connect and hold them together, in such manner as could not well be executed without them, yet in many instances, they are, when stript of all connexion, so very weak and lax, and so dilatable and distractile, that they do little more than connect the bones and retain the synovia; and that the strength as well as the motion of the joints, depends in great measure on the muscles and tendons connected with and passing over them; and this in those articulations which are designed for the greatest quantity, as well as for celerity of motion. Hence it must follow, that as the figure, mobility, action, and strength of the principal joints, depend so much more on the muscles, and tendons in connexion with them, than on their mere ligaments, that the former are the parts which require our first and greatest regard, these being the parts which will necessarily oppose us in our attempts for reduction, and whose resistance must be either eluded or overcome; terms of very different import, and which every practitioner ought to be well apprised of." (See *Pott's Chir. Works*, Vol. 1.)

That the muscles are the chief cause of resistance is strongly evinced by cases, in which the dislocation is accompanied with injury of any vital organ; for then the bone may be reduced by a very slight force. Thus, in a man, who had an injury of his jejunum, and a dislocation of his hip, the bone was most easily replaced. (*A. Cooper, Surgical Essays, Part 1, p. 20.*) In short, any thing which produces faintness or weakness, facilitates the reduction of dislocated bones, as intoxication, nausea and sickness, paralysis, &c.

The following, which are some of the principles laid down by Mr. Pott, merit attention.—

1. Although a joint may have been luxated by means of considerable violence, it does by no means follow, that the same degree of violence is necessary for its reduction.

2. When a joint has been luxated, at least one of the bones of which it is composed, is detained in that unnatural situation by the action of some of the muscular parts in connexion with it; which action, by the immobility of the joint, becomes as it were tonic, and is not under the direction of the will of the patient.

3. That all the force used in reducing a luxated bone, be it more or less, be it by hands, towels, ligatures, or machines, ought always to be applied to the other extremity of the said bone, and as much as possible to that only. Mr. Pott argues, that if the extending force were applied to a distant part of the limb, or to the bone below or adjoining, it would necessarily be lost in the articulation which is not luxated, owing to the yielding nature of the ligaments, and be of

little or no service, in that which is dislocated. This remark, though made by Pott, and generally received as true, is very incorrect; for, it tends to state, that if you pull at the ankle, or wrist, the force does not operate on the hip, or shoulder.

4. That in the reduction of such joints, as are composed of a round head, received into a socket, such as those of the shoulder and hip, the whole body should be kept as steady as possible.

5. That in order to make use of an extending force with all possible advantage, and to excite thereby the least pain and inconvenience, it is necessary that all parts serving to the motion of the dislocated joint, or in any degree connected with it, be put into such a state as to give the smallest possible degree of resistance.

6. That in the reduction of such joints as consist of a round head, moving in an acetabulum or socket, no attempt ought to be made for replacing the said head, until it has by extension been brought forth from the place where it is, and nearly to a level with the said socket. This will show us, says Mr. Pott, a fault in the common ambi, and why that kind of ambi, which Mr. Freke called his commander, is a much better instrument than any of them, or indeed than all; because it is a lever joined to an extensor; and that capable of being used with the arm, in such position as to require the least extension, and to admit the most; besides which it is graduated, and therefore perfectly under the dominion of the operator. It will show us, why the old method by the door or ladder, sometimes produced a fracture of the neck of the scapula; as Mr. Pott saw it do himself. Why if a sufficient degree of extension be not made, the towel over the surgeon's shoulder, and under the patient's axilla, must prove an impediment rather than an assistance, by thrusting the head of the humerus under the neck of the scapula, instead of directing it into its socket. Why the bar, or rolling-pin, under the axilla, produces the same effect. Why the common method of bending the arm (that is, the os humeri) downward, before sufficient extension has been made, prevents the very thing aimed at, by pushing the head of the bone under the scapula, which the continuation of the extension for a few seconds only would have carried into its proper place. To the observation, that mere extension only draws the head of the bone out from the axilla, in which it is lodged, but does not replace it in the acetabulum scapulæ, Mr. Pott replies, that, when the head of the os humeri is drawn forth from the axilla, and brought to a level with the cup of the scapula, it must be a very great and very unnecessary addition of extending force, that will or can keep it from going into it. All that the surgeon has to do, is to bring it to such level; the muscles attached to the bone will do the rest for him, and that whether he will or not.

7. Another of Pott's principles is, that whatever kind or degree of force may be

found necessary for the reduction of a luxated joint, that such force be employed gradually; that the lesser degree be always first tried, and that it be increased gradatim. (See *Pott's Chir. Works*, Vol 1.)

The supposition of the reduction being sometimes prevented by the capsular ligaments, Mr. A. Cooper considers as quite erroneous: he assures us, that in dislocations from violence, those ligaments are always extensively lacerated; and that the idea of the neck of the bone being girt, or confined, by them, is altogether untrue. (*Surg. Essays*, Part 1, p. 18.) But, in addition to the resistance of the muscles, there are in old dislocations three circumstances, pointed out by Mr. A. Cooper as causes of the difficulty of reduction. 1. The extremity of the bone contracts adhesion to the surrounding parts, so that in dissection, even when the muscles are removed, the bone cannot be reduced. 2. The socket is sometimes filled up with adhesive matter. 3. A new bony socket is sometimes formed, in which the head of the bone is so completely confined, that it could not be extricated without breaking its new lodgment. (*Surgical Essays*, Part 1, p. 21.)

Dislocations in general cannot be reduced without trouble; but, after the reduction is accomplished, it is easily maintained. On the contrary, fractures are for the most part easy of reduction; but cannot be kept in this desirable state without difficulty. The moment extension is remitted, the muscles act, the ends of the broken bone slip out of their proper situation with respect to each other, and the distortion of the limb recurs. As a modern writer has observed, the reduction is only a small part of the treatment of fractures: the most essential point of it is the almost daily care, which a fracture demands during the whole time requisite for its consolidation. The contrary is the case in luxations. Here, in fact, the reduction is every thing, if we put out of consideration the less frequent cases, in which the dislocation is complicated, and attended with such grave circumstances, as render it indispensably necessary to continue for a length of time the utmost surgical care. But, even then, the protracted treatment is less for the dislocation itself, than for the extraordinary circumstances, with which it is accompanied. (See *Roux, Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, p. 207.)

All the ancient writers recommend the extending force to be applied to the luxated bone; for instance, above the knee in dislocations of the thigh-bone, and above the elbow in those of the humerus. We have stated, that Pott, advised this plan, and the same practice, which is approved by J. L. Petit, Duverney, and Callisen, is almost generally adopted in this country.

However, many of the best modern surgeons in France, for instance, Fabre, D'Apouy, Desault, Boyer, Richerand, and Leveillé, advise the extending force not to be applied on the luxated bone, but on that

with which it is articulated, and as far as possible from it. It is said that this plan has two most important advantages: first, the muscles, which surround the dislocated bone, are not compressed, nor stimulated to spasmodic contractions, which would resist the reduction; secondly, the extending force is much more considerable, than in the other mode; for, by using a long lever, we obtain a greater degree of power.

In Pott's remarks, we find even him, influenced by the prevailing prejudice against the above practice, that part of the extending force is lost on the joint, intervening between the dislocation, and the part at which the extension is made. This notion is quite unfounded, as every man who reflects, for one moment, must soon perceive. When extension is made at the wrist, the ligaments, muscles, &c. which connect the bones of the fore-arm with the os brachii, have the whole of the extending force operating on them, and they must obviously transmit the same degree of extension, which they receive, to the bone above, to which they are attached. Indeed, this matter seems so plain, that I think it would be an insult to the reader's understanding to say any more about it, than that such eminent surgeons, as have contrary sentiments, can never have taken the trouble to reflect for themselves on this particular subject. Whether the force, necessary to be exerted in some instances, would have a bad effect on the intervening joint, may yet be a question; but, as Desault's practice was very extensive, and he did not find any objection of this kind, perhaps, we have no right to conclude, that such a one would exist.

If, however, the common objection to Desault's plan of applying the extending force be unfounded, the question still remains to be settled, whether this practice is most advantageous on the grounds above specified? This is a point, which, perhaps, cannot be at once peremptorily decided altogether in the negative, or the affirmative, since what may be best in one kind of dislocation, may not be so in another. Thus, Mr. A. Cooper states, that, as far as he has had an opportunity of observing, it is generally best to apply the extension to the bone, which is dislocated; but, that dislocations of the shoulder are exceptions, in which he mostly prefers to reduce the head of the bone by placing his heel in the axilla, and drawing the arm at the wrist in a line with the side of the body, whereby the pectoralis major and latissimus dorsi are kept in a relaxed state. (*Surgical Essays*, Part 1, p. 25.)

Extension may either be made by means of assistants, who are to take hold of napkins, or sheets, put round the part, at which it is judged proper to make the extension; or else a multiplied pulley may be used. In cases of difficulty, Mr. A. Cooper thinks the pulley should always be preferred. "When assistants are employed, their exertions are sudden, violent, and often ill-directed, and the force is more likely to produce laceration

tion of parts, than to restore the bone to its situation. Their efforts are also often uncombined, and their muscles are necessarily fatigued, as those of the patient, whose resistance they are employed to overcome." In dislocations of the hip joint, and in those of the shoulder which have been long unreduced, pulleys should always be employed. (*A. Cooper, Surgical Essays, Part 1, p. 24.*) But, whether pulleys be used, or not, nothing more need be added to what Mr. Pott has stated, concerning the propriety of using moderate force in the first instance, and increasing the extending power very gradually.

The extension should always be first made in the same direction, in which the dislocated bone is thrown; but, in proportion as the muscles yield, the bone is to be gradually brought back into its natural position. Thus the head of the bone becomes disengaged from the parts, among which it has been placed, and is brought back to the articular cavity again by being made to follow the same course, which it took in escaping from it.

Extension will prove quite unavailing, unless the bone, with which the dislocated head is naturally articulated, be kept motionless by counter-extension, or a force at least equal to the other, but made in a contrary direction.

The mode of fixing the scapula and pelvis, in luxations of the shoulder and thigh, will be hereafter described.

In dislocations of ginglymoid joints, extension and counter-extension are only made, for the purpose of diminishing the friction of the surfaces of the joints, so as to be enabled to put them in their natural situation.

When the attempts at reduction fail, the want of success is sometimes owing to the extension not being powerful enough, and the great muscular strength of the patient, which counteracts all efforts to replace the bone.

In the latter case, the patient may be freely bled, and put into a warm bath, so as to make him faint. The opening in the vein should be made large, because a certain evacuation of blood is more likely to produce weakness and swooning, than a gradual discharge of it; and the patient, for the same reason, may be bled as he stands up. In very difficult cases, the expedient of intoxication has been recommended, as when the patient is in this state, his muscles are incapable of making great resistance to reduction. Under these circumstances, opium is also frequently administered, with advantage. When the muscles make considerable opposition, Mr. A. Cooper, instead of bleeding and the warm bath, has sometimes given nauseating doses of tartarized antimony; a practice, which has been occasionally adopted by others. The medicine should be exhibited in repeated doses, until nausea is excited; but, it is not necessary to make the patient vomit; for, as soon as the nauseating effect is produced, "the mus-

cles lose their tone, and dislocations can be reduced with comparatively less effort, and at a more distant time from the accident, than can be effected in any other way." (*A. Cooper, Surgical Essays, Part 1, p. 22.*) In cases of unusual difficulty, this method, together with the warm bath and bleeding, seems rational and judicious: but, except in cases of that description, I should prefer long-continued, unremitting, not too violent, extension, which will at last overcome the muscles of the most athletic man. Sometimes, the resistance made to reduction by such muscles, as act in obedience to the will, may be eluded by the patient's attention being suddenly taken from the injured part, at which moment the action of those muscles is suspended, and a very little effort on the part of the surgeon will reduce the bone. A case, illustrating this circumstance, is recorded by Mr. A. Cooper. (*Part 1, p. 25.*)

Dislocations of orbicular joints can seldom be reduced, after a month, though Desault used to succeed, with great violence, at the end of three or four. Dislocations of ginglymoid articulations generally become irreducible in twenty, or twenty-four days, in consequence of ankylosis.

The reduction of a dislocation is known by the limb recovering its natural length, shape, and direction, and being able to perform certain motions, not possible while the bone was out of its place. The patient experiences a great and sudden diminution of pain; and, very often, the head of the bone makes a noise at the moment when it returns into the cavity of the joint.

In order to keep the bone from slipping out of its place again, we have only to hinder the limb from moving. When splints can act powerfully in steadying the joint, they are very often used, as in dislocations of the ankle, wrist, &c. As the humerus cannot be luxated, except when at some distance from the body, a return of its dislocation will be prevented by confining the arm close to the side in a sling. The spica bandage, applied after such an accident, is more satisfactory to the patient, than really efficacious. Whatever bandage is used to keep the arm from moving, should be put on the lower end of the bone, as far as possible from the centre of motion.

COMPOUND DISLOCATIONS.

Compound Dislocations are those, which are attended with a wound communicating with the cavities of the injured joints. In most instances, this opening in the skin is caused by the protrusion of the bone, but sometimes by the part having struck against some hard, or irregular body. These accidents are frequently attended with great danger; and the same nicety of judgment is requisite in determining, whether amputation ought to be immediately performed, or an effort made to preserve the limb, as in cases of compound fractures, and bad gunshot injuries; and many of the observations

which I shall have to offer upon the latter subjects, will for the most part, be applicable to the present.

The luxation of a large joint, being conjoined with an external wound, leading into the capsular ligament, is a circumstance, that has a particular tendency to increase the danger of the accident. In many cases, we see injuries of this description followed by violent and extensive inflammation, abscesses and mortification, fever, delirium, and death. When the patient is much advanced in years, is much debilitated, or of an unhealthy irritable constitution, compound luxations, especially if attended with much contusion and other injury of the soft parts, and wrongly treated, very often have a fatal termination. This, however, is not the general event of compound dislocations, and whatever may have happened in former times, we now know, that, in the present improved state of surgery, these accidents mostly admit of cure. This statement may be made, without any censure being cast upon every instance of amputation performed in such cases. I know, that this operation is sometimes indispensable directly after the accident, and I am equally aware, that it may become necessary in a future stage, when extensive abscesses, or sloughing, joined with threatening constitutional symptoms, have taken place. My only design is to recommend the endeavour to cure the generality of compound luxations. But, if a case were to present itself, attended with serious contusion and laceration of the soft parts, I should be as earnest an advocate for amputation as any surgeon.

Mr. Hammick, surgeon to the Royal Naval Hospital, Plymouth, in speaking of compound dislocations of the ankle, advises amputation, "where the lower heads of the tibia and fibula are very much shattered; where, together with the compound dislocation of these bones, some of the tarsal bones are displaced and injured; where any large vessels are divided, and cannot be secured without extensive enlargement of the wound, and disturbance of the soft parts; where the common integuments, with the neighbouring tendons and muscles are considerably torn; where the protruded tibia cannot by any means be reduced; and where the constitution is enfeebled at the time of the accident, and not likely to endure pain, discharge, and length of confinement." (*A. Cooper's Surg. Essays, Part 2, p. 146.*) Perhaps, as general remarks, these may not be inaccurate; but, there are exceptions to them. Thus, we find in Mr. A. Cooper's publication several cases, in which compound dislocations of the ankle terminated well, notwithstanding the displacement and removal of the astragalus, other instances of which kind of success are to be found in the records of surgery. (See *Laumonier, in Fourcroy, Méd. éclairée; Percy, in Journ. de Méd. continué Nov. 1811, p. 348.*) However, if the ends of the tibia and tarsal bones, especially the astragalus and the calcis are broken, the operation of

amputation is recommended on high authority. (*A. Cooper's Surg. Essays, Part 2, p. 181.*) But, with regard to the division of large blood-vessels, Mr. A. Cooper states, that he would not at once proceed to amputation on that account. "The case from Mr. Sandford of Worcester, sent me by Mr. Carden, clearly shows, that the division of the anterior tibial artery does not, if it be well secured, prevent the patient's recovery. I also once saw a compound fracture, close to the ankle-joint, accompanied by a division of that artery; and, although the patient was in the hospital, and a brewer's servant, who possessed the worst constitution to struggle against severe injuries, yet this man recovered without amputation." Nor in Mr. A. Cooper's opinion, would all hope be precluded, even if the posterior tibial artery were injured. (*Voc. cit. p. 186.*) For the method of securing these vessels, see *Arteries*.

The following are the circumstances, which Mr. A. Cooper has known to give rise to the necessity for amputation in compound dislocations of the ankle. 1. The advanced age of the patient. 2. A very extensive lacerated wound. 3. Difficulty of reducing the ends of the bones he considers rather as a reason for sawing them off, than for amputation. 4. The extremely shattered state of the bones. 5. Dislocations of the tibia outwards cause greater injury of the bones and soft parts, than those inwards, and more frequently require amputation. 6. Sometimes the bone cannot be kept reduced, owing to the tibia in the dislocation outwards being obliquely fractured. 7. Division of a large blood-vessel, attended with extensive wound of the soft parts. 8. Mortification. 9. Excessive contusion. 10. Extensive suppuration. 11. Necrosis, where the sequestra do not admit of removal. 12. Very great and permanent deformity of the foot. 13. When tetanus comes on, Mr. A. Cooper does not approve of the operation.

The treatment of a compound dislocation requires the reduction to be effected without delay, and with as little violence and disturbance as possible. If any difficulty of reduction should arise from the bone being girt by the integuments, the opening in them should be dilated with a scalpel. The limb is then to be placed in splints, with the necessary pads, eighteen-tailed bandage, &c. Mr. A. Cooper judiciously recommends the portions of this bandage not to be sewed together, "but passed under the leg, so that one piece may be removed when it becomes stiff;" and by fixing another to its end, before it is withdrawn, the fresh piece may be applied, without any disturbance of the limb. (*Surg. Essays, Part 2, p. 120.*) The wound is to be freed from any dirt, clots of blood, or other extraneous matter, and its lips are to be accurately brought together with strips of adhesive plaster. Mr. A. Cooper considers lint dipped in the blood, which oozes out, the best kind of first dressing. The joint is to be covered with linen kept constantly wet with the liquor plumbi acetatis dilutus, or with what is better,

spirit of wine and water; the bandage is to be loosely laid down, and the splints fastened on the limb with their proper straps, or pieces of tape, and the limb is to be kept perfectly at rest in an eligible posture. The patient, if strong and young, is to be bled. This last practice may be more freely adopted in the country, than in London, or large hospitals. An anodyne, the first night, or two, will be highly proper. Saline draughts, antimonials, and a low regimen, are also indicated during the first few days of the symptomatic fever, which commonly follows so serious an accident.

According to Mr. A. Cooper, purgatives should be used with the utmost caution; "for, (says he,) there cannot be a worse practice, when a limb has been placed in a good position, and adhesion is proceeding, than to disturb the processes of nature by the frequent changes of position, which purges produce; and I am quite sure, that, in cases of compound fracture, I have seen patients destroyed by their frequent administration. That which is to be done by bleeding and emptying the bowels, should be effected within an hour, or two, after the accident, before the adhesive inflammation arises." (*Surgical Essays, Part 2, p. 121.*) Here the fracture bed, invented by Mr. Earle, would allow purgatives to be used, without any disturbance of the limb.

If the case takes a favourable course, the constitutional fever will not be excessive, nor will the pain and inflammation of the limb be immoderate. Sometimes, the wound unites, more or less, without suppuration; a circumstance particularly desirable, as tending more than any thing else to lessen the danger, by changing the case, as it were, from a compound into a simple one. In other cases, the wound is not united; but the inflammation and suppuration are not violent, nor extensive; the constitution is not dangerously disturbed; and hopes of ultimate success may be reasonably entertained. When the wound is disposed to heal favourably, adhesive plaster, with or without lint, or a pledget of soft soap cerate, is the best dressing. In other instances, while the suppuration is copious, and the parts are tense and painful, emollient poultices are the most eligible.

When the symptomatic fever, and first inflammatory symptoms, are over, and much discharge prevails, attended with marks of approaching weakness, the patient is to be allowed more food, and directed to take bark, cordials, porter, wine, &c. If his nights are restless, he must have opiates; if he sweats profusely, sulphuric acid; and, in short, all such medicines, as his particular complaints may require, are to be prescribed.

When the inflammation of a compound dislocation is violent, or extensive, general bleeding, the application of leeches, and the use of fomentations, and poultices, are the most likely means of lessening the mischief. Yet, it is only in strong habits, that venesection

to any extent can be prudently practised in large cities, or crowded hospitals.

The following are the instructions, delivered by Mr. A. Cooper, on the subject of dressings. "If the patient complain of considerable pain, in the part in four or five days, the bandage may be raised to examine the wound; and, if there be much inflammation, a corner of the lint (or other dressing) should be lifted from the wound, to give vent to any matter, which may have formed; but, this ought to be done with great circumspection, as there is danger of disturbing the adhesive process, if that be proceeding without suppuration. By this local treatment, it will every now and then happen, that the wound will be closed by adhesion; but, if in a few days it be not, and suppuration take place, the matter, should have an opportunity of escaping; and the lint being removed, simple dressings should be applied. After a week, or ten days, if there be suppuration, with much surrounding inflammation, poultices should be applied upon the wound, leeches in its neighbourhood, and upon the limb at a distance, the evaporating lotion should still be employed; but, as soon as the inflammation is lessened, the poultices should be discontinued." (*Surgical Essays, Part 2, p. 121.*)

In certain examples, the most skilful treatment is unavailing. The joint and limb become affected with considerable pain and swelling; the fever runs high; delirium comes on; and the patient may even perish from the violence of the first symptoms, the limb being generally at the same time attacked by gangrene. If these first dangers are avoided, the wound may yet not heal favourably; the inflammation may be considerable, or of an erysipelatous nature; large abscesses under the fasciæ may be formed; the bones may be affected with necrosis; and the hectic symptoms, and sinking state of the patient, may make the only chance of recovery depend upon amputation. But, even this operation is sometimes deferred till too late, and the patient must be left to his miserable fate.

Whoever gives the smallest reflection to the nature of compound fractures, will perceive, that it is often a matter of the highest importance, to make a right decision at the very beginning, whether amputation should be immediately done, or whether an attempt to save the limb ought to be made. In some instances, the patient's sole chance depends upon the operation being performed at once, without the least delay, and the opportunity of doing it never returns. The surgeon should take off the limb as soon as he has seen the nature of the injury, and not wait till a general tendency to swelling and gangrene has spread through the member, and every action in the system is disturbed. Amputation, under these circumstances, is undoubtedly done with a very diminished chance of success; and, until certain facts were adduced by Baron Larrey, Mr. Lawrence, Mr. A. C. Hutchinson, and others, was

of late years altogether prohibited. (See *Amputation and Mortification*.)

But besides this first critical period, the surgeon often has to exercise a nice degree of judgment in a future stage of the case; I mean, when the suppuration is copious, the wound open, the bones carious, and the health impaired. Here the practitioner may sometimes err, in taking off a limb that might be saved; or, he may commit a worse fault, and make the patient lose his life, in a fruitless attempt to save the member. No precepts can form the right practitioner in this delicate part of surgery; genius alone cannot do it; the opportunity of making observations, and the talent of profiting by them, are here the things which make the consummate surgeon.

It should ever be recollected, in regard to bad compound dislocations, that in young subjects, and in a salubrious air, many cases will do well, which in old persons, and in the polluted atmosphere of London, and crowded hospitals, would be fatal without amputation.

The constitutions of some individuals are so irritable, that whether an attempt be made to save the limb, or amputation be at once performed, the case has a rapid and fatal termination. According to Mr. A. Cooper, persons who are much loaded with fat, "are generally very irritable, and bear important accidents very ill: indeed, says he, they generally die, whichever plan of treatment be pursued." However, he adds, that such corpulent people as take a great deal of exercise, form exceptions to the foregoing remark." (*Surgical Essays, Part 2, p. 195.*)

There is a practice, in regard to compound dislocations, which, I think ought at all events to be adopted only in a very few cases; I mean the plan of sawing off the head of the luxated bone. According to L  veill  , this method is recommended by Hippocrates as a means of accelerating and perfecting the cure. (*Nouvelle Doctrine Chirurgicale, Tom. 2, p. 44.*) However, it seems not to have done sufficient good, in ancient times, to obtain a lasting reputation. In fact, when it was mentioned by the late Mr. Gooch, it had sunk into such oblivion, that it was received as an entirely new proposal. "Compound luxations (says this author) are of a more dangerous nature, than compound fractures, for very plain reasons; but, if a surgeon should judge it advisable to attempt saving a limb under such threatening circumstances, I am inclined to think, from what I have observed, he will be more likely to succeed, by sawing off the head of the bone, especially if it has long been quile out and exposed to the air."

Mr. Gooch afterward takes notice of a case in which Mr. Cooper of Bungay sawed off the heads of the tibia and fibula, and preserved the limb, the patient being able to walk and work for his bread for many years afterward. Other examples are also briefly mentioned, in which the lower head of the radius was sawn off, and the head of the second bone of the thumb.

The late Mr. Hey of Leeds, was induced to make trial of this plan in a compound luxation of the ankle. The example, however, which he published, is decidedly highly unfavorable to the practice, as the following passage will show: "I was in hopes, that this patient would have been able to walk stoutly; but, in this, I was disappointed. He walked indeed without a crutch; but, his gait was slow, his leg remaining weak, and his toes turning outwards, which rather surprised me, as his leg was very straight, when I ceased attending him."

Mr. Hey did not recite this case, with the view of recommending a similar practice in all cases of this accident; for, he had not always adopted it, nor was he of opinion, that the same mode of treatment, whether by replacing the bones, sawing off their extremities, or amputating the limb, ought to be universally practised. When the laceration of the capsular ligament and integuments is not greater, than is sufficient to permit the head of the tibia to pass through them; and when, at the same time, the joint, or contiguous parts, have suffered no other injury; Mr. Hey recommends the replacing of the bone, and an union of the integuments by suture, with the treatment adapted to wounds of the joints.—(*Practical Observations in Surgery, Chap. 11, Edit. 2.*)

That in a few cases, recorded by Mr. Gooch, and Mr. Hey, the patients recovered with a new sort of joint, only proves to my mind, the great resources and activity of nature, and her occasional triumph over the opposition she meets with from bad and injudicious surgery. A limb so treated, must ever afterward be shorter than its fellow, and consequently the patient be more or less a cripple. We have seen, that, in the only instance, published by Mr. Hey, considerable deformity was the consequence of the practice. I cannot help adding my belief, that this gentleman would have experienced more success in the treatment of compound dislocations, had he relinquished the objectionable method of sewing up the wound. In such accidents, every kind of irritation should be avoided as much as possible, and that the wound may be conveniently closed with sticking plaster, the observation of numerous cases in St. Bartholomew's Hospital has perfectly convinced me. In this munificent institution, under the disadvantage of the air of London, and an hospital, compound luxations used, at the period when I was an apprentice there, to be treated with marked success; and, I feel warranted in ascribing the circumstance to the mode of treatment, which was conducted on the principles explained in this section of the dictionary.

The most ingenious arguments, which have yet been urged in behalf of the practice of sawing off the ends of the bones, in compound dislocations of the ankle, are those recently published by Mr. A. Cooper. However, he does not advise the plan, without restrictions. If the dislocation (says

he) can be easily reduced, without sawing off the end of the bone; if it be not too obliquely broken to remain firmly upon the astragalus after being reduced; if the end of the bone be not shattered, for then the small loose pieces of bone should be removed, and the surface of the bone be smoothed by the saw; if the patient be not excessively irritable, and the muscles, affected with violent spasms, impeding reduction, and causing a displacement of the bones after they have been reduced; Mr. A. Cooper advises the immediate reduction of the parts, and uniting the wound by adhesion. In the opposite circumstances, rather than amputate the limb, he would saw off the ends of the bones. (*Surgical Essays, Part 1, p. 164.*)

The only case, in which the plan of sawing off the head of the bone can be at all proper, is when a compound dislocation cannot be reduced, notwithstanding the enlargement of the wound in the skin, and every other possible means. There is no other mode of preventing the formidable symptoms, which would ensue, were the bone left in a state of protrusion through the integuments; nor is there any better way of alleviating such symptoms after they have actually begun. M. Roux gives much praise to the English surgeons for the judicious boldness, which they have evinced in cases of this description. Although Fabricius Hildanus, Ferrand, Desault, Laumonier, and several other French surgeons, have, like many British practitioners, ventured to remove the whole of the astragalus, when this bone was totally separated from the scaphoides, and protruded, in compound luxations, yet M. Roux acknowledges, that the bold practice of sawing off the lower end of the humerus, the lower end of the radius, the lower end of the tibia, and also of the fibula, at the same time, originated with, and was first executed by English surgeons. (*Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, p. 208—209.*)

DISLOCATIONS OF THE LOWER JAW.

The lower jaw can only be luxated forward and either one, or both of its condyles may become dislocated in this direction. Every dislocation, except that forward, is rendered impossible by the formation of the parts. The lower jaw cannot even be dislocated forward, unless the mouth, just before the occurrence of the accident, be very much open. Whenever the chin is considerably depressed, the condyles slide from behind forward, under the transverse root of the zygomatic processes. The cartilaginous cap, which envelopes the condyles, and follows them in all their motions, still affords them an articular cavity; but, the depression of the bone continuing, the ligaments give way, the condyles glide before the *eminentie articulares*, and slip under the zygomatic arches. Hence, a dislocation mostly happens, while the patient is laughing, gaping, &c. A blow on the jaw,

when the mouth is wide open, may easily cause the accident. The case has occasionally arisen from the exercise of great force in drawing out the teeth. Whenever the jaw has once been dislocated, the same causes more easily reproduce the occurrence. In certain individuals, the ligaments are so loose, and the muscles so weak, that a dislocation is produced by any slight attempt to yawn, laugh, or (as Lamotte has observed) to bite any substance, which is rather large. (*Levéillé, Nouvelle Doctrine Chirurgicale, Tom. 2. p. 54.*) There have been persons, who could scarcely ever laugh heartily, without their lower jaws being luxated. But, of all the causes of this occurrence, yawning alone, even without the combination of any external force, is by far the most common.

When the jaw is depressed, and its angles, to the external sides of which the masseters are attached, are carried upwards and backwards, if these muscles contract, the greater part of their force is employed to bring the condyles into the zygomatic depression. (*Boyer.*)

Dislocations of the lower jaw are attended with a great deal of pain, which Boyer imputes to the pressure produced by the condyles on the deep-seated temporal nerves, and those going to the masseters, which nerves pass before the roots of the zygomatic process. The mouth is wide open, and cannot be shut. It is more open in recent dislocations, than in those, which have continued for some time. An empty space is felt before the ear, in the natural situation of the condyles. The coronoid process forms under the cheek bone a prominence, which may be felt through the cheek, or from within the mouth. The cheeks and temples are flattened by the lengthening of the temporal, masseter, and buccinator muscles. The saliva flows in large quantities from the mouth, the secretion of which fluid is greatly increased by the irritation of the air. The arch, formed by the teeth of the lower jaw, is situated more forward than that formed by the teeth of the upper jaw. During the first five days after the accident the patient can neither speak, nor swallow. (*Boyer.*) When only one condyle is dislocated, the mouth is distorted, and turned towards the opposite side, while the fellow-teeth of the jaws do not correspond. However, Mr. Hey asserts, that frequently the position of the chin is not perceptibly altered. (*Practical Observations, p. 322.*)

When the accident has remained unreduced for several days or weeks, the symptoms are not so well marked. In such instances, the chin becomes gradually approximated to the upper jaw; the patient recovers by degrees the faculty of speaking and swallowing; but, he stammers, and the saliva dribbles from his mouth. The sufferings, induced by a dislocated jaw, are certainly great enough to be sometimes fatal, if the case continue unrectified; but, we are not to believe Hippocrates, when he

positively declares the accident mortal, if not reduced before the tenth day.

Monteggia attended a man, two months after such a luxation, which had not been understood, and Fabricius ab Aquapendente assures us that he had never seen the prognostic of Hippocrates verified, though he had had many patients of this sort under his care. (*Levéillé, Nouvelle Doctrine Chir. T. 2. p. 58.*)

Dislocations of the lower jaw are to be reduced in the following manner: The surgeon is first to wrap some linen round his thumbs to keep them from being hurt by the patient's teeth, and then introduce them into the mouth, as far as possible on the grinding teeth. At the same time, he is to place his fingers under the chin and base of the jaw, and while he depresses the molars with his thumbs, he raises the chin with his fingers, by which means the condyles become disengaged from their situation under the zygomas; at which instant the muscles draw those parts so rapidly back into the articular cavities again, that the surgeon's thumbs might sometimes be hurt, did he not immediately move them outward between the cheek and the jaw.

The reduction being accomplished, a fresh displacement is to be prevented by applying a four-tailed bandage, as recommended for the fractured jaw. The patient should for some time avoid eating food which requires much mastication.

The ancients used to place two pieces of stick between the grinding teeth, and, while they used these as levers to depress the back part of the bone, they raised the chin by means of a bandage. John de Vigo has described this method from Salicetus, Lanfranc, and Guido di Cauliaco; but, it is not preferable to the modern plan, in regard to efficacy; and it has the disadvantage of exposing the teeth to injury.

DISLOCATIONS OF THE VERTEBRÆ.

The large surfaces, with which these bones support each other; the number and thickness of their ligaments; the strength of their muscles; the little degree of motion which each vertebra naturally has; and the vertical direction of the articular processes; make dislocations of the dorsal and lumbar vertebræ impossible, unless there be also a fracture of the above-mentioned processes. Of these cases I shall merely remark, that they can only result from immense violence; that the symptoms would be an irregularity in the disposition of the spinous processes, retention or incontinence of the urine and feces, paralysis and a motionless state of the lower extremities, the effects of the pressure, or other injury, to which the spinal marrow would be subjected. Similar symptoms may also arise, when the spinal marrow has merely undergone a violent concussion, without any fracture or dislocation whatever; and it is certain, that most of the cases mentioned by authors as dislocations of the lumbar and

dorsal vertebræ, have only been concussions of the spinal marrow, or fractures of such bones.

The cervical vertebræ, however, not having such extensive articular surfaces, and having more motion, are occasionally luxated. The dislocation of the head from the first vertebra, and of the first vertebra from the second, particularly the last accident, is the most common; but luxations of the cervical vertebra lower down, though very rare, are possible. Indeed, according to Boyer, many examples have happened, in which one of the inferior oblique, or articular processes of a cervical vertebra has been dislocated, so as to cause a permanent inclination of the neck towards the side opposite to that of the displacement. (*Traité des Mal. Chir. T. 4, p. 114.*)

Whether the case, published by Mr. C. Bell, under the name of a subluxation of the spine, ought to be received as an unequivocal specimen of a displacement of the last cervical from the first dorsal vertebra, I cannot pretend to determine. This author speaks of an evident loosening between these two bones; of a considerable space between them; of the destruction of the intervertebral substance; and of an immense quantity of pus around the injured part of the spine; as circumstances seen in the dissection. "On the backpart, the pus had extended under the scapulæ, and on the forepart was bounded by the œsophagus," and, in the spinal canal, it had descended through the whole length of the sheath to the cauda equina. (*C. Bell, Surg. Obs. Vol. 1, p. 148.*)

DISLOCATION OF THE HEAD FROM THE FIRST VERTEBRA, OR ATLAS.

The os occipitis, and first cervical vertebra are so firmly connected by ligaments, that there is no instance of their being luxated from an external cause, and, were the accident to happen, it would immediately prove fatal by the unavoidable compression and injury of the spinal marrow.

Five examples of displacement of the atlas by disease are in the Museum at Leyden, and are described by Sandifort. Boyer has seen one at la Charité; and a very interesting description of a similar case, illustrated by engravings, has been recently published by Schupke (*De Luxatione Spontanea Atlantis et Epistrophei, 4to. Berol. 1816.*) In this tract is collected from the writings of J. P. Frank, (*Delect. Opusc. Vol. 5.*) from those of Reil, (*Feiberlehre, B. 2, § 102;*) and of Rust, &c. an exact detail of the symptoms of the disease; an important topic on which Boyer confesses his inability to give any information. These spontaneous displacements of the atlas may depend upon caries and scrophulous disease of its articular surfaces, or upon an exostosis of its transverse process, or a similar tumour growing from the neighbouring portion of the os occipitis, or petrous portion of the temporal bone. By these causes, the anterior, or posterior

arch, or one of the sides of the atlas, has been made to intercept a third, the half, and even two-thirds of the diameter of the foramen magnum. Notwithstanding the very remarkable constriction of the medulla spinalis, thus occasioned, it is noticed by Boyer, that life may be carried on, and the nutritive functions performed sufficiently well to afford time enough either for the exostoses to attain a large size, or for the ankylosis, binding together the head and most of the cervical vertebræ, to acquire great solidity. According to the same author, the atlas is never found free and distinct, when thus displaced, but is confounded at least with the os occipitis, and mostly with five or six of the subjacent vertebræ. And, another interesting fact is, that, in cases of this description, the joint between the atlas and occiput is never the only one, which is displaced and deformed, unless the disease be very slightly advanced; for, the articulation of the processus dentatus with the atlas, and sometimes that of the point of the same process with the occiput, are considerably affected. Sometimes, the processus dentatus and the occiput retain their natural position with respect to each other, and the atlas alone seems to be displaced between them. Sometimes the second vertebra is out of its place with respect to the os occipitis in the same direction as the atlas, but not in quite so great a degree. Lastly, in some other instances, the two vertebræ are twisted in opposite directions, as, for instance, one to the left, the other to the right; or vice versa. In one of the cases recorded by Sandifort, this kind of lateral displacement in opposite directions was so extensive, that an interspace, only six lines in breadth, was left between their approximated annular margins. An instance was seen by Duverney, where the displacement of the two vertebræ was from before backward, and where the processus dentatus was approximated to the posterior arch of the atlas to the extent of two-thirds of the annular opening in this vertebra. In these cases, nothing can be more obvious, than that there must be a destruction, or at all events a thoroughly diseased state, of the ligaments between the atlas and dentatus, and of those connecting the dental process to the occiput. (*Boyer, Vol. cit. p. 105.*)

As for the treatment of the preceding forms of disease, experience has hitherto furnished little satisfactory knowledge. But, as an analogy is seen between these cases, and the scrophulous and carious affections of other joints, blisters, setons, and issues have been proposed and tried. Rust found these remedies only capable of retarding the progress of the disease, and of producing an abatement of the symptoms. The pain often reaching from the back of the head to the forehead, was rendered less severe; and the difficulty of swallowing was considerably lessened. But, the means here specified were not found adequate to arrest the morbid change in the bones. However, Rust thinks, that greater benefit might be expect-

ed, if a case were to present itself arising altogether from a local cause, without its origin being connected with constitutional disease. (*Salzburger, Med. Chir. Zeitung Jahrgang. 1813, B. 3, p. 108.*)

DISLOCATIONS OF THE FIRST CERVICAL VERTEBRA FROM THE SECOND.

The rotatory motion of the head is chiefly performed by the first vertebra moving on the second. When this motion is forced beyond its proper limits, the ligaments which tie the processus dentatus to the edge of the foramen magnum are torn, and, supposing the head to be forced from the left to the right, the left side of the body of the vertebra is carried before its corresponding articulating surface, while the right side falls behind its corresponding surface. Sometimes the processus dentatus, whose ligaments are ruptured, quits the foramen formed for it by the transverse ligament and the anterior arch of the first vertebra, and presses on the medulla oblongata. But, according to Boyer, the processus dentatus may be displaced in two ways: 1st, It may be carried directly backwards, the transverse and other ligaments being broken. This mode of displacement Boyer considers as the most difficult and uncommon, as it can hardly take place, except from a fall from a great height upon the back of the head, while the spine is bent forwards. (*Traité des Mal. Chir. T. 4, p. 109.*) However, the accident may happen in another manner, as was the case in Mr. C. Bell's instance, where the misfortune occurred from a fall with the chin upon the curb-stone. (*Surg. Obs. Vol. 1. p. 150.*) 2dly, In a violent rotation, in which the face is carried sideways beyond the proper limits, the lateral and accessory ligaments of the processus dentatus may be stretched and twisted spirally round this process. The force operates entirely upon them, and not at all upon the transverse ligament. Now when the lateral and accessory ligaments of the processus dentatus have given way, and an effort to incline the head to one side is kept up, one of the sides of the space, bounded by the transverse ligament, may present itself near the point of the processus dentatus, which may then pass below the transverse ligament without rupturing it.

In children where the processus dentatus is not fully developed, and the ligaments are weaker than in the adult, a perpendicular impulse may break the lateral and accessory ligaments, and then force the processus dentatus under the transverse ligament, without rupturing this latter part; as Boyer conceives must have been the case in the child, which J. L. Petit mentions as having been instantaneously killed by being lifted up by the head.

Lastly, it is asserted, that, when the transverse, lateral, and other ligaments are capable of making very great resistance to force, which tends to rupture them all, and to throw the processus dentatus directly backwards, this process, if at all more slender

than common, may be broken near its base, and the lateral articulations between the two first vertebræ be instantly destroyed. (Boyer, *Vol. cit. p. 110.*)

Patients can hardly be expected to survive mischief of this kind in so high a situation; when the transverse ligament is broken, and the processus dentatus is thrown directly backward against the medulla oblongata, the effect must be instant death, as happened in the case lately recorded by Mr. C. Bell. (*Surg. Obs. Vol. 1, p. 150.*)

According to surgical writers, the causes which may produce this formidable accident, are various: a fall on the head from a high place; the fall of a heavy body against the back of the neck; a violent blow; a forcible twist of the neck; tumbling; standing upon the head; the rash custom of lifting children up by the head, &c. Louis found that the first vertebra was dislocated from the second in the malefactors hanged at Lyons, at which place, the executioner used to give a sudden twist to the body, at the moment of its suspension, and then bear with all his weight upon it. Under such circumstances, Boyer conceives that the processus dentatus would pass under the transverse ligament, without this ligament being ruptured.

Dislocations of the cervical vertebræ are said not to be always fatal, as when they occur at the third, fourth, fifth, or sixth of these bones, and only one articular process is luxated. In these instances, the vertebral canal is not so much lessened as to compress the spinal marrow, and occasion immediate death.

With regard to the prognosis and treatment of all luxations in which the processus dentatus is displaced, the reader need only hear, that such cases are immediately fatal. Mistaken notions have been entertained upon this point, in consequence of particular dislocations of the neck having been successfully treated.

A mother brought her child to Desault, with its neck bent, and its chin turned towards the right shoulder. The accident had been a consequence of the head having been fixed on the ground, while the feet were up in the air. A surgeon happened to be with Desault at the time, and they agreed to make an attempt to reduce the luxation, and to apprise the mother, that though the child might be cured, there was a possibility of its perishing under their hands. Being permitted to do what they judged proper, they fixed the shoulders, and the head was gently raised, and gradually turned into its natural position. The mother was rewarded for her courageous resignation; the child could now move freely; the pain ceased, and a considerable swelling in the situation of the luxation alone remained, and it was dispersed by the application of emollient poultices. (*Levillé, Nouvelle Doctrine Chir. T. 2. p. 62.*)

Another alleged instance of the reduction of a dislocation of the neck is also recorded by Dr. Settin, in vol. 1 of Schmucker's *Vermischte Chirurgische Schriften*.

However, both in this case, and that related of Desault, there can now be little, or no doubt, that the accident was not a dislocation of the dentata from the atlas, but only a luxation of one of the oblique processes of one of the cervical vertebræ lower down. Whenever the processus dentatus is suddenly displaced, or fractured, the effects on the medulla spinalis are inevitably fatal. For more information respecting dislocations of the vertebræ, consult T. E. Schmidt, *De Luxatione Nuchæ*, Haller, *Disp. Chir. 2. 351, Tub. 1747.* S. T. Soemmering, *Bemerkungen über Verrenkung und Bruch des Rückgraths*, 8vo. Berlin, 1793. Boyer, *Traité de Mal. Chir. T. 4, p. 100, &c. 8vo. Paris, 1814.* A. E. Schupke, *De Luxatione Spontanea Atlantis et Epistrophei*, 4to. Berol. 1816. C. Bell, *Surgical Obs. Vol. 1, p. 145, 149, &c. 8vo. Lond. 1816.*

DISLOCATIONS OF THE CLAVICLE.

These are much less common, than fractures, which are said to occur six times more frequently.

The clavicle may be luxated at its sternal extremity, forwards, backwards, and upwards, but never downwards, on account of the situation of the cartilage of the first rib. The luxation forward is the most frequent, and almost the only one ever met with. It may arise from the other end of the clavicle being forced very much backward. Dislocations backwards and upwards are very unusual. To cause the first sort of accident, the shoulder must be violently driven forwards, and at the same time depressed with great force. The dislocation backwards is more rare, than that upwards.

If the dislocation be forwards, a hard circumscribed tumour is felt, or even seen, on the front and upper part of the sternum. When the shoulder is carried forward and outward, this tumour disappears, and previously there was a vacancy where the head of the clavicle ought to be.

When the luxation is upwards, the distance between the sternal ends of the clavicles is diminished.

When the dislocation is backwards, there is a depression where the head of the clavicle ought to be, and the end of the bone forms a projection at the front and lower part of the neck, which, as J. L. Petit remarks, may compress the trachea, œsophagus, jugular vein, carotid artery, and nerves. The head is inclined towards the side, on which the accident itself is situated.

In reducing these dislocations of the sternal end of the clavicle, we are to make a lever of the arm, by means of which the shoulder is brought outwards; and when thus brought outwards, it is to be pushed forwards, if the dislocation be in that direction; backwards, if the dislocation be behind; and upwards, if the dislocation be above.

It is as difficult to keep the bone reduced, as it is easy to reduce it, so smooth and oblique are the articular surfaces.

The same position of the arm, and the

same apparatus, as in fractures of the clavicle, are to be employed. The end of the clavicle, however, can never be kept from rising a little, and this would be the case even were the tourniquet used, which was proposed by Brasdor, for making pressure on the end of the bone.

The dislocation of the capsular end of the clavicle from the acromion is much less common. The luxation upwards is almost the only one that ever occurs. It is possible, however, for the accident to take place downwards, and for the end of the clavicle to glide under the acromion. The rarity of dislocations of the capsular end of the clavicle is owing to the strength of the ligaments tying the clavicle and acromion together.

A fall on the top of the shoulder may cause the dislocation upwards. The scapular end of the clavicle then slides upwards on the acromion, and the shoulder is drawn inwards by the muscles which approximate the arm to the body. The violent action of the trapezius muscle, in pulling upward the clavicle, may tend to produce the accident. Pain at the top of the shoulder, and a projection at the end of the clavicle, under the skin covering the acromion, are symptoms, indicating what has happened. The patient also inclines his head to the affected side, and avoids moving his arm or shoulder.

This dislocation is reduced by carrying the shoulder outwards, putting a cushion in the axilla, and applying Desault's bandage for fractures of the clavicle, (*See Fractures*), making the turns ascend from the elbow to the shoulder, so as to press the luxated end of the bone downward, and keep it in its due situation, at the same time that the elbow is confined close to the side, and supported in a sling, by which means the shoulder will be kept raised and inclined outwards. This plan, which is advised by Boyer, is more efficient than the common practice, which consists in applying a compress, the figure of 8 bandage, and supporting the arm in a sling. However, the exact maintenance of the reduction by any apparatus whatever, is found to be a matter of the greatest difficulty, though it is agreeable to know, that notwithstanding this disadvantage, the cases always have a favourable termination. In the course of my time, I have seen several cases in proof of this statement, and one example was shown me last summer by Mr. Vincent, in St. Bartholomew's Hospital.

DISLOCATIONS OF THE OS BRACHII.

Nature, which varies according to the necessities of different animals, the number of their joints, has also been provident enough to vary the structure of these parts, according to the use of the different portions of their economy. To great moveableness some unite considerable solidity; for instance, the vertebral column. Others are very strong, but only admit of a slight yielding motion, as we observe in the carpus, tarsus, &c. Lastly, other joints admit of

a great latitude of motion; but their strength is easily overpowered by the action of external bodies. Such are, in man, the shoulder-joint, and that between the sternum and clavicle.

The last kinds of articulation are particularly subject to dislocation, and, of all, not one is so often luxated as the shoulder-joint. Bichat mentions, that it appears, from a comparative table, that in some years, this accident, at the Hôtel-Dieu, has been as frequent, and even more so, than dislocations of all the other bones taken collectively.

Here every thing seems to facilitate the escape of the bone from its natural cavity. An oval shallow cavity, surrounded by a margin of little thickness, receives a semi-spherical head, which is twice as broad as the cavity in the perpendicular direction, and three times as extensive from before backward. With respect to the ligaments, the joint is only strengthened by a mere capsule, which is thin below, where nothing opposes a dislocation; but thicker above, where the acromion, coracoid process, and triangular ligament, form an almost insurmountable obstacle to such an accident. With regard to the muscles, and motions of this joint, strong and numerous fasciculi surround the articular surfaces, make them easily move in all directions, and pushing the head of the os brachii against the different points of the capsule, distend this ligamentous bag, and when their power exceeds the resistance, actually lacerate it. As for external bodies, what bone is more exposed than the os brachii, to the effect of their force?

Thus subjected to the influence of these predisposing causes, the os brachii would be in continual danger of being dislocated, if the scapula, which is as moveable as itself, did not furnish a point of support for it, by accompanying all its motions. This point of support accommodates itself to the variations in the position of the head of the os brachii, so that to the moveableness of the articular surfaces, their strength is, in a great measure owing.

The shoulder-joint, which is very liable to luxations in a general sense, is not equally so at all points. There are some, where a dislocation cannot occur; there are others, where, though possibly such an accident has never been observed. Hence, before examining the mechanism of dislocations of this joint, it is essential to determine with precision the directions, in which they may take place. Here, indeed, authors differ in a very singular manner. Sometimes, they employ different terms to express the same thing; and sometimes, the same words to signify different things. Invariably agreed about certain kinds of dislocations, they entertain opposite sentiments concerning others; and, in the midst of these differences, the perplexed surgeon often cannot decide on what basis to found his practice.

Several former writers speak of four kinds

of dislocations of the shoulder; many of three; some acknowledge only two: while others allow the possibility of only one kind.

By those, who enumerated the different directions, in which the bone might be luxated, four cases were particularly noticed. The dislocations were termed *upward, downward, forward, and backward*. Such was the opinion of the predecessors of Hippocrates, who sufficiently demonstrates its inaccuracy. Others divided dislocations of the shoulder into such as take place *downward, upward, outward, and forward*. This division is adopted by Galen, who, however, only cites an example of the luxation forward, and does not illustrate what he means by dislocations upward, and inward.

The second class of writers, among whom was Oribasius, distinguished dislocations into those which occur *downward, forward, and backward*. Sometimes, they named the luxations *downward, outward, and inward*. Paul of Ægina followed this plan, and, no doubt, his meaning is the same as that of Oribasius, only expressed in different terms. Sometimes, they called the dislocations *downward, forward, and upward*. Albucasis did so, and thought the latter case exceedingly uncommon.

The third set believed, that when the head of the os brachii was displaced, it could be carried only *downward into the armpit*, a very common case; or *forward*, an accident less frequent. Celsus is almost the only one, who has established this difference: he remarks, *Humerus modo in aliam excidit, modo in partem priorem*.

Lastly, the fourth body of writers only believed in the dislocation downward; which was the sentiment of Hippocrates, who had seen no other sort of case in his practice. *At verò humerus inferiorem in partem excidit; aliam in partem excidere non audiui*.

The moderns borrowed from the ancients their divisions of dislocations of the shoulder-joint, and, at first, like their predecessors, they only determined in a vague manner the precise situations of the head of the bone. However, they afterward fixed it with more determination, in proportion as they became enlightened by anatomy, and, in particular, took notice of the essential difference between primitive and consecutive luxations.

Petit admits four kinds of dislocations. 1. Downward on the inferior costa of the scapula, very rarely met with. 2. Outward, under the spine of this bone; a case, which as a primitive one, can only occur with difficulty. 3. Inward, into the armpit. 4. Forward, between the coracoid process and the clavicle. Heister, like this eminent practitioner, acknowledged four dislocations; but with a difference both of expression and meaning. One is downward, in the axilla; one forward, under the great pectoral muscle; another backward, under the scapula, and a fourth outward, under the spine of this bone. According to Duverney,

primitive luxations never occur in any direction but downward; the others being all the effect of muscular action.

DIVISION ADOPTED BY DESAULT.

In the midst of these very confused ways of viewing a very simple subject, Desault judged it necessary, in order to acquire determinate ideas, to divide dislocations of the humerus into *primitive*, which are the sudden effect of external violence, and into *consecutive*, which follow the first, by the influence of causes presently to be explained.

Let the oval surface of the glenoid cavity be included within four lines; one representing its upper edge; another its lower; a third its inner edge; and a fourth its external one.

It is manifest, that the head of the humerus cannot be displaced towards the upper edge. There, are situated the acromion and coracoid process, the triangular ligament stretched between them, the tendons of the triceps, supraspinatus, and the fleshy portion of the deltoid, insurmountable obstacles to the luxation of the head of the bone, propelled by any force upward. Besides, what power could this be? Supposing there were such a force, the head of the bone must necessarily be driven outward as well as upward, ere its head would be displaced. This is impossible, because the trunk prevents the lower part of the arm from being directed sufficiently inward to produce this effect.

On the contrary, at the other margins, there is little resistance. At the inferior one, the long portion of the triceps; at the internal one, the tendon of the subscapularis; and at the external edge, those of the infra-spinatus, and teres minor, will readily yield to any power directed against them, and allow primitive luxations to take place, downward, inward, or outward. Downward, between the tendon of the long portion of the triceps, and the tendon of the subscapularis, which last, according to Mr. Cooper, is ruptured; (*Surg. Essays, Part 1, p. 7.*) inward, between the fossa subscapularis, and muscle of this name; outward, between the fossa infraspinata, and infraspinatus muscle.

After being pushed out of its cavity, and first placed in one of these three directions, the head of the humerus often changes its position; and then, to a *primitive* luxation, downward, or inward, a *consecutive* one succeeds. But, a consecutive could never follow a primitive dislocation outward, were this ever met with, as the spine of the scapula would form an obstacle.

A consecutive luxation inward may succeed a primitive one downward: indeed, nothing resists the head of the humerus, in the course which it then follows to get between the fossa subscapularis and the muscle similarly named. On the contrary, should it tend outward, it is opposed by the tendon of the triceps, and notwithstanding what Petit has written, Desault believed

that a consecutive dislocation in this direction never happens.

Sometimes, after the head of the bone has escaped from the internal or inferior part of the capsule, it is carried behind the clavicle, forming a case of consecutive dislocation upward; a specimen of which was preserved in Desault's museum. But, here, the secondary displacement only takes place slowly, and, when it occurs, a reduction can rarely be effected, on account of the strong adhesions, contracted by the surfaces of the bone. Thus, in the specimen referred to, a new cavity was formed behind the clavicle, and the humerus adhered by new kinds of ligaments to the surrounding parts.

The humerus then is subject to four kinds of dislocation. 1. Downward. 2. Outward. In these two directions the accident is always primitive. 3. Inward, which is sometimes primitive, sometimes consecutive. 4. Upward; a case which can never occur except as a consecutive one.

The second and fourth cases are so very rare in comparison with the others, that they alone claim attention.

CAUSES.

The action of external bodies, directed against the arm; but, particularly, falls, in which this part is forced against a resisting body, gives rise to primitive dislocations, and then the different species of the accident are determined, by the particular position of the humerus at the instant, when the injury takes place.

Should this bone be raised from the side, without being carried either forward or backward; should the elbow be elevated, and the fall take place on the side, then the weight of the trunk, almost entirely supported by this bone, forces downward its upper part which stretches and lacerates the lower part of the capsular ligament. Thus a luxation downward is produced, and its occurrence may also be facilitated by the combined action of the latissimus dorsi, pectoralis major, and teres major, muscles, as Fabre has judiciously remarked; for being at this period involuntarily contracted to support the trunk, they act with the power of a considerable lever; the resistance being the head of the bone, which they draw downward, while the fixed point is the lower end of the bone, resting against the ground. Some authors also consider, as the immediate cause of a dislocation downward, the strong action of the deltoid, which is supposed to depress the head of the bone, and push it downward through the capsular ligament. Certain observations seem incontestably to establish this mode of dislocation. Bichat mentions the well-known case of a notary, who luxated his arm downward, in lifting up a register.

The rationale of the primitive luxation inward differs very little from that of the preceding case. The elbow is both separated from the side, and carried backward: in falling, the weight of the body acts on the

humerus, the front part of the capsule is lacerated, and a luxation takes place in this direction.

The dislocation outward is produced in the same sort of way. The elbow is carried forward, towards the opposite shoulder; the capsule is stretched outward, and if a sufficient force act on the limb, it is lacerated. But, how could such a force arise? In a fall, the arm being pushed against the trunk, and kept there, cannot move extensively enough to cause such a laceration. Hence, a luxation outward must necessarily be exceedingly rare, and Desault, in all his experience, never saw such an accident. Besides, when, in a fall, the arm is raised from the side, and inclined forward or backward, the weight of the body only operates upon it obliquely, and the limb is very little exposed to the action of the latissimus dorsi, pectoralis major, and teres major muscles. A few instances of a dislocation of the head of the humerus outward, however, have been recorded. In a dead subject, Boyer remarked a singular inclination of the glenoid cavity backwards, its articular surface, also, presenting on this side an extraordinary elongation, and the humerus readily slipping under the spine of the scapula. (*Traité des Mal. Chir. T. 4, p. 176.*)

In the patient whose history was published by M. Fizeau, and in whom a dislocation of the humerus outwards and backwards, was seen both by that gentleman and Boyer, there was also the particularity, that the luxation was readily reproduced. (*Journ. de Med. par. Corvisart, &c. T. 10, p. 386.*)

Hence, Boyer suspects, that this very rare kind of displacement must have been facilitated by some preternatural disposition of the articular surfaces, especially that of the glenoid cavity. No dislocation must occur more frequently, than that downward, in which the influence of the weight of the body, and of the action of the muscles is direct. The luxation, inward, however, is common, and a multitude of cases, seen by Desault, confirm the reality of this kind of primitive dislocation, though doubted by several modern authors, who are disposed to think with Hippocrates, that all dislocations at first take place downward.

The capsule may only be stretched in a primitive luxation, and then the articular surfaces lose their relations but imperfectly; though most frequently, it is lacerated, and the head of the bone passes through the rupture. Indeed, in all primitive dislocations from violence, and not from paralysis of the deltoid, and a gradual yielding of the capsule, I believe the latter part is always extensively lacerated. In general, authors have paid too little attention to this circumstance, which dissections have repeatedly demonstrated to practitioners, and to Desault in particular. This eminent surgeon had two specimens made of wax; one, of a dislocation inward; the other of one downward; both of which were met with in subjects, who died at the Hôtel Dieu. Bell also makes mention of similar facts, and another

English surgeon, says Bichat, has observed the same occurrence. I suppose Bichat here alludes to Mr. Thompson, who long ago noticed the laceration of the capsule, and particularly called the attention of surgeons to the subject, in the *Medical Observations and Inquiries*.

Desault conceives that the capsule may be sufficiently torn to let the head of the bone escape; but that the opening may afterward form a kind of constriction round the neck of the humerus, so as to prevent the return of the head of the bone into the place, which it originally occupied. The correctness of this statement, however, is positively denied by Mr. A. Cooper, who remarks, that they who entertain this belief, must forget the inelastic structure of the capsular ligament, and never witnessed by dissection the extensive laceration which it suffers in dislocations from violence. (*Surgical Essays, Part. 1, p. 18.*)

When a consecutive luxation follows a primitive one, several causes may concur in producing it. If a fresh fall should happen, while the arm is separated from the trunk, the head of the humerus, which nothing confines, obeys, with the utmost facility, the power displacing it in this manner, and is again pushed out of the situation which it accidentally occupies.

A man in going down stairs, meets with a fall, and dislocates the humerus downward; he immediately sends for Desault, who defers the reduction till the evening. In the mean time, the patient in getting upon a chair, slips and falls again. The pain was more acute, than when the first accident occurred, and Desault, on his return, instead of finding the head of the humerus as it was in the morning, in the hollow of the axilla, finds it behind the pectoralis major muscle.

The action of muscles is a permanent cause of a new dislocation. When the humerus is luxated downward, the pectoralis major, and the deltoid draw upward, and inward, the upper part of this bone, which, only making a weak resistance to their action, changes its position, and takes one in the above double direction.

The various motions imparted to the arm, may also produce the same effect, according to their direction. Thus, in consequence of unskilful efforts to reduce the bone, a luxation inward frequently follows one downward.

SYMPTOMS.

In general, the diagnosis of dislocations of the humerus is attended with no difficulties.

Whatever may be the mode and situation of the dislocation, there always exists, as Hippocrates has remarked, a manifest depression under the acromion, which forms a more evident projection, than in the natural state. Almost all the motions of the arm are painful; some cannot be performed in any degree; and they are all very limited.

The arm cannot move without the shoulder moving also, because the articulation being no longer able to execute its functions, both it and the shoulder form, as it were, one body.

To these symptoms, generally characteristic of every sort of dislocation of the humerus, are to be added such as are peculiar to each particular case. When the luxation is downward, the arm is a little longer, than in the natural state; it is capable of being moved a little outward: but, an acute pain is the inevitable consequence of moving it either forward or backward. The elbow is more or less removed from the axis of the body by the action of the deltoid, and the long head of the biceps, and supraspinatus muscles, are stretched, contract and tend to draw the bone outward. The pain, which arises from this position, compels the patient to lean towards the dislocated limb, to keep the forearm half bent, and the elbow supported on his hip, in such a way, that the arm, having a resting place, may be sheltered from all painful motion, and stretching of the muscles. By this posture alone, Desault was in the habit of detecting a luxation downward, and his diagnosis was seldom found to be erroneous. Thus, in a fracture of the clavicle, the leaning posture of the patient is often, at the first glimpse, characteristic of the accident. In the axilla, a prominence, formed by the head of the humerus, may constantly be felt.

With the general symptoms of dislocations of the humerus, a luxation inward has the following: the elbow, separated from the axis of the body, is inclined a little backward; the humerus seems to be directed towards the middle of the clavicle; motion backward is not very painful, but that forward is infinitely so; there is a manifest prominence under the great pectoral muscle; the arm is very little longer than in the natural state; and the posture is the same, as in the foregoing case.

Were a dislocation outward to present itself, it would be particularly characterized by a hard tumour under the spine of the scapula; by the direction of the elbow forward; by its separation from the trunk; and by the somewhat increased length of the arm.

A projection behind the clavicle; a manifest shortening of the arm; and its direction; would clearly denote a dislocation upward.

Frequently, nothing is more difficult, than to determine, whether the case is a primitive dislocation inward, or a consecutive one; the same symptoms being observable in both cases. An accurate history of the case, by representing the order in which the symptoms occurred, can alone throw light on this point, which is the more interesting, as in the two cases, the means of reduction should vary. In the first, the head of the bone returns, through a short track, into its natural cavity; in the second, it has to tra-

verse a much greater distance to arrive there.

If, as Petit has pretended, there are dislocations backward, sometimes primitive, sometimes consecutive, this remark would be equally applicable to them.

Some analogous symptoms between dislocations of the humerus, the fracture of its neck, and luxations of the scapular end of the clavicle, might here create an uncertainty, if, in the latter case, the absence of a tumour in the armpit, and of a depression under the acromion, did not prevent an error. Uncertainty might arise, if in the fracture of the neck of the humerus, the proper symptoms of a fracture did not prevent a most detrimental mistake, which the occasional direction of the humerus, and a kind of prominence formed by the lower end of the fracture in the axilla, might otherwise cause. (See *Fracture of the Neck of the Humerus*.)

Inflammatory symptoms seldom follow dislocations of the humerus. Many authors, particularly B. Bell, speak of an œdematous swelling of the whole upper extremity, as a frequent consequence of a dislocation inward, and it is referred to the compression of the axillary glands. Experience has not often demonstrated this occurrence at the Hôtel Dieu, except in very old luxations; and when the thing has occurred, very beneficial effects have been obtained, in certain instances, by applying for a few days, a moderately tight bandage from the fingers up to the axilla, after the reduction has been accomplished. Bichat relates a case, in which the œdema did not disappear with the cause, but even rather increased; but the day after a bandage had been applied, the swelling was found diminished by one half.

There is another consequence, to which authors have paid but little attention; though it was known to Avicenna, and was several times observed by Desault. This is a palsy of the upper extremity, arising from the pressure, made by the head of the bone, when dislocated inward, upon the axillary plexus of nerves. This consequence sometimes resists every means of relief.

Indeed, when the nerves have been a long time compressed, the affection is very difficult of cure. Desault several times applied the moxa above the clavicle. The success, which he first experienced on some patients, did not follow invariably in others. But, when the head of the humerus has only made, as it were, a momentary pressure on the nerves, and the reduction has been effected, soon after the appearance of the symptoms, the paralytic affection often goes off of itself, and its dispersion may always be powerfully promoted by the use of volatile liniments.

OF THE REDUCTION.

We may refer to two general classes, the infinitely various number of means, proposed for the reduction of a dislocated humerus. The first are designed to push back,

by some kind of mechanical force, the head of the bone, into the cavity from which it is displaced, either with, or without making previous extension. The others are merely intended to disengage the head of the bone from the place which it accidentally occupies, leaving it to be put into its natural situation by the action of the muscles.

By the first means, art effects every thing; by the second, it limits its interference to the suitable direction of the powers of nature. In the first method, the force externally applied always operates on the bone in the diagonal of two powers, which resist each other at a more or less acute angle; in the last the power is only in one direction.

Here it is only necessary to state, that all the means, intended to operate in the first way, act nearly in the following manner. Something placed under the axilla, serves as a fulcrum, on which the arm is moved as a lever, the resistance being produced by the dislocated head of the humerus, while the power is applied either to the lower part of this bone, or the wrist. The condyles of the humerus being pushed downward and inward, the head of the bone is necessarily moved in the opposite direction, towards the glenoid cavity, into which it slips with more or less facility.

Thus operated the machine, so celebrated among the ancients and moderns, under the name of the *ambi* of Hippocrates; whether used exactly in the form described by him, or with the numerous corrections devised by Paul of Ægina, Ambrose, Paré, Duverney, Freke, &c. By this machine, a double motion is communicated to the head of the humerus, as above explained.

The extension usually moves the bone from its unnatural situation, and is executed in different ways. Sometimes, the weight of the body on one side, and the dragging of the end of the dislocated bone on the other, tend to produce this effect. Such was the action of the ladder, door, &c. described in Hippocrates's *Treatise on Fractures*, and repeated in modern works. Sometimes, the trunk is fixed in an unchangeable manner, while the arm is powerfully extended, as is practised in employing the machine of Oribasius, and was one of the methods formerly adopted in the public places, where wrestlers combated.

Sometimes, no extension is sensibly executed, and while the end of the humerus is pushed outward by a body placed under the axilla, the surgeon pushes it upward into the glenoid cavity.

We shall not here inquire into the inconveniences peculiar to each of these methods. Petit and B. Bell have already done so. We shall only point out the objections, common to all of them.

The exit of the head of the bone, through the lacerated capsule, is not necessarily attendant on the dislocation. Nor is it even possible to know with precision the situation of this opening. Why then should we

make use of an artificial force to direct the head of the bone towards this opening?

However covered the body placed under the axilla may be, to serve as a fulcrum, there is always a more or less inconvenient chafing, frequently dreadful stretching and laceration of parts, in consequence of its application, when the trunk is suspended upon it, as in the instance of the door, &c. In this way, Petit has seen a fracture of the neck of the humerus produced, and even a laceration and aneurism of the axillary artery.

Few surgeons have ready at hand the different kinds of apparatus. Hence, trouble and loss of time in getting them; time, which is of so much moment in the reduction; this being always the more easy, the sooner it is accomplished.

When the luxation is consecutive, how can mechanical means bring back the head of the bone, through the track it has taken? For instance, if to a dislocation downward one inward has succeeded, the head of the bone must necessarily be brought down, before it can be replaced in its cavity. The above artificial means often act repugnantly to the action of the muscles, which is a chief and essential agent in the reduction.

If the dislocation should be upward, they would obviously be ineffectual.

Perhaps, however, they might be advantageously employed, when a primitive luxation downward is quite recent, and when the head of the bone is very near its cavity. Then the inferior costa of the scapula presents an inclined plane, along which the end of the bone can easily glide, when propelled by any kind of external force. No doubt, it is to this tendency of the head of the bone to be replaced, that we must attribute the success, certainly exaggerated, but in part real, on which the inventor of such machines endeavours to establish the superiority of his plan.

But, in this case, it is useless to multiply artificial powers, when natural means suffice, and when we can accomplish the reduction with the hands more effectually, because we can vary the motions with more precision.

Thus Desault very often employed the following method with great success. The patient being seated upon a chair of moderate height, he took hold of the hand on the affected side, placed it between his knees, which he moved downward and backward, in order to make the extension and disengage the head of the bone, while an assistant held back the trunk to effect the counter-extension. This was sometimes executed by the weight of the body, and effort of the patient. At the same time, the surgeon's hands being applied to the arm, in such a way, that the four fingers of each were put in the hollow of the axilla, and the thumbs on the outer part of the arm, pushed upward, and a little outward, the head of the humerus, which usually returned with ease into its natural cavity.

Petit explains this plan, though not as

here described, but complicated with the use of a napkin, passed under the patient's axilla, and over the surgeon's neck, who contributes to raise the dislocated end of the bone, by lifting up his head. This accessory method was considered by Desault as useless and little methodical, preventing all variation in the direction of the impulse given to the head of the bone. The hands alone are always sufficient, and a multitude of instances attest the efficacy of this method, employed in Desault's way.

When the luxation downward was very recent, Desault in two, or three times, succeeded in reducing it, by a still more simple process. Marie-Louise Favert fell in going down stairs, dislocated her arm downward, and was conveyed, immediately after the accident, to the Hôtel-Dieu. Desault having recognized the disorder, placed his left hand under the axilla, to serve as a fulcrum, while with the right, applied to the lower and outer part of the arm, he depressed the humerus towards the trunk, and at the same time raised the upper part of the bone. The head of the humerus, directed upward and outward by this double motion, returned into the glenoid cavity, without the least resistance. The arm was placed in a sling for two days, and, on the fourth, the patient resumed her wonted labour.

Dislocations downward are not the only ones, to which the first of the above simple plans is applicable. Primitive luxations inward sometimes yield to its adoption. Two examples of such success are to be found in the *Journal de Chirurgie*.

REDUCTION BY EXTENSION ALONE.

For the most part, however, the preceding methods are inadequate, and extension must be made, which, when it is employed alone, forms a second sort of means for reducing dislocations of the shoulder. In ordinary cases of dislocation downward and forward, Celsus recommends simple extension. Albucasis was acquainted with no other mode. Douey, Douglas, and Heister, among the moderns, have absolutely rejected the use of machines, as always useless, and frequently dangerous. Lastly, Dapouin and Fabre examined with great exactness the process of extension, pointed out the manner of rendering it most advantageous in all cases, by the proper application of the extending force; and, in the dislocation of the humerus in particular, they obviated the inconvenience of pulleys, placed under the arm-pit on the affected side, and proved that the motion, vulgarly termed coaptation, was of no utility.

In order to reduce a dislocation of the humerus, it is necessary to have a sufficient number of assistants, so as to increase the power according to the resistance which is to be overcome. But, two are usually sufficient for making the extension: in doing which, one should employ a linen pad, of sufficient thickness to project above the level of the pectoralis major, and latissimus dorsi. There must also be two bandages:

one made of linen, several times doubled, four inches wide, and eight or nine feet long; the other a towel, folded in the same way, but not always wanted.

The patient may either sit in a chair of moderate height, or lie down upon a table, which is firmly fixed, and covered with a mattress.

Desault, for a long while, used to put the patient in the first of these positions, which, indeed, is generally preferred. In it the arm may be advantageously drawn in a transverse direction; but if, as is often the case, there be occasion to make extension upward or downward, the assistant is then obliged to rise up, and depress himself, has not sufficient power, finds himself obstructed, and cannot vary, at the pleasure of the surgeon, the direction in which the arm is to be extended. This position is also much more fatiguing to the patient, than one in which the trunk is equally supported upon a horizontal plane. Hence, Desault, in the latter years of his practice, abandoned the first position, and invariably adopted the last.

The patient being put in the proper position, the linen compress is applied to the axilla, on the side affected, and upon this compress the middle of the first extending bandage is placed, the two heads of which ascend obliquely before and behind the chest, meet each other at the top of the sound shoulder, and are held there by an assistant, so as to fix the trunk, and make the counter extension. The action of this bandage does not affect the margin of the pectoralis major and latissimus dorsi, in consequence of the pad projecting higher than them. If this were not attended to, these muscles being drawn upward, would pull the humerus in this direction, and thus destroy the effect of the extension, which is to be made in the following manner:—

Two assistants take hold of the fore-arm, above the wrist; or else the towel, doubled several times, is to be applied to this part. The two ends are to be twisted together, and held by one or two assistants, who are to begin pulling in the same direction in which the humerus is thrown. After this first proceeding, which is designed to disengage the head of the bone from its accidental situation, another motion is to be employed, which differs according to the kind of luxation. If this should be downward, the arm is to be gradually brought near the trunk, at the same time that it is gently pushed upward. Thus, the head of the bone being separated from the trunk, and brought near the glenoid cavity, usually glides into this situation with very little resistance.

When the luxation is inward, after the extension has been made in the direction of the humerus, the end of this bone should be inclined upward and forward, in order that its head may be guided backward; and *vice versa*, when the luxation is outward.

When the head of the bone has been disengaged by the first extension, the motion imparted to it by the rest of the extension,

should in general be exactly contrary to the course which the head of the bone has taken, after quitting the glenoid cavity.—When there is difficulty experienced in replacing the head of the bone, we should, after making the extension, move the bone about in various manners, according to the different direction of the dislocation, and the principle just noticed. This plan often accomplishes what extension alone cannot; and the head of the bone, brought by such movements towards its cavity, returns into it, during their execution.

When the dislocation is consecutive, it is the first extension, made in the direction of the displaced bone, which brings back its head to the situation where it was primitively lodged, and the case is then to be managed just as if it were a primitive dislocation. Often it is only at the moment of the reduction, that it is possible to distinguish, whether a luxation is of one or the other kind. Indeed, as the reduction mostly takes place of itself, when the extension is properly made, if the head be situated consecutively inward, it is seen to descend along the internal part of the scapula, then to proceed to the lower part, and, lastly, to ascend towards the opening in the capsule, into which it returns.

When the extension is properly made, the reduction is almost spontaneously effected. Indeed, whatever may be the kind of primitive dislocation, it is clear, that the muscles on one side of the articulation must be put upon the stretch, while those on the other must be relaxed. Hence, a change must necessarily follow both in their directions and contractions, and also in the direction of these contractions. From this change, the muscles, when they act, instead of drawing back the head of the bone towards the ruptured capsule, pull it in another direction, and thus produce a consecutive dislocation.

But, if by rectifying things, the extension should chance to restore to the muscles their former direction, then obeying their natural irritability, increased by the stretching of the extending power, they will bring back the head of the bone to the opening in the capsule, and oblige it to enter with much more certainty, than the efforts of a surgeon could do, who is always ignorant of the precise situation of this opening.

It follows from what has been said:—1. That all the art of treating dislocations, consists in giving a proper direction to the extending force. 2. That in general the coaptation is useless. 3. That reducing a dislocation does not consist in putting back the head of the bone into its cavity; but, in putting the muscles in a proper state for accomplishing this reduction, and that here, as every where else, art is only the handmaid of nature.

There are cases, however, in which the action of the muscles, being perverted by the oldness of the dislocation, and by the adhesions contracted with the surrounding parts, it becomes necessary to employ such means, as will serve to force, as it were, the

head of the bone into its cavity, to which the muscles cannot bring it.

With reasoning is combined experience, which is always the most effectual proof of this doctrine, both respecting reductions of the dislocated humerus, and of such accidents in general. Desault only employed extension, variously diversified, till he had put the muscles in a state favourable for accomplishing reduction. The most prompt success constantly crowned this part of his practice, and, doubtless, much of this success must be imputed to his wisely refusing to interfere in too great a degree.

For the purpose of preventing the head of the bone from slipping out of its place again, the elbow should be kept some days quiet, and close to the side in a sling. After the reduction of a dislocation, which has happened downward, the facility of a fresh displacement is said to depend very much upon the extent to which the tendon of the subscapularis muscle has been lacerated. (*A. Cooper's Surgical Essays, Part 1, p. 7.*)

The French apply the bandage, which Desault recommended for the fractured clavicle.

OF SOME CIRCUMSTANCES, RENDERING THE REDUCTION DIFFICULT.

1. Narrowness of the opening in the Capsule.

While Desault considers this circumstance as one of the chief impediments to the return of the head of the humerus into the glenoid cavity, Pott and Mr. A. Cooper are of opinion, that the capsular ligament can never create any such difficulty. According to Desault, the obvious indication is to enlarge such an opening, by lacerating its edges. This is fulfilled by moving the bone about freely, in every direction, particularly in that in which the dislocation has taken place. Now, by pushing the head of the bone against the capsule already torn, the latter becomes lacerated still more, in consequence of being pressed between two hard bodies. The reduction, which is frequently impracticable before this proceeding, often spontaneously follows, immediately after it has been adopted. In the *Journal de Chirurgie* are two cases, by Anthaume and Faucheron, establishing this doctrine.

Mr. C. White, of Manchester, also believed, that the reduction was sometimes prevented by the head of the bone not being able to get through the laceration in the capsule again. He succeeded in reducing some cases which he supposed to be of this nature, in the following manner: having screwed an iron ring into a beam at the top of the patient's room, he fixed one end of the pulleys to it, and fastened the other to the dislocated arm by ligatures attached to the wrist, placing the arm in an erect position. In this way he drew up the patient, till his whole body was suspended; but, that too much force might not be sustained by the wrist, Mr. White at the same time

directed two other persons to support the arm above the elbow. He now used to try with his hands to conduct the arm into its place, if the reduction had not already happened, as was sometimes the case. Occasionally, a snap might be heard, as soon as the patient was drawn up; but, the reduction could not be completed, till he was let down again, and a trial made with the heel in the arm pit. When no iron ring was at hand, Mr. White used to have the patient raised from the ground by three or four men, who stood upon a table. (*Cases in Surgery, p. 95.*)

2. Oldness of the Dislocation.

This is a second impediment to reduction, still more difficult to surmount than the foregoing. The head of the bone, which has lodged a long while in its accidental situation, contracts adhesions to it. The surrounding cellular substance becomes condensed, and forms, as it were, a new capsule, which resists reduction, and which, when such reduction cannot be accomplished, supplies in a certain degree, the office of the original joint, by allowing a considerable degree of motion.

In such cases, the common advice is, that no attempt at reduction should be made, as it would be useless in regard to the dislocation, and might be injurious to the patient, from the excessive stretching of parts. This was for some time the doctrine of Desault; but, in his latter years, experience led him to be bolder.

Complete success, obtained in dislocations, which had existed from fifteen to twenty days, encouraged him to attempt reduction at the end of thirty, and thirty-five days, and, in the two years preceding his death, he succeeded, three or four times, in reducing dislocations which had existed two months and a half, and even three months, both when the head of the bone was situated at the lower, and at the internal part of the scapula.

However violent or protracted the extension may have been, none of the terrible consequences with which authors threaten us, ever occurred. One accident, which it was difficult to foresee, and of which we shall speak presently, only took place in two instances.

In these cases, it is necessary, before making the extension, to move the bone about extensively in all directions, for the purpose of first breaking its adhesions, lacerating the condensed cellular substance, which forms an accidental capsule, and of producing, as it were, a second dislocation, in order to remove the first. Extension is then to be made in the ordinary way, but with an additional number of assistants.

The first attempts frequently fail, and the dislocated head of the bone continues unmoved, notwithstanding the most violent efforts. In this case, after leaving off the extension, the arm is to be again moved about most extensively. The humerus is to be carried upward, downward, forward,

and backward. Force the resistances. Let the arm describe a large segment of a circle, in the place where it is situated. Let it be once more rotated on its axis; then let the extension be repeated, and directed in every way. Thus, the head of the bone will first be disengaged by the free motion, and afterward reduced.

In these cases, when the dislocation, in consequence of being very old, presents great obstacles to reduction, even though the attempts made for this purpose should fail, they are not entirely useless. By forcing the head of the bone to approach the glenoid cavity, and even placing it before the cavity, and making it form new adhesions, after the destruction of the old ones, the motions of the arm are rendered freer. Indeed, they are always the less obstructed, the nearer the head of the bone is to its natural situation. Notwithstanding the encouragement, given by Desault, to making attempts to reduce old dislocations of the humerus, experience proves, that when the bone has been out of its place more than a month, success is rarely obtained. And as for the danger which may arise from long protracted immoderate force, a case, which, I have elsewhere cited, proves, that caution is here a virtue, which cannot be too highly commended. (See *First Lines of Surgery*, Vol. 2, p. 465.)

3. Contractions of the Muscles.

A third impediment to the reduction of every kind of dislocation, is the power of the muscles, which is augmented beyond the natural degree, in consequence of their being on the stretch. Sometimes, this power is so considerable, that it renders the head of the bone immovable, though the most violent efforts are made. Here the means to be adopted are such as weaken the patient, bleeding, the warm bath, nauseating doses of tartarized antimony, as advised by Loder, Mr. A. Cooper, &c.; opium, &c. Should the patient happen to be intoxicated at the time of his being first seen by the surgeon, the opportunity would be very favourable to reduction, as the muscles would then be capable of less resistance. Extension unremittingly, but not violently, continued for a length of time, will ultimately fatigue the resisting muscles, and overcome them with more safety and efficacy, than could be accomplished by any sudden exertion of force. In all cases of difficulty, pulleys should be preferred.

The swelling about the joint, brought on by the accident, usually disappears without trouble.

Another consequence, which seldom occurs in practice, but which Desault saw twice, is a considerable emphysema, suddenly originating at the time of reduction. In the middle of such violent extension, as the long standing of the dislocation requires, a tumour suddenly makes its appearance under the great pectoral muscle. Rapidly increasing, it spreads towards the armpit, the whole extent of which it soon occupies. It

reaches backward, and, in a few minutes, sometimes becomes as large as a child's head. A practitioner, unacquainted with this accident, might take it for an aneurism, occasioned by the sudden rupture of the axillary artery, by the violent extension. But, if attention be paid to the elasticity of the tumour, its fluctuation, the situation where it first appears, commonly under the great pectoral muscle, and not in the axilla; the continuance of the pulse; and the unchanged colour of the skin; the case may easily be discriminated from a rupture of the artery. (*Œuvres Chir. de Desault, par Bichat, T. 1.*)

For dispersing the above kind of swelling, the lotio plumbi acetatis, and gentle compression with a bandage, are recommended.

I shall conclude the subject of luxations of the shoulder with the following singular observation, recorded by Baron Larrey.

"Among the curious anatomical preparations, (says he) which I saw in the cabinet of the University of Vienna, there was a dissected thorax, shown to me by Professor Prokaska, in which the whole orbicular mass of the head of the right humerus, engaged between the second and third true ribs, projected into the cavity of the chest. This singular displacement was the result of an accidental luxation occasioned by a fall on the elbow, while the arm was extended and lifted from the side. The head of the humerus, after tearing the capsular ligament, had been violently driven into the hollow of the axilla, under the pectoral muscles, so as to separate the two corresponding ribs, and pass between them. The diameter of the head of the bone surmounted this obstacle, and penetrated entirely into the cavity of the thorax, pushing before it the adjacent portion of the pleura. Every possible effort was made in vain to reduce this extraordinary dislocation. The urgent symptoms, which arose, were dissipated by bleeding, warm bathing, and antiphlogistic remedies. The arm, however, remained at a distance from the side, to which condition, the patient became gradually habituated, and, after several years of suffering and oppression, he at length experienced no inconvenience. The patient was about sixteen or seventeen, when he met with the accident; and he lived to the age of thirty-one, when he died of some disease, which had no concern with the dislocation. His physicians were anxious to ascertain the nature of this curious case, of which they had been able to form only an imperfect judgment. They were much surprised to find, upon opening the body, the head of the humerus lodged in the chest, surrounded by the pleura, and its neck closely embraced by the two ribs above specified. They were still more astonished to find, instead of a hard spherical body covered with cartilage, only a very soft membranous ball, which yielded to the slightest pressure of the finger. The cartilage and osseous texture of the whole portion of the humerus, contained within the cavity of the chest, had entirely disappeared. *Les absorbans s'en étaient emparés* (says M. Larrey.)

et comme autant de généraux fidèles, ils avaient cherché à détruire par portions, n'ayant pu l'expulser en masse, un ennemi qui s'était furtivement introduit dans un domicile où sa présence devait être importune et nuisible. Of the humerus, there only remained some membranous rudiments of its head, and a great part of these seemed to belong to the pleura costalis. (See *Larrey's Mémoires de Chirurgie Militaire*, Tom. 2, p. 405—407.

DISLOCATIONS OF THE FORE-ARM FROM THE HUMERUS.

Notwithstanding the extent of the articular surfaces of the radius and ulna, the strength of the muscles and ligaments surrounding the joint, and the mutual reception of the bony eminences, rendering the articulation a perfect angular ginglymus, a dislocation of both the radius and ulna off the humerus, is an accident for which a surgeon is sometimes consulted. The radius and ulna are most frequently luxated backward; sometimes laterally, but very rarely forward: the latter luxation cannot occur without a fracture of the olecranon. Indeed, it is so uncommon, that neither Petit nor Desault ever met with it. The luxation backwards is facilitated by the small size of the coronoid process, which may slide behind the humerus, when this is forcibly pushed downwards and forwards, and ascend as high as the cavity, which receives the olecranon in the extended state of the forearm.

Lateral luxations are much less frequent, and are always incomplete. The great extent of the articular surfaces in the transverse direction, the reciprocal adaptation of their inequalities, and especially the strength of the ligaments and muscles, which, arising from the internal and external condyles of the inferior extremity of the humerus, go to the fore-arm and hand, give great strength to the articulation, and render it nearly impossible for any violence to produce a complete lateral luxation, which also, if it were to occur, would be attended with such mischief to the soft parts, as would require immediate amputation.

In the luxation backwards, the radius and ulna may ascend more or less behind the humerus; but the coronoid process of the ulna is always carried above the articular pulley, and is found lodged in the cavity destined to receive the olecranon. The head of the radius is placed behind and above the external condyle of the humerus. The annular ligament, which confines the superior extremity of the radius to the ulna, may be lacerated: in which case, even when the bones are reduced, it is difficult to keep them in their proper places, as the radius tends constantly to quit the ulna.

This accident always takes place from a fall on the hand; for, when we are falling, we are led by a mechanical instinct to bring our hands forwards to protect the body. If in this case the superior extremity, instead of resting vertically on the ground, be placed

obliquely with the hand nearly in a state of supination, the repulsion which it receives from the ground will cause the two bones of the fore-arm to ascend behind the humerus, whilst the weight of the body pressing on the humerus, directed obliquely downwards, forces its extremity to pass down before the coronoid process of the ulna.

The fore-arm is in a state of half flexion, and every attempt to extend it produces acute pain. The situation of the olecranon, with respect to the condyles of the humerus, is changed. The olecranon, which, in the natural state, is placed on a level with the external condyle, which is itself situated lower than the internal, is even higher than the latter.

The case may be mistaken for a fracture of the olecranon, of the head of the radius, or even of the inferior extremity of the humerus. Such a mistake is attended with very bad consequences; for, if the reduction be not effected before the end of fifteen or twenty days, the reduction afterward is frequently impossible. The swelling which supervenes in twenty-four hours after the accident, renders the diagnosis more difficult; but, notwithstanding the assertion of Boyer, I believe the olecranon and internal condyle, are never so obscured, that the distance between them cannot be felt to be increased. It is true, that the rubbing of the coronoid process and olecranon against the humerus, may cause a grating noise, similar to that of a fracture; and some attention is certainly requisite to establish a diagnosis between a fracture of the head of the radius, and a dislocation of the fore-arm backwards.

As Boyer observes, when we consider the extent of the articular surfaces, and the great distance which they must be thrown ere they cease to be in contact, it is evident that a luxation backward must be attended with serious injury of the surrounding soft parts. The lateral ligaments are also constantly ruptured, and sometimes the annular ligament of the radius. Probably the lower insertions of the biceps and brachialis internus would likewise be more frequently lacerated, by the violent protrusion of the head of humerus forwards, were it not, that their attachments are at some distance from the joint. This mischief, however, occasionally takes place, and then the fore-arm is observed to be readily placed in any position, and not to retain one attitude, as is generally the case in dislocations. The lower end of the humerus, indeed, has been known not only to lacerate these muscles, but to burst the integuments, and present itself externally; an instance of which is recorded by Petit, and two such cases I saw myself during my apprenticeship at St. Bartholomew's. Boyer justly remarks, that it is difficult to conceive how, under these circumstances, the brachial artery and median nerve can escape. In fact, this vessel has sometimes been ruptured, and mortification of the limb been the consequence; but, this injury of the artery, and the laceration of the muscles and skin are rare occurrences. (*Traité des Mal. Chir.*

T. 4, p. 215.) Nor, if the artery were wounded, would gangrene be invariably the result; for, if my memory is correct, an instance in which the limb was saved, notwithstanding such a complication, is mentioned by Mr. Abernethy in his lectures, though, no doubt the risk would be great.

The following method of reducing the case, is advised by Boyer:—The patient being firmly seated, an assistant to take hold of the middle part of the humerus, and make counter-extension, while another assistant makes extension at the inferior part of the fore-arm. The surgeon, seated on the outside, grasps the elbow with his two hands, by applying the fore-fingers of each to the anterior part of the humerus, and the thumbs to the posterior, with which he presses on the olecranon, in a direction downwards and forwards. This method will in general be successful. If the strength of the patient, or the long continuance of the luxation, render it necessary to employ a greater force, extension is to be made with a towel applied on the wrist, and a cushion is to be placed in the axilla, and the arm and trunk fixed, as is done in cases of luxation of the humerus.

A bandage may afterwards be applied, in the form of a figure of 8, and the arm kept in a sling. The laceration, which always takes place, is invariably followed by more or less swelling, which is to be combated by antiphlogistic means.

At the end of seven or eight days, when the inflammatory symptoms are nearly gone, the articulation is to be gently moved, and the motion is to be increased every day, in order to prevent an anchylosis, to which there is a great tendency.

In this luxation, the annular ligament which confines the head of the radius to the extremity of the ulna, is sometimes torn, and the radius passes before the ulna. In such cases pronation and supination are difficult and painful, though the principal luxation has been reduced. The head of the radius may be easily replaced by pressing it from before backwards, and it is to be kept in its place by a compress, applied to the superior and external part of the fore-arm. The bandage and compress are to be taken off every two or three days, and reapplied. This is advisable, on account of the necessity of moving the articulation to prevent anchylosis.

If the luxation be not soon reduced, it becomes irreducible; the heads of the radius and ulna grow to the backpart of the humerus, and the patient can neither bend nor extend his arm. However, in certain cases, especially in young persons, some motion is in time acquired; the heads of the radius and ulna forming for themselves cavities in the humerus, in which they perform some motions, but always imperfectly.

In a modern publication, an instance of a dislocation of the heads of the radius and ulna backward is related, where the lower end of the humerus protruded through the integuments, and as it could not be reduced,

it was sawn off. The patient, a boy, recovered the full use of his arm. (*Evans, Pract. Obs. on Cataract; Compound Dislocations, &c. p. 101, Wellington, 1815.*)

A luxation forwards should be treated as a fracture of the olecranon, with which it would be inevitably accompanied. Here, on account of the great injury done to the soft parts, it would also be right to bleed the patient copiously, and put him on the antiphlogistic regimen.

As to lateral luxations, either inwards or outwards, they are always incomplete, and easily discovered. They are reduced by extending the humerus and fore-arm, and at the same time pushing the extremity of the humerus, and the two bones of the fore-arm in opposite directions.

These luxations cannot be produced without considerable violence; but when the bones are reduced, they are easily kept in their place. It will be sufficient to pass a roller round the part, to put the fore-arm in a middle state, neither much bent nor extended, and to support it in a sling. But much inflammation is to be expected from the injury done to the soft parts. In order to prevent, or at least mitigate it, the patient is to be bled two or three times, and put on a low diet, and the articulation is to be covered with the lotio plumbi acet. or an emollient poultice. It is scarcely necessary to repeat, that the arm is to be moved as soon as the state of the soft parts will admit of it. (*Boyer, sur les Maladies des Os, T. 2.*)

A dislocation of the fore-arm backward, is said to occur ten times as frequently as lateral luxations; and those forward are so rare, that no comparison whatever can be drawn. (*Œuvres Chir. de Desault, T. 1.*)

An incomplete lateral luxation may be produced by a blow, which drives the upper part of the fore-arm violently outward, or inward. A footman, says Petit, in falling from a coach, had his arm entangled in the spokes of a wheel, and a dislocation outward was the consequence. Another man luxated his fore-arm inward, by falling from his horse and driving his arm against an uneven place.

When the ulna is pushed into the situation of the radius, the space between the olecranon and internal condyle is much greater than natural, and the radius cannot be easily rotated, nor the fore-arm bent and extended, in a perfect manner.

The dislocation inward must be uncommon, as the form of the bones is almost an insurmountable obstacle to such an accident. It may happen, however, as the authority of Petit confirms.

All recent dislocations of the elbow are easily reduced, and as easily maintained so; for a displacement is prevented by the reciprocal manner in which the articular surfaces receive each other, and by their mutual eminences and cavities. This consideration, however, should not lead us to omit the application of a bandage in the form of a figure 8, and supporting the arm in a sling.

DISLOCATION OF THE RADIUS FROM THE ULNA.

The majority of authors, who have written on dislocations of the fore-arm, have not separately considered those of the radius. Some detached observations, on luxations of its superior extremity, are to be found here and there; a subject, which was first well treated of by Duverney. But, dislocations of its lower end, which are more frequent, remained unnoticed, until Desault favoured the profession with a particular account of them.

The radius, the moveable agent of pronation and supination, rolls round the ulna, which forms its immoveable support, by means of two articular surfaces; one above, slightly convex, broad internally, narrow outwardly, and corresponding to the little sigmoid cavity of the ulna, in which it is lodged; the other below, concave, semi-circular, and adapted to receive the convex edge of the ulna. Hence, there are two joints, differing in their motions, articular surfaces, and ligaments.

Above, the radius, in pronation and supination, only moves on its own axis; below, it rolls round the axis of the ulna. Here, being more distant from the centre, its motions must be both more extensive and powerful, than they are above. The head of the radius, turning on its own axis in the annular ligament, cannot distend it in any direction. On the contrary, below the radius, in performing pronation, stretches the posterior part of the capsule, and presses it against the immoveable head of the ulna, which is apt to be pushed through, if the motion be forced. A similar event, in a contrary direction, takes place in supination. The front part of the capsule, being rendered tense, may now be lacerated.

Add to this disposition, the difference of strength between the ligaments of the two joints. Delicate and yielding below; thick and firm above; their difference is very great. The upper head of the radius, supported on the smaller immoveable articular surface of the ulna, is protected from dislocation in most of its motions. On the contrary, its lower end, carrying along with it, in its motions, the bones of the carpus, which it supports, cannot itself derive any solid stability from them.

From what has been said, the following conclusions may be drawn: 1. That with more causes of luxation, the lower articulation of the radius has less means of resistance; and that under the triple consideration of motions, ligaments tying the articular surfaces together, and the relations of these surfaces to each other, this joint must be very subject to dislocation. 2. That, for opposite reasons, the upper joint must rarely, or according to Desault, never be exposed to such an accident. This author here excludes from consideration, cases in which the annular ligament of the radius is lacerated in a luxation of both heads of the radi-

us and ulna backwards; an accident, the reality of which is admitted. But, Desault particularly confines his doubts to a dislocation of the upper head of the radius from the lesser sigmoid cavity of the ulna, as a single and uncomplicated injury, suddenly produced by an external cause, and, therefore, neither to be confounded with the cases above specified, nor with other examples, in which the displacement happens slowly, especially in children, in consequence of a diseased or relaxed state of the ligaments.

Notwithstanding the opinion of Desault, some instances of dislocation of the upper head of the radius, suddenly produced by external causes, are recorded by Duverney; the particulars of another case were transmitted to the French Academy of Surgery; and I have lately been informed of four examples, which have been met with in this country.

Two of these cases occurred in the practice of Mr. Dunn, of Scarborough; one in that of Mr. Lawrence; and the other was attended by Mr. Earle. Baron Boyer says, that many instances are now known, in which the upper head of the radius has been dislocated backwards; indeed, in opposition to what Desault has stated, he asserts, that dislocations of the lower joint between the radius and ulna are more rare, than those of the upper joint between the same bones. The latter accident he has twice seen himself, but he believes that no authentic case of a dislocation forwards is yet upon record. (*Mal. Chir. T. 4, p. 248.*)

The displacement backwards is described by this author, as occurring more readily and frequently in children, than in adults, or old subjects. The reason of this circumstance is ascribed to the lesser firmness both of the ligaments, and of the tendinous fibres of the exterior muscles, which fibres, in a more advanced age, contribute greatly to strengthen the external lateral ligament. In a child, also, the little sigmoid cavity of the ulna is smaller, and the annular ligament, extending further round the head of the radius, is longer, and more apt to give way. Hence, in a subject of this description, efforts, which may not at first produce a dislocation, if frequently repeated, cause a gradual elongation of the ligaments, a change in the natural position of the bones, and, at length, a degree of displacement as great as in a case of luxation, suddenly and immediately effected. (*Traité des Mal. Chir. T. 4, p. 239.*)

Another fact, mentioned by Boyer, is, that the dislocation of the upper head of the radius backwards is always complete, its articular surfaces being perfectly separated both from the lower end of the humerus, and from the little sigmoid cavity of the ulna. The usual cause of the accident is a pronation of the fore-arm, carried with great violence beyond the natural limits.

In a dislocation of the head of the radius backwards, the fore-arm is bent, and the hand fixed in the state of pronation. Supi-

nation can neither be performed by the action of the muscles, nor by external force; and every attempt to execute this movement produces a considerable increase of pain. The hand and fingers are moderately bent, and the upper head of the radius may be observed forming a considerable projection behind the lesser head of the humerus. In the case, which was mentioned to me by my friend Mr. Lawrence, the head of the radius lay upon the outside of the external condyle.

The reduction is to be accomplished by extending the fore-arm, and endeavouring to bring it into the supine posture, at the same time, that the surgeon tries to press with his thumb the head of the radius forwards, towards the lesser tubercle of the humerus, and into the little sigmoid cavity of the ulna again. Success is indicated by the patient being now able to perform the supine motion of the hand, and to bend and extend the elbow with freedom.

For the purpose of preventing a return of the displacement, and giving nature an opportunity of repairing the torn ligaments, measures must be taken to hinder the pronation of the hand. Boyer recommends with this view a roller, compresses, and a sling; but, it appears to me, that a splint, extending nearly to the extremity of the fingers, and laid along the inside of the fore-arm, with a pad of sufficient thickness to keep the hand duly supine, would be right, in addition to the sling, roller, &c.

DISLOCATION OF THE LOWER END OF THE RADIUS.

The causes are, 1. Violent action of the pronator and supinator muscles. Thus, Desault has published the case of a laundress, who dislocated the lower end of the ulna backwards from the radius, by a powerful pronation of her hand in twisting a wet sheet. (*Boyer, Traité des Mal. Chir. T. 4, p. 249.*)

2. External force, moving the radius violently into a state of pronation, and rupturing the back part of the capsule; or into a state of supination, and breaking its fore-part.

Hence, there are two kinds of dislocation; one of the radius forward; the other, backward. The first is very frequent; the second is much less so. The latter case never presented itself to Desault, but once, in the dead body of a man, who had both his arms dislocated, and of whose accident no particulars could be learnt. The head of the ulna was found placed in front of the sigmoid cavity of the radius, and in contact with the os pisiforme, to which it was connected by a capsular ligament. (*Boyer, Traité des Mal. Chir. T. 4, p. 249.*)

The other case in which the ulna was thrown backwards, occurred very often. Doubtless, this difference is owing to all the principal motions of the radius being in the prone direction.

This observation is confirmed by the fact,

that the lower joint of the radius, in the dead subject, may be dislocated as easily by a supine, as a prone motion of this bone.

The symptoms of a luxation of the lower end of the radius from the ulna forward are; constant pronation of the fore-arm; an inability to perform supination, and great pain on this being attempted; an unusual projection at the back of the joint, in consequence of the protrusion of the little head of the ulna through the capsule; the position of the radius is more forward, than natural; constant adduction of the thumb, which is almost always extended; a half-bent state of the fore-arm, and very often of the fingers, which posture cannot be changed, without considerable pain. More or less swelling around the joint. This sometimes comes on immediately, but always afterward, if the reduction remain unaccomplished. The condition of the joint may thus be obscured, and the accident mistaken for a sprain. The serious consequence of this mistake is, that no attempt at reduction is made, and the articular surfaces having time to contract adhesions, the disorder is rendered irremediable, and the prone and supine movements of the hand, are for ever lost, and the action of the fingers seriously impaired.

A luxation of the radius backward is characterized by symptoms the reverse of those above mentioned. They are a violent supination of the limb; inability to put it prone; pain on making the attempt; a tumour in front of the fore-arm formed by the head of the ulna; a projection backward of the large head of the radius; and abduction of the thumb.

When the dislocation is forward, an assistant is to take hold of the elbow, and raise the arm a little from the body; while another is to support the hand and fingers.

The surgeon is to take hold of the end of the fore-arm with both his hands; one applied to the inside, the other to the outside, in such a manner, that the two thumbs meet each other in front of the limb, between the ulna and radius, while the fingers are applied to the back of the wrist. He is then to endeavour to separate the two bones from each other, pushing the radius backward, and outward, while the ulna is held in its proper place. At the same time, the assistant, holding the hand, should try to bring it into a state of supination, and consequently the radius, which is its support. Thus pushed, in the direction opposite that of the dislocation, by two powers, the radius is moved outward, and the ulna returns into the opening of the capsule, and into the sigmoid cavity.

If chance should present a dislocation of the lower head of the radius backward, or in other words, of the lower head of the ulna forwards, the same kind of proceeding, executed in the opposite direction, would serve to accomplish the reduction. (*See Œuvres Chir. de Desault, T. 1.*) The history of such a case is recorded by Boyer. (*Mal. Chir. T. 4, p. 253.*)

DISLOCATIONS OF THE WRIST.

The carpal bones may be luxated from the lower ends of the radius and ulna forwards, backwards, inwards, or outwards. The first two cases, especially that backwards, are the most frequent. The dislocation backwards is rendered easy by the direction of the convex articular surfaces of the scaphoid, lunar, and cuneiform bones, which sloping more backwards than forwards, must make them more disposed to slip in this direction, than any other. The accident may be caused by a fall on the back of the hand, while much bent; in which event the first row of the carpal bones slide backwards into the oblong cavity of the radius, lacerate the posterior ligament, and form an eminence behind the lower ends of the bones of the fore-arm. This prominence, the depression in front of the wrist, and the extraordinary flexion of the hand, which cannot be extended, are the characteristic signs of this kind of dislocation. The dislocation forwards generally arises from a fall on the palm, the fingers being extended, and more force operating on the lower than upper part of the palm. The luxation is sometimes not complete; and the hand remains painfully extended. As many tendons run before the wrist, and the annular ligament is pushed forward, the prominence formed by the carpal bones, in front of the ends of the radius and ulna, is not easily detected, and the case may be mistaken for a sprain.

Dislocations inwards, or outwards, are never complete. The projection of the carpal bones at the inner or outer side of the joint, and the distortion of the hand, make such cases sufficiently evident.

Recent dislocations of the wrist, particularly such as are incomplete, are easy of reduction; but when the displacement has been suffered to continue some time, more difficulty is experienced, and in a few days, all attempts are generally unavailing. This observation applies to all dislocations of ginglymoid joints; and I cannot, therefore, too strongly condemn the waste of time in trials to disperse the swelling of the soft parts, ere the bones are replaced; an absurd plan, which I am sorry to say, is sanctioned by Boyer. (*Mal. Chir. T. 4, p. 260.*)

For the purpose of reducing the dislocated bones, gentle extension must be made, while the two surfaces of the joint are made to slide on each other in a direction contrary to what they took when the accident occurred.

In dislocations of the wrist, numerous tendons are always seriously sprained, and many ligaments lacerated; consequently a good deal of swelling generally follows, and the patient is a long time in regaining the perfect use of the joint. Hence, the propriety of bleeding, low diet, and opening, cooling medicines; while the hand and wrist should be continually covered with linen wet with the *lotio plumbi acetatis*, and the fore-arm

and hand kept in splints, which ought to extend to the end of the fingers, so as to prevent a return of the displacement. The limb must also remain quiet in a sling.

When the ruptured ligaments have united, liniments will tend to dispel the remaining stiffness and weakness of the joint.

Sometimes the lower head of the radius is driven through the skin at the inside of the wrist, between the radial artery, and the mass formed of the flexor tendons of the wrist and fingers. Cases of this description, when well managed, generally have a favourable termination, as we see in the case reported by M. Thomassin. (*Journ. de Med. T. 39.*)

If the smallness of the opening in the skin cause an impediment to reduction, the integuments should be divided with a knife.

DISLOCATIONS OF THE CARPUS, METACARPUS, FINGERS AND THUMB.

A dislocation of the carpal bones from each other seems almost impossible. The os magnum, however, has been known to be partially luxated from the deep cavity formed for it in the os scaphoides and os lunare. This displacement is produced by too great a flexion of the bones of the first phalanx on those of the second, and the os magnum forms a tumour on the back of the hand. (*Chopart; Boyer; Richerand.*)

Chopart once met with a partial luxation of the os magnum in a butcher. Baron Boyer has seen several examples of the accident, which, he says, is more common in women than men; a circumstance, which he imputes to the ligaments being looser in females, and to the bones of the carpus in them having naturally a greater degree of motion. The tumour increases, when the hand is bent, and diminishes, when it is extended. The case does not produce any serious inconvenience. If the wrist be extended, and pressure be made on the head of the os magnum, the reduction is easily accomplished; though a renewal of the displacement cannot be prevented, unless the extension and compression be kept up by means of a suitable apparatus, during the whole time, requisite for the healing of the torn ligaments. As the inconveniences of the accident are slight, few patients will submit to any tedious, irksome treatment; and sometimes the surgeon is never consulted, till it is too late to think of replacing the bone. In general, therefore, the surgeon is obliged to be content with treating the case as a sprain, or contusion.

The connexion of the metacarpal bones with one another, and with those of the carpus, is so close, and the degree of motion so slight, that a dislocation can hardly take place. The first metacarpal bone, which is articulated with the os trapezium, and admits of the movements of flexion, extension, abduction, and adduction, is capable of being luxated; but the accident is uncommon for reasons explained in my other work.

Although from the nature of the joint, between the first metacarpal bone and the trapezium, one might infer, that a dislocation is possible in the four directions, backwards, forwards, inwards, and outwards, yet, if we are to believe Boyer, the first case is the only one which has been observed. The accident is produced by the application of external force to the back of the metacarpal bone, which is suddenly and violently thrown into a state of flexion, the case usually arising from a fall on the outer edge of the hand. In this circumstance, the upper head of the bone is forcibly driven backwards, the capsular ligament is lacerated, the extensor tendons of the thumb are pushed up, and the head of the bone slips behind the trapezium.

For an account of the symptoms and treatment of this accident, I must refer to the 4th Ed. of the *First Lines of the Practice of Surgery*, Vol. 2, p. 469.

The first phalanges of the fingers may be dislocated backwards off the heads of the metacarpal bones. A luxation forwards would be very difficult, if not impossible, because the articular surfaces of the metacarpal bones extend a good way forwards, and the palm of the hand makes resistance to such an accident. The first phalanx of the thumb, in particular, is often dislocated backwards, behind the head of the first metacarpal bone, in which case it remains extended, while the second phalanx is bent.

These dislocations should be speedily reduced; for, after eight or ten days, they become irreducible. In a luxation of the first bone of the thumb, which was too old to be easily reduced, and where the part was thrown behind the head of the metacarpal bone, Desault proposed cutting down to the dislocation, and pushing the head of the bone into its place with a spatula. Even in cases, which are quite recent, this kind of dislocation frequently cannot be reduced without the utmost difficulty; and the different proposals which have been made, respecting this particular accident, by Mr. Evans, the late Mr. Hey, Mr. C. Bell, and Boyer, are highly deserving the notice of the surgical practitioner, who will find them explained in my other work. Dislocations of the thumb and little finger inwards, and that of the thumb outwards, (which are possible cases) and luxations of the first phalanges of the other fingers backwards, are all reduced by making extension on the lower end of the affected thumb, or finger, and at the same time pressing the head of the bone towards its natural situation.

After the reduction, the thumb, or finger, affected, should be rolled with tape, and surrounded and supported with pasteboard, till the lacerated ligaments have united; care being taken to keep the hand and forearm quiet in a sling. The luxation of the first phalanx of the thumb, behind the metacarpal bone, requires peculiar treatment, as I have elsewhere explained.

DISLOCATIONS OF THE BONES OF THE PELVIS.

Experience proves, that the bones of the pelvis, notwithstanding the vast strength of their ligaments, may be dislocated by violence; thus, the os sacrum may be driven forwards towards the interior of the pelvis; the ossa ilium may be displaced forwards and upwards; and the bones of the pubes may be totally separated at the symphysis, and an evident degree of moveableness occur between them. For the production of these accidents the operation of enormous force is requisite; and, in fact, their usual causes are falls from a great height; the fall of a very heavy body against the sacrum, at a period when the body is fixed; and the pressure of the pelvis, between a wall, or post, and the wheel of a carriage, or wagon. Hence, the dislocation is generally the least part of the mischief occasioned by such kinds of violence, and the case is commonly attended with concussion of the spinal marrow, injury of the sacral nerves, extravasation of blood in the cellular substance of the pelvis, or cavity of the peritoneum, injury of the kidneys, and fracture of one, or more, of the bones of the pelvis. As Mr. A. Cooper has remarked, some of these cases, complicated with fracture, are liable to be mistaken for dislocations of the thigh: When, says this gentleman, a fracture of the os innominatum happens through the acetabulum, the head of the femur is drawn upwards, and the trochanter somewhat forwards, so that the leg is shortened, and the knee and foot are turned inwards. Such a case, therefore, may be readily mistaken. If the os innominatum is disjoined from the sacrum, and the pubes and ischium are broken, the limb is slightly shorter than the other; but, the knee and foot are not turned inwards. These accidents may generally be detected by a crepitus perceived in the motion of the thigh, when the surgeon applies his hand to the crista of the ilium, and there is greater motion, than in a dislocation of the thigh. (*A. Cooper, Surgical Essays, Part 1, p. 49.*)

In addition to the complications which may attend a dislocation of the bones of the pelvis, and arise immediately from the external violence, the case is always followed by inflammation, which may be very serious, not only on account of the extent of the articular surfaces affected, but because such inflammation may extend to the peritoneum, and viscera of the abdomen and pelvis, as I have myself seen in two or three instances.

Lewis relates a case, in which the os ilium of the right side was found separated from the sacrum, so as to project nearly three inches behind it. This accident was caused by a heavy sack of wheat falling on a labourer. (*Mem. de l'Acad. de Chir. T. 4, 4to.*)

In a case, recorded by Mr. A. Cooper, the posterior part of the acetabulum was broken off, and the head of the thigh-bone had slipped from its socket; the fracture

extended across the innomatum to the pubes, the bones of which were separated at the symphysis nearly an inch asunder. The ilia were separated on each side, and the left os pubis, ischium, and ilium broken. (*Surgical Essays, Part. 1, p. 50.*) In the same work may also be perused another case of fracture of the body of the os pubis and ramus of the ischium, combined with a luxation of the right os innominatum from the sacrum, and laceration of the ligaments of the symphysis of the pubes.

When these cases do not prove fatal from the direct effect of the great violence committed on many parts, or from peritonitis, the same unpleasant event sometimes follows rather later from suppuration of the articular surfaces taking place, and abscesses forming in the cellular membrane of the pelvis. (*Boyer, Traité des Mal. Chir. T. 4, p. 147.*)

A case, in which a dislocation of the left os innominatum upwards had a successful termination, was attended by Enaux, Hoin, and Chaussier, and is published in a modern work. (*Mem. de l'Acad. des Sciences de Dijon.*) As the reduction could not be accomplished at first, antiphlogistic treatment was followed for some days, when new attempts to replace the bone were made, but could not be continued, as they caused a recurrence of pain and other bad symptoms. A third trial, made at a later period, was not more effectual; and all thoughts of reduction were then abandoned. After the patient had been kept quiet some time, though not so long as was wished, he quitted his bed, and began to walk about on crutches. I do not understand, however, as is asserted, how the weight of the body could now bring about the reduction, which had been previously attempted in vain. Be this as it may, the result was the patient's recovery. The fact clearly proves, as Boyer observes, that, in cases of this description, the most important object is not to aim at the reduction, but rather to oppose, by every means in our power, inflammation and its consequences. Frequently, the use of the catheter is necessary, and, sometimes an incontinence of urine, or the involuntary discharge of the feces, demands the strictest attention to cleanliness. In these cases, if the patient live any time, there is also another source of danger, consisting in a tendency to sloughing, in the soft parts, on which the patient lies, and which, when they have been bruised, require still greater vigilance.

The os coccygis is not so easily dislocated as fractured. Boyer, however, has seen it displaced in a man, who was greatly emaciated by disease. This subject had considerable ulcerations about the coccyx, and the bone itself was bare. There was an interspace of nearly two inches, between the sacrum and base of the os coccygis. In proportion as the man regained his strength, the bone recovered its right position, and, at length united to the os sacrum, notwithstanding the action of the levatores ani,

which are inserted into it. (*Boyer.*) This case, however, was not an accidental luxation; and it clearly arose from the destruction of the ligaments by disease.

Authors mention two kinds of dislocation, to which the os coccygis is liable; one, inward; the other, outward. The first is always occasioned by external violence; the second, by the pressure of the child's head in difficult labours. Pain, difficulty of voiding the feces and urine, tenesmus, and inflammation, sometimes ending in abscesses, which interest the rectum, are symptoms said to attend and follow dislocations of the os coccygis.

The best authors now regard all schemes for the reduction useless, as the bone will spontaneously return into its place as soon as the cause of displacement ceases; and the introduction of the finger within the rectum, and handling of the painful and injured parts, are more likely to increase the subsequent inflammation, and produce abscesses, than have any beneficial effect. In short, the wisest plan is to be content with enjoining quietude, and adopting antiphlogistic measures.

DISLOCATION OF THE RIBS.

J. L. Petit was silent on this subject, as he thought such cases never occurred. Since his death, a French surgeon, Buttel, has related an instance, which he supposed to be a dislocation of the posterior extremity of the rib from the vertebræ; but Boyer clearly proves, that there were no true reasons for this opinion, and that the case was only a fracture of the neck, or end of the bone, near the spine. (*Traité de Mal. Chir. T. 4, p. 123.*)

Ambrose Paré, Barbette, Juncker, Platner, and Heister, not only admit the occurrence of luxations of the ribs, but describe different species of them. Lieutaud also extended the term luxations to cases, in which the head of the rib is separated by disease, the pressure of aneurisms, &c.

In a modern work may be read the particulars of a case, where all the ribs are said to have been dislocated from their cartilages. The accident arose from the chest being violently compressed between the beam of a mill and the wall. In such a case, there is no means of reduction, except the effect produced by forcible inspirations; nor are there any modes of relief, but bleeding, and the application of a roller round the chest. (*See C. Bell's Surg. Obs. p. 171.*)

DISLOCATIONS OF THE THIGH-BONE.

The head of the thigh-bone may be dislocated upwards on the dorsum of the ilium; upwards and forwards on the body of the os pubis; downwards and forwards on the foramen ovale; and backwards on the ischiatic notch.

The dislocation upwards and backwards, and that downwards and forwards, are the most frequent.

The common kind of dislocation of the thigh-bone upwards, or the dorsum of the ilium, is attended with the following symptoms. The thigh is shorter than its fellow, a little bent, and carried inwards. The knee inclines more forwards and inwards than the opposite one; the leg and thigh are turned inwards, and the foot points in this direction: the toe resting, as Mr. A. Cooper remarks, against the tarsus of the other foot. (*Surgical Essays. Part. 4, p. 27.*) There is an approximation of the trochanter major to the anterior superior spinous process of the ilium, and at the same time it is elevated and carried a little forwards. It is also less prominent, than that on the opposite side, and the natural roundness of the hip has disappeared. The natural length of the limb cannot be restored, without reducing the luxation: the foot, cannot be turned outwards, and any attempt to do so causes pain; but, the inclination of the foot inwards may be increased. (*Boyer.*)

When an attempt is made to draw the leg away from the other, it cannot be accomplished; but the thigh may be slightly bent across its fellow.

A dislocation on the dorsum of the ilium is generally at once readily discriminated from a fracture of the neck of the thigh-bone, within the capsular ligament, by the rotation of the limb inwards; a position, which is unusual in a fracture of any part of the os femoris. "In a fracture of the neck of the thigh-bone (says Mr. A. Cooper) the knee and foot are generally turned outwards; the trochanter is drawn backwards: the limb can be readily bent towards the abdomen, although with some pain; but, above all, the limb, which is shortened from one to two inches by the contraction of the muscles, can be made of the length of the other by a slight extension, and when the extension is abandoned, the leg is again shortened. If, when extended, the limb is rotated, a crepitus can often be felt, which ceases when rotation is performed under a shortened state of the limb. * The fractured neck of the thigh bone, within the capsular ligament, rarely occurs but in advanced age, and it is the effect of the most trifling accidents, owing to the absorption, which this part of the bone undergoes at advanced periods of life. Fractures external to the capsular ligament occur at any age; but, generally in the middle periods of life; and these are easily distinguished by the crepitus, which attends them, if the limb is rotated, and the trochanter is compressed with the hand. The position is the same as in fractures within the ligament. The proportion of fractures of the neck of the thigh-bone, which I have seen, is at least four cases to one of dislocation." (*A. Cooper, Surg. Essays, Part 1, p. 28.*)

To reduce this dislocation, the patient should be placed on his opposite side upon a table firmly fixed, or a large four-posted bedstead. A sheet, folded longitudinally, is first to be placed under the perineum, and

one end being carried behind the patient, the other before him, they are to be fastened to one of the legs, or posts of the bed. Thus the pelvis will be fixed, so as to allow the necessary extension of the thigh-bone to be made. Great care must be taken during the extension to keep the scrotum and testicles, or the pudenda in women, from being hurt by the sheet passed under the perineum. The patient must be further fixed by the assistants.

The best practitioners of the present day in France, advise the extending force to be applied to the inferior part of the leg, in order to have it as far as possible from the parts, which resist the return of the head of the bone into its natural situation. In this country, surgeons generally prefer making the extension by means of a sheet, or the strap of a pulley, fastened round the limb just above the condyles of the os femoris. The direction in which Mr. A. Cooper makes the extension, is in the line made by the limb, when it is brought across the other thigh a little above the knee. As soon as the head of the bone has been brought on a level with the acetabulum by the assistants, who are making the extension, the surgeon is to force it into this cavity by pressing on the great trochanter; or by rotating the knee and foot gently outwards, as practised by Mr. A. Cooper.

The extension should always be made in a gradual and unremitting manner: at first, gently; but afterward more strongly; never violently. The difficulty of reduction arises from the great power and resistance of the muscles, especially the glutei and triceps, which will at length be fatigued, so as to yield to the extending force, if care be taken, that it be maintained the necessary time, without the least intermission. Sometimes, when there is difficulty in bringing the head of the bone over the lip of the acetabulum, Mr. A. Cooper raises it by placing his arm under it near the joint.

The disappearance of all the symptoms, and the noise made by the head of the bone, when it slips into the acetabulum, denote, that the reduction is effected. This noise, however, is not always made when pulleys are used. The bone is afterward to be kept from slipping out again, by tying the patient's thighs together with a bandage placed a little above the knees. The patient should be kept in bed at least three weeks; live low, and rub the joint with a camphorated liniment. Due time must be given for the lacerated ligaments to unite, and the sprained parts to recover; premature exercise may bring on irremediable disease in the joint.

Mr. Hey gives the following description of the way, in which he reduced a case of this kind.

"The extension of the limb must be made in a right line with the trunk of the body; and, during the extension, the head of the bone must be directed outwards as well as downwards. A rotatory motion of the os femoris on its own axis, towards the spine,

(the patient lying prone) seems likely to elevate the great trochanter, bring it nearer to its natural position, and direct the head of the bone towards the acetabulum. These circumstances led to the following method. A folded blanket was wrapped round one of the bed-posts, so that the patient, lying in a prone position, and astride of the bed-post, might have the affected limb on the outside of the bed. The bed was rendered immovable, by placing it against a small iron pillar, which had been fixed for the purpose of supporting the curtain rods. The leg was bent to a right angle with the thigh, and was supported in that position by Mr. Lucas, who, when the extension should be brought to a proper degree, was to give the thigh its rotatory motion, by pushing the leg inwards, that is, towards the other inferior extremity. Mr. Jones sat before the patient's knee, and was to assist in giving the rotatory motion, by pushing the knee outwards at the same moment. I sat by the side of the patient, to press the head of the bone downwards and outwards during the extension. Two long towels were wrapped round the thigh just above the condyles, one towel passing on the inside of the knee, the other on the outside. Three persons made the extension; but when we attempted to give the thigh its rotatory motion, we found it confined by the towel which passed on the inside of the knee and leg. We therefore placed both the towels on the outside; and in this position the extending force concurred in giving the rotatory motion. The first effort that was made, after the towels were thus placed, had the desired effect, and the head of the bone moved downwards and outwards into the acetabulum." (*Hey's Practical Observations*, p. 313.)

For the purpose of facilitating the reduction, many surgeons endeavour to produce a temporary faintness by a copious venesection, immediately before the extension is begun; a practice, which, when the patient's state of health does not forbid it, is advisable, as lessening very materially the resistance of the muscles. Mr. A. Cooper gives it his general approbation, as well as the warm bath, and nauseating doses of tartarized antimony. After taking away from twelve to twenty ounces of blood, this gentleman places the patient in a bath heated to 100 degrees, and gradually raised to 110 degrees, until a faintness is induced. While in the bath, the patient is also to take a grain of tartarized antimony every ten minutes, until nausea is excited, when he is to be removed from the bath, put in blankets, and placed between two strong posts, in each of which a staple is fixed, or he may be placed on the floor, into which two rings may be screwed. The manner in which Mr. A. Cooper performs the reduction with pulleys, having been detailed in the 2d vol. of the *First Lines of Surgery*, I shall not here repeat it. In all cases of difficulty, the above-mentioned debilitating means, the intoxicating effect of a liberal dose of opium, and

the use of pulleys, for the reduction, appear to me to deserve commendation.

Luxations of the thigh bone, downwards and forwards upon the obturator foramen, are the next in frequency to those upon the dorsum of the ilium. The accident is facilitated by the great extent, to which the abduction of the thigh can be carried; by the notch at the inferior and internal part of the acetabulum; by the weakness of the orbicular ligament on this side; and by the ligamentum teres not opposing, nor being necessarily ruptured by it; that is to say, it is only broken, when the head of the femur has been carried with great violence, further from the acetabulum than common. The head of the bone is thrown between the obturator ligament, and obturator externus muscle.

The symptoms are as follows: the injured limb is longer than its fellow, the head of the femur being situated lower than the acetabulum; the trochanter major, which is less prominent than natural, is removed to a greater distance from the anterior superior spinous process of the ilium, and the thigh is flattened, in consequence of the elongation of the head of the muscles. A hard round tumour, formed by the femur, is felt at the inner and superior part of the thigh, towards the perineum. The leg is slightly bent; and the knee and foot, I believe, are generally turned outwards. However, according to Mr. A. Cooper's experience, the foot, though widely separated from the other, is generally turned neither outwards, nor inwards; but, he has seen a little variation in this respect, in different instances. Hence, he prefers as the diagnostic symptoms, the bent position of the body, the separated knees, and the increased length of the limb. (*Essays*, Part 1, p. 37.) The latter symptom alone is a sufficient indication of the accident not being a fracture.

Dislocations on the obturator foramen, are very easy of reduction. The pelvis having been fixed, the extension is to be made downwards and outwards, so as just to dislodge the head of the bone. The muscles then generally draw it into the acetabulum, on the extending force being gradually relaxed, if the upper part of the bone be pulled outward, with a bandage, and the ankle be at the same instant inclined inwards. Thus, the limb is used as a lever, with very considerable power.

Mr. Hey says, that "In this species of dislocation, (downwards and forwards,) as the head of the bone is situated lower, than the acetabulum, it is evident, that an extension made in a right line with the trunk of the body, must remove the head of the bone farther from its proper place, and thereby prevent, instead of assisting, reduction. The extension ought to be made with the thigh at a right angle, or inclined somewhat less than a right angle, to the trunk of the body. When the extension has removed the head of the bone from the external obturator muscle, which covers the great foramen of

the os innominatum, the upper part of the os femoris must then be pushed or drawn outwards; which motion will be greatly assisted by moving the lower part of the os femoris, at the same moment, in a contrary direction; and, by a rotatory motion of the bone upon its own axis, turning the head of the bone towards the acetabulum." (Hey, 316.)

The ensuing case illustrates Mr. Hey's practice.

"The lower bed-post, on the right side of the bed on which the patient lay, was placed in contact with a small immoveable iron pillar (about an inch square in thickness,) such as in our wards are used for supporting the curtain rods of the beds. A folded blanket being wrapped round the bed-post and pillar, the patient was placed astride of them, with his left thigh close to the post, and his right thigh on the outside of the bed. A large piece of flannel was put between the blanket and the scrotum, that the latter might not be hurt during the extension.

"The patient sat upright, with his abdomen in contact with the folded blanket which covered the bed-post. He supported himself by putting his arms round the post, and an assistant sat behind him to prevent him from receding backwards. He was also supported on each side.

"Two long towels were put round the lower part of the thigh, after the part had been well defended from excoriation by the application of a flannel roller. The knot which the towels form, was made upon the anterior part of the thigh, that the motion intended to be given to the leg might not be impeded by the towels.

"The thigh being placed in a horizontal position, or rather a little elevated, with the leg hanging down at right angles to the thigh, I sat down upon a chair, directly fronting the patient, and directed a gentle extension to be made by the assistants standing at my left side. This was done with the view of drawing the head of the bone a little nearer to the middle of the thigh, and the extension had this effect. I then placed the two assistants, who held the towels, at my right side, by which means the extension would be made in a direction a little inclined to the sound limb. Mr. Logan stood on the right side of the patient, with his hands placed on the upper and inner side of the thigh, for the purpose of drawing the head of the bone towards the acetabulum, when the extension should have removed it sufficiently from the place in which it now lay.

"I desired the assistants to make the extension slowly and gradually; and to give a signal when it arrived at its greatest degree. At that moment, Mr. Logan drew the upper part of the bone outwards, while I pushed the knee inwards, and also gave the os femoris a considerable rotatory motion, by pushing the right leg towards the left. By these combined motions, the head of the os femoris was directed upwards and outwards, or, in other words, directly towards the acetabulum,

into which it entered at our first attempt made in this manner.

"The scrotum, as the patient assured me, was not hurt in the least by the extension." (Hey, p. 318.)

The thigh-bone is sometimes luxated upwards and forwards on the pubes. The whole limb is turned outwards, and shortened by one inch; the trochanter major is nearer the anterior superior spinous process of the ilium than natural; the head of the bone forms a tumour in the groin above the level of Poupert's ligament, on the outer side of the femoral artery and vein; and, pressing on the anterior crural nerves, causes great pain, numbness, and even paralysis; and the knee is generally carried backwards.

In the account of the position of the limb, however, authors vary; and, in opposition to what Boyer has stated, Mr. A. Cooper remarks, that there is a slight flexion forwards and outwards. (*Surgical Essays, Part 1, p. 45.*)

The head of the bone felt in the groin, and the impossibility of rotating the limb inward distinguish this case from a fracture of the neck of the bone.

In reducing this dislocation, Mr. A. Cooper recommends the extension to be made in a line behind the axis of the body, so as to draw the thigh-bone backwards; and, when such extension has been continued some time, a napkin is to be put under the upper part of the bone, and its head lifted over the pubes and edge of the acetabulum.

The last dislocation of the thigh remaining to be spoken of, is that backwards.

In this case, according to the valuable description of it given by Mr. A. Cooper, the head of the thigh-bone is placed on the pyriformis muscle, between the edge of the bone which forms the upper part of the ischiatic notch and the sacrospinous ligament, being behind the acetabulum, and a little above the level of the middle of that cavity. The limb is generally not more than half an inch shorter than its fellow; and the knee and foot are turned inwards, but not nearly in so great a degree as in the dislocation on the dorsum of the ilium. The thigh inclines a little forward, the knee is slightly bent, and the limb is so fixed, that flexion and rotation are in a great measure prevented.

Mr. A. Cooper considers this dislocation as the most difficult, both to detect and reduce: difficult to detect, because the length of the limb, and the position of the knee and foot, are but little changed; difficult to reduce, because the head of the bone is placed deeply behind the acetabulum, and requires to be drawn over the edge of the socket, as well as towards it. In thin subjects, a hard tumour is felt at the posterior and inferior part of the buttock, and the great trochanter is removed further from the spine of the ilium.

The pelvis being fixed, the extension is to be made downwards and forwards, across the middle of the other thigh, so as to dislodge the head of the bone, while the sur-

geon, with a napkin, placed just below the trochanter minor, pulls the upper part of the femur towards the acetabulum. In this case, pulleys are preferable for making the extension.

DISLOCATIONS OF THE PATELLA.

This bone may be luxated outwards, or even inwards, when violently pushed in this direction. The luxation outwards is the most frequent, because the bone more easily slips in this direction off the outer condyle of the femur, than inwards. The assertion made by some authors, that the dislocation inwards is the most common, is quite erroneous, as I have elsewhere more particularly considered. (See *First Lines of Surgery*, Vol. 2.) In confirmation of what has been here observed, I may mention, however, the opinion of Mr. A. Cooper, who states, that the bone is most frequently thrown on the external condyle, where it produces a projection; and this circumstance, with an incapacity of bending the knee, is evidence of the nature of the injury (*Surgical Essays*, Part 1, p. 66.) The generality of cases are easily reduced by pressure, when the extensions of the leg have been completely relaxed; but, owing to a lax state of the ligament of the patella, or other predisposing causes, the bone is sometimes difficultly kept in its proper situation, unless a roller be applied. The inflammatory affection of the joint is to be opposed by bleeding, purging, and the use of the lotio plumbi subacetatis. The joint must be kept quiet a few days, and then gently moved in order to prevent stiffness.

DISLOCATIONS OF THE KNEE.

The tibia may be luxated forward, backward, or to either side; accidents, which may be complete, or incomplete. As Boyer observes, complete dislocations of the upper head of the tibia are exceedingly rare, because the articular surface of the condyles of the femur is so extensive, that the tibia cannot be entirely removed from it, without a prodigious laceration of the ligaments, tendons, and all the rest of the soft parts.

The condyles of the femur are disposed in such a manner, that, in the extreme flexion of the leg, the articular cavities of the upper head of the tibia are still in contact with those bony eminences; and this circumstance, together with the resistance made by the ligament of the patella, the patella itself, and the tendon of the extensor muscles of the leg, renders a sudden dislocation of the tibia backwards so difficult, that Boyer seems even to question the possibility of the accident, notwithstanding the case recited by Heister. (*Traité des Mal. Chir. T. 4, p. 366.*) That this accident, however, sometimes really happens, no longer admits of dispute: the case is noticed by Mr. A. Cooper as producing the following appearances; a shortened state of the limb; a projection of the condyles of the

os femoris; a depression in the situation of the ligament of the patella; and a bending of the leg forwards. This latter statement, I conceive, must be a mistake; and my suspicion is corroborated by Boyer, who declares, that, in the dislocation of the head of the tibia backwards, the leg is bent to a very acute angle, and cannot be extended again. (*Mal. Chir. T. 4, p. 369.*) It appears further, from the particulars of the example of this accident seen by Dr. Walshman, that the dislocation may even be complete, the head of the tibia being thrown behind the condyles of the femur into the ham. The tendinous connexion of the patella to the rectus muscle was ruptured; and, probably, without a laceration of that tendon, or of the ligament of the patella, such a degree of displacement could scarcely have happened (*Surgical Essays*, part 2, p. 74.)

But, if a sudden dislocation of the tibia from the femur backwards is uncommon, the same remark cannot be made respecting a displacement in that direction, gradually produced by the effects of disease. Several cases of the latter kind have fallen under my own observation.

A dislocation of the head of the tibia forwards, from the condyles of the femur, cannot happen without the greatest difficulty; for the accident must be attended with a laceration of the lateral, crucial, and oblique, or posterior ligaments, all which tend to prevent the leg from being too far extended; and, in addition to all this injury, Boyer, calculates, that the heads of the gastrocnemius, the popliteus, and the extensor tendons of the leg, would be immoderately stretched, and even torn. An example of this luxation was seen in Guy's hospital in 1802. According to Mr. A. Cooper, while the tibia projects forward the thigh-bone is depressed, and thrown somewhat laterally, as well as backwards. The os femoris makes such pressure on the popliteal artery, as to prevent the pulsation of the anterior tibial artery on the instep; and the patella and tibia are drawn forwards by the rectus muscle. (*Surgical Essays*, part 2, p. 73.)

Dislocations inwards or outwards, though more frequent than the foregoing cases, are still to be considered as rare, and are always incomplete. In the dislocation inwards, the condyle of the os femoris is thrown upon the external semilunar cartilage, and the tibia projects at the inner side of the joint, so as at once to disclose the nature of the accident; and a depression may be felt under the external condyle. In the luxation of the head of the tibia outwards, the condyle of the os femoris is thrown upon the inner semilunar cartilage, or, as Mr. A. Cooper says, rather behind it. In both these cases, this gentleman thinks, that the tibia is rather twisted upon the os femoris, so that the condyle of the latter bone is thrown somewhat backwards, as well as outwards, or inwards.

I have stated, that lateral luxations of the tibia from the femur are almost always in-

dislocation inwards seems to be established by the 402d Obs. of Lamotte.

Whenever the tibia is dislocated from the femur, the accident has generally happened either while some force was operating upon that bone, at a period when the femur was fixed and immovable, or else while the thigh-bone was propelled, or twisted with great violence, while the leg itself was firmly fixed.

The bones of the leg are sometimes twisted outward, and the internal lateral ligament ruptured; but this may happen without the crucial ligament being broken. On the other hand, when the bones of the leg are violently twisted inward, the crucial ligaments, and external lateral ligament, must inevitably be ruptured.

These accidents are all most easily reduced, by making gentle extension, and pushing the head of the tibia in the proper direction. The grand object, after the reduction, is to avert inflammation of the knee, and promote the union of the torn ligaments. The first demands the rigorous observance of the antiphlogistic plan—bleeding, leeches, low diet, opening medicines, and a cooling evaporating lotion; both require the limb to remain perfectly motionless. With respect to splints, I conceive, that their pressure would be objectionable. As soon as the ligaments have grown together, and the danger of the inflammation is over, which will be in about three weeks, the joint should be gently bent and extended every day, in order to prevent stiffness. Liniments will now also be of service.

In this section, we must notice the cases, which were first described by the late Mr. Hey, and are named by Mr. A. Cooper partial luxations of the thigh-bone from the semilunar cartilages. Mr. Hey observes, that the disorder may happen either with, or without contusion. When no contusion has occurred, or the effects of it are removed, the joint, with respect to shape, appears uninjured. If there is any difference from its usual appearance, it is that the ligament of the patella seems rather more relaxed than that of the sound limb. The leg is readily bent, or extended by the hands of the surgeon, and without pain to the patient: at most, the degree of uneasiness, caused by this flexion and extension, is trifling. But, the patient himself cannot freely bend, nor perfectly extend the limb in walking; and he is compelled to walk with an invariable and small degree of flexion. Yet, though the leg is stiff in walking, it may be freely moved, while the patient is sitting down.

Mr. Hey ascribes this complaint to any causes which had the effect of hindering the condyles of the os femoris from moving truly in the hollow formed by the semilunar cartilages, and articular depressions of the tibia; an unequal tension of the lateral, or crucial ligaments; or some slight derangement of the semilunar cartilages. (*Pract. Obs. p. 333, ed. 2.*) Mr. A. Cooper says, the most frequent cause of the accident is the point of the foot, while everted, striking against any projection, when pain is

immediately felt in the knee, and the patient becomes incapable of perfectly extending the leg. He has also known the case produced by a person's suddenly turning in bed, and the clothes not suffering the foot to turn as quickly as the rest of the body. A sudden twist of the knee inwards may also displace the semilunar cartilages.

Mr. A. Cooper gives the following explanation of the case. The semilunar cartilages are united to the tibia by ligaments, which, when relaxed, allow the cartilages to be easily pushed from their natural situation by the condyles of the femur, which then come into contact with the head of the tibia; and now, upon an attempt being made to extend the leg, a complete movement of this kind is prevented by the edges of the semilunar cartilages. (*Surgical Essays, Part 2, p. 76.*) In several examples recorded by Mr. Hey, a cure was effected by placing the patient upon an elevated seat, extending the joint, while one hand was placed above the knee, and then suddenly moving the leg backwards, so as to make as acute an angle with the thigh as possible. (*Pract. Obs. p. 337.*) This manœuvre seems to have the effect of restoring the semilunar cartilages to their natural position. Sometimes, however, it will not answer; and, in one such case, mentioned by Mr. A. Cooper, the patient used to accomplish the reduction by sitting upon the ground, and then bending the thigh inwards and pulling the foot outwards. A knee-cap laced tightly, and furnished with a strong leather strap just below the patella, was requisite in this instance for preventing a return of the displacement. In another case, subject to frequent relapses, these were at length hindered by a bandage with four rollers attached to it, which were tightly applied above and below the patella. (*A. Cooper, Surgical Essays, Part 2, p. 77.*)

Compound dislocations of the knee are generally deemed cases demanding amputation.

DISLOCATIONS OF THE FIBULA.

According to Mr. A. Cooper, luxations of the upper head of the fibula, from relaxation of the ligaments, are more frequent than those from violence. The head of the bone is thrown backwards. The bone is easily replaced, but immediately slips behind the tibia again. When the case is attended with disease, repeated blisters are recommended; and, afterwards, a strap to confine the bone in its natural situation. (*Surg. Essays, part 2, p. 105.*) In other instances, a roller, a compress applied over the head of the fibula, and a splint along this bone, would be proper. (*Boyer, Mal. Chir. T. 4, p. 374.*) The latter author has seen a displacement of the whole fibula upwards, accompanying a dislocation of the foot outwards. This case must be exceedingly unfrequent, as it is resisted not only by the ligaments of the upper joint of the fibula, but also by those very strong ligamentous complete: but, the possibility of a complete

hands, which bind the malleolus externus to the astragalus and os calcis. In all the cases which I have seen, the pressure of the astragalus, when driven outwards, has broken the fibula. In the instance mentioned by Boyer, the double luxation of the fibula was readily reduced, by rectifying the position of the foot, and bringing the astragalus into its proper place again with respect to the tibia.

DISLOCATIONS OF THE FOOT.

The tibia may be dislocated from the astragalus inwards or outwards; forwards or backwards; and either of these luxations may be complete or incomplete. The dislocation inwards is the most common; the foot being thrown outwards, and its inner edge resting upon the ground, while the fibula is broken about two or three inches above the ankle. Upon dissection, as Mr. A. Cooper observes, the end of the tibia is found resting upon the inner side of the astragalus, and, if the accident has been produced by a jump from a considerable height, the lower end of the tibia, where it is connected to the fibula by ligament, is split off, and remains attached to the latter bone. The broken end of the fibula itself is carried down upon the astragalus, occupying the natural situation of the tibia. The malleolus externus remains in its natural situation, with two inches of the fibula, and the piece of the tibia, which is split off. The capsular ligament, attached to the fibula, and the three strong fibular tarsal ligaments, are uninjured. (*Surgical Essays, Part 2, p. 107.*)

One thing, very essential to be understood in this case, is, that the fracture of the fibula is here the first mischief, without which the dislocation could not have happened. The fibula may easily be fractured without any luxation of the foot, but the above-described dislocation can never take place unpreceded by a fracture of the fibula; and, grave and serious as the displacement of the joint is, it is always a secondary event. (*Dupuytren, Annuaire Med. Chir. 1819, p. 3.*)

It was to this particular case, joined with the fracture of the fibula, that Mr. Pott drew the attention of surgeons, as affording a striking example of the benefit derived from relaxing the muscles; the instance in which, "by leaping or jumping, the fibula breaks within two or three inches of its lower extremity. When this happens, the inferior fractured end of the fibula falls inward towards the tibia, that extremity of the bone which forms the outer ankle is turned somewhat outward and upward, and the tibia having lost its proper support, and not being of itself capable of steadily preserving its true perpendicular bearing, is forced off from the astragalus inwards; by which means the weak bursal, or common ligament of the joint, is violently stretched, if not torn, and the strong ones, which fasten the tibia to the astragalus and os calcis, are always lacerated; thus producing, at

the same time, a perfect fracture and a partial dislocation, to which is sometimes added a wound in the integuments, made by the bone at the inner ankle. By this means, and indeed as a necessary consequence, all the tendons which pass behind or under, or are attached to the extremities of the tibia and fibula, or os calcis, have their natural direction and disposition so altered, that, instead of performing their appointed actions, they all contribute to the distortion of the foot, and that by turning it outward and upward."

When this accident is accompanied, as it sometimes is, with a wound of the integuments of the inner ankle, and that made by the protrusion of the bone, the danger and difficulties of the case are seriously increased.

"By the fracture of the fibula, the dilatation of the bursal ligament of the joint, and the rupture of those which should tie the end of the tibia firmly to the astragalus and os calcis, the perpendicular bearing of the tibia on the astragalus is lost, and the foot becomes distorted; by this distortion the direction and action of all the muscles already recited are so altered, that it becomes (in the usual way of treating this case) a difficult matter to reduce the joint; and, the support of the fibula being gone, a more difficult one to keep it in its place after reduction. If it be attempted with compress and strict bandage, the consequence often is a very troublesome, as well as painful ulceration of the inner ankle, which very ulceration becomes itself a reason why such kind of pressure and bandage can be no longer continued; and if the bone be not kept in its place, the lameness and deformity are such as to be very fatiguing to the patient, and to oblige him to wear a shoe with an iron, or a laced buskin, or something of that sort, for a great while, or perhaps for life.

"All this trouble, pain, difficulty, and inconvenience, are occasioned by putting and keeping the limb in such position as necessarily puts the muscles into action, or into a state of resistance, which in this case is the same. This occasions the difficulty in reduction, and the difficulty in keeping it reduced; this distorts the foot, and by pulling it outward and upward makes that deformity which always accompanies such accident; but if the position of the limb be changed, if by laying it on its outside, with the knee moderately bent, the muscles forming the calf of the leg, and those which pass behind the fibula, and under the os calcis, are all put into a state of relaxation and non-resistance, all this difficulty and trouble do in general vanish immediately; the foot may easily be placed right, the joint reduced, and by maintaining the same disposition of the limb, every thing will in general succeed very happily, as I have many times experienced." (*Pott.*)

I think the profession are much indebted to Mr. A. Cooper, for his application of terms to dislocations of the ankle, which

are liable to no mistake or confusion. Thus, when he speaks of a dislocation of the tibia inwards or outwards, backwards or forwards, the case spoken of is immediately known. On the contrary, when authors write about dislocations of the ankle, or foot, in any named direction, their meaning may be various and misinterpreted. We find this exemplified in Dupuytren's valuable memoir on fractures of the lower end of the fibula; for, instead of terming the above case, a dislocation of the foot outwards, as the generality of writers have done, he thinks it should be named a dislocation of the foot inwards, on account of the direction in which the astragalus is carried. (*Annuaire Med. Chir.* p. 3, 1819.)

With respect to the treatment of the preceding case, Dupuytren admits, that Pott's method easily effects a reduction, though incapable of maintaining it; but, as I have endeavoured in the 2d Vol. of the First Lines of Surgery, to explain the practice recently proposed at the Hôtel-Dieu, it would be useless repetition to enter into the subject again. Mr. A. Cooper appears to prefer the mode of treatment on Mr. Pott's principles; but gives one very essential piece of advice, which is, that the splint, upon which the outer part of the limb rests, may have a foot-piece, "to give support to the foot, prevent its eversion, and preserve it at right angles with the leg. If much inflammation succeeds, leeches are to be applied to the parts, and the constitution will require relief by taking blood from the arm." (*Surgical Essays, Part 2*, p. 108.)

When the tibia is dislocated outwards, the internal lateral ligaments are always ruptured, or pulled away from the bones, and the inner malleolus broken, previously to the fracture of the fibula. On a part of this statement, however, Dupuytren and Mr. A. Cooper differ, as the latter mentions, that the deltoid ligament remains unbroken. In some cases, according to Mr. A. Cooper, the fracture is not confined to the malleolus, but passes obliquely through the articular surface of the tibia, which is thrown forwards and outwards upon the astragalus, in front of the malleolus externus. Sometimes, the astragalus is fractured, and the lower extremity of the fibula broken into several splinters. He states, also, that, when the fibula is not broken, the external lateral ligaments are ruptured. The foot is thrown inwards, its outer edge resting upon the ground; while a considerable projection is made by the malleolus externus under the skin. The accident is generally caused by the passage of the wheel of a carriage over the leg, or a violent twist of the foot inwards in jumping, or falling. (*A. Cooper, Vol. cit.* p. 113.)

The reduction is accomplished by relaxing the muscles of the calf, making extension in the axis of the leg, and pressing the lower head of the tibia inwards towards the astragalus. "The limb is to be laid upon its outer side, resting upon a splint with a

foot-piece, and a pad is to be placed upon the fibula just above the outer angle, and extending a few inches upwards, so as in some measure to raise that portion of the leg, and prevent the tibia and fibula slipping from the astragalus, as well as lessen the pressure of the malleolus externus upon the integuments. (*Surg. Essays, Part 2*, p. 113.) Mr. A. Cooper also enjoins paying the strictest attention to hindering the foot from being twisted inwards, or pointed downwards.

Dupuytren's manner of treating this case, is described in the second Vol. of the First Lines of Surgery.

A complete dislocation of the lower head of the tibia forwards cannot happen, without the fibula being first broken, and either the base of the malleolus internus fractured, or its point torn away. The foot being then acted upon by the extensor and flexor muscles, and unretained by the malleoli and their ligaments, yields to the powerful operation of the muscles of the calf, the astragalus passing behind the tibia, while this projects forward under the tendons and skin of the instep. (*Dupuytren, Annuaire Med. Chir.* p. 187, 4to. Paris, 1819.) The foot of course is much shortened, the heel lengthened, and firmly fixed, and the toes point downwards. Upon dissection the tibia is found to rest upon the upper surface of the os naviculare, and os cuneiforme internum. The anterior part of the capsular ligament is torn through; the deltoid ligament is only partially lacerated; and the three ligaments of the fibula remain unbroken. (*A. Cooper, Vol. cit.* p. 109.)

This case is much more difficult of reduction, than the instance in which the foot is thrown inwards; and the cause is owing to the powerful manner, in which the muscles resist the extension of the parts, and placing them in their natural position again. As Dupuytren observes, it is true, that such resistance may be lessened by relaxing the muscles, and drawing the patient's attention from his limb, plans which fully answer for the reduction of the other above-mentioned case; yet, in that now under consideration, they are insufficient, and here a greater effort is required to bring the foot from behind forwards, and to place the astragalus under the tibia. And, a still greater difficulty is to keep the parts reduced during the time necessary for the fibula and torn ligaments to be firmly united. In fact, the upper surface of the astragalus, which is convex from behind forwards, is so slippery, that it is hard to make the tibia rest securely on the articular pulley of that bone, which is itself incessantly acted upon by the extensor muscles of the leg, so as to have a tendency to slip behind the lower head of the tibia. In addition therefore to the bent posture, Dupuytren deems it necessary here to employ an apparatus, which propels the foot forward, and the lower head of the tibia backwards. (*Annuaire Med. Chir.* p. 188.) As this apparatus has

been described in the second Vol. of the First Lines of Surgery, I need not explain it again.

Mr. A. Cooper prefers keeping the limb upon the heel, resting upon a pillow. A splint, with a suitable pad, and a foot-piece, is to be applied to each side of the leg, care being taken to keep the foot well supported at a right angle with the leg. (*Surgical Essays, Part 2, p. 110.*)

Besides the complete dislocation of the tibia forwards, a partial case is sometimes met with, where one-half of the articular surface of the bone rests upon the os naviculare, and the other on the astragalus. According to Mr. A. Cooper, the fibula is broken; the foot appears but little shortened; nor is there any considerable projection of the heel. The foot points downwards; it cannot be put flat on the ground, and is nearly stiff; and the heel continues drawn up. The accident, if not detected and rectified in its early stage, afterwards admits of no relief, the change in the state of the muscles, and the position in which the fibula has united, not suffering any reduction, even though great force be employed.

Dislocations forwards or backwards, of the tibia, are not common: during fifteen years, Dupuytren has scarcely met with two, or three cases; though he has seen some hundreds of lateral dislocation. It must be obvious to every body, says he, that when the foot is violently bent, or extended, many powerful muscles resist the movement in question, and prevent the mischief, with which the articulation is threatened. (*Annuaire Med. Chir. de Hospitaux de Paris, p. 34.*) A luxation of the tibia from the astragalus backwards, Mr. A. Cooper has never had an opportunity of observing; a proof of the rarity of the accident.

A luxation of the astragalus, either simple or complicated, with a laceration of the integuments, as Mr. Hey has remarked, is an accident, which does not often occur. Above, the astragalus is articulated with the tibia and fibula; below, it is united, by means of a capsular ligament, to the os calcis; while, in front, it is connected to the os naviculare by a capsular, and broad internal lateral ligament. Thus situated, it is evident, that its displacement is not likely to happen with great frequency; and yet, this observation must be received only as a comparative one; for, the cases of dislocation of the astragalus, now upon record, are rather numerous.

When a dislocation of the lower head of the tibia is combined with one of the astragalus from the os calcis, and os naviculare, and the ligaments, which kept these bones together, are nearly destroyed, while a considerable portion of the astragalus itself protrudes through the wound in the integuments, if it be judged prudent to attempt the preservation of the limb, it is best perhaps to imitate Desault, Ferrand, Trye, and Evans, and extract the astragalus altogether.

A luxation of the astragalus, unattended with a wound in the skin, is a serious and

embarrassing accident; for, in general, the reduction is so difficult, that it is not many years since the case was deemed a ground for amputation. (See *Gooch's Chir. Cases, &c.*) When the displacement in question happens, the astragalus is generally thrown forwards upon the os naviculare, forming a tumour on the instep, and inclining a little either to the outer, or inner side of the foot. In many cases of this description, the reduction is found to be impracticable. Here, as Boyer observes, the impediment does not depend upon the head of the bone being constricted in the narrow opening of the capsule; but rather upon the impossibility of making the extending force, and the pressure of the surgeon's hands, operate with much effect upon the displaced bone. However, an example is recorded by Desault; where the reduction was accomplished by dividing the skin, and then extending the incision through a part of the ligaments. In the *Journal de Chir.* another case is also related of a simple dislocation of the astragalus from the os calcis, and os naviculare, where the reduction was easily performed by common means. Boyer conceives it probable, that, in these cases, most of the ligaments, uniting the astragalus to the os calcis, and os naviculare were ruptured, and that the first of these bones was therefore sufficiently moveable to admit of being replaced by the pressure of the fingers. But, the luxated astragalus may be so wedged between the tibia, os calcis, and os naviculare, that its reduction is impossible, as Boyer has actually seen. In the case, here referred to, things were left to take their course, except that every possible means was employed to keep off inflammation. The result was, that the skin, covering the projection of the astragalus at the inner and upper part of the foot, sloughed, and amputation was at length deemed necessary. (*Mal. Chir. T. 4, p. 400.*) In another case, recorded by Mr. Hey, pressure was made with a tight bandage on the prominence of the astragalus, and the soft parts over it became gangrenous; yet, a recovery followed without amputation, all the projecting portion of the astragalus having gradually come away in fragments. (*Hey's Pract. Obs. p. 384, Ed. 2.*) In an instance, recently published by Dupuytren, a person dislocated the astragalus by alighting with great violence upon the heel, the bone being driven forwards by the pressure, which it had sustained between the tibia and os calcis, so as to form a protuberance under the skin of the instep. As the reduction was found impracticable, a cut was made down to the displaced bone, with the intention of extracting it; but, Dupuytren found, that he could not remove it so readily as he expected; nor yet could he replace it; and, it was not till after a tedious operation, that he succeeded in taking it away. The difficulty arose from the upper surface of the bone being turned downwards, while the back projection of what was naturally the lower part of it took hold of the fibula

in the manner of a hook. (*Annuaire Med. Chir. des Hopitaux de Paris*, 1819, p. 28.)

In another modern valuable publication, two cases of dislocation of the astragalus are related. One was a simple luxation of the astragalus inwards, the os calcis, and the rest of the foot being thrown outwards. The reduction was easily performed by fixing the knee, then extending the foot gently and directly from the leg, by laying hold of the heel with one hand, and placing the other on the dorsum of the foot; and lastly, by pressing the foot inwards, whilst counter-pressure was made with the knee upon the opposite side of the lower extremity of the tibia. The other instance, alluded to, was a compound luxation, in which the astragalus was displaced outwards, and the other tarsal bones thrown inwards. Reduction was accomplished first by bending the leg so as to relax the muscles, and then by extending the foot, as above explained, and rotating it outwards. (*A. Cooper, Surgical Essays, Part 2, p. 207.*)

By heavy weights falling upon the foot, a dislocation is sometimes produced at the transverse joint between the astragalus and os calcis behind, and the os naviculare and os cuboides in front.

Mr. A. Cooper has twice seen the os cuneiforme internum dislocated, and, in both cases, the head of the bone naturally connected to the os naviculare, projected inwards and somewhat upwards, being drawn in this direction by the action of the tibialis anticus muscle. In neither instance was the reduction accomplished; and, in one, the patient had so trivial a lameness, that the functions of the foot were expected to be in time perfect again. (*Surgical Essays, Part 2, p. 209.*)

The phalanges of the toes are sometimes dislocated, and the first bone of the great toe is frequently luxated from the first metatarsal bone; but I am not aware, that these cases are attended with any particular difficulty in the reduction, like some dislocations of the thumb.

Wellington, 1816. *Astragalus removed; shattered end of the fibula sawn off; protruded lower end of the humerus similarly removed; a compound dislocation of the shoulder-joint; and head of the metacarpal bone of the thumb, dislocated, in two instances towards the palm, and, on account of the difficulty of reduction, exposed by an incision, and sawn off.*

DISTICHIA, or DISTICHIASIS. (from *dis*, twice, and *stixis*, a row.) *Gorrhæus, Heister*, and *St. Ives*, apply this term to an affection in which each tarsus has a double row of eyelashes, which, inclining inward, irritate the eye, and keep up ophthalmia. Such authors speak of this, as a very frequent complaint; but, the author of the present article in the *Encyclopédie Méthodique, Partie Chirurgicale*, remarks, that he has never met with it at all, though, in ulceration of the eyelids, he has often seen a certain number of the eyelashes incline inward, and cause a good deal of disturbance to the eye, already in a state of inflammation. This disorder cannot properly be called distichiasis. However it may be, all writers recommend plucking out such eyelashes, as assume an unnatural direction. Some of the hairs are first to be taken out one after the other, and a few days are allowed to elapse before the operation is repeated. In order that the eyelashes may be more completely extirpated, and that others may not grow in the same situation, the places from which they grow are usually touched with the argenti nitratum. (See *Trichiasis*.)

DURA MATER, FUNGOUS TUMOURS OF. The dura mater, the outer membrane of the brain, was so named by the ancients, on account of its hardness, and its being formerly supposed to be the source of all the other membranes of the body.

Fungous tumours of the dura mater, the true nature of which was ascertained late in the last century, did not escape the notice of the ancient writers; but the disease is very imperfectly described by them, and under an erroneous denomination. They supposed, that the swelling was of the encysted kind, or what they termed *natta, tolpa, testudo*, and that it gradually altered and destroyed the cranium. They sometimes mistook the fungous, or sarcomatous tumour of the dura mater for coagulated blood, or

for ill-conditioned excrescences, like those which make their appearance on ulcers attended with caries. Such are the ideas, which seem to be conveyed by some imperfectly detailed cases in the writings of Lanfranc, Guido di Cauliaco, Theodoricus, and other authors of the thirteenth and fourteenth centuries. Amatus Lusitanus has given the appellation of lupus with caries to a fungous tumour of the dura mater. The swelling occurred in a child eight years old, who died in convulsions, two days after an opening had been made in it.—(*Centur. 5 obs. 8.*) Another similar case, which happened in a child, and was noticed by Camerarius at Paris, is styled a singular bony excrescence. (*Ephemer. curios. natur. decad. 2, ann. 6, 1687, obs. 99.*) Lastly Cattier, a physician of Montpellier, has recorded the history of a lady, who died from the consequences of a fungous tumour of the dura mater. The disease was so acutely painful, as to compel the patient to cry out. The swelling was opened with caustic. Pimprenelle, a Parisian surgeon, recommended the trepan to be employed; but his advice was overruled. After death a fungus of the dura mater, with a perforation in the skull, was detected, and it is described by the author as a hard, stony substance, accompanied with points and asperities. (*Obs. Med. obs. 15, p. 48.*—See *Lassus, Pathologie Chirurgicale, Tom. 1, p. 498. Edit. 1809.*)

The old surgeons, ignorant of the real character of fungous tumours of the dura mater, used often to commit the most serious and fatal mistakes in the treatment. These diseases are of a chronic nature, and make their appearance gradually, in the form of a tumour, which makes its way through the bones of the cranium, rises up, and insensibly blends itself with the integuments, which seem, as it were, to make a part of it. Such fungous tumours of the dura mater may originate spontaneously at any part of this membrane; but they are particularly apt to grow on the surface, which is adherent to the upper part of the skull, or to its basis. They are firm, indolent, and chronic, seeming as if they were the consequence of slow inflammation, affecting the vessels, which supply the dura mater, and inosculate with those of the diploe. It is very difficult, one might say impossible, to determine, whether, in an affection of this kind, the disease begins in the dura mater, or the substance of the bone itself. The general belief, however, is, that the bone is affected secondarily, and that the disorder originates in the dura mater. The patient, who is the subject of the first case, related in a memoir by M. Louis, had received no blow upon the head, and could only impute his complaint to a fall, which he had met with four, or five months previously, and in which the head itself had not received any violence; but, from this time, he experienced a stunning sensation, which continued till he died. The cranium and dura mater were found both equally diseased. Though this case may tend to prove, that fungous tumours of

the dura mater may form spontaneously, yet, it is not the less confirmed by the examination of a vast number of cases, that this affection more frequently follows blows on the head, than any other cause. Hence, a slow kind of thickening of the dura mater is produced, which ends in a sarcomatous excrescence, the formation of which always precedes the destruction of the bone. In the memoir published by M. Louis in the fifth volume, 4to. of those of the Royal Academy of Surgery, there is a very interesting case, illustrating the nature of the present disease.

The subject was a young man, aged twenty-one, who had a considerable tumour on the left side of the head, which was taken for a *hernia cerebri*. (See this Article.) The swelling had begun in the region of the temple, and had gradually acquired the magnitude of a second head. The external ear was displaced by it, and pushed down as low as the angle of the lower jaw. At the upper part of the circumference of the base of the tumour, the inequalities of the perforated bone, and the pulsations of the brain, could be distinctly felt. Some parts of the mass were elastic and hard, others were soft and fluctuating. A plaster, which had been applied, brought on a suppuration at some points, from which an ichorous matter was discharged. Shiverings and febrile symptoms ensued, and the man died in less than four months, in the year 1764. On dissection, a sarcomatous tumour of the dura mater was detected, together with a destruction of the whole portion of the skull, corresponding to the extent of the disease.

When a tumour of this nature has decidedly formed, it makes its way outward through all the parts, soft or hard, which are opposed to it. The swelling, in becoming circumscribed, is partly blended with the dura mater, and its pressure produces an absorption of such parts of the skull, as oppose its enlargement. It unexpectedly elevates itself externally, confounding itself with the scalp, and presents itself outwardly in the form of a preternatural, soft, yielding swelling, which even sometimes betrays an appearance of a decided fluctuation, or a pulsation, which may make it be mistaken for an aneurismal tumour. When once the swelling has made its exit from the cavity of the cranium, it expands on every side under the integuments, which readily make way for its growth. The scalp becomes distended, smooth, and oedematous over the extent of the tumour, and lastly it ulcerates. The matter, discharged from the ulcerations, is thin and sanious; the outer part of the tumour is confounded with the integuments and edges of the skull, on which it rests, so that, in this state, it is easy to mistake the tumour for one, whose base is altogether external. While the swelling thus increases in size externally, it also enlarges internally. The latter change takes place in particular, while the opening in the cranium is not large enough to admit the whole mass of the tumour, which then depresses the brain, and

lodges in an excavation, which it forms for itself. But this cavity quickly diminishes, and becomes reduced almost to nothing, as soon as the tumour projects outwardly. The tables of the skull are absorbed to let the swelling arrive externally; but, it is remarked, that the internal, or vitreous table, is always found much more extensively destroyed, than the external one. Sometimes, new bony matter is found deposited around the opening in the cranium.

It is asserted, that, whatever may be the situation of a fungous tumour of the dura mater, the outer layer of this membrane, upon which the disease forms, is alone altered, the inner layer and the pia mater being always unchanged. (*Lassus, Pathologie Chirurgicale, Tom. 1, p. 501. Edit. 1809.*)

In one of these cases, detailed by Walther, the inner layer of the dura mater was quite natural, though one half of the tumour, which was very large, was within the skull, where it had formed for itself a deep excavation in the posterior lobe of the brain. And, what is remarkable, notwithstanding this latter change, the patient, the day before her death, retained all her intellectual faculties, and the power of voluntary motion. (*Journ. für Chirurgie von C. Graefe and Ph. v. Walther, B. 1, p. 64—65, 8vo. Berlin, 1820.*)

According to surgical writers, fungous tumours of the dura mater have been caused by contusions of the skull, falls on the buttocks, concussions of the head or whole body, lues venerea, scrofula, inveterate rheumatism, &c. The three last of the alleged causes, however, seem to be little better than mere conjecture; and the same may be said of Walther's idea, that the disease is of a similar nature to white swelling of the joints, (*Graefe's Journ. B. 1, p. 104.*) beginning rather in the bone, than the dura mater.

Children of the most tender years are even liable to the disease. M. Louis has related, that a child two years of age, died of a fungus of the dura mater, which had produced a swelling above the right ear, attended with a destruction of a portion of the parietal and temporal bones. (*Mém. de l'Acad. de Chirurgie, Tom 5, 4to. p. 31.*)

Though the common opinion is, that these fungi grow entirely from the dura mater, Sandifort asserts, that the vessels of the diploe have a considerable share in their production. (*Descriptio Musei Anat. Acad. Lugd. T. 1, p. 152.*)

A similar belief was entertained by Heister and Kaufmann, and is espoused by Siebold and Walther, the latter imputing the disease to a simultaneous affection of the vessels of the dura mater, and pericranium, attended with an absorption of the earthy part of the bone. (*Journ. für Chir. von C. Graefe, &c. p. 91—93.*)

The existence of a fungous tumour of the dura mater cannot be ascertained, as long as there is no external change. The effects, produced, may originate from so many causes, that there would be great risk of a gross mistake in referring them to any par-

ticular ones. This is not the case, when there is an opening in the skull. Then a hardness, felt from the very first at the circumference of the tumour, denotes that it comes from within. When the swelling is carefully handled, such a crackling sensation is perceived, as would arise from touching dry parchment stretched over the skin. On making much pressure, pain is occasioned, and sometimes a numbness in all the limbs, stupefaction, and other more or less afflicting symptoms. The tumour, in some measure, returns inward, especially, when not very large, and gradually rises up outward again, when the pressure is discontinued. Sometimes, there is pain; at other times, there is none; which may be owing to the manner in which the tumour is affected by the edges of the bone, through which it passes. The pain is often made to go off by compression, but returns as soon as this is taken off. The tumour has an alternate motion, derived from the pulsation of the brain, or of the large arteries at its base. This throbbing motion has led many practitioners to mistake the disease for an aneurism, as happened in the second case related in the memoir of M. Louis. When the tumour is pushed sideways, and the finger carried between it and the edge of the bone, through which the disease protrudes, the bony edge may be felt, touching the base of the swelling, and more or less constricting it. This symptom, when distinguishable, added to a certain hardness and elasticity, and sometimes a facility of reduction, forms a pathognomonic mark, whereby fungous tumours of the dura mater may be discriminated from herniæ of the brain, external fleshy tumours, abscesses, exostoses, and other affections, which at first sight resemble them.

Probably, however, some variety in the symptoms prevails in different instances; for, in the cases recorded by Walther, there was no pulsation, strictly so called, but merely an obscure movement, or an alternate distention and flaccidity, arising from influx of blood into the vessels of the diseased mass; the tumours could not be pushed within the cranium in the slightest degree; nor did the attempt cause any of the effects usually observed to proceed from pressure on the brain. No aperture could be felt in the skull, much less could the irregular edges of the bone around the tumour be distinguished. (*Journ. für Chir. B. 1, p. 57—61, &c. 8vo. Berlin, 1820.*)

Whatever movements also were perceptible in the swellings, Walther is convinced could not be communicated to them by the pulsations of the subjacent brain; because they were wedged, as it were, in an aperture in the skull, and adherent to the dura mater beneath them, and to the superincumbent periosteum, so that, even in the dead subject, they did not admit of being pushed in the least more outwards without difficulty, and the employment of strong pressure. (*Vol. cit. p. 57.*)

Indeed, this tight constriction of the tu-

tumour not only explains why stupor, paralysis, &c. were not brought on in these particular examples by external pressure, but also why the edges of the hole in the skull could not be felt; and the small size of the same opening, in relation to the magnitude of the swelling, fully accounts in my opinion for the circumstance of the swellings not sinking inwards under pressure. But, I am far from being convinced with Walther, that fungi of the dura mater are in their nature always irreducible, (see *Vol. cit. p. 82*;) a belief, which he grounds upon the connexion of the diseased mass with the vessels of the diploe; its constriction by the bone; and its expansion under, as well as above, the cranium. Here, I think Walther is as wrong in saying, that none of these fungi can possibly be reduced, as others would be in asserting that it is their invariable character to be reducible. These differences must chiefly depend upon the size of the swelling, in relation to that of the aperture in the skull.

Generally speaking, fungous tumours of the dura mater are very dangerous, as well on account of their nature, as of the difficulty of curing them in any certain manner, and of the internal and external disorder, which they may occasion. Such as have a pedicle, the base of which is not extensive; which are firm in their texture, without much disease in the surrounding bone, are moveable, not very painful, and in persons, who are in other respects quite well, are in general reputed to be the least perilous. These are the cases, in which a cure may be attempted, with a hope of success, though the event is always exceedingly doubtful.

When the contrary of what has been just related occurs, when the disease is of long continuance, and the brain already affected, nothing favourable can be expected.

Compression is the most simple means of cure, and that which has naturally occurred to such practitioners, as have mistaken the disease for an aneurism, or a hernia cerebri. The efficacy of this method has been further misconceived, because the tumour, when not very large, has sometimes been partly, or even wholly reduced, without any bad consequences. This had no little share in leading to errors, concerning the true character of the disease. But, as might be conceived, this reduction, only being attended with temporary success, and having no effect whatever on the original cause of the affection, the symptoms returned, and the tumour rose up again, the moment the compression was discontinued. There is a fact in the memoir of M. Louis, which seems to evince, that good effects may sometimes be produced by compression judiciously employed. A woman, brought to the brink of the grave by the symptoms, occasioned by a tumour of the above kind, having rested with her head, for some time, on the same side as the tumour, found the swelling so suddenly reduced, without any ill effects, that she thought herself cured by some miracle. Compression artfully kept up, by means of a piece of tin, fastened to her cap, prevented the protrusion

of the tumour again. The pressure, however, not having been always very exact, the symptoms every now and then recurred, while the tumour was in the act of being depressed again, and they afterward ceased, on the swelling having assumed a suitable position. The symptoms were, doubtless, occasioned by the irritation, which the tumour suffered, in passing the inequalities around the opening, through which it protruded. The patient lived in this state nine years, having every now and then trances, in one of which, attended with hiccough and vomiting, she perished.

As compression cannot be depended upon, the following safer method may be tried. It consists in exposing the tumour with a knife, which is certainly preferable to caustics, the action of which is very tedious and painful, and can never be limited or extended with any degree of precision. A crucial incision may be made through the scalp covering the tumour, and the flaps dissected up and reflected, so as to bring all the bony circumference into view. Then with trephines repeatedly applied, or with what would be better, Mr. Hey's saws, all the margin of the bone should be carefully removed. Now, if it be true, that the vessels of the diploe are chiefly concerned in the supply of the diseased mass, we see that this source of its growth must be destroyed by the foregoing proceeding.

The tumour, thus disengaged on all sides, may be cut off with a scalpel; and such arteries as bleed much should be tied. Then, instead of applying caustic, as sometimes advised, perhaps, it would be better to remove every part of both layers of the dura mater immediately under the situation of the excrescence. By this means, and the removal of the surrounding bone and diploe, all chance of the regeneration of the tumour would be prevented. In attempting the excision of a fungus of the dura mater, it is certainly an interesting point to know, whether the tumour has an intimate vascular connexion with the diploe, and pericranium, as asserted by Siebold, Walther, and some other respectable authorities; though the importance of the information on this subject to the practitioner is somewhat lessened by his being aware, that it is necessary always to begin with sawing away the bone in the immediate vicinity of the diseased mass. In the dissection of one case, Walther found the pericranium thickened for a considerable extent around the disease, and closely connected with the tumour by vessels. (*Vol. cit. p. 100.*)

When the tumour is sarcomatous, and its pedicle small and narrow, as sometimes happens, one should not hesitate to cut it off.

This method is preferable to tying its base with a ligature, a plan which could not be executed, without dragging, and seriously injuring the dura mater. The excision is also preferable to caustics, which cause great pain, and very often convulsions. In performing the extirpation, we should remove the whole extent of the tumour, and, if possible, its root, even though it may ex-

tend as deeply as the internal layer of the dura mater. This step must not be delayed, for the disease will continue to increase, so as to affect the brain, become incurable, and even mortal. It is to such decision, that we must impute the success, which attended the treatment of the Spaniard Avalos, of whom Marcus Aurelius Severinus makes mention. The above nobleman was afflicted with intolerable headaches, which no remedy could appease. It was proposed to him to trepan the cranium, an operation to which he consented. This proceeding brought into view, under the bone, a fungous excrescence, the destruction of which proved a permanent cure of the violent pains, which the disease had occasioned. It is not mentioned in this case, whether the internal layer of the dura mater was healthy or not; but, there is foundation for believing, that if the extirpation of these tumours be undertaken in time, and bold measures be pursued, as in the instance just cited, success would often be obtained. Indeed, reason would support this opinion; for, when the disease is not extensive, it is necessary to expose a much smaller surface of the dura mater.

It appears to me, however, that trepanning can never be warrantable, unless the disease be indicated by some external changes. I saw my late master, Mr. Ramsden, trepan a man for a mere fixed pain in one part of the head, on the supposition, that there was a tumour under the bone; but no tumour was found, and the operation caused inflammation of the dura mater, and proved fatal.

No doubt, in some cases, the hemorrhage will be considerable, as was exemplified in the instance in which Walther made an incision at the base of one of these fungi, in order to ascertain its nature: two pints of blood being lost from several vessels of very large size ere they could be secured; and the further use of the knife discontinued.

M. Louis has described other tumours, which grow from the surface of the dura mater, when this membrane has been denuded, as after the application of the trephine. They only seem to differ from the preceding cases in not existing before the opening was made in the skull. These cases are not to be confounded with the hernia cerebri. (See this Article.) See on the preceding subject, *Mémoire sur les Tumeurs fungueuses de la Dure-Mère*, par M. Louis, in *Mém. de l'Académie de Chirurgie*, Tom. 5, 4to., or Tom. 13, 12mo. *Encyclopédie Méthodique, Partie Chirurgicale*, art. *Dure-Mère*. J. P. Kaufmann, de *Tumore Capitis fungoso post Cariem Cranii exorto*. Helmst. 1743. Lassus, *Pathologie Chirurgicale*, Tom. 1, p. 497. Edit. 1809. J. and C. Wenzel, *über die Schwammigen Auswuchse auf der aussern Hirnhaut*. Fol. Mainz. 1811. In this work, the sentiments of M. Louis are espoused. Ph. v. Walther in *Journ. für Chirurgie von C. Gräfe, &c.* B. 1, P. 55, &c. 8vo. Berlin. 1820. The latter writer criticises the opinions of the Wenzels, and, of course, differs considerably from Louis on several points, some of which I have noticed in the foregoing pages.

For an account of inflammation of the dura mater, See *Head, Injuries of*.

E.

EAR, DISEASES OF.

AN organ, so valuable and necessary to the perfection of our existence, as the ear, should have all the resources of surgery exerted for the preservation of its integrity, and the removal of the diseases, with which it may be affected. What, indeed, would have been our lot, if nature had been less liberal, and not endued us with the sense of hearing? As Leschevin has observed, we should then have been ill-qualified for the receipt of instruction; a principal inlet of divine and human knowledge would have been closed; and there being no reciprocal communication of ideas, our feeble reason could never have approached perfection. Even our life itself being as it were dependent upon all such bodies as surround us, would have been incessantly exposed to dangers. The eyesight serves to render us conscious of objects, which present themselves before us, and, when we judge them to be hurtful, we endeavour to avoid them. But, to say nothing of our inability of looking on all sides at once, our eyes become of no service to us, whenever we happen to be enveloped in darkness. The hearing is then

the only sense that watches over our safety. It warns us, not only of every thing which is moving about us, but likewise of noises, which are more or less distant. Such are the inestimable advantages which we derive from this organ. Its importance, when healthy, makes it worthy of the utmost efforts of surgery, when diseased. (Leschevin, in *Mémoires sur les Sujets proposés pour le Prix de l'Acad. Royale de Chirurgie*, Tom. 9, p. 111, 112. Edit. 12mo.)

It is not many years since the diseases of the ear were a subject, on which the greatest ignorance and the most mistaken opinions prevailed; and, indeed, how could any correct pathological information be expected, while anatomists had not given a complete and accurate description of the organ itself? Also, notwithstanding what has now been made out, respecting disorders of the ear, it is generally admitted, that they still require further investigation, and renewed industry. Though Duverney, Valsalva, Morgagni, &c. dispelled some of the darkness, which covered this branch of surgery, they left a great deal undone. Since their time, science has been enriched with the valuable discoveries of Cotunni, Meckel,

Scarpa, and Compagetti; the two first of whom demonstrated, that the labyrinth is filled with a limpid fluid, and not (as was pretended) with confined air; while the two last distinguished anatomists favoured the public with the first very accurate description of the parts composing the labyrinth, especially the semicircular canals.

In 1763, the French Academy of Surgery offered a prize for the best essay on diseases of the ear, and, two years afterwards the honour was adjudged to that of Leschevin, senior surgeon of the hospital at Rouen. This memoir is still of great value, few modern treatises being more complete. The most useful contributors to our stock of information on the Pathology of the ear, subsequently to M. Leschevin, have been Kritter, and Lentin (*Ueber das Schwere Gehoer. Leipz. 1794*;) Trampel (*Armen's Magaz. B. 2, 1798*;) Pfingsten (*Vieljahrige Erfahrung ueber die Gehoerfehler, Kiel, 1802*;) Alard (*sur le Catarrhe de l'Oreille, Svo. Paris, 1807, 2d Edit.*) Mr. A. Cooper, (*Phil. Trans. 1802.*) Portal (*Anat. Med. 1803.*) J. C. Saunders, (*Anat. and Dis. of the Ear, 1806.*) Baron Boyer (*Mal. Chir. T. 6.*) Saissy, in an essay, which received the approbation of the Medical Society of Bordeaux; and Professor Rosenthal in a short but sensible tract on the pathology of the ear. (See *Journ. Complem. T. 6, 1820.*)

But, notwithstanding the laudable endeavours of so many men of eminence, the pathology of the internal ear, and the treatment of its diseases, are far, I may say, very far from a high state of improvement. To further advances, indeed, some discouraging obstacles present themselves: the auditory apparatus is extremely complicated; the most important parts of it are entirely out of the reach of ocular inspection; the anatomy of the organ is perhaps not yet completely unravelled; the exact uses and action of several parts of it, anatomically known, are still involved in mystery; the opportunities of dissecting the ear in a state of disease are neither frequent, nor duly watched, and even when they are taken, and when vestiges of disease, or imperfection, are traced to particular parts of the organ, the utmost difficulty is experienced in drawing any useful practical conclusion, because the natural uses of those parts, and the precise manner in which they contribute to the perfection of the ear, are not known to the most enlightened physiologists. We are here nearly in the same helpless dilemma, as a watchmaker would be, were he, in examining the interior of a watch, to find parts broken and out of order, the exact uses of which, in the perfection of the instrument, he had not first studied and comprehended. In fact, the physiology of the ear is but very imperfectly understood; and, as Rosenthal remarks, (*Journ. Complem. T. 6, p. 17.*) if, notwithstanding the progress made in optics, and the complete knowledge of the structure of the eye, a perfect explanation has not yet been given of the phenomena of this organ, as an

instrument of vision, we cannot wonder, that, with far more circumscribed information about acoustics, and the greater difficulty of unravelling the structure of the ear, so little progress should have been made in the physiology of the latter organ. Were it practicable in acoustics to arrive at that precision and certainty, which would enable us to establish laws in the theory of sound, as fixed as those which relate to light, this void in physiological science might perhaps be obviated. But, Rosenthal justly argues, that hitherto the approach to perfection has not been made, and this notwithstanding the learned and valuable labours of Chladni. (*Akustik. 4to. Leipz. 1802.*) Some facts, however, are admitted to be well ascertained, and the researches of Autenrieth and Kerner (*Reil's Archir. für die Physiol. T. 9, p. 313—376.*) are honourably mentioned; for, though they only elucidate the function of the conductor-part of the ear, they are of unquestionable importance to the medical practitioner. It is clearly proved, that the difference in the length and breadth of the meatus auditorius, the form of the membrana tympani, and the make of the cavity of the tympanum, modify sound; that is to say, that the differences of structure of the auricle and meatus auditorius externus, which merely receive and concentrate the sonorous undulations, as these emanate from a vibrating body, can only influence the degree of force, or weakness of the sound; while, on the contrary, the differences of structure in the membrane and cavity of the tympanum are not limited to this effect, but the greater or less tension of the one, and the more or less considerable capacity of the other, appear to alter in greater or lesser degree the particular character of the sound. (*Journ. Complem. T. 6, p. 20.*)

1. Wounds and Defects of the External Ear.

The external ear, which is a sort of instrument calculated for concentrating the undulations or waves of sound, may be totally cut off, without deafness being the consequence. For a few days after the loss, the hearing is rather hard; but the infirmity gradually diminishes, the increased sensibility of the auditory nerve compensating for the imperfection of the organic apparatus. (*Richter and Nosogr. Chir. T. 2, p. 122, Edit. 2.*)

Dr. Hennen says, that he has met with a case, where the external ear was completely removed by a cannon shot, and yet the sense of hearing was as acute as ever. (*Principles of Military Surgery, p. 348, Ed. 2.*) Another case, recorded by Wepfer, also proves, that a total loss of the auricle may not cause any material injury of hearing, for the patient of whom he speaks had had the whole of the external ear destroyed by ulceration, and yet could hear as well as before the loss. (*Kritter und Lentin Ueber das schwere Gehoer, p. 19, Leipz. 1794.*) However, if we are to credit the statement of other writers, the recovery is generally far less complete. Thus Leschevin notices, that they who have lost the external ear, or have it naturally too flat,

or ill shaped, have the hearing less fine. The defect can only be remedied by an artificial ear, or an ear trumpet, which, receiving a large quantity of the sonorous undulations, and directing them towards the meatus auditorius, thus does the office of the external ear. (*Prix. de l'Acad. Royale de Chir. T. 9, p. 120, Edit. 12mo.*)

Wounds are not the only causes, by which the external ear may be lost: its separation is sometimes the consequence of ulceration, and sometimes the effect of the bites of horses and other animals. In cold climates, it is frequently frozen, and afterwards attacked with inflammation and sloughing. When the external ear is not totally separated from the head, the surgeon should not despair of being able to accomplish the reunion of it. This attempt should always be made, however small a connexion the part may have with the skin; for, in wounds of this kind, the efforts of surgery have occasionally succeeded beyond all expectation.

Wounds of the external ear, whatever may be their size and shape, do not require different treatment from that of the generality of other wounds. The reunion of the divided part is the only indication, and it may be in most instances easily fulfilled by means of methodical dressings. Such writers, as have recommended sutures for wounds of the ear, (says Leschevin,) have founded this advice upon the difficulty of applying to the part a bandage, that will keep the edges of the wound exactly together. The cranium, however, affords a firm and equal surface, against which the external ear may be conveniently fixed. Certainly, it is not more easy to secure dressings on the nose than the ear; and yet, cases are recorded, in which the cartilaginous part of the nose was wounded, and almost entirely separated, and the union was effected without the aid of sutures. (See *Mém. de M. Pibrac sur l'Abus des Sutures*, in *Mem. de l'Acad. de Chir. Tom. 3.*)

In wounds of the ear, then, we may conclude, that sutures are generally useless and unnecessary. As examples may occur, however, in which the wound may be so irregular and considerable as not to admit of being accurately united, except by this means, it should not be absolutely rejected. An enlightened surgeon will not abandon altogether any curative plans; he only points out their proper utility, and keeps them within the right limits. When sticking plaster, simple dressings, and a bandage, that makes moderate pressure, appear insufficient for keeping the edges of a wound of the ear in due contact, the judicious practitioner will not hesitate to employ sutures.

When a bandage is applied to the external ear, it should only be put on with moderate tightness, since much pressure gives considerable uneasiness, and may induce sloughing. In order to prevent these disagreeable effects, Leschevin advises us to fill the space behind the ear with soft wool or cotton, against which the part may be compressed without risk. (*Op. cit. p. 119.*)

Baron Boyer remembers a medical stu-

dent, who was compelled by an ulcer on the sacrum to lie for a long time on his side, in which posture the pressure on the ear caused a slough of the antihelix, and after the separation of the dead part, an aperture, large enough to receive the end of the little finger, was left in the pinna or auricle.

In the application of sutures to the ear, the ancients caution us to avoid carefully the cartilage, and to sew only the skin. They were fearful that pricking the cartilage would make it mortify, "*ce qui est souvent-fois arrivé*," says Paré. But notwithstanding so respectable an authority, as Leschevin has remarked, the moderns make no scruple about sewing cartilages. In wounds of the nose, Verduc expressly directs the skin and cartilage to be pierced at once, and the success of the plan is put out of all doubt by a multitude of facts. The same treatment may also be safely extended to the ear.

Celsus, lib. 8, c. 6, speaks of fractures of the cartilage of the ear; but, such an accident seems hardly possible, unless the part be previously ossified. Leschevin and Boyer have never met with such a case, either in practice, or in the works of surgical writers.

In this section, a few malformations of the external ear require notice. Sometimes the orifice of the meatus auditorius is diminished by the tragus, antitragus, and antihelix being depressed into it. Here the excision of these wrongly-formed eminences has been recommended, as a surer means of perfecting the sense of hearing, than the use of any tube, or dilating instruments. The tragus has been known to project considerably backwards, and to apply itself most closely over the orifice of the meatus, which was also a mere slit, instead of a round opening. In one case of this description, relief was obtained by the introduction of tubes, calculated to maintain the tragus in its proper position. (*Dict. des Sciences Med. T. 38, p. 28.*)

Sometimes the outer ear is entirely wanting. Thus Fritelli has given an account of a child in this condition, whose physiognomy at the same time strongly resembled that of an ape. (*Orteschi Giorn di Med. T. 3, p. 80.*) Oberteuffer has also recorded an example of a total deficiency of the auricles in an adult, who yet heard very well. (*Stark's Neues Archiv. B. 2, p. 638. J. F. Meckel Handbuch der Pathol. Anat. B. 1, p. 400, Leipz. 1812.*)

Many years ago, I remember a child, which was shown to several medical gentlemen in London, as a curiosity; it was entirely destitute of all appearance of external ears, and no vestiges of the meatus auditorii could be seen, these openings being completely covered by the common integuments. Yet the child could hear a great deal, though the sense was certainly dull and imperfect. I remember that the circumstance of the patient hearing so well as he did, was what excited considerable surprise. I am sorry I do not more particularly recollect, at the

present time, the degree in which this sense was enjoyed, and several other circumstances, such as the child's age, power of speech, &c. The example, however, is interesting, inasmuch as it proves, that even a deficiency of the auricles, combined with an imperforate condition of both ears, may be unattended with complete deafness, provided the internal and more essential parts of these organs are sound and perfectly formed.

Baron Boyer attended a young man, the lobule of one of whose ears extended in a very inconvenient manner over the cheek: the redundant portion was removed with a pair of scissors, and the wound soon healed.

The auricle, not being a very irritable part, is not often inflamed, and when it is so, the affection is generally of an erysipelatous character. Portal has seen the part nearly an inch thick; and he takes notice of the prodigious thickness, which the lobe of the ear sometimes acquires in women, who wear very heavy ear-rings, which keep up constant irritation. Small encysted and adipose swellings occasionally grow under the skin of the external ear, and demand the same treatment as swellings of the same nature in other situations. (See *Tumours*.) Lastly, the external ear is frequently the seat of scrofulous, and other ill-conditioned ulcers. These cases generally require cleanliness, alterative medicines, and to be dressed with the ung. hydrarg. nitrat. or a solution of the nitrate of silver; and sometimes when the sores resist for a long time the effects of medicine and the usual dressings, they will soon heal up, if the treatment be assisted with a blister, or seton, kept open on the nape of the neck. (See *Dict. des Sciences Med.* T. 38, p. 28, 29.)

2. Of the Meatus Auditorius, and its Imperfection.

This is the passage, which leads from the cavity of the external ear, called the concha, down to the membrane of the tympanum. It is partly cartilaginous, and partly bony, and has an oblique winding direction, so that its whole extent cannot be easily seen. There are circumstances, however, in which it is proper to look as far as possible into the passage. Such is the case, when the surgeon is to extract any foreign body, to remove any excrescence, or to detect any other occasion of deafness. Fabricius Hildanus gives a piece of advice upon this subject, not to be despised; namely, to expose the ear to the rays of the sun, in order to be enabled to see the very bottom of the meatus auditorius externus.

The surgical operations practised on the meatus auditorius are confined to opening it, when preternaturally closed, extracting foreign bodies, washing the passage out with injections, and removing excrescences, which may form there.

The case which we shall next treat of, is the imperforation of the meatus auditorius externus, a defect with which some children are born.

When the malformation exists in both

ears, it generally renders the subject dumb, as well as deaf, for, as he is incapable of imitating sounds, which he does not hear, he cannot of course learn to speak, although the organs of speech may be perfect, and in every respect rightly disposed. In this case, the surgeon has to rectify the error of nature, and, (to use the language of Leschevin,) he has to give by a double miracle, hearing and speech to an animated being, who, deprived of these two faculties, can scarcely be regarded in society as one of the human race. How highly must such an operation raise the utility and excellence of surgery in the estimation of the world!

When the meatus auditorius externus is merely closed by an external membrane, the nature of the case is evident, and the mode of relief equally easy. But, when the membrane is more deeply situated in the passage, near the tympanum, the diagnosis is attended with more difficulty, and the treatment with greater trouble.

If the preternatural membrane is external, or only a little way within the passage, it is to be divided with a bistoury; the small flaps are to be cut away; a tent, of a suitable size, is to be introduced into the opening; and the wound is to be healed *secundum artem*, care being taken to keep it constantly dilated, until the cicatrization is completed.

When the obstruction is deeply situated, we must first be sure of its existence, which is never ascertained, or even suspected, till after a long while. It is not till after children are past the age, at which they usually begin to talk, that any defect is suspected in the organ of hearing, because until this period, little notice is taken, whether they hear or not. As soon as it is clear, that this sense is deficient, the ears should always be examined with great attention, in order to discover, if possible, the cause of deafness. Sometimes, the infirmity depends upon a malformation of the internal ear, and the cause does not then admit of detection. The most convenient method of making the examination is to expose the ear, which is about to be examined, to the light of the sun. In this situation, the surgeon will be able to see beyond the middle of the bony part of the meatus, if he places his eye opposite the orifice of the passage, and takes care to efface the curvature of the cartilaginous portion of the canal, by drawing upward the external ear. If the passage has been carefully cleansed, before the examination, the skin, forming the obstruction, may now be seen, unless it be immediately adherent to the tympanum.

When the preternatural septum is not closely united to the tympanum, its destruction should be attempted, and hopes of effecting the object, either suddenly, or gradually, may reasonably be entertained. According to Leschevin, the particular situation of the obstruction is the circumstance, by which the surgeon ought to be guided in making a choice of the means for this operation. If the membranous partition is so

far from the tympanum, that it can be pierced without danger of wounding the latter part, there can be no hesitation in choosing the plan to be adopted. In the contrary state of things, Leschevin is an advocate for the employment of caustic, not only on account of the risk of injuring the tympanum with a cutting instrument, but, also, because, if the puncture were ever so well executed, a tent could not be introduced into it, so as to prevent it from closing again.

In the first case, a very narrow sharp-pointed bistoury should be used: after its blade has been wrapped round with a bit of tape to within a line of the point, it is to be passed perpendicularly down to the preternatural membrane, which is to be cut through its whole diameter. The instrument being then directed first towards one side, then the other, the crucial incision is to be completed. As the flaps, which are small and deeply situated, cannot be removed, the surgeon must be content with keeping them separated by means of a blunt tent. The wound will heal just as favourably as that occasioned in removing the imperforation of the concha, or outer part of the meatus auditorius. (*Prix de l'Acad. de Chir. p. 124—126, T. 9.*) In the second case, that is to say, when the risk of wounding the tympanum leads us to prefer the employment of caustic, the safest and most commodious way of putting the plan in execution would be that of touching the obstruction, as often as circumstances may require, with the extremity of a bougie armed with the *argentum nitratum*. In the intervals of the applications, no dressings need be introduced, except a bit of clean soft cotton, for the purpose of absorbing any discharge, which may take place within the passage.

It is manifest, that if the whole, or a considerable part of the meatus auditorius externus were wanting, the foregoing measures would be insufficient. The following observations of Leschevin merit attention: "I do not here allude to cases, in which a malformation of the bone exists. I know not, whether there are any examples of such an imperforation; but, it is clear, that it would be absolutely incurable. I speak of a temporal bone perfectly formed in all its parts, and the meatus auditorius of which, instead of being merely lined by a membrane, as in the natural state, is blocked up by the cohesion of the parietes of this membrane throughout a certain extent of the canal; just as the urethra, rectum, or vagina, is sometimes observed to be not simply closed by a membrane, but by a true obliteration of its cavity.

"Such a defect in the ear may be congenital, and it may also arise from a wound, or ulceration, of the whole circumference of the meatus auditorius externus, this canal having become closed by the adhesion of its parietes, on cicatrization taking place.

"Such an imperforation, whether congenital or accidental, must certainly be more difficult to cure, than the examples

treated of above; but, (says Leschevin) I do not for this reason believe, that the case ought to be entirely abandoned. Yet, I would not have the cure attempted in all sorts of circumstances. For instance, if the defect only existed in one ear, and the other were sound, I would not undertake the operation, because, as the patient can hear tolerably well on one side, the advantages which he might derive from having the enjoyment of the other ear, would not counterbalance the pain and bad symptoms occasioned by such an experiment, the success of which is extremely uncertain. I would not then run the risk of making a perforation, except in a case of complete deafness; and I propose this means only as a dubious one upon the fundamental maxim, so often laid down, that it is preferable to employ a doubtful remedy, than none at all.

"With respect to the mode of executing this operation," says Leschevin, "the trocar seems the most eligible instrument. I would employ one, that is very short, and the point of which is bluntish, and only projects out of a cannula as little as possible. This construction would indeed make the instrument less adapted to pierce any thing; but, still, as the parts to be perforated are firm, their division might be accomplished sufficiently well; and the inconvenience of a trivial difficulty in the introduction of the trocar is comparatively less, than that which would attend the danger of wounding with a sharper point the membrane of the tympanum. I would plunge the point of the instrument into the place, where the opening of the meatus auditorius externally ought naturally to be, and which would be denoted, either by a slight depression, or at all events by attending to the different parts of the ear, especially the tragus, which is situated directly over this passage. I would push in the trocar gently, in the direction of the canal formed in the bone, until the point of the instrument felt as if it had reached a vacant space. Then, withdrawing the trocar, and leaving the cannula, I would try whether the patient could hear. I would then introduce into the cavity of the cannula itself a small, rather firm tent, of the length of the passage, or a small bougie. By means of a probe, I would push it to the end of the cannula, which I would now take out, observing to press upon the tent, which is to be left in. The rest of the treatment consists in keeping the canal pervious, making it suppurate, and healing it with common applications. One essential caution, however, would be that of keeping the part dilated long after it had healed: otherwise, it might close again, and a repetition of the operation become necessary. This happened to Heister, as he himself apprizes us, and it occurred to Roonhuysen in treating imperforations of the vagina.

"If the cohesion of the parietes of the meatus auditorius externus were to extend to the tympanum inclusively, the operation would be fruitless; but, as it is impossible

to ascertain this circumstance, before the attempt is made, the surgeon would incur no disgrace by relinquishing the operation, and giving up the treatment of an incurable disease. If, then, after the trocar were introduced to about the depth of the tympanum, the situation of which must be judged of by our anatomical knowledge, no cavity were met with, the operation should be abandoned; and, if in these circumstances, any one were to impute the want of success to the inefficacy of surgery, or the unskillfulness of the surgeon, he would act very unfairly.

"It is also plain, that such an operation could cure a congenital deafness, only inasmuch as it might depend upon the imperforation; for, if there should exist, at the same time, in the internal ear, any malformation, destructive of the power of the organ, the remedying of the external defect would be quite useless." (*Leschevin, in Prix de l'Acad. de Chirurgie, Tom. 9, p. 127, 132.*)

We find, that this author entertains a great dread of wounding the tympanum, and certainly he is right in generally insisting upon the prudence of avoiding such an accident. It will appear, however, in the sequel of this article, that under certain circumstances, puncturing the tympanum has been successfully practised, as a mode of remedying deafness. The operation, however, demands caution; for, if done so as to injure the connexion of the malleus with the membrana tympani, the hearing must ever afterward be very imperfect.

3. Unusual smallness of the Meatus Auditorius Externus.

Imperforation is not the only congenital imperfection of the meatus auditorius; this passage is occasionally too narrow for the admission of a due quantity of the sonorous undulations, and the sense is of course weakened. Leschevin mentions, that M. de la Metrie found this canal so narrow in a young person, that it could hardly admit a probe. What has been observed, concerning the imperforation, is also applicable to this case. If it depends upon malformation of the bone, it is manifestly incurable; but, if it is owing to a thickening of the soft parts, within the meatus, hopes may be indulged of doing good by gradually dilating the passage by tents, which should be increased in size from time to time, and, lastly, making the patient wear for a considerable time, a tube, adapted to the part in shape. (*Leschevin, in Prix de l'Acad. de Chirurgie, Tom. 9, p. 132.*)

Mr. Earle has lately published a case, in which the diameter of the meatus auditorius was considerably lessened by a thickening of the surrounding parts, and especially of the cuticle, attended with a discharge from the passage, and great impairment of hearing. A cure was effected by injecting into the passage a very strong solution of the nitrate of silver, which in a few days, was followed by a detachment of the thickened portions of cuticle. This evacuation was assisted by throwing warm water into

the passage. (*See Med. Chir. Trans. Vol. 10, p. 411, &c.*) Boyer was consulted for a deafness, which arose from a malformation, which consisted of a flattening of the meatus, its opposite sides being for some extent in contact. The patient was advised to wear in the ear a gold tube of suitable shape, by which means he was enabled to hear perfectly well.

4. Faulty shape of the Meatus Auditorius Externus.

Anatomy informs us, that this passage is naturally oblique, and somewhat winding; and natural philosophy teaches us the necessity of such obliquity, which multiplies the reflections of the sonorous waves, and thereby strengthens the sense. This theory, says Leschevin, is confirmed by experience; for, there are persons, in whom the meatus auditorius is almost straight, and they are found to be hard of hearing. If there is any means of correcting this defect, it must be that of substituting, for the natural curvature of the passage, a curved and conical tube, which must be placed at the outside of the organ, just like a hearing trumpet. The acoustic instrument, invented by Deckers, which is much more convenient, might also prove useful. (*Op. cit. p. 133.*)

5. Extraneous Substances, Insects, &c. in the Meatus Auditorius Externus.

Foreign bodies met with in this situation are inert substances, which have been introduced by some external force; insects, which have insinuated themselves into the passage; or the cerumen itself, hardened in such a degree as to obstruct the transmission of the sonorous undulations. Worms, which make their appearance in the meatus auditorius, are always produced subsequently to ulcerations in the passage, or in the interior of the tympanum, and, very often, such insects are quite unsuspected causes of particular symptoms. In the cases of surgery, published in 1778, by Acrel, there is an instance confirming the statement just offered. It is the case of a woman, who, having been long afflicted with a hardness of hearing, was suddenly seized with violent convulsions, without any apparent cause, and soon afterward complained of an acute pain in the ear. This affection was followed by a recurrence of convulsions, which were still more vehement. A small tent of fine linen, moistened with a mixture of oil and laudanum, was introduced into the meatus auditorius, and, on removing it the next day, several small round worms were observed upon it, and, from that period, all the symptoms disappeared. To this case, we shall add another from Morgagni. A young woman consulted Valsalva, and told him, that when she was a girl, a worm had been discharged from her left ear; that another one, about six months ago, had also been discharged, very much like a small silkworm in shape. This event took place after very acute pain in the same ear, the forehead and temples. She added, that

since this, she had been tormented with the same pains, at different intervals, and so severely, that she often swooned away for two hours together. On recovering from this state, a small worm was discharged, of the same shape as, but much smaller than, the preceding one, and she was now afflicted with deafness and insensibility on the same side. After hearing this relation, Valsalva no longer entertained any doubt of the membrane of the tympanum being ulcerated. He proposed the employment of an injection, in order to destroy such worms as yet remained. For this purpose, distilled water of St. John's wort, in which mercury had been agitated, was used. In order to prevent a recurrence of the inconvenience, Morgagni recommends the affected ear to be closed up when the patient goes to sleep, in autumn and summer. If this be not done, flies, attracted by the suppuration, enter the meatus auditorius, and, while the patient is unconscious, deposit their eggs in the ear. Acrel, in speaking of worms, generated in the meatus auditorius observes, that there is no better remedy for them, than the decoction of ledum palustre, injected into the ear, several times a day. However, as this plant cannot always be procured, an infusion of tobacco in oil of almonds may be used, a few drops of which are to be introduced into the ear, and retained there by means of a little bit of cotton. This application, which is not injurious to the lining of the passage, is fatal to insects, and especially to worms. It will answer in cases where caterpillars, ants, earwigs and other insects have insinuated themselves into the meatus auditorius; though it is generally considered better first to endeavour to extract them. A piece of lint, smeared with honey, often suffices for this purpose, and when they cannot be extracted by this simple means, they may be taken out with a small pair of forceps. The latter method serves also for the extraction of cherry-stones, peas, or other seeds which have been introduced into the meatus auditorius. If such substances should make too much resistance, forceps with stronger blades for breaking the extraneous bodies must be employed, and then the fragments are to be extracted piecemeal. But, in these cases, before attempting the extraction, a little oil of almonds should be injected. The presence of foreign bodies in the ear often occasions the most extraordinary symptoms, as we may see in the fourth observation of Fabricius Hildanus, Cent. 13.

After four surgeons, who had been successively, consulted had in vain exerted all their industry to extract a bit of glass from the left ear of a young girl, the patient found herself abandoned to the most excruciating pain, which soon extended to all the side of the head, and which, after a considerable time, was followed by a paralysis of the left side, a dry cough, suppression of the menses, epileptic convulsions, and, at length, an atrophy of the left arm. Hildanus cured

her, by extracting the piece of glass, which had remained eight years in her ear, and had been the cause of all this disorder. Although the extraction must have been very difficult, it does not appear that Hildanus found it necessary to practise an incision behind the ear, as some authors have advised, and among them, Duverney, who has quoted the foregoing case. We must agree with Leschevin, that such an incision does not seem likely to facilitate the object very materially; for, it must be on the outside of the extraneous substance, which is in the bony part of the canal. The incision enables us, in some measure, to avoid the obliquity of the passage, as Duverney has observed; but it is not such obliquity of the cartilaginous portion of the canal, that can be a great impediment; for, as it is flexible, it may easily be made straight, by drawing upwards the external ear. Hence, Fabricius ab Aquapendente rejected this operation, first proposed by Paulus Aegineta; and it is justly disapproved of by Leschevin. (*Prix de l'Acad. de Chir. Tom. 9, p. 147, Edit. 12mo.*)

Sabatier relates a case, in which a paper ball, which had been pushed into the meatus auditorius, made its way by ulceration into the cavity of the tympanum, where an abscess formed, which communicated with the interior of the cranium. (*Diet. des Sciences Med. T. 7, p. 8.*)

6. Meatus Auditorius obstructed with thickened, or hardened Cerumen.

The cerumen, secreted in the meatus auditorius by the sebaceous glands, frequently accumulates there in large quantities, and becoming harder and harder, at length acquires so great a degree of solidity as entirely to deprive the patient of the power of hearing. Galen has remarked, *è numero eorum quæ meatum obstruunt, sordes esse quæ in auribus colligi solent*. This species of deafness is one of those kinds, which are the most easy of cure, as is confirmed by observers, especially Duverney. Formerly frequent injections, either with simple olive oil, or oil of almonds, were recommended. The injection was retained by a piece of cotton, and when there was reason to believe that the matter was sufficiently softened, an attempt was made to extract it by means of a small scoop-like instrument. Various experiments were made by Hargrath, at Chester, in 1769, from which it appears that warm water is preferable to oil. The water dissolves the mucous matter, which connects together the truly ceruminous particles, and which is the cause of their tenacity; other applications only succeeding by reason of the water which they contain.

The lodgment of hard pellets of wax, if neglected, may ultimately produce ulceration of the tympanum, and other serious mischief. Thus, in one case, Ribes and Chaussier found the handle of the malleus separated from its head, partly destroyed, and covered with the hardened cerumen that

had made its way into the tympanum. (See *Dict. des Sciences Med.* T. 38, p. 30.)

"The symptoms (says Mr. Saunders) which are attached to the inspissation of the cerumen are pretty well known. The patient, besides his inability to hear, complains of noises, particularly a clash or confused sound in mastication, and of heavy sounds, like the ponderous strokes of a hammer.

"The practitioner is led by the relation of such symptoms to suspect the existence of wax; but he may reduce it to a certainty by examination.

"Any means capable of removing the inspissated wax may be adopted; but syringing the meatus with warm water is the most speedy and effectual, and the only means necessary. As the organ is sound, the patient is instantaneously restored." (*Anatomy of the human Ear, with a Treatise on its Diseases, by J. C. Saunders, 1806, p. 27, 28.*)

In order to throw an injection into the ear with effect, a large syringe, capable of holding, at least, six or eight ounces, should be employed; and the fluid should be injected with a good deal of force, care being taken to let it enter in the natural direction, and not against one of the sides of the passage. The surgeon must also avoid pressing the pipe too deeply into the ear, so as to hurt the tympanum. As the fluid regurgitates with considerable rapidity, a small basin is to be held close up to the ear at the time of using the syringe, so as to catch the water, and hinder it from wetting the patient's clothes; for the surer prevention of which a napkin is also to be laid over the shoulder. In general it is necessary to throw the water into the ear six or seven times, or more, ere the pellets of wax are loosened, and entirely brought out; and, sometimes, the injections will not completely succeed the first day on which they are employed. The evening before the syringe is to be used, it may occasionally be best to drop a little sweet oil into the ear.

7. Discharges from the Meatus Auditorius.

Purulent discharges from the ear either come from the meatus auditorius externus itself, or they originate from suppuration in the tympanum, in consequence of blows on the head, abscesses after malignant fevers, the small-pox, or the venereal disease. In such cases, the little bones of the ear are sometimes detached, and escape externally, and complete deafness is most frequently the consequence. However, in a few instances, total deafness does not always follow even this kind of mischief, as I myself have witnessed on one or two occasions. There is greater hope when the disorder is confined to the meatus; as judicious treatment may now avert the most serious consequences. In Acrel's surgical cases, there is a case relative to the circumstance of which we are speaking. Suppuration took place in the meatus auditorius externus, in

consequence of acute rheumatism, which was followed by vertigo, restlessness, and a violent headach. The matter discharged was yellowish, of an aqueous consistence, and acid smell. The meatus auditorius was filled with a spongy flesh. On introducing a probe, our author felt a piece of loose rough bone, which he immediately took hold of with a pair of forceps, and extracted. From the time when this was accomplished, the discharge diminished; and, with the aid of proper treatment, the patient became perfectly well.

The meatus auditorius, like all other parts of the body, is subject to inflammation. This is frequently produced by exposure to cold. It is hardly necessary to say, that generally topical bleeding and antiphlogistic means are indicated. The meatus auditorius should also be protected from the cold air, particularly in the winter season, by means of a piece of cotton.

Mr. Saunders observes, "When the means employed to reduce the inflammation have not succeeded, and matter has formed, it is generally evacuated, as far as I have observed, between the auricle and mastoid process, or into the meatus. If it has been evacuated into the meatus, the opening is most commonly small, and the spongy granulations, squeezed through a small aperture, assume the appearance of a polypus. Sometimes the small aperture, by which the matter is evacuated, is in this manner even closed, and the patient suffers the inconvenience of frequent returns of pain from the retention of the discharge. When the parts have fallen into this state, it will be expedient to hasten the cure by making an incision into the sinus, between the auricle and mastoid process.

"It occasionally happens, that the bone itself dies, in consequence of the sinus being neglected, or the original extent of the suppuration. The exfoliating parts are the meatus externus of the os temporis or the external lamina of the mastoid process. (P. 24, 25.)

8. Excrescences in the Meatus Auditorius.

Though the membrane, lining the meatus auditorius, is very delicate, it is not the less liable to become thickened, and to form polypous excrescences. This case, however, is not common. As such tumours are ordinarily firmer in their texture than polypi of the nose, they are sometimes not so easily extracted with forceps. When they are situated near the external orifice, and admit of being taken hold of with a small pair of forceps, or a hook, they may easily be cut away, when drawn outward, and this without any reason for fearing hemorrhage. This, indeed, is usually very trivial. When the tumours are more deeply situated, Mr. B. Bell recommends the use of a ligature. Here the same plan may be pursued as will be explained in the article *Polypus*. But, it sometimes happens, that the excrescences cannot be removed in this manner; as instead of being adherent by a narrow

neck, they have a broad base, which occupies a considerable extent of the passage. In such cases, the use of escharotics has been absurdly proposed; but, as these applications cannot be used without risk of injuring the membrane of the tympanum, it is better to have recourse to another method. (*Encyclopédie Méthodique; Partie Chirurgicale, Art. Auditif conduit.*) Mr. B. Bell recommends dilating the passage with bougies; but it is obvious that the pressure of such instruments would also be very likely to irritate and inflame the membrane of the tympanum.

9. Herpes of the Meatus Auditorius.

An herpetic ulcerous eruption sometimes affects the meatus auditorius and auricle, producing considerable thickening of the skin, and so great an obstruction of the passage, that a good deal of deafness is the consequence. Mr. Saunders remarks, that, in this case, "the ichor, which exudes from the pores of the ulcerated surface, inspissates in the meatus, and not only obstructs the entrance of sound, but is accompanied with a great degree of fœtor. This disease is not unfrequent. I have never seen it resist the effect of alterative medicines," the use of injections containing the oxymuriate of quicksilver, and the application of the unguentum hydrargyri nitrati. Mr. Saunders exhibited calomel as the alterative, and, in one instance, employed a solution of the argentum nitratum, as an injection. (Page 25, 26.) When the disease is obstinate, a seton should be made on the nape of the neck, or a blister be applied behind the ear.

10. Affections of the Tympanum.

The ear is sometimes affected with a puriform ichorous discharge, attended with a loss of hearing, proportionate to the degree of disorganization which the tympanum has sustained. Frequently, on blowing the nose, air is expelled at the meatus auditorius externus; and, when this is the case, it is evident, that the discharge is connected with an injury, or destruction of the membrana tympani. However, when the Eustachian tube is obstructed with mucus, or matter, or when it is rendered impervious, and permanently closed by inflammation, the membrana tympani may not be perfect, and yet, it is clear, no air can in this state be forced out of the external ear in the above manner. An examination with a blunt probe, or with the eye, while the rays of the sun fall into the passage, should therefore not be omitted. If the membrane have any aperture in it, the probe will pass into the cavity of the tympanum, and the surgeon feel that his instrument is in contact with the ossicula.

In this manner, the affection may be discriminated from an herpetic ulceration of the meatus auditorius externus. The causes are various: In scarlatina maligna, the membrana tympani occasionally inflames, and sloughs; all the ossicula are discharged, and, if the patient live, he often continues

quite deaf. An earach, in other words, acute inflammation of the tympanum is the most common occasion of suppuration in this cavity, in which, and the cells of the mastoid process, a good deal of pus collects. At length the membrana tympani ulcerates, and a large quantity of matter is discharged; but, as the secretion of pus still goes on, the discharge continues to ooze out of the external ear.

Instead of stimulating applications, inflammation of the tympanum demands the rigorous employment of antiphlogistic means. Unfortunately, it is a too common practice, in this case, to have recourse to acrid spirituous remedies. Above all things, the repeated application of leeches to the skin behind the external ear, and over the mastoid process, should never be neglected. As soon as the inflammation ceases, the degree of deafness occasioned by it, will also disappear. This, however, does not always happen.

When an abscess is situated in the cavity of the tympanum, Mr. Saunders thinks, that the membrana tympani should not be allowed to burst by ulceration, but be opened by a small puncture. (P. 31.) However, unless there were the strongest ground for believing, that the Eustachian tube were impervious, this advice, I think, ought not to be followed, more especially as the symptoms are generally too vague to afford any degree of certainty in the diagnosis.

Sometimes the disease, of which we are treating, is more insidious in its attack: slight paroxysms of pain occur, and are relieved by slight discharges. The case goes on in this way, until, at last, a continual discharge of matter from the ear takes place. The disorder is destructive in its tendency to the faculty of hearing, and it rarely stops until it has so much disorganized the tympanum and its contents, as to occasion total deafness. Hence, Mr. Saunders insists upon the propriety of making attempts to arrest its progress,—attempts which are free from danger; and he censures the foolish fear of interfering with the complaint, founded on the apprehension, that bad constitutional effects may originate from stopping the discharge.

If the case be neglected, the tympanum is very likely to become carious; before which change, the disease, says Mr. Saunders, is mostly curable.

Mr. Saunders divides the complaint into three stages: 1. A simple puriform discharge. 2. A puriform discharge complicated with fungi and polypi. 3. A puriform discharge with caries of the tympanum. As the disease is local, direct applications to the parts affected are chiefly entitled to confidence. Blisters and setons may also be advantageously employed. Mr. Saunders's practice consisted in administering laxative medicines and fomenting the ear, while inflammatory symptoms lasted, and afterward injecting a solution of the sulphate of zinc, or cerussa acetata.

In the second stage, when there were

fungi, he removed or destroyed them with forceps, afterward touched their roots with the *argentum nitratum*, or injected a solution of alum, sulphate of zinc, or *argentum nitratum*.

Writers describe a relaxed state of the *membrana tympani*, as a cause of deafness. If, says a late author, after a discharge from the *meatus auditorius externus*, or cavity of the tympanum, or a dropsy of the latter cavity, the hearing remains hard, there is reason to suspect, that the infirmity may depend upon relaxation of the membrane of the tympanum, or paralysis of the internal muscle of the malleus. This suspicion will be strengthened, if the deafness should increase in damp, and lessen in dry weather; and particularly, if it be found, that the hearing is benefited by introducing into the ear dry warm tonic applications, such as the smoke of burning juniper-berries, or other astringent vegetable substances. The decoction of bark, used as an injection, is also said to have done good.

The relaxation of the tympanum, alleged to proceed from a rupture of the muscle of the malleus, is deemed incurable; but it is not so with the case, which depends upon paralysis of this muscle. Here tonic injections into the tympanum, through the Eustachian tube, are recommended. (*Dict. des Sciences Med. T. 38, p. 50.*) Electricity, stimulating liniments and gargles, and a blister, might also be tried.

Imperfect hearing is supposed sometimes to arise from preternatural tension of the membrane of the tympanum, indicated by the patient hearing better in wet than dry weather, and by his hearing what is spoken in a low tone, near his ear, better than any thing said in a loud manner. The opinions, delivered by writers on the causes of this affection, are only uncertain conjectures. The local treatment recommended, consists of injecting into the *meatus auditorius*, emollient decoctions, or warm milk, or introducing into the passage a dossil of soft cotton, dipped in oil of sweet almonds. Nothing certain is known respecting the proper constitutional treatment, as must be clear from our ignorance of the causes of this form of disease of the ear.

Hardness of hearing appears sometimes to be caused by a chronic thickening of the membrane of the tympanum; and it is alleged, that there are cases of this description, which proceed from syphilis, and require mercury. An issue in the arm nearest the affected ear, and emollient and slightly stimulant injections, are likewise commended. When the tympanum was so considerably thickened, that there was no chance of restoring it to a healthy state, Portal questioned whether it might not be advisable to make a small opening in it? (*Précis de Chir. Pratique, T. 2, p. 480.*) This operation, which is said to have been first suggested by Cheselden, will be considered in the ensuing section.

Morgagni found the cavity of the tympanum intersected by numerous membranes,

which impeded the movements of the ossicula. (*Epist. an. 6, § 4.*)

Meckel does not mention any example of a deficiency of all the ossicula. (*Handb. des Pathol. Anat. B. 1, p. 402.*) Mersanni, however, found the incus wanting. (*Bonnet Sepulch. T. 1, sect. 19, Obs. 4, § 1.*) Caldani, the malleus and incus. (*Epist. ad Haller, T. 6, p. 142.*) The latter case was unattended with any bad effect on the hearing; the first with deafness. In a deaf child, three years of age, Bailly found the ossicula of only 1-3 their proper size. (*Bonnet Sepulch. T. 1, sect. 19, Obs. 4, § 3.*) In an example, where the fenestra rotunda was obstructed, Cotunni found the ossicula twice as large as natural. (*De labyrinthi auris contentis, § 72, and Meckel's Handb. des Pathol. Anat. B. 1, p. 402.*) A case, in which all the ossicula were wanting, is now on record. (*See Dict. des Sciences Med. T. 38, p. 114.*)

11. Obstruction of the Eustachian Tube.

This is often a cause of a considerable degree of deafness, because it is necessary for perfect hearing, that air should be conveyed from the mouth through this passage into the cavity of the tympanum, which now can no longer happen.

A degree of deafness generally attends a severe cold, which is accounted for by the Eustachian tube being obstructed with thickened mucus. Mr. Saunders tells us, that the obstruction most frequently arises from syphilitic ulcers in the throat, or sloughing in the cynanche maligna. The deafness comes on when such sores are healed, that is, when the obstruction is complete. The descent of a nasal polypus into the pharynx, and enlarged tonsils, have also been known to close the tube. (*P. 42.*)

When the Eustachian tube is obstructed, the patient cannot feel the *membrana tympani* crackle, as it were, in his ear, on blowing forcibly with his nose and mouth stopped. Previous ulceration, or disease, of the throat will sometimes facilitate the diagnosis.

When the Eustachian tube is obstructed with mucus, it has been proposed to employ injections, which are to be thrown by means of a syringe and catheter, into the guttural orifice of that canal. This operation, however, is alleged to be always attended with trouble, and, when the *os spongiosum inferius* happens to be situated near the floor of the orbit, the introduction of any instrument, like a female catheter, would be impracticable. (*Richerand Nosogr. Chir. T. 2, p. 131, edit. 2.*)

Mr. A. Cooper had noticed, that hearing was only impaired, not lost, when suppurations in the tympanum had injured, and even destroyed the *membrana tympani*, and that the degree of deafness by no means equalled what resulted from an obstruction of the Eustachian tube. Hence, when the tube was permanently obliterated, he conceived, that a small puncture of the *membrana tympani* might be the means of enabling the patient to hear. This gentleman reports four cases,

in which the experiment was made with success.

The operation consists in introducing an instrument, resembling a hydrocele trocar, but curved, into the meatus auditorius externus, and pushing it through the anterior and inferior part of the membrana tympani; a place rendered most eligible, on account of the situation of the chorda tympani and manubrium of the malleus, parts which should be left uninjured. The instrument must not be introduced far, lest it wound the vascular lining of the tympanum, and cause a temporary continuance of the deafness by an effusion of blood. When the puncture is made, in proper cases, and in a judicious manner, hearing is immediately restored. A small hole in the membrana tympani now conveys the air into the cavity of the tympanum, answering the same purpose as the Eustachian tube.

The surgeon will be able to operate with more ease, if he take care to lessen the curvature of the meatus auditorius by drawing upward the external ear.

There is some chance of a relapse in consequence of the opening closing up. This consideration led Richerand to propose making the aperture with caustic, so as to destroy a part of the membrane. (*Nosogr. Chir. T. 2, p. 132, edit. 2.*) The suggestion is not likely to be adopted, on account of the inconveniences of applying caustic within the ear. Mr. Saunders is an advocate for making the opening large. This gentleman instantaneously restored the hearing of one patient who had been deaf thirty years, in consequence of a destruction of a part of his palate by syphilis. (*P. 45.*) In an instance where a young man had been deaf for eight years, apparently from obstruction of the Eustachian tube by swellings and disease about the throat. Paroisse also restored the hearing directly, by perforating the anterior and inferior part of the tympanum. (*Opuscules de Chir. p. 309, 8vo. Paris, 1806.*) The practice has also been successfully adopted by Michaelis in one case, and Hunold has tried it in a vast number of examples, two-thirds of which succeeded. (*Dict. des Sciences Med. T. 38, p. 63.* Mr A. Cooper's cases are in the *Phil. Trans. for 1802.*)

Puncturing the membrana tympani has been attended with some degree of success in France, where it has been tried by Itard, Celliez, and Maunoir, &c. It is not to be dissembled, however, that it is liable to failure. Dubois performed the operation in four instances, without success. (*Richerand Nosogr. Chir. T. 2, p. 132.*)

In most cases, the patients benefited are said to have experienced pain just after the trochar was withdrawn. The organ, not being accustomed to sound, had become so extremely sensible, that it could bear the gentlest impression of the sonorous vibrations, and the patient's first request after the perforation had been made, was, that persons near him might speak softly. This

excessive tenderness of the sense gradually subsides.

The two principal objections made to the foregoing practice, are the risk of injuring that part of the tympanum, which is connected with the malleus, and the tendency of the puncture to heal up again. (*See Dict. des Sciences Med. T. 38, p. 57; Maunoir in Journ. de Med. T. 13; Sabatier, Traité d'Anatomie, T. 2, p. 186.*) The author of the article Oreille in the latter dictionary, who cannot, however, be deemed at all partial to the operation, delivers the following judgment concerning it:—1. It is the only operation, which is likely to answer, where the tympanum is cartilaginous or ossified, and the rest of the organ is sound. 2. It will be attended with some success, where the Eustachian tube is closed, and this defect cannot be otherwise removed. 3. It will be useless where the cavity of the tympanum is filled with matter, which is too thick to escape through the puncture. 4. When deafness depends on paralysis of the auditory nerve. 5. When the infirmity arises from inflammation of the ear or nervous irritation. 6. From fevers, the Eustachian tube being pervious.

The limits of this work will not allow me to introduce the directions given by various authors for injecting fluids into the Eustachian tube. Wathen, Baron Boyer, and the latest surgeons, who have considered this operation, seem to agree, that it is more easily performed by passing the tube through one of the nostrils, than the mouth. Wathen's instruments are described in *Phil. Trans. 1794*; those of Baron Boyer in *Traite des Mal. Chir. T. 6, p. 391*; and those of another modern advocate for this operation, in *Dict. des Sciences Med. T. 38, p. 108.* The latter author, after stating how his tubes, which are four French inches in length, and shaped somewhat like an italic S, are introduced, enumerates the following as the advantages derived from their employment. 1. Fluid applications may be conveyed into the Eustachian tube, the cavity of the tympanum, and the mastoid cells, and deeply seated obstinate ulcerations within these parts cured. 2. The same parts can be cleared from any mucus with which they are obstructed. 3. Blood extravasated within the tympanum, from blows on the head, can be washed out. 4. Chalky substances, which sometimes form in the tympanum, may be brought out in the same manner. 5. Through the tube a stilet can be passed into the Eustachian tube, so as to perforate a congenital septum, or any cicatrix, obstructing the entrance of that passage. 6. When the sensibility of the auditory nerve is dull, the effect of fluids thrown into the tympanum, can be tried.

12. Of perforating the Mastoid Process.

Of all the cases of deafness, for which Arneman and others have recommended this operation, that attended with an abscess and caries of this process is the only one, in which the practice is now at all sanctioned.

An instance is related by Jasser, in which the carious surface of the right mastoid process was exposed by an incision, and an opening detected with a probe. An injection was thrown into the aperture with a syringe, when, to the astonishment of Jasser and his patient, the fluid gushed out of the right nostril. The plan was repeated for a few days, and, at the end of three weeks, the part was healed, and the hearing greatly improved. This success induced Jasser to make a perforation in the left mastoid process, the ear on that side being deaf, and to employ the injection, which was also discharged from the left nostril. The hearing, however, was not so completely restored in this as it had been in the right ear; but the wound healed up, without any extolations. (*Journ. de Med. Feb. 1793.*) The idea of perforating the mastoid process was suggested long before the time of Jasser. Riolan, in various parts of his works, suggests the propriety of making a small perforation in several cases of deafness, and tinnitus aurium, attended with obstruction of the Eustachian tube. Rolin- cius also advised a similar opening to be made in the mastoid process with a trocar, in cases of dropsy of the cavity of the tympanum and of the mastoid cells. Jasser, however, was the first who actually made the experiment, and his example was followed by Hagstroem, whose attempt did not succeed, the completion of the operation having been interrupted by profuse hemorrhage, and no benefit done to the hearing. The injections also appear to have caused, in this instance, alarming symptoms, violent pain in the head, loss of vision, sense of suffocation, and syncope. The fluid entered the mastoid cells, without any of it issuing, either by the nostrils or mouth. (*Op. cit.*)

The operation was successfully tried by Löffler. The injection did not pass into the mouth, yet the hearing was restored, though it was lost again when the wound closed. Hence, a new opening was made, and kept from healing by means of a piece of cat-gut. The patient was afterward able to hear when his mouth was open.

The perforation of the mastoid process was not approved of by Morgagni; indeed, it must often fail, as both Morgagni and Hagstroem have observed, on account of complete bony partitions preventing all communications between the mastoid cells; and sometimes the mastoid process, instead of being cellular, is perfectly solid, an instance of which is recorded by A. Murray.

13. Diseases of the Labyrinth.

These are much more diversified than might, at first, be supposed, and, if we admit the two doubtful cases, said to depend upon the state of the lymph of Cotunni, there are not less than seven different species of disease affecting the labyrinth:—1. Disease of the fenestra ovalis, and fenestra rotunda, as ulceration, thickening, &c. 2. Malformation of these apertures. 3. Malformation of the labyrinth. 4. Inflamma-

tion of the nervous membrane, which lines its cavities. 5. Alteration of the liquor of Cotunni. 6. Deficiency of the same fluid. 7. Affections of the nerve of hearing.

No doubt deafness (and that kind of it which so frequently foils the most skilful men) often arises from an insensible state of the portio mollis of the auditory nerve, or of the surfaces, on which its filaments are spread. This affection is analogous to the amaurosis, or gutta serena, in which, though every part of the eye may seem to possess its natural structure, sight is lost, because the rays of light only strike against a paralytic, or insensible retina. Mr. Saunders dissected the ears of two deaf patients, with the greatest care, but could not discover the least deviation from the natural structure. In the commencement of deafness from a paralytic affection of the auditory nerve, Mr. A. Cooper remarked, that the secretion of cerumen was diminished, and, when the deafness became worse, was totally suppressed. And another particular symptom of paralysis of the auditory nerve, pointed out by the same author, is the patient's inability to hear the sound of a watch placed between the incisor teeth.

With respect to the causes of a paralytic affection of the auditory nerve, they are mostly buried in great obscurity, and some of them probably depend upon congenital imperfection of the nerve, or brain itself. It seems, however, that a part of the causes, to which we allude, act mechanically, as an extravasation of blood, a steatoma, or an exostosis; while others operate upon the ear by sympathy, as is the case when deafness is produced by the presence of worms in the bowels.

Mr. Saunders remarks, that all the diseases of the internal ear may be denominated nervous deafness; the term, in this sense, embracing every disease, the seat of which is in the nerve, or parts containing the nerve. Nervous deafness is attended with various complaints in different cases, noises in the head of sundry kinds, the murmuring of water, the hissing of a boiling kettle, rustling of leaves, blowing of wind, &c. Other patients speak of a beating noise, corresponding with the pulse, and increased by bodily exertion, in the same degree as the action of the heart. (*Saunders, p. 47.*)

According to this author, there is a syphilitic species of nervous deafness, attended with a sensation of some of the above peculiar noises: and one case is related, in which the hearing was completely restored, in five weeks, by a mercurial course.

Mr. Saunders relieved several cases of nervous deafness by confining patients to low diet, giving them calomel freely, repeated doses of sulphate of soda, magnesia, sometimes twice, sometimes thrice, a week, or according to circumstances, and applying blisters behind the ears at intervals of a week. The plan requires perseverance.

Electricity has been highly recommended for the cure of nervous deafness, though the prospect of benefit from it most entirely

depend upon the nature of the cause of the infirmity. It is allowed to be sometimes useful in cases of incomplete paralysis of the auditory nerve; but, it cannot be of any service where the Eustachian tube, the cavity of the tympanum, or the mastoid cells, are obstructed. It is set down as hurtful, when the patients are very irritable, and subject to vertigo, bleeding from the nose, great determination of blood to the head, &c. (*Dict. des Sciences Med.* T. 38, p. 124.) The evidence, in favour of the efficacy of galvanism, is still more scanty and questionable.

Whether in certain cases of deafness from torpor of the auditory nerve, the introduction of tonic injections into the cavity of the tympanum, through the Eustachian tube, will answer in the manner stated by a late writer, future experience must determine. (*Dict. des Sciences Med.* T. 38, p. 120—121.)

This article, I think, may be usefully concluded with a few general, but sensible observations on the various kinds of deafness, made by a modern writer. According to Professor Rosenthal, all the disorders of the sense of hearing may be comprised under three principal forms.

1. Deafness (*Surditas, Cophosis*) in which the faculty of hearing articulated sounds is completely annihilated.

2. Hardness of hearing (*Dysacua*) in which this faculty is so diminished, that articulated sounds cannot be heard, without the assistance of a particular apparatus.

3. Alteration, or diminution of hearing (*Paracusis*) in which the faculty of hearing articulated sounds, in the natural way, is imperfect for want of precision.

1. Deafness, Rosenthal distinguishes into two degrees, the first of which is marked by an absolute impossibility of hearing at all; the second, by a power of still distinguishing certain sounds, as whistling, the vowels, &c. The first is usually congenital, and a cause of dumbness.

The discrimination of these two degrees, Rosenthal considers of great importance in practice, and especially in institutions for the deaf and dumb; because the exceedingly fine sense of touch, with which deaf persons are sometimes gifted, is apt to be mistaken for the faculty of hearing. This fact is illustrated by some interesting experiments made by Pfingsten on deaf and dumb persons. (*Vieljaehrige Erfahrung ueber die Geheerfehler der Taubstummen*, Kiel, 1802, p. 32.) A deaf and dumb girl, who was at needlework in a room near the house-door, regularly gave notice whenever it was opened or shut. As the door was furnished with a little bell, which rung loud enough whenever the door moved to be plainly heard in the neighbouring room, and, with the exception of this noise, no other impulse nor shock could be distinguished, Pfingsten was surprised at the circumstance. Desirous of ascertaining how the girl really knew about the movements of the door, he caused the bell to be rung

with great force without the door being opened: the child was perfectly unconscious of the noise. The bell was afterward kept still, while a person opened and shut the door so softly, that Pfingsten himself could not hear it; yet, the child instantly gave warning, that somebody had entered. The inference was, that the chair, on which she sat, communicated to her legs and back a certain impulse, which made her conscious of the motion of the door.

The dissection of the ears of deaf and dumb persons has evinced some facts, explanatory of the cause of the loss of hearing. Among other things, it appears, that complete deafness, whether congenital, or acquired, more frequently depends upon morbid alterations of the soft parts, than upon any irregularity in the formation of the bones. Thus, in the body of a person, who had been deaf and dumb while living, Hoffmann found the auditory nerve diminished in size, while every other part of the organ was perfectly natural. Arnemann found the nerve harder than common. Dr. Haighten met with an instance, in which the vestibulum was filled with a caseous substance. (*A case of original deafness, in Mem. of the Med. Society, Vol. 3, p. 1—15.*) Duvernoy and Sandifort found the auditory nerve strongly compressed by a steatoma. In one case, Itard found every part of the ear apparently so natural, that the deafness could not be ascribed to paralysis of the nerve. In another, the infirmity depended upon obstruction of the passages. In a third, the cavity of the tympanum, and the vestibulum, contained small portions of calcareous matter. He has also seen the tympanum filled with a thick yellow lymph, or a thin fluid enclosed in membranous cells. In the dissection of the body of a deaf and dumb person, Rosenthal noticed, among other remarkable circumstances, a greater hardness of the auditory, than of the facial nerve, and preternatural firmness of the medulla oblongata. Thickening of the membrane of the tympanum. The bony roof of the cavity of the tympanum not thicker than paper, and just over the junction of the malleus with the incus, the bony substance was so absorbed, that an appearance like that of membrane alone remained. The mastoid cells, cavity of the tympanum, and the Eustachian tubes contained a limpid yellow fluid. In the tympanum, the periosteum was thickened, forming small cells around the ossicula, which were of their natural structure. Nothing particular was remarked in the labyrinth.

In a small proportion of instances, the above degree of deafness has been traced to anomaly in the structure of the solid parts. Thus, Mundini found the cochlea composed of only one circle and a half. (*Opusc. Acad. Bonon.* 1791, T. 7, p. 422.) Valsalva found the stapes adherent to the fenestra ovalis. (*De Auris Humanâ*, cap. 11;) and Reimarns the ossicula entirely wanting. (*Kunstrieb der Thiere*, p. 57.)

In the first degree of deafness above described, which when congenital, must excite

suspicion of serious malformation of the organ, and abolition of the nervous influence, and when acquired indicates a complete injury of the functions of the nerve, the prognosis, as Rosenthal observes, must be unfavourable. Nor can it be otherwise in the second congenital degree of the disease, though only a partial imperfection of the organ and nerve can here be supposed. On the other hand, when the latter degree is acquired, there is more prospect of relief, because merely a partial alteration in the soft parts is to be suspected.

2. *Hardness of hearing.* Rosenthal also distinguishes several degrees of, what is termed, hardness of hearing. In the first, the patient cannot hear a distant noise, and especially high tones; but, he can perceive, though it is true not in a very distinct manner, articulated sounds, when the voice is a good deal raised. In the second degree, he hears and distinguishes both high and low tones very well, and also words, but only when the voice is somewhat raised.

These two cases are better understood, inasmuch as it is tolerably well ascertained, that the immediate cause of the infirmity is some alteration in that part of the organ, which serves as a conductor for the vibrations of sound, or else an increased sensibility of the nerve, all the internal ear being in other respects right.

Among alterations of the conducting parts of the organ, Rosenthal comprehends:

1. A total obliteration of the meatus auditorius externus, its imperforation, or complete absence. These cases may almost always be detected by a superficial examination, the patient only hearing when some solid bodies are placed between his teeth, while his dull perception of sounds does not appear to be much lessened when the ear is covered.

2. Diseases of the cavity of the tympanum, as inflammation of its membranous lining, caries of its parietes, or collections of blood, pus, or other fluid, in its cavity. Rosenthal thinks there can be no doubt, that inflammation and suppuration in the tympanum are much more frequent than is generally supposed, the former affection being often mistaken for a slight attack of rheumatism. In dissecting aged subjects, he has frequently found the membrane of the tympanum thickened and opaque, and he could only impute this appearance to previous inflammation.

After detailing a case, illustrative of the symptoms of inflammation within the tympanum, and a few observations on caries, and collections of fluid in that cavity, Rosenthal notices the *hardness of hearing, connected with nervous irritability*, in the treatment of which case, he insists upon the advantage that would result from a knowledge of the particular species of morbid excitement prevailing in the patient. But, as nothing very certain can be made out on this point, and only conjectures can follow some dissections of bodies, that the affection consists either in a determination of blood

to the part, or in a partial paralysis of the auditory nerve, the exact nature and form of which are quite incomprehensible, it is absolutely necessary to attend solely to the diagnosis of the nervous affection in general. This diagnosis will be facilitated; 1st. If the patient has been previously very sensible to the impression of certain tones, or sound in general. 2dly. If the power of hearing has been lost all on a sudden, without any mark of inflammation. 3dly. If the affection coincides with other nervous disorders.

3. *Alteration, or Diminution of Hearing.* Between the most perfect hearing, congenital or acquired, and this point of diminution of the faculty of hearing, Rosenthal observes, there are a great many degrees, the cause of which is the more difficult to comprehend, as the circumstances of structure, which enable every part to perform its functions with freedom and perfection, are not yet made out. If, says he, it were in our power to determine what is truly the regular structure of each part, we should then be furnished with a means of judging correctly of the anomalies of function, the changes in which would be indicated quite as clearly as in the eye, by shades of organization, absolutely in the same way, as we judge of the modifications, which the image of objects must undergo at the bottom of the ocular mirror, by the greater or less convexity of the cornea, or lens, or the consistence of the other humours.

In the present state of physiological and pathological knowledge of the ear, therefore, Rosenthal conceives, that little can be attempted with respect to a scientific classification of these cases of altered, or diminished hearing. As the cavity of the tympanum and its contents are the parts, which have principal influence over the intensity of sound, and a great share in the propagation of articulated sounds, their faulty condition must here be chiefly the subject for consideration. And, among their numerous defects, traced by dissection, and already specified in the foregoing columns, Rosenthal particularly calls the attention of the reader,

1. To alterations of the membrane of the tympanum, whether proceeding from congenital malformation, or situation, or from thickening, ossification, perforation, or laceration of the same part.

2. The lodgment of some fluid in the cavity of the tympanum, more frequently produced, than is commonly supposed, by obstruction of the Eustachian tube. In most new-born infants, Rosenthal has also found the cavity of the tympanum filled with a thick, almost gelatinous fluid, which for some days is not absorbed, and is probably the cause of the indifference, evinced by new-born children, to sounds, which are even so intense as to be offensive to the ears of an adult.

3. Alterations of the membrane of the fenestra rotunda, such as its imperfect formation, or erroneous situation, its thickened state, &c.

But, it is remarked by Rosenthal, that as the difference in the intensity of sound may occasion a modification in the sensations of the ear, the merely conducting parts of the auditory apparatus must not be forgotten, as the external ear and the meatus auditorius externus, which regulate the quantity of sonorous waves, which strike the auditory nerve. However, the malformations of the meatus, and the state of the ceruminous secretion within it, are observed by Kritter and Lentin (*Ueber das Schwere Gehoere*, L. 19, Leipzig, 1794.) to have more effect on the hearing, than defects of the auricle itself, the whole of which, as we have stated, may be lost without any material deafness being produced. Lastly, Rosenthal calls our attention to the nervous action, or influence, which, whether too much raised, or depressed, may equally render the hearing dull; and some useful information may for the most part be derived from attending to the patient's general sensibility. (See *Journ. Complém. T. 6*, p. 21, &c. *Duverney de l'Organe de l'Ouïe*, 12mo. 1633; *P. Kennedy, A Treatise on the Eye, and on some of the Diseases of the Ear*, 8vo. Lond. 1713. *A. D. T. 6*, p. 17, 8vo. Paris, 1820. For an account of malformations of the organ, see *Meckel's Handbuch der Pathol. Anat. B. 1*, p. 400, &c. 8vo. Leipzig, 1812.)

ECCHYMOSIS. (from *εκχυνω*, to pour out) A superficial, soft swelling, attended with a livid or blue colour of the skin, produced by blood extravasated in the cellular substance.

The causes of ecchymosis are falls, blows, sprains, &c. which occasion a rupture of the small vessels on the surface of the body, and a consequent effusion of blood, even without any external breach of continuity. Ecchymosis is one of the symptoms of a contusion. (See *Contusion*.) A considerable ecchymosis may originate from a very slight bruise, when the ruptured vessels are

capable of pouring out a large quantity of blood, and particularly when the parts contain an abundance of loose, cellular substance. In general, ecchymosis does not make its appearance immediately after the blow, or sprain, and sometimes not till several hours after the application of the violence: at least, it is not till this time that the black, blue, and livid colour of the skin is most conspicuous. A black-eye, which is only an ecchymosis, is always most disfigured six or eight hours after the receipt of the blow.

In the article *Bleeding*, we have noticed how an ecchymosis may arise from the blood getting out of the vein into the adjacent cellular substance.

Common cases of ecchymosis may generally be easily cured, by applying discutient lotions, and administering one or two doses of any mild purgative salt. The best topical applications are vinegar, the lotio muriatis ammoniæ; spirit. vin. camph. and the liquor ammon. acet.

The object is to avert inflammation, and to promote the absorption of the extravasated fluid.

In cases of ecchymosis, I have seen such success attend the practice of dispersing collections of extravasated blood, by means of absorption, that the plan of evacuating it by an incision, seems to me to be seldom necessary. When an opening is made, and air is admitted, the portion of blood, which cannot be pressed out, soon putrefies, and extensive inflammation and suppuration, are the too frequent consequences.

The quick and powerful action of the absorbent vessels in removing extravasations of blood, can now be no longer called in question, when we daily see it proved in modern practice, that the largest aneurismal swellings are thus speedily diminished and removed, after the operation of tying the arteries, from which such tumours arise.

I wish, however, the preceding observations merely to convey a general condemnation of the practice of opening swellings containing extravasated blood; for, no surgeon is more assured, than I am myself, that there are particular exceptions, in which the plan is highly proper and necessary. Thus, whenever a case of extensive ecchymosis, or a large tumour of extravasated blood, either excites suppuration, or creates excessive pain from distention, it is better to practise a free opening. So it sometimes happens, in cases of aneurism, that the skin breaks after the artery has been tied, and some of the blood escapes; but the remainder putrefies, and soon becomes blended with purulent matter in the sac. Here the making of a free incision for the discharge of the irritating contents of the swelling, with due attention to every caution, delivered in the article *Aneurism*, will often be followed by beneficial effects.

ECTROPIUM. (from *εκτροπω*, to divert.) A turning out, or an eversion of the eyelids.

It is remarked by Scarpa, that just as excessive relaxation of the skin of the eyelids,

and a morbid contraction of their lining, near the edges, in consequence of ulcerations and cicatrices, occasion a faulty inclination of the tarsus and eyelashes against the eye; so, sometimes, an elongation and swelling of the membranous lining of the eyelids, or too great a contraction and shortening of the skin of the eyelid itself, or neighbouring parts, produce an opposite disorder to *trichiasis*, viz. an eversion of the eyelids, termed *ectropium*.

Of course, in respect to causes, there are two species of this disease; one produced by an unnatural swelling of the lining of the eyelids, which not only pushes their edges from the eyeball, but also presses them so forcibly, that they become everted; the other, arising from a contraction of the skin covering the eyelid, or of that in the vicinity, by which means the edge of the eyelid is first removed for some distance from the eye, and afterward turned completely outward, together with the whole of the affected eyelid.

The morbid swelling of the lining of the eyelids, which causes the first species of *ectropium*, (putting out of present consideration a similar affection incidental to old age) arises mostly from a congenital laxity of this membrane, afterward increased by obstinate chronic ophthalmies, particularly of a scrofulous nature, in relaxed, unhealthy subjects; or else the disease originates from the small-pox affecting the eyes.

While the disease is confined to the lower eyelid, as it most commonly is, the lining of this part may be observed rising in the form of a semilunar fold, of a pale red colour, like the fungous granulations of wounds, and intervening between the eye and eyelid, which latter it in some measure everts. When the swelling is afterward occasioned by the lining of both eyelids, the disease assumes an annular shape, in the centre of which the eyeball seems sunk, while the circumference of the ring presses, and everts the edges of the two eyelids so as to cause both great uneasiness and deformity. In each of the above cases, on pressing the skin of the eyelids with the point of the finger, it becomes manifest that they are very capable of being elongated, and would readily yield, so as entirely to cover the eyeball, were they not prevented by the intervening swelling of their membranous lining.

Besides the very considerable deformity which the disease produces, it occasions a continual discharge of tears over the cheek, and, what is worse, a dryness of the eyeball, frequent exasperated attacks of chronic ophthalmia, incapacity to bear the light, and, lastly, opacity and ulceration of the cornea.

The second species of *ectropium*, or that arising from a contraction of the integuments of the eyelids, or neighbouring parts, is not unfrequently a consequence of puckered scars, produced by the confluent small-pox; deep burns; or the excision of cancerous, or encysted tumours, without saving a sufficient quantity of skin; or, lastly, the disorder is the effect of malignant carbun-

cles, or any kind of wound attended with much loss of substance. Each of these causes is quite enough to bring on such a contraction of the skin of the eyelids, as to draw these parts towards the arches of the orbits, so as to remove them from the eyeball, and turn their edges outward. No sooner has this circumstance happened, than it is often followed by another one equally unpleasant, namely, a swelling of the internal membrane of the affected eyelids, which afterward has a great share in completing the eversion. The lining of the eyelids, though trivially everted, being continually exposed to the air, and irritation of extraneous substances, soon swells, and rises up, like a fungus. One side of this fungus-like tumour covers a part of the eyeball; the other pushes the eyelid so considerably outward, that its edge is not unfrequently in contact with the margin of the orbit. The complaints induced by this second species of *ectropium*, are the same as those brought on by the first; it being noticed, however, that in both cases, whenever the disease is inveterate, the fungous swelling of the inside of the eyelids becomes hard, coriaceous, and, as it were, callous.

Although in both species of *ectropium*, the lining of the eyelids seems equally swollen, yet the surgeon can easily distinguish to which of the two species the disease belongs. For, in the first, the skin of the eyelids, and adjoining parts, is not deformed with scars, and by pressing the everted eyelid with the point of the finger, the part would with ease cover the eye, were it not for the intervening fungous swelling. But, in the second species of *ectropium*, besides the obvious cicatrix and contraction of the skin of the eyelids, or adjacent parts, when an effort is made to cover the eye with the everted eyelid, by pressing upon the latter part with the point of the finger, it does not give way so as completely to cover the globe, or only yields, as it ought to do, for a certain extent; or it does not move in the least from its unnatural position, by reason of the integuments of the eyelids having been so extensively destroyed, that their margin has become adherent to the arch of the orbit.

According to Scarpa, the cure of this disease cannot be accomplished with equal perfection in both its forms, the second species being, in some cases, absolutely incurable. For, as in the first species of *ectropium*, the disease only depends upon a morbid intumescence of the internal membrane of the eyelids, and the treatment merely consists in removing the redundant portion, art possesses many efficacious means of accomplishing what is desired. But, in the second species of *ectropium*, the chief cause of which arises from the loss of a portion of the skin of the eyelids, or adjacent parts, which loss no known artifice can restore, surgery is not capable of effecting a perfect cure of the malady. The treatment is confined to remedying, as much as possible, such complaints as result from this kind of eversion, and this can be done in a more or less satis-

factory manner, according as the loss of skin of the eyelid is little or great. Cases, in which so much skin is deficient that the edge of the eyelid is adherent to the margin of the orbit, Scarpa abandons as incurable. *Si nimum palpebræ deest, says Celsus, nulla id restituere curatio potest: (lib. 7. cap. 7.)* In the second species of ectropium, Scarpa thinks, that the degree of success attending the cure may always be estimated by remarking to what point the eyelid admits of being replaced, on being gently pushed with the end of the finger towards the globe of the eye, both before and after the employment of such means as are calculated to effect an elongation of the skin of the eyelid; for, it is to this point, and no further, that art can reduce the everted part, and permanently keep it so replaced.

When the first species of ectropium is recent, the fungous swelling of the lining of the eyelid not considerable, and, consequently, the edge of the eyelid not much turned out, and in young subjects (for in old ones the eyelids are so flaccid that the disease is irremediable,) Scarpa prefers destroying the fungous surface of the internal membrane of the eyelid by the repeated application of the *argenti nitratum*. In recent cases, where the patient is weak and irritable, (or a child) Beer commences the treatment with simply applying every day the tincture of opium, which, after a time, is to be strengthened by the addition of naphtha. To the relaxed conjunctiva he afterward applies escharotic eyesalves, and, last of all, the nitrate of silver, and muriate of antimony. Where the part is hard and callous, he precedes the employment of caustic by scarifications. (*Lehre, &c. B. 2, p. 136.*)

For remedying the considerable and inveterate form of the first species of the disease, the quickest and surest plan is to cut away the whole of the fungous swelling closely from the muscular substance, on the inside of the eyelid. This is the advice both of Beer and Scarpa. And, indeed, even in most cases which are not so slight, as to yield to mere astringent applications, this practice is now commonly preferred in this country to the use of caustic, the action of which is more tedious and painful, and less under control. The following is Scarpa's description of the operation.

The patient being seated, with his head a little inclined backward, the surgeon, with the index and middle finger of his left hand, is firmly to keep the eyelid everted, and holding a small pair of curved scissors, with convex edges, in his right, he is completely to cut off the whole fungosity of the internal membrane of the eyelid, as near as possible to its base. The same operation is then to be repeated on the other eyelid, should that be affected with the same disorder. If the excrescence should be of such a shape that it cannot be exactly included within the scissors, it must be raised as much as possible with forceps or a double-pointed hook, and dissected off at its base, by means of a small bistoury with a convex edge. This last

mode is preferred by Beer to the use of scissors, and I confess that it has always appeared to me the most convenient. The bleeding, which seems, at the beginning of the operation as if it would be copious, stops of itself, or as soon as the eye is bathed with cold water. The surgeon is then to apply the dressings, which are to consist of two small compresses, one put on the upper, the other on the lower arch of the orbit, and over these the uniting bandage, in the form of the *monoculus*, or so applied as to compress and replace the edges of the everted eyelids, in order to make them cover the eye. On the first removal of the dressings, which should take place about twenty-four or thirty hours after the operation, the surgeon will find the whole, or almost the whole, of the eyelid in its natural position. The treatment should afterward consist in washing the ulcer on the inside of the eyelid twice a day with simple water, or barley water, and *mel rosæ*, until it is completely well. If towards the end of the cure, the wound should assume a fungous appearance, or the edge of the eyelid seem to be too distant from the eyeball, the wound on the inside of the eyelid must be rubbed several times with the *argenti nitratum*, for the purpose of destroying a little more of the membranous lining, so that, when the cicatrization follows, a greater contraction of it may take place, and the edge of the eyelid be drawn still nearer the eye. Proper steps must be taken, however, for resisting the principal cause on which the ectropium depends, particularly chronic ophthalmia, a relaxed and varicose state of the conjunctiva, &c. (*See Ophthalmia.*)

In the second species of ectropium, or that produced by an accidental contraction of the skin of the eyelids, or neighbouring parts, the curative indication does in no respect differ from what it is in the foregoing instance. If a contraction of the integuments has proved capable of everting the eyelid, the excision of a piece of the internal membrane of the part, and the cicatrix which will follow, must also be capable, for the same reason, of bringing back the eyelid into its natural position. But, since nothing can restore the lost skin, the shortened state of the whole eyelid, in whatever degree it exists, must always continue, even after any operation the most skilfully executed. Hence, the treatment of the second species of ectropium will never succeed so perfectly as that of the first, and the replaced eyelid will always remain shorter than natural, in proportion to the quantity of integuments lost. It is true, that in many cases the eversion seems greater than it actually is, in regard to the small quantity of skin lost or destroyed: for, when the disease has once begun, though the contraction of the skin may be trivial, in consequence of the little quantity of it deficient, still the swelling of the lining of the eyelid, which never fails to increase, at last brings on a complete eversion of the part. In these cases, the cure may be accomplished with such success, as is sur-

prising to the inexperienced; for, after the fungous swelling of the internal membrane of the eyelid has been cut off, and the edge of the part approximated to the eyeball, the shortening of the eyelid, remaining after the operation, is so trivial, that it may be considered as nothing in comparison with the deformity and inconvenience occasioned by the ectropium. Whenever, therefore, the retraction of the skin of the everted eyelid, and the consequent shortness of it, are such as not to prevent its rising again and covering the eye, if not entirely, at least moderately, the surgeon should cut away the internal membrane of the everted eyelid, as already explained, so as to produce a loss of substance on the inside of the everted eyelid. This may be done most conveniently, either with the convex-edged curved scissors, or small convex-edged bistoury. In inveterate cases of ectropium, in which the tumid lining of the eyelids has become hard and callous, it is best to apply to the everted eyelid, for a few days before the operation, a soft bread and milk poultice, in order to render the part flexible, and more easily separated than it could be in its former rigid state.

The division of the cicatrices, which have given rise to the shortening and eversion of the eyelid, as Scarpa observes, does not procure any permanent elongation of this part, and consequently it is of no avail in the cure of the present disease. We see the same circumstance occur after deep and extensive burns of the skin of the palm of the hand and fingers: whatever pains may have been taken, during the treatment, to keep the hand and fingers extended, no sooner is the cicatrization thus completed, than the fingers become irremediably bent. The same thing happens after extensive burns of the skin of the face and neck. Fabricius ab Aquapendente, who well knew the inutility of making a semilunar cut in the skin of the eyelids, for the purpose of remedying their shortening and eversion, proposes, as the best expedient, to stretch them with adhesive plasters, applied to them and the eyebrow, and tied closely together. Whatever advantage may result from this practice, the same degree of benefit may be derived from using, for a few days, a bread and milk poultice, afterward oily embrocations, and, lastly, the uniting bandage, so put on as to stretch the shortened eyelid in an opposite direction to that produced by the cicatrix; a practice which Scarpa thinks should always be carefully tried, before resorting to the operation.

The patient being seated, if an adult, or placed on a table with his head a little elevated, and held by proper assistants, if a child, the surgeon, with a small convex-edged bistoury, is to make an incision of sufficient depth into the internal membrane of the eyelid, among the tarsus, carefully avoiding the situation of the puncta lachrymalia. Then he should raise with a pair of forceps, the flap of the divided fungous membrane, and continue to detach it with

the bistoury, from the subjacent parts, all over the inner surface of the eyelid, as far as where the membrane quits this part, to be reflected over the front of the eye, under the name of *conjunctiva*. The separation being thus far accomplished, the membrane is to be raised still more with the forceps, and cut off with one, or two strokes of the scissors, at the lowest part of the eyelid. The compresses and bandage, to keep the eyelid replaced, are to be applied, as above directed. On changing the dressings, a day or two after the operation, the eyelid will be found, in a great measure, replaced, and the disfigurement, which the disease caused, greatly amended. The operation is rarely followed by bad symptoms, such as vomiting, violent pain, and inflammation. However, should they occur, the vomiting may be relieved by means of an opiate clyster, and as for the pain and inflammation, attended with great tumefaction of the eyelid operated upon, these complaints may be cured by applying a poultice, or bags filled with emollient herbs, at the same time employing internal antiphlogistics, until the inflammation and swelling have subsided, and suppuration has commenced on the inside of the eyelid, on which the operation has been done. After this, the treatment is to consist in washing the part, twice a day, with barley-water and mel rosæ, and, lastly, in touching the wound a few times with the *argentum nitratum*, in order to keep the granulations within certain limits, and to form a permanent cicatrix, proper for maintaining the eyelid replaced. (*Scarpa sulle Malattie degli Occhi.*)

In cases, in which the eversion is considerable, Sir W. Adams has never found the simple incision of the fungus, as practised by Scarpa, sufficient to effect a radical cure, and he therefore tried a new mode of operating. In his first attempts, he employed a very small curved bistoury, the point of which he carried along the inside of the eyelid, at its outer angle, downwards, and outwards, as far as the point of reflection of the conjunctiva would admit. He then pushed it through the whole substance of the everted eyelid and its integuments, and cut upwards through the tarsus, making an incision nearly half an inch in length. With a curved pair of scissors, he next snipped off a piece of the edge of the tarsus, about one-third of an inch in width, and he afterward removed with the same instrument, the whole of the diseased conjunctiva. When the bleeding had ceased, Sir W. Adams passed a needle and ligature through the whole substance of the two divided portions, and brought them as accurately into contact as possible. Finding, however, that too much integument had been left at the lower part of the incision, he employed, in future operations, instead of the scalpel, a pair of straight scissors, with which he cut out an angular piece of the lid, resembling the letter V. Latterly, Sir W. Adams has found it advantageous to leave about a quarter of an inch of the lid adjoin-

ing its external angle, and after shortening the part as much as necessary, he brings the edges of the incision together with a suture. (See *Practical Observations on the Ectropium, &c.* by W. Adams, p. 4 and 5, Lond. 1812.)

On the subject of the foregoing proposal M. Roux observes; "What Sir W. Adams says, with a view of enhancing the value of his own method, about the frequent recurrence of ectropium, when the conjunctiva is simply cut out, is a gratuitous assertion, contradicted by experience. I have already, in a very great number of cases, undertaken the cure of ectropium in the common way: the operation always succeeded as much as the degree, or other circumstances, of the disease allowed; and I have not yet observed an instance of a relapse. (*Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, p. 291.) If this new operation, however, will cure the ectropium, caused by the contraction of cicatrices, as its inventor describes, or produce great improvement, as the experience of Mr. Travers confirms, (*Synopsis of the Diseases of the Eye*, p. 235.) it is clear, that, though it may not be necessary in ordinary cases, its usefulness will not be entirely lost. The contracted scar must of course be divided, in addition to the other proceedings.

E. C. Keck de Ectropio, Tubing. 1733. Scarpa's Osservazioni sulle Malattie degli Occhi, Ed. 5, cap. 6. to which writer I am chiefly indebted for the preceding account of the Disease. Richter's Anfangsgr. der Wundarzneikunst, Band 2, p. 473, &c. Wenzel's Manuel de l'Occuliste. Peller, Recueil d'Obs. sur les Maladies des Yeux. Sir W. Adams, Pract. Observ. on Ectropium, or Eversion of the Eyelids, with a description of a new operation for the cure of that Disease; on the modes of forming an artificial pupil; and on Cataract, 8vo. Lond. 1812. M. Bordenave, "Mémoire dans lequel on propose un nouveau procédé pour traiter le renversement des Paupières," in Mem. de l'Acad. Royale de Chirurgie, T. 13, p. 156 et seq. Edit. 12mo. It was in this memoir, that the proposal of removing a portion of the inside of the eyelid for the cure of ectropium was first made, and its efficacy illustrated by facts. Here may also be found the best historical account of the different methods of treatment, which have prevailed from the earliest periods of surgery. Consult also Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, par P. J. Roux, p. 289—292; Paris, 1815. G. J. Beer, Lehre von den Augenkrankheiten, B. 2, p. 133, &c. 8vo. Wien. 1817. Benj. Travers, Synopsis of the Diseases of the Eye, p. 234, 356, &c. 8vo. Lond. 1820.

ECZEMA, or **ECZEMA** (from *εκζωω*, to boil out,) is characterized by an eruption of small vesicles on various parts of the skin, usually close, or crowded together, with little or no inflammation round their bases, and unattended by fever. It is not contagious. (*Bateman's Synopsis*, P. 250, Ed. 3.) There are several varieties of this disease,

the most remarkable of which is the *eczema rubrum* from the irritation of mercury. This form is attended with quickened pulse and a white tongue; but the stomach and sensorium are not materially disturbed. (See *Mercury*.)

EFFUSION. (from *effundo*, to pour out.) In surgery, means the escape of any fluid out of the vessel, or viscus, naturally containing it, and its lodgment in another cavity, in the cellular substance, or in the substance of parts. Thus, when the chest is wounded, blood is sometimes effused from the vessels into the cavity of the pleura; in cases of false aneurisms, the blood passes out of the artery into the interstices of the cellular substance; in cases of fistulae in perinaeo, the urine flows from the bladder and urethra into the cellular membrane of the perineum and scrotum; and, when great violence is applied to the skull, blood is often effused even in the very substance of the brain.

Effusion also sometimes signifies the natural secretion of fluids from the vessels; thus surgeons frequently speak of the coagulable lymph being effused on different surfaces. (See *Extravasation*.)

ELECTRICITY. Among the aids of surgery, electricity once held a conspicuous and important situation. It has, however, met with a fate, not unusual with remedies too much cried up and too indiscriminately employed; that of having fallen into an undeserved degree of neglect.

Whatever its effects may be on the system, it certainly possesses this advantage over other topical remedies, that it may be made to act on parts very remote from the surface.

Electricity, as a topical remedy for surgical diseases, is chiefly used in amaurosis, deafness, some chronic tumours, and abscesses, weakness from sprains, or contusions, paralysis, &c.

In cases of suspended animation, electricity is sometimes an important auxiliary for the restoration of the vital functions. (See *J. Curry's Obs. on Apparent Death, &c.* Ed. 2, 1815.)

ELEVATOR. An instrument for raising depressed portions of the skull.

Besides the common elevator, now generally preferred by all the best operators, several others have been invented; as, for instance, the tripod elevator, and another, which was first devised by M. J. L. Petit, and afterward improved by M. Louis.

The common elevator is an exceedingly simple instrument, being a mere lever, the end of which is somewhat bent, and made rough, in order that it may less readily slip away from the piece of bone, which is to be raised. This instrument may be used by forming a fulcrum for it, either in the hand, which holds it, or upon the fingers of the other hand; or the operator may make a fixed point for it on the edge of the opening made with the trephine, or of that which the accidental violence has occasioned.

One piece of the tripod elevator consists of three branches uniting above in one common trunk. The latter part is pervaded by a long screw, having below a kind of hook, and above a sort of handle for turning it. It was by means of the hook, drawn up by turning the screw, that the depressed portion of bone was elevated.

The inventors of the tripod elevator were certainly very well acquainted with the imperfections of the common one; and they endeavoured to obviate them, by procuring a firmer fulcrum, and a greater degree of power. But it was necessary to change the situation of their elevator, as often as there was occasion to raise a different portion of bone; and the hook being connected with an inflexible piece of steel, the direction of which was always the same as that of the instrument, it became troublesome and difficult to place the hook under the piece of bone, which stood in need of being raised.

These inconveniences induced J. L. Petit to contrive a new elevator, which consisted of a lever, mounted on a handle, and straight throughout its whole length, except just at its very end, which was slightly curved, in order that it might be more conveniently put under the portion of bone, which was about to be elevated. The lever was pierced at various distances from its bent end, with several holes, intended for the reception of a little kind of moveable screw-peg, which was fixed upon the top of a sort of bridge. This latter part of the instrument consisted of an arch, the ends of which were long and covered with small pads, while, on its centre, was placed the little screw-peg already mentioned. It was the intention of Petit, that the peg should be joined to the bridge by means of a hinge; and as he found that it was frequently necessary to elevate several different pieces of bone, he thought, that the peg should not be completely fastened in the hole, but that it should be capable of being moved about in any wished-for direction. With this construction, however, it was found, that the peg would only allow the lever to be applied with its edge obliquely, under the bone about to be raised, when the part of the cranium was situated to the right or left.

Louis conceived, that it would be a great improvement of Petit's elevator, if a sort of pivot were substituted for the hinge. The lever would then admit of being readily moved in every direction, and put under any point of bone, without any occasion to alter the position of the bridge or fulcrum.

I have only to add, respecting elevators for fractures of the skull, that all the best modern surgeons content themselves with the common one, which is the most simple, and, in the hands of a surgeon, who knows how to use it, is found to answer every desirable purpose.

ELYTROCELE. (from *ελτρον*, the vagina, and *κελε*, a tumour.) A hernia in the vagina.

EMBROCATIO ALUMINIS. R. Aluminis ℥ij. Aceti spiritus vinosi tenuioris, sing. ℞ss. For chilblains and diseased joints.

EMBROCATIO AMMONIÆ. R. Liq. ammon. ℥i. Ætheris sulphurici ℥ss. Spir. Lavandulæ ℥ij. M. For sprains and bruises.

EMBROCATIO AMMONIÆ ACETATÆ CAMPHORATÆ. R. Linim. Camph. Liq. ammon. acet. sing. 3vj. Liq. Ammon. ℥ss. M. For sprains, bruises, and chilblains, not in a state of suppuration.

EMBROCATIO AMMONIÆ ACETATÆ. R. Liq. ammon. acet. Lin. sapon. sing. 3j. M. For bruises, with inflammation.

EMBROCATIO LYTTE CUM CAMPHORA. R. Tinct. Lyttæ Spirit. camph. sing. 3j. M. This may be used in any case, in which the object is to stimulate the skin. It should be remembered, however, that the absorption of lyttæ will sometimes bring on strangury.

EMBRYOTOMIA. (from *εμβρυον*, a fœtus, and *τομή*, to cut.) The operation of cutting into the womb, in order to extract the fœtus. (See *Cæsarean Operation*.)

EMPHYSEMA. (*εμφυσημα* from *φυσω*, to inflate.) A swelling, produced by air in the cellular substance.

The common cause of this affection is a fractured rib, by which the vesicles of the lungs being wounded, the air escapes into the cavity of the thorax. But, as the rib at the moment of its being fractured, is pushed inwards, and wounds the pleura, which lines the ribs and intercostal muscles, part of the air most commonly passes through the pleura, and the lacerated muscles into the cellular membrane, on the outside of the chest, and thence it is diffused through the same membrane over the whole body, so as to inflate it sometimes in an extraordinary degree. This inflation of the cellular membrane has been commonly looked upon, as the most dangerous part of the disease; but very erroneously, as will appear in the sequel. (*Hewson, Med. Obs. and Inquiries, Vol. 3.*)

Emphysema is most frequent after a fractured rib, because there is a wide laceration of the lungs, and no exit for the air; it is less frequent in large wounds with a knife, or broad sword, because the air has an open and unimpeded issue; it is again more frequent in deep stabs with bayonets, or small swords; and it is peculiarly frequent in gun-shot wounds, because the orifice in the skin inflames, and swells, while the wound is wider within. (*J. Bell on Wounds of the Breast, P. 265, Ed. 3.*)

The symptoms, attending emphysema, are generally of the following kind. The patient at first complains of a considerable tightness of the chest, with pain, chiefly in the situation of the injury, and great difficulty of breathing. This obstruction of respiration gradually increases, and becomes more and more insupportable. The patient soon finds himself unable to lie down in bed, and cannot breathe, unless when his

body is in an upright posture, or he is sitting a little inclined forward. The countenance becomes red and swollen. The pulse, at first, weak and contracted, becomes afterward irregular. The extremities grow cold, and, if the patient continue unrelieved, he soon dies, to every appearance suffocated.

The emphysematous swelling, wheresoever situated, is easily distinguished from œdema, or anasarca, by the crepitation, which occurs on handling it, or a noise, like that which takes place on compressing a dry bladder half filled with air. (*Encyclopédie Méthodique; Partie Chirurgicale, Art. Emphysema.*)

The tumour is colourless and free from pain. It does not of itself descend into depending parts, though by pressure it may be made to change its situation. It is elastic, that is to say, it may be pressed down, but it rises up again as soon as the pressure is discontinued. The swelling never retains the impression of the end of the finger, or, in the language of surgery, never *pits*. The part affected is not heavy. The tumour first makes its appearance in one particular place; but, it soon extends itself over the whole body, and causes an extraordinary distention of the skin. (*Richter's Anfangsgr. der Wundarzn. B. 1, p. 451.*)

The wound of the pleura and intercostals may sometimes be too small to suffer the air to get readily into the cellular membrane, and inflate it, but may confine a part of it in the cavity of the thorax, so as to compress the lungs, prevent their expansion, and cause the same symptoms of tightness of the chest, quick breathing, and sense of suffocation, which water does in the hydrops pectoris, or matter in the empyema.—(*Hewson.*)

To understand, why the air passes at all out of the wound of the lungs, we must advert to the manner in which inspiration and expiration are naturally carried on. It is well known, that in the perfect state, the surface of the lungs always lies in close contact with the membrane lining the chest, both in inspiration and expiration. The lungs themselves are only passive organs, and are quite incapable, by any action of their own, of expanding and contracting, so as to maintain their external surface always in contact with the inside of the thorax, which is continually undergoing an alternate change of dimensions. Every muscle, that has any share in enlarging and diminishing the capacity of the chest, must contribute to the effect of adapting the volume of the lungs to the cavity, in which they are contained, as long as there is no communication between the cavity of the pleura, and the external air. In inspiration, the thorax is enlarged in every direction, the lungs are expanded in the same way, and the air entering through the windpipe into the air-cells of these organs, prevents the occurrence of a vacuum.

But, in cases of wounds, when there is a free communication between the atmos-

phere and inside of the chest, no sooner is this cavity expanded, than the air naturally enters it at the same time, and for the same reasons, that the air enters the lungs through the trachea, and the lung itself remains proportionally collapsed. When the thorax is next contracted, in expiration, the air is compressed out of the lung, and also out of the bag of the pleura, through the external wound, if there be a direct one, in which circumstance, the emphysematous swelling is never extensive.

But, in the case of a fractured rib, attended with a breach in the pleura costalis, pleura pulmonalis, and air-cells of the lungs, there is no direct communication between the cavity of the chest and the external air; in other words, there is no outward wound in the parietes of the thorax. There is, however, a preternatural opening formed between the air-cells of the lungs and the cavity of the chest, and also another one between the latter space, and the general cellular substance of the body, through the breach in the pleura costalis. The consequence is, that when the chest is expanded in inspiration, air rushes from the wound in the surface of the lungs, and insinuates itself between them and the pleura costalis. The lungs collapse in proportion, and the place, which they naturally occupied, when distended, is now occupied by the air. When, in expiration, the dimensions of the chest are every where diminished, the air, now lodged in the bag of the pleura, cannot get back into the aperture in the collapsed lung, because this is already full of air, and is equally compressed on every side, by that which is confined in the thorax. Were there no breach in the pleura costalis, this air could not now become diffused; the muscles of inspiration would next enlarge the chest, remove the pressure from the surface of the wounded lung, more air would be sucked out of it, as it were, into the space between the pleura costalis and pleura pulmonalis, and this process would go on, till the lungs of the wounded side were completely collapsed. But, in the case of a fractured rib, or narrow stab, in which there is also a breach in the pleura costalis, without any free vent outward, for the air, which gets out of the lung into the cavity of the pleura, as soon as the expiratory powers lessen the capacity of the chest, this air, not being able to pass back through the breach in the collapsed lung, is forced through the laceration, or wound, in the pleura costalis, into the common cellular substance.

It is through the communicating cells of this structure, that the air becomes most extensively diffused over the whole body, in proportion as the expiratory muscles continue in their turn to lessen the capacity of the chest, and pump the air, as it were, through the breach in the pleura costalis, immediately after it has been drawn out of the wound of the lung, in inspiration. (*See John Bell on Wounds of the Breast, and Halliday on Emphysema, 1807.*)

To prove that the confinement of air in the chest is the cause of the dangerous symptoms attending emphysema, Hewson adverts to the histories of some remarkable cases, published by Littre, Mery, W. Hunter, and Cheston. (See *Mem. de l'Acad. Royale des Sciences*, for 1713, *Med. Observations and Inquiries*, Vol. 2, and *Pathological Inquiries*.)

In Littre's case, the patient, who had been wounded in the side with a sword, could not breathe, without making the most violent efforts, especially during the latter part of his disease: he died on the fifth day.

In Mery's instance, the fourth and fifth true ribs were broken by a coach passing over the chest; the patient's respiration was much impeded from the first, and became more and more difficult till he died, which was on the fourth day after the accident.

In Dr. Hunter's case, the patient had received a considerable hurt on his side by a fall from his horse. He had a difficulty of breathing, which increased in proportion as the skin became elevated and tense; it was laborious as well as frequent. His inspiration was short, and almost instantaneous, and ended with a catch in the throat, which was produced by the shutting of the glottis: after this he strained to expire for a moment without any noise, then suddenly opening the glottis, he forced out his breath with a sort of groan, and in a hurry, and then quickly inspired again; so that his endeavours seemed to be to keep his lungs always full; inspiration succeeded expiration as fast as possible. He said, his difficulty of breathing was owing to an oppression or tightness across his breast, near the pit of the stomach. He had a little cough, which exasperated his pain, and he brought up blood and phlegm from his lungs. He was relieved by scarifications, and recovered.

In Mr. Cheston's case, the man had received a blow on the chest. He had a constant cough, bringing up, after many ineffectual efforts, a frothy discharge, lightly tinged with blood; he seemed to be in the greatest agonies, and constantly threatened with suffocation. His pulse was irregular, and sometimes scarcely to be felt, his face livid, and, when he was sensible, which was only now and then, he complained of a pain in his head. On passing a bandage round his chest, with a proper compress to prevent the discharge of air into the cellular membrane, and to confine the motion of the thorax, the patient cried out that he could not suffer it. A strong compression by the hand alone affected him in the same way. Notwithstanding bleeding, repeated scarifications, and other means, his sense of suffocation, and difficulty of breathing increased. On the fourth day, the air no longer passed into the cellular membrane, when on a sudden inclining his head backward, as it were, for the admission of more air than usual, his breathing became more dif-

ficult and interrupted, he turned wholly insensible, and soon afterwards died.

Littre, Mery, and Cheston, opened their patients after death.

Besides a wound of the lungs and fractured rib, Littre found a considerable quantity of blood in the cavity of the thorax, and was sensible of some fetid air escaping, on his first puncturing the intercostals and pleura. The wounded lobe was hard and black, and the other two of the same side were inflamed.

In Mery's patient, no blood was extravasated, nor was there any thing preternatural, except the fractured ribs, the wound of the pleura, and that of the lungs.

Cheston found a fracture of the tenth and eleventh ribs, and a wound of the lungs. The lungs below the wound were livid, and more compact than usual; but every thing else was natural, no extravasation, no inflammation, no internal emphysema.

Hewson made several experiments on animals, tending to prove, that air in their chests produced great difficulty in breathing, such as occurs in cases of emphysema; and, in one case, which he examined after death, air was actually discharged on puncturing the thorax.

The object of Mr. Hewson's paper is to recommend making an opening in the chest for the purpose of giving vent to the air confined in that cavity, just as is done for the discharge of pus, in cases of empyema, or of water, in those of hydrops pectoris.

In wounds of the lungs, says this author, whether occasioned by fractured ribs, or other causes, when symptoms of tightness and suffocation come on, so far should we be from dreading the emphysematous swelling of the cellular membrane, that we should rather consider it as a favourable symptom, showing that the air is not likely to be confined in the thorax; and so far should we be from compressing the wound to prevent the inflation, or emphysema, that we should rather dilate it (if not large enough already) or perform the paracentesis thoracis. We may judge of the necessity of this operation from the violence of the symptoms, such as the oppressed breathing, &c. For when these are not considerable, and the air passes out of the chest with sufficient freedom, the operation is then unnecessary.

If the disease is on the right side, the best place for performing the operation, says Mr. Hewson, will be on the forepart of the chest, between the fifth and sixth ribs; for, there the integuments are thin, and, in the case of air, no depending drain is required. But, if the disease is on the left side, it will be more adviseable to make the opening between the seventh and eighth, or eighth and ninth ribs, in order that we may be sure of avoiding the pericardium. As large penetrating wounds are inconvenient on account of the air entering by the aperture in such a quantity, as to prevent the expansion of the lungs, a small wound will be eligible, especially as air does not require a large

one for its escape. Mr. Hewson recommends dissecting cautiously with a knife, in preference to the coarse and hazardous method of thrusting in a trocar.

There is one error prevailing in Mr. Hewson's paper, for which he has been justly criticised by Mr. John Bell; viz. the idea that it is possible and proper to make the collapsed lung expand by making an opening in the chest. Bromfield and B. Bell have both imbibed the same erroneous opinions, and proposed plans for exhausting the air and expanding the lung. It is very certain that it is impracticable to make the collapsed viscus expand, until the breach in it is closed, and this closure is greatly promoted by the quiet state, in which the collapsed lung remains; a state, also, the most favourable for the stoppage of any bleeding from the pulmonary vessels.

The true object then of making an opening into the thorax, when the symptoms of suffocation are violent, is not to obtain an expansion of the lung on the affected side, nor to take the pressure of the air from it; but, to remove the pressure caused on the opposite lung by the distention of the mediastinum, and, at the same time, to diminish the pressure of the air on the diaphragm. The lung on the affected side must continue collapsed, and it is most advantageous that it should do so. The opposite lung is that, which for a time must of itself carry on respiration, and it is known to be fully adequate to this function, provided the quantity of air, on the other side of the chest, does not produce too much pressure on the mediastinum, and diaphragm.

Mr. John Bell concludes his remarks on this subject, with advising the following practice:—

1st. When the crackling tumour begins to form over a fractured rib, small punctures should be made with the point of a lancet, as in bleeding; and if the point be struck deep enough, the air will rush out audibly. But, as (supposing the lung is not adherent to the inside of the chest) this air was in the thorax, before it came into the cellular substance, it is plain, that the thorax is still full, and that the lung of that side is already collapsed and useless, and must continue so. The purpose, therefore, of making these scarifications, and especially, of making them so near the fractured part, is not to relieve the lungs, but merely to prevent the air spreading more widely beneath the skin.

2d. If the air should have spread to very remote parts of the body, as to the scrotum, and down the thighs, it will be easier to make small punctures in those parts, to let out the air directly, than to press it along the whole body, till it is brought up to the punctures made on the chest, over the wounded part.

3d. If, notwithstanding free punctures, and pressing out the air in this way, you should find by the oppression, that either air, or blood, is accumulating within the cavity of the thorax, so as to oppress not the wounded

lung only, which was of course collapsed and useless from the first, but the diaphragm, and through the diaphragm to affect also the sound lung; then a freer incision must be made, through the skin and muscles, and a small puncture should be cautiously made through the pleura, in order to let out the air, or blood, confined in the thorax.—(*John Bell, Op. cit. p. 278.*)

In all these cases, copious and frequently repeated venesection is generally proper.

After a few days, the wound, in the collapsed lung, is closed by the adhesive inflammation, so that the air no longer passes out of it into the cavity of the chest, and the outer wound may therefore be healed. What air is already there is ultimately absorbed, and the lung, expanding in proportion, resumes its original functions.

The application of a bandage round the chest is sometimes practised in cases of emphysema, and its utility, when the ribs are broken, has been highly spoken of by Mr. Abernethy. "Pressure by bandage (says he) not only hinders the air from diffusing itself through the cellular substance, but serves to prevent it from escaping out of the wounded lung, and, of course, facilitates the healing of the wound, which would be prevented by the constant transmission of air. Its early application, therefore will often prevent a very troublesome symptom, whilst, at the same time, by keeping the fractured bones from motion, it greatly lessens the sufferings of the patient." (*Abernethy's Surgical Works, Vol. 2, p. 179.*)

Where emphysema is complicated with a fractured rib, the latter injury is unquestionably a reason in favour of a bandage. But, whether the pressure of the roller will be useful, or hurtful, with respect to the emphysema itself, or the state of the lungs, and respiration, may be questionable. As for its tendency to resist the diffusion of air in the common cellular membrane, this circumstance does not appear to me important, because the air, thus diffused, much as it disfigures the patient, is nearly harmless, at least as long as the interlobular texture of the lungs remains uninflated; a danger, also, which no bandaging, as far as I can judge, has any tendency to prevent. Neither will a bandage have so much effect in hindering the diffusion of air, as scarifications, with this important additional consideration, that punctures, or small incisions, made over the broken rib, prevent the spreading of the air by letting it escape, while a bandage can only do so by more or less resisting its escape from the cavity of the pleura, which mode of operation in some cases would dangerously interfere with the continuation of respiration by the lung of the opposite side. At the same time, I believe, that where the air extravasated within the injured side of the chest is not in such quantity, as to oppress the sound lung, and a rib is broken, a bandage will generally afford great relief. Indeed, it is but justice to Mr. Abernethy to state, that he does not recommend the employment of a bandage

in all cases of emphysema. "Patients (says he) will not always be able to wear a bandage, when one lung is collapsed, particularly if any previous disease has existed in the other, as it equally confines the motions of the ribs on both sides, and as every possible enlargement of the chest becomes necessary for the due admission of the air into the lung, which still executes its functions. Under these circumstances, if the emphysema continues, (and its continuance must always denote that the wound in the lung is not closed,) I should esteem it the best practice to make a small opening into the chest, so that the external air might have a free communication with that cavity; and then the injured lung must remain motionless till its wound is healed, and the mediastinum, will, in every state of the thorax, preserve its natural situation." (*Abernethy, Vol. cit. p. 183.*)

Emphysema has been known to arise from the bursting of a vomica and ulceration of the surface of the lungs; but, the air which escapes, in this instance, cannot find its way into the cavity of the thorax, because the inflammation, which precedes the abscess and ulceration of the aircells, closes those which are adjacent, and produces an adhesion of the edges of the vomica, or ulcer, to the inner surface of the chest, so as entirely to separate the two cavities. We are not acquainted with any instance of the symptoms, imputed to the confinement of air in the chest, originating from suppuration and ulceration of the surface of the lungs; but, Palfyn, Dr. Hunter, and the author of the article *Emphysema*, in the *Encyclopedie Methodique, Partie Chirurgicale*, have seen cases, in which emphysema originated from abscesses of the lungs, attended with adhesion to the pleura, and ulcerations in the situation of such adhesion. In these instances, the pus having made its way through the pleura and intercostal muscles, the air escapes also through the same track, so as to pass into the cellular membrane on the outside of the chest.

A violent effort of respiration has, sometimes, produced a certain degree of emphysema, which first makes its appearance about the clavicles, and afterward spreads over the neck and adjacent parts. The efforts of labour have been known to occasion a similar symptom; but, no bad consequences followed. (*Medical Communications, Vol. 1, p. 176; Blackden in Med. Facts and Experiments, Vol. 2, and Wilmer's Obs. in Surgery, p. 143.*)

Louis has described an emphysema of this sort, which, on account of its cause, and the indication which it furnishes to the practitioner, is highly important. This famous surgeon had occasion to remark it in a young girl, who died suffocated, from a bean falling into her windpipe, and he considers it, as a pathognomonic symptom of such an accident, concerning the existence of which it is so essential not to commit any mistake. (*See Bronchotomy.*) This emphysema made its appearance on both sides of the neck, above the clavicles, and came on

suddenly, on the third day after the accident. The inspection of the body proved, that the lungs and mediastinum were also in an emphysematous state. The retention of the air, confined by the foreign body, produced, says Louis, at each attempt to expire, and, especially, when the violent fits of coughing occurred, a strong propulsion of this fluid towards the surface of the lung, into the spongy substance of this viscus. Thence, the air passed into the cellular texture, which unites the surface of the lung to the pleura pulmonalis; and, by communications from cells to cells it caused a prodigious swelling of the cellular substance, between the two layers of the mediastinum. The emphysema, increasing, at length made its appearance above the clavicles. This tumefaction of the lung, and surrounding parts, in consequence of air getting into their spongy and cellular texture, is an evident cause of suffocation, and the swelling seems so natural an effect of the presence of a foreign body in the trachea, that one can hardly fail to think it an essential symptom, though no author has made mention of it. (*Mém. de l'Acad. de Chir. Tom. 4, in 4to.*) The emphysematous swelling, sometimes formed in the axilla, in the reduction of a dislocated shoulder, (*See Dislocation*) was accounted for by Desault and Bichat, on the same principle as the foregoing case, viz. a rupture of one of the air-cells, by the patient's efforts to hold his breath during the reduction of the bone. How far the explanation of the cause may be true, has been questioned. (*See Dict. des Sciences Med. T. 12, p. 15;*) the fact itself admits of no doubt, and is both curious and interesting.

An emphysematous swelling of the head, neck, and chest, has also been noticed in typhoid fevers. Dr. Huxham relates an instance of this sort, in a sailor of a scorbutic habit. (*Medical Observations and Inquiries, Vol. 3, Art. 4.*) A case of spontaneous emphysema has likewise been described by Dr. Baillie. (*See Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge, Vol. 1, p. 202.*)

A curious example of what has been called a spontaneous emphysema, is recorded by Mr. Allan Burns: "The patient was a strong athletic man, who, about six years previous to his application at the Royal Infirmary, had received a smart blow on the neck, from the keel of a boat. This injury was soon followed by the formation of a firm tense tumour on the place which had been hurt. The swelling increased very slowly, during the five years immediately succeeding its commencement; but, during the sixth, it received a very rapid addition to its bulk. At this time, it measured nearly six inches in diameter, seemed to be confined by a firm and dense covering, and the morbid parts had an obscure fluctuation. From the first to the last, the tumour had been productive of very little pain.

"Judging from the apparent fluctuation, that the tumour was encysted, it was resolved, at a consultation, to puncture the swelling, draw off its contents, and then pass

a seton through it. By plunging a lancet into it, only a very small quantity of blood, partly coagulated, and partly fluid, was discharged,—a quantity so trifling, that, after its evacuation, the size of the tumour was not perceptibly reduced. A seton was passed through the swelling. At this time the man was in perfect health.

"About ten hours after the operation, the patient was seized with extremely violent rigours, followed by heat, thirst, pain in the back, excessive pain in the tumour, and oppressive sickness.

"An emetic was prescribed, but, instead of producing vomiting, it operated as a cathartic. To remove the irritation the seton was withdrawn. The pain in the tumour, however, and the general uneasiness continued to increase, and thirty hours subsequent to making the puncture, air began to issue from the track of the seton; and, afterward the cellular membrane of the neck, and of the other parts of the body in succession, became distended with a gaseous fluid. In the course of a few hours, after the commencement of the general emphysema, the man died.

"Twelve hours after death, when the body was free from putrefaction, it was inspected. The emphysema was neither increased, nor diminished since death, and some idea may be formed of its extent, when the scrotum was distended to the size of the head of an adult. Even the cavities of the heart, and the canals of the blood-vessels, contained a considerable quantity of air. We could discover no direct communication between the tumour and the trachea or lungs, although such was carefully sought for." (*A. Burns on the Surgical Anatomy of the Head and Neck*, p. 51—53.)

From such cases, we may infer, with the preceding writer, that from the mere rupture of a few of the bronchial cells, occasioned by irregular action of the lungs, or by some other internal cause, a spontaneous diffusion of air may take place in the cellular texture of the body. Such examples are dependent on the same cause as the emphysema from injury of the lungs; only the rupture of the bronchial cells in the former cases is less obvious.

Surgeons often observe a partial emphysema in cases of gangrene. Here, however, it is hardly necessary to observe, the air is the product of putrefaction, and the disorder has not the smallest connexion with any injury, or disease of the air-cells of the lungs.

EMPLASTRUM AMMONIACI CUM ACETO. R. Ammoniaci purif. ℥ij. Acidi Acetici ℥ij. Ammoniacum in aceto liquefactum evapora in vase ferreo ad emplastri crassitudinem.

EMPLASTRUM AMMONIACI SCILLITICUM. R. Gummi ammoniaci ℥j. Aceti Scillitici, q. s. ut fiant emplastrum, quo pars affecta tegatur.

Mr. Ford found this last plaster useful in some scrofulous affections. It may be rendered more stimulating by sprinkling it with squills. (*Ford on the Hip-joint*, p. 59.) It was recommended by Swediaur; *London Medical Journal*, Vol. 1, p. 198.

EMPLASTRUM AMMONIACI CUM HYDRARGYRO. Discutient.

EMPLASTRUM AMMONIACI CUM CICUTA. R. Gummi ammon. ℥ij. Extracti Conii ℥ij. Liq. Plumb. acet. ℥j.

Dissolve the ammoniacum in a little vinegar of squills, then add the other ingredients, and boil them all slowly to the consistence of a plaster. Discutient.

EMPLASTRUM AMMONIÆ. R. Sapon. ℥ij. Emplastr. Plumbi. ℥ss. Ammon. mur. ℥j.

The two first articles are to be melted together, and when nearly cold, the muriated ammonia, finely powdered, is to be added. This plaster stimulates the skin, excites the action of the absorbents, and disperses many chronic swellings and indurations.

EMPLASTRUM CANTHARIDIS. (See *Blister*.)

EMPLASTRUM GALBANI COMPOSITUM. L. P. (*Olim emplastrum lithargyri comp.*) Properties discutient.

EMPLASTRUM HYDRARGYRI. L. P. (*Olim emplastrum litharg. cum hydrargyro.*) Properties discutient.

EMPLASTRUM LYTTEÆ. L. P. (See *Blister*.)

EMPLASTRUM PLUMBI. L. P. (*Olim emplastrum lithargyri, or diachylon plaster.*)

EMPLASTRUM RESINÆ. L. P. (*Olim emplastrum lithargyri cum resina.*) The common adhesive, or sticking plaster.

EMPLASTRUM SAPONIS. The plaster commonly used for fractures. It is also frequently applied to bruised parts, and to many indurations of a chronic nature.

EMPHYEMA. (from *ἐν*, within, and *πύρρ*, pus, or matter.) A collection of purulent matter in the cavity of the chest.

The ancients made use of the word, "em-

pyema" to express every kind of internal suppuration. It was *Ætius* who first restricted the term to the collections of matter, which sometimes form in the cavity of the pleura, or membrane lining the chest; and all the best modern surgeons invariably attach this meaning alone to the expression.

The operation for empyema properly means the making of an opening into the thorax, for the purpose of giving vent to the matter, collected in the cavity of the pleura, though the phrase with several writers denotes making an incision into the chest, in order to let out any effused, or confined fluid, whether matter, blood, an aqueous fluid, or even air. The necessity for having recourse to such an operation, however, does not often present itself. I would not wish to be supposed to assert, that inflammation of the lungs, pleura, mediastinum, diaphragm, and even of the liver, does not sometimes terminate in suppuration. Certainly, the latter event is occasionally produced; but, when it does happen, the matter does not always make its way into the cavity of the chest: frequently external abscesses form, or the pus is either coughed up, or discharged with the stools.

Acute and chronic abscesses not unfrequently form in the cellular substance, between the pleura and the ribs and intercostal muscles. A swelling occurs between two of those bones; the skin does not undergo any change of colour; a fluctuation is distinguishable, and sometimes an extensive œdema is observable.

With respect to abscesses, formed in the cellular substance, connecting the pleura costalis to the intercostal muscles, they rarely burst into the chest, the pleura always being considerably thickened. However, in order to keep them from spreading extensively, as well as to obviate any possibility of their breaking inwards, the best rule is to make an early, and, if possible, a depending opening. The motions of respiration then both promote the exit of the matter, as well as the contraction of the cavity, in which it was lodged; and the disease, if unattended with caries, generally terminates favourably.

It often happens, however, that the ribs are carious, and then the cure is more tedious and difficult. A modern writer, indeed, informs us, that, when the inside of the rib is extensively carious, or when the caries is near the junction of the bone to the spine, the fistula is incurable. (*Lassus Pathologie Chirurgicale*, Tom. 1, p. 128, Edit. 1809.) On the other hand, another surgeon of vast experience recommends us to endeavour to separate the diseased bone, either by cutting it away, or employing the trepan. (*Pelletan Clinique Chir.* T. 3, p. 253.) Were a part of a diseased rib to admit of being sawn away, Mr. Hey's convex saw would be a more proper instrument for the purpose, than a trepan.

An abscess of the preceding kind may be so situated, and attended with such a pulsation, as greatly to resemble an aneu-

rism of the origin of the aorta. An interesting case of this description is detailed by *Pelletan*. (*Clinique Chir.* T. 3, p. 254,) and another was seen by *Baron Boyer*. (*Traité des Mal. Chir.* T. 7, p. 333.)

When the surface of the lungs and that of the pleura costalis have become adherent to each other, in the situation of the abscess, so as to constitute what is termed *encysted empyema*, the pus, disposed by a law of nature to make its way to the surface of the body, generally occasions ulceration of the intercostal muscles, and collects on the outside of them. An abscess of this kind comes on with a deep-seated pain in the part affected: an œdematous swelling, which retains the impression of the finger; and a fluctuation, which is at first not very distinct, but, from day to day, becomes more and more palpable, and, at length, leads the surgeon to make an opening.

If this be not done when the fluctuation becomes perceptible, the abscess may possibly insinuate itself into the cavity of the pleura, in consequence of the adhesion being in part destroyed by ulceration. *Sabatier* affirms, that the case may take this course, even when the abscess has been punctured, and while a free external opening exists; and this experienced surgeon has adduced a fact in confirmation of such an occurrence. (See *Médecine Opératoire*, Tom. 2, p. 249.)

In a few instances, the surface of the lung ulcerates, and the matter is voided from the trachea. But in the majority of examples, the pus makes its way outwards, through the pleura costalis. If inflammation occurs in the anterior mediastinum, and ends in suppuration, the abscess may possibly burst into neither of the cavities of the chest; but, make its way outward, after rendering the sternum carious, as happened in the example recorded by *Van Swieten*. (*Comment. on Boerhaave's 895th Aphorism.*)

But, though collections of matter in the anterior mediastinum are influenced by the general law, whereby abscesses in general tend to the surface of the body, and though it be true, that they rarely burst inwardly into the cavity of the pleura, the contrary may happen, as is proved by the 9th case in *La Martinière's* memoir on the operation of trepanning the sternum. Here the event was the more extraordinary, as there was already an external opening in the abscess.

External injuries, such as the perforation of the sternum with a sword, (*Vanderwel*, *Obs.* 29, *Cent.* 1.) a contusion, or a caries of this bone, may give rise to an abscess in the anterior mediastinum. *Galen* has recorded a memorable example, where the abscess was the consequence of a wound of the forepart of the chest. After the injury, which was in the region of the sternum, seemed quite well, an abscess formed in the same situation, and being opened healed up. The part, however, soon inflamed and suppurated again. The abscess could not now be cured. A consultation was held, at which *Galen* attended. As the sternum was

obviously carious, and the pulsation of the heart was visible, every one was afraid of undertaking the treatment of the case, since, it was conceived, that it would be necessary to open the thorax itself. Galen, however, engaged to manage the treatment, without making any such opening, and he expressed his opinion, that he should be able to effect a cure. Not finding the bone so extensively diseased, as was apprehended, he even indulged considerable hopes of success. After the removal of a portion of the bone, the heart was quite exposed (as is alleged,) by reason of the pericardium having been destroyed by the previous disease. After the operation, the patient experienced a speedy recovery.

J. L. Petit met with an abscess in the anterior mediastinum, in consequence of a gunshot wound in the situation of the sternum. The injury had been merely dressed with some digestive application; no dilatation, nor any particular examination of the wound had been made. The patient, after being to all appearances quite well, and joining his regiment again, was soon taken ill with irregular shiverings, and other febrile symptoms. Petit probed the wound, and found the bone affected. As there was a difficulty of breathing, he suspected an abscess either in the diploe, or behind the sternum, and, consequently, he proposed laying the bone bare, and applying a trepan. This operation gave vent to some sanious matter, and, as soon as the inner part of the sternum was perforated, a quantity of pus was discharged. The patient was relieved, and afterward recovered. (*Petit, Traité des Mal. Chir. T. 1, p. 80.*)

Another instance, in which an abscess behind the sternum was cured by making a perforation in that bone opposite the lower part of the cavity, in which the matter collected, is recorded by De la Martinière. (*Mém. de l'Acad. de Chir. T. 12, Ed. 12mo.*)

When, in consequence of inflammation, an abscess forms deeply in the substance of the lungs, the pus more easily makes its way into the air-cells, and tends towards the bronchiæ, than towards the surface of the lungs. In this case, the patient spits up purulent matter. When the opening, by which the abscess has burst internally, is large, and the pus escapes from it in considerable quantity at a time, the patient is in some danger of being suffocated. However, if the opening be not immoderately large, and the pus, which is effused, be not too copious, a recovery may ensue. Abscesses in the substance of the diaphragm, and collections of matter in the liver, may also be discharged by the pus being coughed up from the trachea, when the parts affected become connected with the lungs by adhesions, and the abscesses of the liver are situated on its convex surface. When the collection of matter in the liver occupies any other situation, the abscess frequently makes its way into the colon, and the pus is discharged with the stools. Several cases of this kind are related by authors: Sabatier has recorded two

in his *Médecine Opératoire*; Le Dran makes mention of others; and Pemberton, in his book on the Diseases of the Abdominal Viscera, p. 36, relates additional instances of a similar nature.

I shall now proceed to the consideration of empyema strictly so called. Sometimes it is a consequence of a penetrating wound of the chest; occasionally it proceeds from the bursting of one or more vomices; in a few examples, it arises from the particular way, in which abscesses of the liver burst; (*Journ. de Med. T. 3, p. 47. Morgagni, Epist. 30, art. 4.*) but in the greater number of instances, it originates from pleuritic inflammation, especially that of the chronic kind. (*Boyer, Traité des Mal. Chir. T. 7, p. 352.*) Empyema very rarely takes place in both sides of the chest, but is almost always limited to one cavity of the pleura.

According to Baron Boyer, when empyema arises from thoracic inflammation, pleuritis, or pneumonia, the symptoms, characterizing it, are always preceded by those of the disease, of which the effusion of pus upon the diaphragm is the effect. Inquiry must therefore be made, whether the patient has pleurisy, or peripneumony, the symptoms of which have lasted longer than a fortnight; and whether, after a transient amendment, there have been frequent shiverings, followed by a low continued fever, with nightly exacerbations. Now, these first circumstances justify the belief, that the inflammatory disorder has terminated in suppuration, and that the symptoms afterward experienced, depend upon effusion of matter in the chest. Some of these arise from the mechanical action of the pus upon the lungs, heart, and parietes of the chest, and belong also to other effusions in the thorax; the rest may be said to be the effects of ulceration and suppuration of the parts on the animal economy, and therefore, particularly belong to empyema.

First, of the common symptoms, respiration is difficult, short, and frequent; the patient suffers great oppression, and experiences a sense of suffocation, and of weight upon the diaphragm. He cannot move about, even for a short time, without being quite out of breath, and threatened with syncope. He has an almost incessant, and very fatiguing cough, which is sometimes dry, sometimes attended with expectoration. (*Boyer, Traité des Mal. Chir. T. 7, p. 356.*)

No surgical writer, with whom I am acquainted, has treated with more discrimination, than Mr. Samuel Sharp, of the symptoms produced by collections of matter in the chest. He remarks, that it has been almost universally taught, that, when a fluid is extravasated in the thorax, the patient can only lie on the diseased side, the weight of the incumbent fluid on the mediastinum becoming troublesome, if he places himself on the sound side. For the same reason, when there is fluid in both cavities of the thorax, the patient finds it most easy to lie on his back, or to lean forwards, in order that the fluid may neither press upon the mediasti-

num, nor the diaphragm. But, it is noticed by Mr. Sharp, that, however true this doctrine may prove in most instances, there are a few, in which, notwithstanding the extravasation, the patient does not complain of more inconvenience in one posture than another, nor even of any great difficulty of breathing. (See *Le Dran's Obs.* 217, and *Marchetti*, 65.)

On this account, observes Mr. Sharp, it is sometimes less easy to determine, when the operation is requisite, than if we had so exact a criterion, as we are generally supposed to have. But, says he, though this may be wanting, there are some other circumstances, which will generally guide us with a reasonable certainty. He states, that the most infallible symptom of a large quantity of fluid in one of the cavities of the thorax, is a preternatural expansion of that side of the chest, where it lies; for, in proportion as the fluid accumulates, it will necessarily elevate the ribs on that side, and prevent them from contracting so much in expiration as the ribs on the other side. This change is said to be most evident, when the surgeon views the back of the chest. (*Boyer, Vol. cit. p. 357.*) Mr. Sharp also refers to *Le Dran's Obs.* 211, vol. 1, in order to prove, that the pressure of the fluid on the lungs may sometimes be so great, as to make them collapse, and almost totally obstruct their function. When, therefore, says Mr. Sharp, the thorax becomes thus expanded, after a previous pulmonary disorder, and the case is attended with the symptoms of a suppuration, it is probably owing to a collection of matter. The patient, he observes, will also labour under a continual low fever, and a particular anxiety from the load of fluid.

Besides this dilatation of the cavity by an accumulation of the fluid, the patient will be sensible of an undulation, which is sometimes so evident, that a bystander can plainly hear it in certain motions of the body. Mr. Sharp adds, that this was the case with a patient of his own, on whom he performed the operation; but the fluid in this instance, he says, was very thin, being a serous matter, rather than pus. Sometimes, when the practitioner applies his ear close to the patient's chest, while this is agitated, a noise can be heard, like that produced by shaking a small cask, not quite full of water. (See *Dr. Archer's Case in Trans. of the Fellows, &c. of the King's and Queen's College of Physicians in Ireland, Vol. 2, p. 2.*) In this instance, the fluid resembled whey.

According to the same author, it will also frequently happen, that though the skin and intercostal muscles, are not inflamed, they will become œdematous in certain parts of the thorax; or, if they are not œdematous, they will be a little thickened; or, as *Boyer* states, the intercostal spaces are widened, and, when the empyema is considerable, instead of being depressed, as they are in thin persons, they project beyond the level of the ribs. (*Mal. Chir. T. 7, p. 357.*) These symptoms, joined with the enlargement of the thorax, and the preceding affection of

the pleura, or lungs, seem unquestionably to indicate the propriety of the operation. But, observes Mr. Sharp, among other motives to recommend it upon such an emergency, this is one, that if the operator should mistake the case, an incision of the intercostal muscles would neither be very painful, nor dangerous. (See *Critical Inquiry into the present State of Surgery, sect. on Empyema.*)

"The difficulty of lying on the side, opposite to the collection of pus," says *Le Dran*, "is always accounted a sign of an empyema. This sign, indeed, is in the affirmative; but, the want of it does not prove the negative; because, when there is adhesion of the lungs to the mediastinum, the patient may lie equally on both sides." (*Le Dran's Obs. p. 108, Edit. 2.*) The explanation of this circumstance, offered by *Le Dran*, is, that when the cyst, in which the matter is contained, is between the mediastinum and the lungs, the mediastinum gradually yields to the volume of the pus, in proportion as it is formed, and the cyst in which it is contained becomes dilated; "whence habitude becomes a second nature." Whereas, in an empyemal person, in whom the lung is not adherent to the mediastinum, and who lies on the side opposite to that, on which the collection of pus is situated, the mediastinum is on a sudden loaded with an unusual weight of fluid. (*P. 111.*)

Richerand contends, that the difficulty of breathing which patients with extravasated fluid in the chest experience in lying upon the side, opposite to that on which the disease is situated, never originates, as has been commonly taught and believed, from the fluid pressing upon the mediastinum and opposite lung. "I have (says he) produced artificial cases of hydrothorax, by injecting water into the thorax of several dead subjects, through a wound made in the side. This experiment can only be made on subjects, in which the lungs are not adherent to the parietes of the chest. In this way, from three to four pints of water were introduced. I then cautiously opened the opposite side of the chest: the ribs and lungs being removed, the mediastinum could be distinctly seen, reaching from the vertebræ to the sternum, and supporting, without yielding, the weight of the liquid, in whatever position the body was placed.

"It is evident, then, that patients, with thoracic extravasations, lie on the diseased side, in order not to obstruct the dilatation of the sound side of the respiratory organs, one part of which is already in a state of inaction. It is for the same reason, and in order not to increase the pain by the tension of the inflamed pleura, that pleuritic patients lie on the diseased side. The same thing is observable in peripneumony; in a word, in all affections of the parietes of the chest." (*Richerand, Nosogr. Chir. T. 4, p. 168, 169. Edit. 2.*)

It appears to me, that there may be some truth in the foregoing statement; but the experiments are far from being conclusive,

with respect to the assertion, that, in cases of empyema, hydrothorax, &c. the fluid on one side of the chest does not compress the opposite lung. In the first place, the quantity of fluid is frequently much larger than that which Richerand injected. Secondly, although the mediastinum may not be apt to yield at once to the weight of a liquid suddenly injected into one side of the thorax; yet, it may do so by the gradual effect of disease. Thirdly, many of the phenomena of emphysema seem adverse to Richerand's inference.

Although surgeons should be aware, that patients with empyema can sometimes lie in any position, without particular aggravation of the difficulty of breathing, yet it ought to be distinctly understood, that the generality of patients with this disease cannot place themselves on the side, opposite to that, on which the collection of pus is situated, without having their respiration very materially obstructed. Another circumstance, also, which deserves to be mentioned while we are treating of the symptoms of empyema, is, that the œdema of the integuments is sometimes not confined to the thorax, but extends to more remote parts, on the same side of the body as the collection of matter. Both the foregoing remarks are confirmed by an interesting case, which has been published by Mr. Hey of Leeds.

Sep. 3, 1788, Mr. Hey was desired to visit John Wilkinson, who had been ill ten days of the influenza. The patient was found labouring under a fever, attended with cough, difficulty of breathing, and pain in the left side of the thorax. He was bled once; had repeated blisters applied to the chest; and took nitre and antimonials, with a smooth linctus to allay his cough. He was repeatedly relieved by these means, especially by the application of the blisters; but repeatedly relapsed. At last, he became so ill, that he breathed with the utmost difficulty, and "could not lie on the right side, without danger of immediate suffocation."

Mr. Hey found the patient in the state, just now described, on the 17th of September. "His face, and especially his eyelids, were a little swollen on the left side." The left side of the thorax was larger than the right, and its integuments were œdematous. Upon pressing the intercostal muscles, they felt distended; they yielded a little to a strong pressure, but rebounded again. The abdomen, especially at its upper part, appeared to be fuller than in the natural state. (See *Hey's Practical Obs. in Surgery*, p. 476.) This last symptom is also particularly noticed by Boyer. (*Mal. Chir. T. 7. p. 357.*)

Another remarkable symptom, which is occasionally produced by collections of matter in the chest, is an alteration in the position of the heart. I have seen a patient in St. Bartholomew's Hospital, who had so large a quantity of matter in the left bag of the pleura, that it completely displaced the heart, which pulsated against the inside of the chest, at a considerable distance to the right of the sternum. This man's life might probably have been saved, had paracentesis tho-

racis been performed in time. Some suspected an aneurism from the throbbing on the right of the sternum; and the case was not fully understood till after death, when the body was opened. A little attention to the symptoms, however, might have convinced any man of moderate understanding, that it was an empyema, and that making an opening, for the discharge of the matter, afforded the only rational chance of preserving life. There had been pain and inflammation in the chest, followed by shiverings; there was very great difficulty of breathing; the heart, which previously used to beat in the usual place, no longer did so; but now, pulsated on the right side of the thorax.

That the heart should be displaced in this manner by any large collection of fluid in the right cavity of the thorax, one would naturally expect; but it is an occurrence, that has not been much noticed by surgical writers. Baron Larrey, however, has related a highly interesting case, where the heart was not only pushed considerably to the right of the sternum, but its action was so much impeded by the derangement of its position, that the pulse in the large arteries was thereby rendered extremely feeble. In this instance, also, the diaphragm had descended so low down, as to force some of the small intestines into the cavity of the pelvis. (*Mémoires de Chirurgie Militaire*, T. 3. p. 447, &c.) Pelletan has also recorded an example, in which a collection of fluid in the left cavity of the chest displaced the heart, the pulsations of which were perceptible betwixt the third and fourth ribs of the right side, near the sternum. (*Clinique Chir. T. 3. p. 276.*) Baron Boyer speaks of one case, in which the displacement of the heart was so extensive, that its pulsations were felt near the right axilla. (*Traité des Mal. Chir. T. 7. p. 357.*) In the anatomical collection at Strasburgh, is also a preparation exhibiting the displacement of the heart into the right side of the chest, by matter in the left pleura, the left lung being nearly annihilated. (*Lobstein compte de son Museum Anat. p. 39. 8vo. 1820.*) The heart is sometimes thrust downwards by collections of fluid in the chest, and its pulsation is distinguishable in the epigastrium. (*Hodgson on the Diseases of Arteries and Veins*, p. 95.)

When the cavity of the pleura contains fluid, and the surgeon strikes the thorax repeatedly with the ends of his fingers, a dull sound is said to be produced, quite different from what would occur, were the chest in its natural state. But, as Boyer remarks, this symptom, to which so much importance has of late been attached, being common to extravasations in the thorax, and several other diseases, will not denote empyema, unless combined with other signs of this affection. Nor will any useful information be derived from the above percussions, except the practitioner has had a good deal of experience in them, and they are repeatedly practised with the patient in different positions. (*Mal. Chir. T. 7. p. 357.*)

The symptoms of empyema are frequently very equivocal, and the existence of the

disease is generally somewhat doubtful. Pannarolius opened a man, whose left lung was destroyed, at the same time that the thorax contained a considerable quantity of pus. Although the patient had been ill for two months, he had suffered no difficulty of breathing, and had had only a slight cough. Le Dran met with a case of nearly the same kind. A patient, who had been for three days affected with a considerable oppression, and an acute pain on the left side of the chest, got somewhat better. He felt no material difficulty of breathing, on whatever side he lay. The only thing which he complained of, was a sense of fluctuation in his thorax, and a little obstruction of his respiration, when he was in a sitting posture. These symptoms did not seem sufficiently decided to justify the operation, and it was delayed. The febrile symptoms continued with cold sweats, and the patient died on the eighth day. Five pints of pus were found collected in the chest. (See *Le Dran's Observations in Surgery*, p. 109, 110, Edit. 2.)

The symptoms, more particularly depending upon empyema itself, that is to say, upon the disease and suppuration within the chest, are nearly the same as those, which accompany all large deep-seated abscesses. The fever, attending the thoracic inflammation, which ends in suppuration, gradually diminishes, but does not entirely cease. On the contrary, it soon changes into hectic, attended with flushings of the cheeks, heat of the palm of the hands, and exacerbations every evening, and after meals. In the night, the upper parts of the body are covered with perspiration; the patient is tormented with insatiable thirst; his appetite quite fails; his debility becomes extreme; he is subject to frequent fainting fits; diarrhoea ensues; and the finger nails become curved, shining, and of the yellow tinge, observable all over the body. At length, the utmost emaciation, and the facies Hippocratica come on, frequently attended with dilated pupils, and enfeebled vision, and indicating the approach of death.

As the operation of empyema, and some other particulars, relating to this subject, are treated of in another part of this Dictionary, (See *Paracentesis of the Thorax*) it will only be necessary for me here to subjoin a list of works, which may be advantageously consulted for information on empyema. *A. Vater, et J. E. Mutillet, Empyema, e vomica pulmonis, rupta in cavitate pectoris dextram effusa, indique pulmo hujus lateris compressus penitusque ab officio remotus*, Wittemb. 1731, (Haller, *Disp. ad Morb.* 2, 4031.) *Gerardus le Maire, Diss. de Empyemate*, 4to. ENCANTHIS. (from *en*, and *καθ'ος*, the angle of the eye.)

The encanthis, at its commencement, is nothing more, says Scarpa, than a small, soft, red, and sometimes rather livid, excrescence, which grows from the caruncula lachrymalis, and, at the same time, from the neighbouring semilunar fold of the conjunctiva. The inveterate encanthis is ordinarily of considerable magnitude; its roots extend beyond the caruncula lachrymalis, and semilunar fold, to the membranous lining of one or both eyelids. The patient experiences very serious inconvenience from its origin, and interposition between the commissure of the eyelids, which it necessarily keeps asunder, on the side towards the nose.

The encanthis keeps up a chronic ophthalmia, impedes the action of the eyelids, and in particular, prevents the complete closure of the eye. Besides, partly by compressing, and partly by displacing the orifices of the puncta lachrymalia, it obstructs the free passage of the tears into the nose.

According to Scarpa, this excrescence, on its first appearance, is commonly granulated, like a mulberry, or is of a ragged and fringed structure. Afterward, when it had acquired a certain size, one part of it represents a granulated tumour, while the rest appears like a smooth, whitish, or ash-coloured substance, streaked with varicose vessels, sometimes advancing as far over the conjunctiva, covering the side of the eye next to the nose, as where the cornea and sclerotica unite. In this advanced state, the encanthis constantly interests the caruncula lachrymalis, the valvula semilunaris, and the membranous lining of one, or both eyelids. In addition to the roots, which in such circumstances connect the excrescence with the caruncula lachrymalis, the semilunar fold, and the conjunctiva of the globe of the eye, the encanthis emits an appendage, or prominent, firm elongation, along the inside of the upper, or lower eyelid, in the direction of its edge. The middle, or body, of the encanthis, divides near the cornea, as it were, like a swallow's tail, to form two appendages, or elongations, one of which extends along the inner surface of the upper eyelid by the margin of which it is covered, while the other shoots in a direction from the

internal towards the external angle, along the inside of the lower eyelid, which also conceals it beneath its edge.

The body of the encanthis, or that middle portion of the whole excrescence which reaches from the caruncula lachrymalis, and semilunar fold, inclusively, over the conjunctiva almost to the junction of the sclerótica with the cornea, sometimes forms a prominence, as large as a small nut, or chestnut. At other times, it is of considerable size, but depressed and broken down, as it were, at its centre. Still, however, the body of the encanthis preserves that granulated appearance which prevailed at first; while one or both the appendages, on the inside of the eyelids, appear rather like a fleshy than a granulated substance.

On turning out the inside of the eyelids, these appendages, or elongations of the encanthis, form a prominence projecting forward. When both eyelids are equally affected, and turned inside out, the appendages conjointly represent, as it were, a ring, the back of which rests on the globe of the eye.

Sometimes, the encanthis assumes a cancerous malignancy. This character is evinced by the dull-red, leaden, or (as Beer says) the bluish red colour of the excrescence; by its excessive hardness, and the lancinating pains which occur in it, and extend to the forehead, the whole eyeball, and the temple, especially when the tumour has been slightly touched. It is also evinced by the propensity of the excrescence to bleed, by the partial ulcerations on its surface, which emit a fungous substance, and a thin and exceedingly acrid discharge. The disease is constantly attended with epiphora, and preceded by a scirrhus induration of the caruncle. The eyeball and neighbouring bones, which are of a spongy texture, are said to participate very soon in the disease, the lower eyelid also becoming everted. (*Beer, Lehre von den Augenkr. B. 2, p. 187, 188.*) This form of encanthis only admits of palliative treatment; unless, indeed, an effort be made to extirpate it entirely, together with the whole of what is contained in the orbit, and even then the event is dubious.

Beer joins Scarpa in the statement, that the operation rarely proves successful, and adds, that it is always followed by an incurable weeping, and a considerable eversion of the lower eyelid. (*Vol. cit. p. 189.*) Fortunately, the truly cancerous encanthis is uncommon: and Mr. Travers, who was a surgeon to the London Eye Infirmary several years, never met with an instance of it. (*Synopsis of Diseases of the Eye, p. 103.*)

The benign encanthis, how large soever it may be, is always curable by extirpation. Those instances which are small, incipient, and granulated, like a mulberry, or of a fringed structure, which originate either from the caruncula lachrymalis, or the semilunar fold of the conjunctiva, or from both these parts together, and even in part from the internal commissure of the eyelids, may be raised by means of a pair of forceps, and cut

off from the whole of their origin, closely to their base, with the curved scissors with convex edges. In the performance of this operation, it is unnecessary to introduce a needle and thread through this little excrescence, as some are wont to do, for the purpose of raising it, and destroying more accurately all its origins and adhesions. The same object is fulfilled by means of forceps, without inconveniencing the patient with a puncture of this kind, and drawing a thread through the part, in order to make a noose. However, in cutting out an encanthis of this small size, care should be taken not to remove, together with that portion of the excrescence which originates from the caruncula lachrymalis, any more of this latter body than what is absolutely necessary for the precise eradication of the disease, in order that no irremediable weeping may be occasioned.

When the little excrescence has been detached from all its roots, says Scarpa, the eye must be washed several times with cold water in order to cleanse it from the blood, and then it is to be covered with a piece of fine linen and a retentive bandage. On the 5th, 6th, or 7th day, the inflammation arising from the operation entirely ceases, and the suppuration from the wound is accompanied with the mucous appearance already described. The little wounds are then to be touched with a piece of alum, scraped to a point like a crayon, and the vitriolic collyrium, containing the mucilage of quince seeds, is to be injected into the affected eye several times a day. If these means should not bring about the wished-for cicatrization; but, on the contrary, the small wounds situated on the caruncula, and internal commissure of the eyelids, should become stationary, and covered with proud flesh, the *argenti nitratum* ought to be applied to them. The conjunctiva, however, should be avoided as much as possible, especially if at all wounded. When the fungous granulations have been destroyed, the cure may be perfected by the collyrium already mentioned, or rather by introducing, thrice a day, between the eyeball and internal angle of the eyelids, the powder of tutty, and the *armenian bole*. Bidloo extols very much powdered chalk, either alone or in conjunction with burnt alum. (*Exercit. Anat. Chir. Decad. 2.*)

Excision is equally applicable to the inveterate encanthis, which is of considerable size, and broken down at its body, or which forms a prominence as large as a nut, or chestnut, with two fleshy appendages extending along the inner surface of one or both eyelids. The application of a ligature to such an excrescence ought never to be regarded as a method of cure; for the large inveterate encanthis never has a sufficiently narrow neck to admit of being tied. On the contrary, when the tumour is voluminous, its roots invariably extend to the caruncula lachrymalis, the semilunar fold, and the conjunctiva covering the eyeball, oftentimes nearly as far as the cornea. In this state,

also, the encanthis has one or two fleshy appendages, which reach along the membranous lining of one or both eyelids. Hence, though the ligature were to produce a separation of the body of the encanthis, one or both the appendages would still remain to be extirpated. This second operation could only be accomplished with the knife. In this disease, there is no foundation for the fear of hemorrhage, to which the advocates for the ligature attach so much importance; for, cases are recorded of considerable inveterate encanthes being removed without the least untoward occurrence from loss of blood. To these, Scarpa observes, he could add a great number of his own, so that no doubt can now be entertained on this point.

Peffier relates a case, in which an encanthis was followed by a dangerous hemorrhage, though it had been cut out by an expert oculist. He enters, however, into no detail concerning the nature of the complaint, nor the way in which the operation was performed; circumstances from which one might deduce the reason of this unusual accident. Indeed, the same author adds, "I have often performed this operation for such excrescences, and have never met with a similar occurrence." (*Receuil d'Observ. sur les Maladies de l'Œil, Part 2. Obs. 118.*)

When the encanthis is large and inveterate, with two extensive fleshy elongations, one on the inside of the upper eyelid, and the other on that of the lower one, we are to proceed in the following manner. The patient being seated, an assistant is to turn out the inside of the upper eyelid, so as to make one of the appendages of the encanthis project outward. By means of a small bistoury, a deep incision is next to be made into the elongation, in the direction of the margin of the eyelid; and then having taken hold of and drawn it forwards with a pair of forceps, we are to separate it throughout its whole length, from the inside of the upper eyelid, proceeding from the external towards the internal angle of the eye, as far as the body or middle of the encanthis. We are then to do the same to the lippomatous appendage on the inside of the lower eyelid. Afterward the body of the encanthis is to be elevated, if possible, with a pair of forceps; but when this instrument will not answer the purpose, a double hook must be employed. This middle portion is now to be detached, partly by the bistoury and partly by the curved scissors, from the subjacent conjunctiva, on the globe of the eye, from the semilunar fold, and from the caruncula lachrymalis; dividing the substance of this last part more or less deeply, according to the depth and hardness of the large inveterate encanthis. Here it is proper to state distinctly, that when we have to deal with an old, large tumour of this nature, deeply rooted in the caruncula lachrymalis, it is not regularly in our power to preserve a sufficient quantity of the substance of this part, to prevent the tears from dropping over the cheek after the wound is healed.

The eye is to be repeatedly washed with cold water.

The rest of the treatment, consequent to the extirpation of a large encanthis, is almost the same as what was explained in speaking of the small incipient case. Bathing the eye very frequently in the lotion of mallows, and employing anodyne, detergent collyria, are the best local means, until the mucous appearance, preceding suppuration, has taken place on the surface of the wound. Then we may have recourse to mild astringent ointments and collyria. The mildest topical applications are generally the best, both in the first stage of suppuration, as well as afterward, particularly when, together with the encanthis, we have removed a considerable piece of the conjunctiva, which covered the eyeball towards the nose, and was intimately connected with the body of the excrescence.

Consult Scarpa sulle *Mallattie degli Occhi*. Ed. 5, Cap. 12; Richter, *Anfangsgr. der Wundarzn.* Band 2, p. 473, &c. Edit. 1802. G. J. Beer, *Lehre von den Augenkr.* B. 2, P. 187, 8vo. Wein. 1817. On the whole, I consider Scarpa's observations the most correct and valuable, and they have therefore been freely employed in the foregoing article.

ENCEPHALOCLE. (from *εγκέφαλος*, the brain, and *κλήη*, a tumour.) A hernia of the brain. (See *Hernia Cerebri*.)

ENCYSTED TUMOURS. (See *Tumours Encysted*.)

ENEMA. (from *ενεμα*, to inject.) A clyster.

The following are some of the most useful clysters employed in the practice of surgery.

Cathartic.

- R. Decocti Hordei ℥j.
Sodæ Muriatis ℥j.—Misce.
R. Decocti Avenæ ℥j.
Olei Olivæ ℥ij.
Magnesiæ Sulphatis ℥j.—Misce.

Anodyne.

- R. Mucilaginis Amyli, Aquæ distillatæ sing. ℥ij. Tincturæ Opii guttas xl.—Misce.
R. Olei Olivæ ℥iv. Tincturæ Opii guttas xl.—Misce.

The two latter clysters are particularly useful in cases in which there is great irritation about the rectum, bladder, or urethra. They have great effect in diminishing spasmodic affections of this canal and the neck of the bladder.

Tobacco.

Employed in cases of strangulated Hernia.

R. Nicotianæ ℥j. Aq. ferventis ℥j. The plant is to be macerated ten minutes, and the liquor then strained for use. One half should be first injected, and soon afterward the other, unless the clyster should operate with dangerous violence, as it sometimes does in particular constitutions.

ENTEROCLE. (from *εντέρα*, the bowels, and *κλήη*, a tumour.) A hernia, in which the contents of the tumour are intestine.

ENTERO-EPIPOCELE. (from *enteron*, the bowels, *epiploon*, the omentum, and *κλῆν* a tumour.) A hernia, in which the contents of the swelling are both intestine and omentum.

ENTROPIUM. (from *εν* and *τροπον*, to turn.) An inversion of the eyelids. (See *Trichiasis*.)

EPIGLOTTIS SHOT AWAY. The practice of Baron Larrey furnishes a curious example, in which the epiglottis of a French soldier was shot off at the battle of Alexandria, on the 21st of March, 1801. The ball entered at the angle of the jaw, crossed the throat obliquely, and came out at the opposite side of the neck. The base of the tongue was grazed, and the epiglottis shot away; the patient spit it up after the accident, and showed it to the surgeon, who first saw him. One may be convinced of the fact by an account of the symptoms.

The patient was not in much pain; but his voice was hoarse, feeble, and scarcely audible.

When he first attempted to swallow, he was seized with a convulsive suffocating cough, attended with vomiting. Annoyed by thirst, which the extreme heat of the weather and the irritation of the wound excited, he incessantly repeated his attempts to drink; but always with the same result. Four days were passed in this deplorable condition. He already experienced violent complaints at his stomach; continual loss of sleep; he had a small accelerated pulse, and was beginning to look thin.

Such was the state of this wounded soldier, when Larrey saw him on the fifth day. After making a few inquiries about what had passed after the accident, attempting to make the patient drink, and examining the interior of the mouth, Larrey was convinced, that the paroxysms of suffocation, and the inability to swallow depended upon the permanent opening of the glottis, the lid of which had been shot away. The prognosis of the injury was exceedingly unfavourable, and there can be no doubt, that, if the patient had been abandoned to the resources of nature, he would have died in the course of a few days. The indications were equally difficult to fulfil: the most urgent was to appease the hunger and thirst, with which this poor soldier was afflicted. Larrey fortunately, was provided with an elastic gum tube, constructed for the œsophagus. This instrument was introduced with the usual precautions, into the pharynx, and by means of it, the patient was given some drink, which relieved him much, and afterward some rich broth. The patient was fed in this manner for six weeks, at the end of which time, he was able, without the assistance of the tube, to swallow thick panado, and thickened rice, made into little balls. The powers of speech and deglutition in time became much more perfect; in consequence, as Larrey imagines, of an enlargement of the arytenoid cartilages, and an expansion of that part of the base of the tongue which lies next to the glottis,

having formed a sort of substitute for the epiglottis. (*Mémoires de Chirurgie Militaire*, T. 2, p. 145—149.)

The foregoing case illustrates, in a convincing manner, the importance and utility of elastic gum tubes for conveying nourishment and medicines down the œsophagus in wounds about the throat. All practitioners, and, especially, military surgeons, should be duly impressed with the necessity of having such an instrument always at hand. The patient, whose case is above recited, owed his preservation altogether to this means, without which he must have been starved to death.

In the fourth vol. of the above work, P. 247, is recorded another case, in which a gun-shot wound, that took away the epiglottis, and broke the os hyoides, was successfully treated.

EPIPHORA. (from *επιφερω*, to carry with force.) By this term is meant an accumulation of tears on the anterior part of the eye, in consequence of which, the person afflicted is not only under the necessity of frequently wiping them away, but vision is injured by the morbid refraction, which they produce of the rays of light that enter the pupil. *Stillicidium lachrymarum* is distinguished by modern writers from epiphora: the cause of stillicidium lies in some obstacle to the absorption and conveyance of the tears from the lacus lachrymarum into the sac. Epiphora, on the other hand, consists in a superabundant secretion of tears, and is a disease of the secreting, not of the excreting parts, of the lachrymal organs. (See *W. M. Kenzie's Valuable Essay on the Diseases of the Lachrymal Organs*, p. 47. 8vo. Lond. 1819, and *Beer Lehre von den Augenkr. B. 2.*)

EPIPOCELE. (from *epiploon*, the omentum, and *κλῆν*, a tumour.) A hernia, formed by a protrusion of the omentum. (See *Hernia*.)

EPULIS. (from *επι*, upon, and *κλῆν*, the gums.) A small tubercle on the gums. It is said sometimes to become cancerous. The best plan of cure is to extirpate it with a knife.

ERETHISMUS. (from *ερεθίζω*, to irritate.) The state of irritation, attending the early stage of acute diseases. Mr. Pearson has described a state of the constitution, produced by mercury acting on it as a poison. He calls it the *mercurial erethismus*, and mentions, that it is characterized by great depression of strength, anxiety about the præcordia, irregular action of the heart, frequent sighing, trembling, a small, quick, sometimes intermitting pulse, occasional vomiting, a pale contracted countenance, a sense of coldness; but the tongue is seldom furred, nor are the vital and natural functions much disturbed. In this state, any sudden exertion will sometimes prove fatal. Mr. Pearson advises, with a view of preventing the dangerous tendency of this affection, the immediate discontinuance of the use of mercury; and exposing the patient to a dry cool air. The incipient

erethismus may often be averted by the camphor mixture with large doses of the volatile alkali, if mercury be also left off. Sarsaparilla is also beneficial, when the stomach will bear it. (*Pear on Lues Venerea*, page 156, &c. Edit. 2.)

ERYSIPELAS. (from *ἐρύω*, to draw, and *πλάσας*, adjoining.) St. Anthony's fire; so called, from its tendency to draw the neighbouring parts into the same state, or, in other words, from its propensity to spread.

Erysipelas may be defined to be an inflammatory, cutaneous, and trivially elevated swelling, attended with a redness, which disappears, and leaves a white spot for a short time after being touched with the end of the finger, and the affection, which is not like phlegmon regularly circumscribed, is characterized by a remarkable propensity to spread.

The part is generally of a bright red colour, clear, and shining. The tumour is not accompanied by throbbing, and a burning heat and tingling are felt, rather than acute pain. In many instances, vesications arise; a circumstance, which led Dr. Willan to include the disease in the order *Bulla*. However, if we mean this arrangement to extend to what is named *local*, or *accidental erysipelas*, as well as to the *idiopathic* forms of the disorder, there cannot be a doubt of its inaccuracy, many examples of erysipelas from local irritation being characterized neither by fever, nor vesications.

The Greeks, admitting into their theories of medicine the metaphysical principles of philosophy, and the superstitious ideas of the Pythagoreans, respecting numbers, agreed in the existence of four elements, four radical qualities, four temperaments, and consequently four humours and four species of tumours, produced by stagnation, or a diseased alteration of the humours above mentioned.

Phlegmon, according to their theory, was formed by the blood, erysipelas by the bilious, œdema by the pituitous, and scirrhus by the melancholic or atrabilious temperament. But as this theory was often contradicted by observation, they were obliged to have recourse to the supposition of a mixture of the humours, by means of which tumours of a mixed description were formed; whence, no doubt, we derive the distinction of simple or true erysipelas, (produced merely by extravasation and deposit of the bilious humour, under the skin;) from the compound or spurious, which took its name from the humour at the time most prevalent; hence the names of phlegmonous, œdematous, scirrhus, erysipelas, &c.

In order to have just ideas respecting the various forms of erysipelas, the first thing is to establish an eligible classification of them. Desault prefers the division of erysipelas into *phlegmonous*, *bilious*, and *local*; (*Chir. Journ. Vol. 2.*) an arrangement which seems founded on experience and correct observation. Mr. Pearson also divides the complaint into three forms, viz. the *phlegmonous*, the *œdematous*, and *gangrenous*; (*Prin-*

ciples of Surgery, Chap. x.) Burserius notices, 1. The *idiopathic*, or *primitive erysipelas*, or that which arises spontaneously from an internal cause, unpreceded by any other disease. 2. *Symptomatic*, or *secondary erysipelas*, depending on another affection, by which its progress is completely influenced. 3. *Accidental erysipelas*, or that which is casually excited by some external manifest cause. (*Instit. Med. Prac. T. 2. C. 2. Sec. Lips. 1798.*)

In the *bilious erysipelas*, which would be classed, as an *idiopathic* case, the swelling is trifling, and often imperceptible, the skin of a rose-colour, generally a little verging towards yellow. The sensation, which the patient experiences is neither that of tension nor pulsation, but a painful smarting, similar to what results from the application of hot water, or from exposure to the burning rays of the sun.

Towards the period of the invasion of this disease, and often several days previously, the appetite is lost, the mouth bitter, the tongue moist, and covered with a yellow mucus. Nausea and sometimes bilious vomitings come on. The patient becomes weak and dejected, and is affected with wandering pains and considerable heat, without any particular dryness of the skin or violent sense of thirst. Sometimes the disease begins with fever, more or less violent, preceded by shivering and violent pain in the head.

In the *phlegmonous erysipelas*, the skin is more raised than in the preceding species, the swelling harder and deeper, and of a darker colour. There is generally a slight degree of tension of the integuments, with pungent pain, and occasionally a sensation of throbbing. On the first days of the attack, there is neither bitterness in the mouth, nor nausea, the skin and tongue become dry, and are accompanied with a violent sense of thirst; the pulse is full and hard, indicating plethora. This form of erysipelas most frequently occurs in the face, usually affecting only one side of it; sometimes it seizes one of the extremities; and, in both cases, it is ushered in by a smart feverish attack. (*Bateman, Synopsis of Cutaneous Diseases, P. 126, Ed. 3.*)

At the expiration of a few days, particularly when the disease has been treated by bleeding and an antiphlogistic regimen, the tongue becomes foul and moist at its edges, bitterness of the mouth and nausea supervene, and the disease, in its progress, presents little difference from bilious erysipelas. (*Parisian Chirurgical Journal, Vol. 2, p. 24, &c.*)

The following is a description of phlegmonous erysipelas, as it sometimes appears when it attacks the head.

The attack is mostly preceded by shiverings, complaints about the region of the heart, and other symptoms very similar to those which indicate the approach of an intermittent fever. The heat is often accompanied with a little delirium, and almost always with drowsiness of a more or less

evident kind. The swelling generally makes its appearance on the second night, or third day of the fever, attacking the forehead, the cheeks, the nose, or eyelids. This swelling is elastic and smooth; but it is not distinctly circumscribed, and it gradually spreads over such parts of the face as were not at first affected. The skin becomes of a bright red colour; occasionally having a tendency to a livid hue; in other instances having a mixture of yellow. These colours disappear when pressure is made on the part affected, but very soon reappear when such pressure is discontinued. The patient experiences a burning heat, and a disagreeable pricking in the part, rather than any acute pain; sometimes he complains of a very troublesome itching. The surface of the tumour is shining, and, as it were, semi-transparent; but without hardness, tension, or any sensation of throbbing. The eyelids are often so swollen that the patient cannot see, and the whole countenance is exceedingly disfigured. On more or less of the erysipelatous tumour vesications arise on the fourth, or fifth day; they are filled with a transparent serous fluid, and bear a great resemblance to those which are occasioned by boiling water. They commonly burst, or subside on the fifth, or sixth; the fluid, which is discharged, sometimes excoriating the neighbouring parts. Frequently, there is even a slight ulceration at their base, which ulceration, in the worst sort of cases, assumes a gangrenous appearance, and falls rapidly into a state of complete mortification. When the disease takes a more favourable course, the fever now begins to abate; the vesications dry up; and, at the end of eight or twelve days, the cuticle peels off, and the scabs, situated in places which were occupied by the vesications, fall off. The degree of danger depends materially on the delirium and other symptoms indicating an affection of the brain. When phlegmonous erysipelas attacks the face, the termination of the disorder in suppuration is very rare. (*Bateman, Vol. cit. p. 127.*)

According to several writers, the seat of erysipelas in the greater number of cases is the very surface of the cutis; its most vascular and nervous part. (*Dict. des Sciences Med. T. 13, p. 255.*) And, perhaps, it may be true, that the disorder here commences, and is most intense. Yet, there can be no doubt, that the affection generally extends more deeply, and affects the subjacent cellular membrane, particularly in cases of phlegmonous erysipelas. The affection of the cellular membrane, however, is very different from what happens in phlegmonous inflammation. In true erysipelas, healthy pus is rarely found enclosed in a circumscribed cavity; and when there is any secretion of purulent matter, a feel is communicated, on compressing the part, almost like that which a sponge would give. In such cases, the cellular substance is frequently gangrenous.

It does not appear to me, that any very exact information has yet been established

respecting the causes of erysipelas. We absolutely know nothing about the immediate cause; the prevailing ideas concerning the predisposing causes are vague; and only those causes, termed exciting, appear entitled to much confidence. They are:

1. Violent passions, such as anger, acute grief, &c.
2. Exposure to the heat of the sun, or that of the fire, too long continued.
3. The impression of cold damp air.
4. The action of various vegetable, mineral, and animal poisons.
5. Wounds, contusions, fractures, the stings of insects, &c.

In most cases, erysipelas would seem to be intimately dependent on the state of the constitution. Thus, persons in the habit of drunkenness, and other kinds of intemperance, and who, in a state of intoxication, meet with local injuries, often have erysipelatous inflammation in consequence of them. Other subjects, who lead more regular lives, experience, when they meet with similar injuries, healthy phlegmonous inflammation.

The opinion of Hippocrates and Galen, with respect to the origin of this disorder from a congestion of the bile, is universally known to all initiated in the profession of Surgery. This old doctrine has been, in some measure, revived by Tissot, and many other believers in the humoral pathology, who attribute the cause of erysipelas to an acrid humour, commonly a bilious one, diffused through the mass of the blood. But, much as I despise the absurdity of this theory, observation obliges me to confess, that the complaint seems frequently to be connected with a wrong state of the chylipoietic viscera, and especially of the liver.

A further proof, that erysipelas is mostly dependent on constitutional causes, is, that the affection most frequently happens in autumn, or in any season, when hot weather is succeeded by cold and wet.

Erysipelas frequently attacks both sexes; but women are thought to be rather more subject to it than men, and the reason for this circumstance, generally mentioned, is the greater delicacy and tenderness of the skin in females. But, it would be quite as rational to suspect their weaker and more irritable constitutions, and their sedentary mode of life. In lying-in hospitals, and other charites for the reception of children, new-born infants are often afflicted with a species of erysipelas, which begins in the umbilical region, and thence extends to the pudenda. This case, which sometimes terminates in gangrene, and proves fatal, has been ascribed by some writers to injury done to the navel-string during labour, and by others to the bad air frequently allowed to accumulate in establishments of the above description; a cause, which too often renders complaints, which are at first trivial, ultimately fatal.

Sometimes, the complaint is scarcely cured in one place, when it makes its appearance in another, and when this tendency is evinced in a great degree, the case is termed

erysipelas ambulans, vel erraticum. La Motte has published a striking instance of this form of the disease. A child, between nine and ten years of age, was attacked with erysipelas of the scalp, forehead, and ears, which afterward extended to the neck, and then to the shoulders, while the scalp and face became free from it: in proportion as the disease spread downwards, all the upper parts got well, so that, in the end, there was no portion of the surface of the body, which had escaped, even down to the fingers and toes, the parts last of all affected. (*Obs. Chir.*)

A very uncommon variety of disease is an *universal erysipelas*. No disorder is more subject, than the present, to relapses; but a remarkable thing, sometimes attending the return of the complaint, is its being sometimes strictly *periodical*. In chlorotic women, the erysipelatous attack is occasionally made every month just at the period when the menses should take place. (*Hoffman.*) This periodical nature of erysipelas has been observed in men: Lorry knew two male patients, one of whom used to be attacked with erysipelas twice a year at the time of the equinox; the other had only one attack annually, which was wont to happen in the beginning of the spring. My friend, Mr. Maul of Southampton, lately informed me of an erysipelas, which was both periodical and universal, affecting a lady several times, at intervals of two years.

A doctrine has been started, that erysipelas is sometimes propagated by contagion. (*Wells, in Trans. for the Improvement of Med. and Surg. Knowledge, Vol. 2, Art. 17, 1800.*) But, as Dr. Bateman has truly remarked, such cases are, at all events, extremely rare, and perhaps never happen in well-ventilated and cleanly houses. (*Synopsis, &c. p. 131.*) In places of an opposite description, the infection of many individuals together might be explained by the operation of the same exciting causes upon them all, without any supposition of contagion.

The characters which distinguish erysipelas from phlegmon are:

1. The inflammatory swelling, which takes place in the former, is not so elevated as in the latter, and is never plainly circumscribed.

2. In most cases, the surface of the skin seems as if it were burnt.

3. The redness, though of a bright description, disappears on pressure.

4. The sense of throbbing, and darting pain, attendant on phlegmon, is not observable.

5. The inflamed part is free from tension, and appears as if it were affected with œdema, or rather with emphysema; only one can perceive no crepitation.

It must not be inferred from these differences, that erysipelas is to be considered as a disease essentially distinct from those, which are called inflammatory, as it has some characters in which it manifestly approaches them. Like phlegmonous inflam-

mations, it may be excited by any local irritation. Like other inflammations, it may end in suppuration, though of a less perfect sort, than that in which phlegmon ends, and rarely contained in a circumscribed cavity. The pulse, in phlegmonous erysipelas, is frequent, hard, sometimes full; and when the patients are bled, their blood has the same appearance, and is covered with the same kind of inflammatory crust, as blood taken away in other kinds of inflammation.

It is proper, however, to notice, that practitioners are not universally agreed with respect to the nature of the pulse in erysipelas: it is, according to some, particularly Mr. Pearson, soft, frequent, and often irregular. But, if due attention be paid, this difference will be found to depend on particular circumstances. In the *phlegmonous* erysipelas, the pulse will always be fuller than in the *bilious*. In the impure air of hospitals, and in all places, where the air is impregnated with carbonic acid gas, and other noxious gases, we find, that various affections decidedly inflammatory, especially those which are attendant on wounds, affect the body, and the sanguiferous system in particular, in a very different manner from what is observed when the patients are living in a more salubrious air. All inflammations assume a character more or less unfavourable, in consequence of the influence of bad air. This is particularly striking in cases of erysipelas. In such instances, living in an impure atmosphere has a singular effect in augmenting the sense of weakness and dejection, which patients always experience in a certain degree; and, in these cases, it may even go so far as to produce a total alteration of the state of the pulse. But, if attention be paid to the disease in a situation where the atmosphere is not impregnated with putrid effluvia, it will be found to put on a very different shape. The symptoms of dejection, of nervous irritation, and of cerebral disturbance, are much less conspicuous, and the state of the pulse, especially in patients who have not been previously debilitated by other diseases, bears a great resemblance to that which takes place in an inflammation of the chest.

Besides bad air, many other circumstances, which do not even belong to the nature of erysipelas, may have a share in producing an alteration of its symptoms. Thus, while inflammations of another kind, such as pleurisy and acute rheumatism, particularly affect robust persons, in whom the vital principle exists with a great deal of energy, erysipelas is prone to attack persons who are aged, or of delicate and depraved constitutions. The latter is also seen making its appearance as a symptom, in weakened parts, which have in a certain degree been deprived of their tone, as is the case with œdematous parts. It is not surprising, that, in these different cases, in which the tone of the system has already suffered, the state of the pulse, in persons affected with erysi-

pelas, should seem different from what it is in individuals, who are more healthy and robust.

Treatment of Erysipelas.

The treatment of *idiopathic* erysipelas varies according to the causes, symptoms, complications, and anomalies of the disease, and may be divided into *internal* and *external*. That the mode of relief must be very different in *phlegmonous* erysipelas from what it is in other varieties of the disorder, must be plain to every body, who has the least knowledge of the nature of diseases in general.

Common cases of *acute*, or *phlegmonous* erysipelas, yield to mild purgatives, and a light vegetable diet, with which remedies practitioners usually conjoin diaphoretics and the saline mixture. Whether bleeding is right or not in this species of erysipelas, is a point, on which different sentiments prevail. I believe, however, that venesection in the milder forms of the complaint is now pretty generally allowed to be unnecessary, nor is it necessary to repeat bleeding in any case of erysipelas so frequently as is done in other inflammatory diseases. We ought to be guided, however, in this respect, by the state of the pulse, and other symptoms, never forgetting the patient's age, strength, and other important considerations. *Cæteris paribus*, the patient will bear bleeding better in the country, and in an open, pure air, than in a large city, and especially in an hospital. And, as has been truly remarked, unless there be a considerable tendency to delirium, or coma, blood-letting can seldom be repeated with advantage, at least in large towns. (*Pearson's Principles of Surgery; Bateman's Synopsis*, p. 132, Ed. 3.) Instead of this practice the latter author judiciously recommends local bleeding and blistering, but not upon, or very near the diseased surface, whereby he avoids producing the troublesome sores, the frequency of which in former times, after taking blood from erysipelatous parts, led Mr. B. Bell to pronounce a general condemnation of the method. Alexander of Tralles, and Paré had a high opinion of the beneficial effects of plenty of fresh, cool air in cases of erysipelas, and the truth of this sentiment is acknowledged by all the best physicians and surgeons of the present day. Care should be taken also, that the patient be not covered with too much clothing; a piece of advice delivered by the first of the two preceding writers.

Cullen, whose theories induced him to regard erysipelas as a species of putrid fever, combined with evacuates the use of bark, wine, and other antiseptics. But, as Dr. Bateman correctly observes, the administration of cinchona and opium, in cases of *acute* or *phlegmonous* erysipelas, is certainly unnecessary, and appears to be of equivocal safety.

In the *bilious* erysipelas, whatever degree of heat or fever might exist, Desault gave, in the first instance, a grain of tartarized antimony dissolved in a considerable quantity of fluid; and the symptoms generally

diminished as soon as the effects of the medicine had ceased. He had seen them entirely subside, although the medicine produced no other sensible alteration, in the animal economy, than an increase of the insensible perspiration and urine: sometimes the symptoms resisted these evacuations, and he was obliged to have recourse once or twice, or even more frequently, to the use of the emetic drink. When the erysipelas was cured, and the bitterness in the mouth and fever had subsided, two or three purges of cassia and manna, with a grain of emetic-tartar, were exhibited; during the cure, the patient was ordered to drink freely of a diluting ptisan, acidulated with oxymel: and as soon as the symptoms were mitigated, the diet of the patient was allowed to be more nourishing and generous; for, when it was too spare, the case was remarked never to proceed so favourably, particularly in hospitals, where the air, generally speaking, is unhealthy. In the bilious erysipelas, Desault observed, that the cases of the patients, who had been bled previously to their admission into the hospital, were invariably the most serious and obstinate, particularly, when the bleeding had been frequently repeated.

In cases of bilious erysipelas, many modern practitioners would be bolder with antimonials than Desault, first, by imitating Richter, and giving an emetic at the commencement of the attack, and then by exhibiting more freely either antimonial powder, or tartarized antimony, with a dose or two of calomel.

In *phlegmonous* erysipelas, Desault was an advocate for bleeding in the beginning of the disorder, and, this practice he followed up by the administration of tartarized antimony and evacuates.

In cases of *idiopathic* erysipelas, whether *phlegmonous* or *bilious*, external applications have been deemed useless, or hurtful, by a large proportion of practitioners, among whom is Desault. In the early stage of the disease, Dr. Bateman has found powdery substances, like flour, starch, chalk, &c. increase the heat and irritation, and afterward when the fluid of the vesications oozes out, such substances produce additional irritation, by forming with the concreting fluid hard crusts upon the tender surface. This practice is also condemned by Mr. Pearson. The only plan, perhaps, which is unobjectionable, as a means of allaying the irritation produced by the discharge from the vesication, is that advised by Dr. Willan, and which consists in fomenting, or washing the parts from time to time with milk, bran and water, or a decoction of elder-flowers and poppy-heads. In the early stage of the inflammation, Dr. Bateman has found great relief derived from moderate tepid washing, or the application of the diluted liquor ammon. acet. (*Synopsis of Cutaneous Diseases*, p. 133, Ed. 3.)

Though Desault forbids local remedies in cases of *idiopathic* erysipelas, he does not extend the prohibition to examples, either

of bilious or phlegmonous erysipelas, from a contusion, wound, or an ulcer; regimen and internal medicines, according to Desault, here being insufficient, unless topical applications are employed to abate the local irritation, and excite suppuration. With this view, he commends cataplasms, but he deems one caution essential, viz. that the application of the poultice should not extend much below the contused surface, or the edges of the wound. If any application is permitted on the rest of the erysipelatous surface, he thinks, that it should be the liquor plumbi acetatis dilutis made weak. (*Parisian Chirurg. Journ. Vol. 2.*)

Mr. Pearson prefers mild warm cataplasms, composed of the powders of anniseed, fennel, camomile flowers, &c. mixed with a fourth part, or an equal quantity, of bread, and a proper quantity of milk. Linseed powder, he says, may sometimes prove a convenient addition.

Little more need be said, respecting the treatment of *secondary*, or *symptomatic* erysipelas. Generally less important than the other disease, with which it is associated, its management is quite subordinate to that of the latter affection. Thus, when erysipelas makes its appearance round a wound, or ulcer, the practice only requires to be somewhat modified according to the circumstances, state, and nature of the injury, or sore.

As for what is termed *accidental* erysipelas, or that caused by casual local irritation, applied directly to the skin, as from acrid substances, heat, friction, the sting of insects, &c. the removal of the cause, the employment of cold, or even ice-cold lotions, and other antiphlogistic means, are the only measures essentially necessary.

Cases of universal erysipelas have been successfully treated by warm-bathing, aperient medicines, and small doses of the acetate of potassa. (*Dict. des Sciences Med. T. 13, p. 266.*)

In the *œdematous* erysipelas, perhaps, bleeding is never admissible. The loss of even a very small quantity of blood may have the most fatal consequences. One should also be exceedingly sparing of other evacuations. A determination to the skin should in particular be kept up by antimonials, and irritation and pain soothed by administering the æther sulphuricus, camphor, opium, &c. When the disorder seems to shift its situation to any internal part, and particularly to the brain, blisters should be applied between the shoulders, to the head or legs, without the least delay. And, it is in the *œdematous* erysipelas more especially, that the patient's strength should be supported by tonic remedies, wine, bark, and cordials.

In cases of *phlegmonous* erysipelas, if the inflammation continues in an unabated form beyond the seventh, or eighth day, suppuration is to be apprehended. Here Boyer recommends the employment of emollient applications, and immediately a fluctuation is distinguishable (or even what he terms

"*un empatement purulent*") he advises the surgeon to make such incisions as may be necessary for the discharge of the matter. He also states, that the incisions should be made at several depending points. (See *Boyer's Traité des Maladies Chirurgicales, T. 2, p. 22.*) It appears from the observations of Mr. A. C. Hutchison, late surgeon to the Naval Hospital at Deal, that seafaring men are very liable to phlegmonous erysipelas of the extremities, particularly of the legs. The cause is ascribed to the irritation of the salt water, and the friction of their loose coarse trowsers. In this description of patients, the disease frequently proceeds rapidly to the gangrenous state, and the consequence is the loss of many lives and limbs. Even when the danger of mortification is avoided, abscesses often occur, which spread between the muscles and under the integuments to a surprising extent: "from the ankle to the trochanter, and over the glutæi muscles." In the first few cases, which came under the care of Mr. Hutchison, this gentleman's plan of treatment, in addition to the usual medical means, consisted of *local bleeding by means of cupping glasses*, followed by fomentations. Subsequently, however, he adopted the method of making *several free incisions with a scalpel on the inflamed surface*, in a longitudinal direction, *through the integuments, and down to the muscles, as early in the disease as possible, and before any secretions have taken place.* These incisions may be about an inch and a half in length, two or three inches apart, and vary in number from six to eighteen, according to the extent of surface which the disease is found to occupy. Mr. Hutchison states, that these incisions will yield between fifteen and twenty ounces of blood, and give relief to the tense skin, at the same time that they form channels for the escape of fluid, and the prevention of bags of matter. After the operation, fomentations, or saturnine lotions, are employed.

By the preceding kind of treatment Mr. Hutchison thinks the fatal termination of the disease may be rendered less frequent, and gangrenous mischief wholly prevented. He supports this assertion with observing, that he never lost a case in the Deal Hospital for the last five years, during which the practice was followed. (*See Med. Chir. Trans. Vol. 5, p. 278, &c.*)

On the proposal of this new treatment, I shall make very little comment, because I have never seen it tried. But, I shall venture to state, that I have not much opinion of it. What? are all the principles of surgery now so changed, and is the nature of the human body and constitution so altered, that inflamed parts are to be soothed by maiming and wounding them, or to use the author's words, by making "from six to eighteen incisions" in them? I would beg leave to ask, whether from six to eighteen deep cuts down to the muscles could ever be made in an uninfamed part, without producing inflammation? It is to be remarked, however, that formerly Mr. Hutchison, ha-

fore his adoption of this plan, used to apply to the part affected cupping glasses, which every surgeon knows will often of themselves irritate so much by their pressure, independently of the scarifications, as to make the sound skin inflame, and sometimes slough. We must not wonder, therefore, that his early treatment of phlegmonous erysipelas did not answer. As we have mentioned above, on the authority of Boyer and other eminent surgeons, incisions may undoubtedly become necessary in erysipelas, but, not before there is matter to be discharged. When once its existence is ascertained, the employment of the knife cannot too speedily follow.

With regard to the treatment of the gangrenous erysipelas, nothing more need be said than what is contained in the article on mortification.

Chir.* T. 1, p. 118, &c. Edit. 2. Lassus, *Pathologie Chir.* T. 1, p. 8, &c. Edit. 1809. *Traité des Maladies Chir.* par M. le Baron Boyer, Tom. 2, p. 6, et seq. A. C. Hutchison in *Med. Chir. Trans.* Vol. 5, p. 278, &c. and *Practical Obs. in Surgery*, 1816. T. Bateman, *A Practical Synopsis of Cutaneous Diseases*, p. 125, &c. Ed. 3. *Dict. des Sciences Med.* Vol. 13, p. 263, &c.

ERYTHEMA. (from *erythra*, red.) A redness of any part. A mere rash or efflorescence, not accompanied by any swelling, vesication, or fever, circumstances which, according to Dr. Bateman, distinguish it from erysipelas. (*Synopsis of Cutaneous Diseases*, p. 119, Ed. 3.) Its six varieties are described in the latter work. For the erythema mercuriale, see *Mercury*. The term is often wrongly applied to eruptions, attended with redness, and distinct papular and vesicular elevation, as we see in the instance of mercurial erythema, which Dr. Bateman says should be named *eczema*.

ESCHAR. (from *eschara*, to form a scab, or crust.) This term is applied to a dry crust, formed by a portion of the solids deprived of life. When any living part has been burnt by the actual, or potential cautery, all that has been submitted to the action of this application, loses its sensibility and vital principle, becomes hard, rough on the surface, and of a black, or gray colour, forming what is properly named an *eschar*, a slough, produced by caustics, or actual fire.

ESCHAROTICS. (from *eschara*, to form a crust over.) Applications, which form an eschar, or deaden the surface on which they are put. By escharotics, however, surgeons commonly understand the milder kinds of caustics, such as the *hydrargyri nitrico-oxydum*, *subacetate of copper*, &c.

EXÆRESIS. (from *exaiguo*, to remove.) One of the divisions of surgery adopted by

the old surgeons; the term implies the removal of parts.

EXCORIATION. (from *excoria*, to take off the skin.) A separation of the cuticle; a soreness, merely affecting the surface of the skin.

EXFOLIATION. (from *exfolia*, to cast the leaf.) The separation of a dead piece of bone from the living, is termed *exfoliation*.

One part of a bone is never separated from another by the rotting of the dead part, for that which comes away is as firm as it ever was. Exfoliation takes place with most expedition in bones, which have the fewest cells, and whose texture is the closest. Before any part of a bone can be thrown off by exfoliation, it must be dead. But, even then till the process of exfoliation begins, the bone adheres as strongly as ever, and would remain for years, before it could be separated by putrefaction alone. The human bones are composed of two substances, viz. a true animal matter, and an earthy one, the phosphat of lime, which are only mixed with each other. A dead bone acts on the system, in the same manner, as any other extraneous body. It stimulates the adjacent living parts, in consequence of which, such a process is begun, as must terminate in its being thrown off. The effects of this stimulus are, first, that the living adjacent bone becomes more vascular; a circumstance, which always takes place, when a part has more to do, than is just sufficient for the support of life. Secondly, that the earth of the living part, where it is in contact with the dead bone, is absorbed; and there the bone becomes softer, and adheres by its animal matter only. As Mr. Wilson has stated, "before any mark of separation is seen on the surface, the living bone surrounding the dead, for the extent of a mere line, has become as soft as if it had been steeped in acid." (*On the Skeleton and Diseases of the Bones*, p. 281, 8vo. London, 1820.) Thirdly, that the living animal part is at last absorbed along the surface of contact: this part of the process commences, however, long before the last is finished; and both of them begin at the surface; though, in their course, they do not every where take place in an equal degree at the same time. Fourthly, in proportion to the waste made by the last part of the process, granulations arise from the living surface, and fill up the intermediate space, so that there is no vacuum. These different stages together constitute ulceration. When any part of a bone is once loose, it is pushed to the surface in the same manner, as most other inanimate bodies would be, and this stage is partly mechanical, and partly a continuation of ulceration. A proof of the third stage, above mentioned, may be derived from cases, in which people die, while exfoliation is going on. A small groove, or worm-eaten canal, can then be discovered, which becomes gradually deeper, and follows the irregularities of the living and dead surfaces. After the application of the tre-

pan, a circular piece of bone is frequently thrown off, which is always less than the space from which it came. This, as Mr. Hunter observed, would never be the case were there not a loss of substance.

"Although (says Mr. Wilson) in general the absorption takes place in the living bone, it still appears, that, under peculiar circumstances, the absorbing vessels have the power of acting on and removing the substance of dead bone. This happens after the dead part has been separated from the living, and when from its shape, and the form of the living surrounding bone, it is prevented from obtaining a passage to the surface of the body; as in exfoliations of the cranium, when the inner table of the exfoliated part is broader and wider than the outer table." (*On the Skeleton, &c. p. 282.*) In very hard bones, the colour of the dead, exfoliating portion is generally white; but, in softer bones, it is yellow, dark, and sometimes black. (*Wilson, op. cit.*)

It was anciently believed, that whenever a bone was denuded, the exposed surface must necessarily exfoliate, and, this being taken for granted, the old surgeons used to put immediately in practice whatever they thought best calculated to bring on an exfoliation as quickly as possible. For this purpose, the actual cautery was usually applied to the part of the bone which was uncovered, and as, under such treatment, a portion of the bone was of course killed, and then exfoliated, the prejudiced practitioner believed, that he had only accelerated a process which must of necessity have followed in a more slow and tedious manner.

According to Mr. Hunter, neither caustics nor the actual cautery hasten exfoliation; they only produce death in a part of the bone, which is the first step towards exfoliation, and if they ever hasten exfoliation, when the bone is already dead, it must be by producing inflammation in the adjacent living bone; a change that makes it exert a power of which it was previously incapable.

Exfoliation is not a necessary consequence of a bone being laid bare, and deprived of its periosteum. If the bone be in other respects uninjured, healthy, and enjoying a vigorous circulation of blood through its texture, granulations will be generated on the surface of such bone, which will cover and firmly adhere to it, without the smallest exfoliation being thrown off, especially in young subjects. But if caustic, stimulating, or drying applications be made use of, or the bone be left for a considerable time exposed, the circulation in the superficial portion of it will necessarily be disturbed and destroyed, and that part of the surface, through which the circulation ceases to be carried on, will be separated and cast off by the process of exfoliation.

If any application to an exfoliating portion of bone be at all efficacious, it must be one which will stop the mortification in the affected bone, and promote the absorption of those particles of phosphate of lime, which form the connexion between that

which is living and that which is actually dead. And as the bone dies from the same causes as the soft parts mortify, we should at least follow in practice the same principles which we adopt in the latter instance; and though, from the inferior vascularity, and vital power of bones, we cannot expect surgery to have as much control over their affections as over those of the soft parts, yet every good will thus be obtained which it is possible to acquire. Attention to such principles will at least teach us to refrain from making the death of part of a bone more extensive than it would be, if the cautery, caustics, and strong astringents, were not employed.

The best mode of attempting to prevent an exfoliation from occurring at all in a bone that has been exposed by a wound, is to cover the part again, as soon as possible, with the flesh, which has been detached from it. This, as I shall hereafter notice, (*see Head, Injuries of,*) may generally be practised with advantage, when the scalp has been detached from the cranium, provided the flap have still even the most limited connexion with the rest of the integuments.

When the exposed bone cannot be covered, it should be dressed with the mildest and simplest applications, with plain lint, or lint spread with the unguentum cetaceum.

The dead pieces of bone, when very tedious in exfoliating, when wedged in the substance of the surrounding living bone, and when so situated as to admit of being safely sawn, or cut away, may sometimes be advantageously removed in this manner. (*See Caries and Necrosis.*) In such operations, Mr. Hey's saws may be employed with great convenience; and where these are not applicable, that invented by Mr. Machell, and described in Mr. A. Cooper's *Surgical Essays*, or another devised by Graefe, and explained by Schwalb (*De Serra Orbiculari, 4to. Berol. 1819.*) deserve to be recollected.

In speaking of necrosis, I shall have occasion to notice the efficacy of blisters, kept open with the savin cerate, in quickening the process by which dead portions of bone are loosened, as particularly pointed out by the late Mr. Crowther, in his work on the white swelling.

Tenon published three *Memoirs on the Exfoliation of Bones*. The two first are inserted at pages 372, and 403. *Mem. de l'Acad. des Sciences*, 1758; the third at p. 223 of the same *Work*, for 1760. EXOMPHALOS. (from $\epsilon\zeta$, out of, and $\sigma\mu\phi\alpha\lambda\omicron\varsigma$, the navel.) A hernia at or near the navel.

EXOPHTHALMIA. (from $\epsilon\zeta$, out, and $\sigma\phi\theta\alpha\lambda\mu\omicron\varsigma$, the eye.)

In the case to which the most judicious surgical writers apply the terms *exophthalmia*, *ophthalmoptosis*, *ptosis bulbi oculi*, the eyeball is of its natural size, and free from disease; it merely changes its situation, and partly or completely protrudes from the orbit. It is only confusing the subject to consider, as specimens of this disease, the cases in which the globe of the eye is affected with enlargement, and on that account projects from the orbit in a preternatural degree, as happens in *hydrophthalmia*, *staphyloma*, and cancerous diseases of the eye. When the globe of the eye is pushed entirely out of the orbit, it generally lies upon the temple, or cheek, and vision is totally destroyed. There are instances, however, in which a considerable degree of sight was recovered, notwithstanding the *exophthalmia* was complete, and had lasted several years. (*Hope in Phil. Trans. for 1744. Richter's Bibl. 4 Band. p. 343.*)

There are three descriptions of causes which may occasion *exophthalmia*.

1. The first and least common is a violent concussion of the head. A man fell from a height of about fifteen or sixteen feet, and pitched upon his head. The right eye was forced out of its socket, and hung over the cheek. The patient was deprived of his senses immediately after the accident, and affected with coma. There was a contusion over the right parietal bone, but no fracture. The eye spontaneously resumed its natural position a short time after the accident, and in the course of a month, with the assistance of low diet and repeated bleeding, the cure was completed. (*Mém. de l'Acad. de Chirurgie, Tom. 1, p. 198, 4to.*) It has been alleged, that the eye has been forced out of the orbit in a violent fit of sneezing. But such cases, says Richter, are very uncommon, and always imply a considerable relaxation of those parts, which serve to retain the eye in its socket, or some other predisposing causes, to which attention should be paid in the treatment. (*Richter, Anfangsgr. der Wundarz. B. 3, p. 407, Ed. 1795.*)

2. A far more frequent cause of *exophthalmia* is a thrust in the eye with an instrument which is narrow enough to pass between the orbit and the eyeball, so as to push the latter out of its place.

A stick, a tobacco pipe, (*White's Cases in Surgery, p. 131.*) a foil, &c. may cause the accident. Repeated experience proves, says Richter, that, in such cases, though the

optic nerve and muscles of the eye may be forcibly stretched, the interior parts of the organ seriously injured, and the dislocated eye generally deprived of the faculty of seeing, yet, when the organ is replaced as speedily as possible, it not only sometimes recovers its natural motion, but also its original power of vision. (See *Scultet. Appendix, Obs. 69. Covillard, Obs. 27. Borellus, Centur. 3, Obs. 54. Rhodius, Centur. 1, Obs. 84. White's Cases, p. 131*.) But before we reduce the eye Richter advises us always to examine the instrument, which was pushed into the orbit; as, when it is brittle, a fragment of it may remain behind in the socket, and require to be extracted by means of the finger or a probe. When the weapon is pointed and hard, it sometimes pierces the bones of the orbit, and enters the brain, nose, or antrum. In the first case, which is often difficult to ascertain immediately, though after a time it is generally rendered plain enough by the symptoms induced, the consequences are mostly fatal. In the two other cases, although the danger is not pressing, yet the surgeon should be very attentive, in the event of suppuration, to procure and maintain a ready outlet for the matter.

There is generally little difficulty in replacing the eye. Frequently it returns of itself into its natural situation again, as soon as any trivial obstacles to its reduction are removed; and in other instances, it easily admits of being put into its proper place with the hand. The indication, says Richter, is always accomplished with more facility, the sooner it is attempted. When the protrusion has existed several days, and the eye and other parts in the orbit are already inflamed, Richter recommends us to endeavour to diminish the inflammation by general antiphlogistic means, and external emollient applications, before we try to replace the eye, and the reduction of this organ is afterward to be effected in a gradual manner. When the optic nerve, and one or more of the muscles of the eye are torn, no hope can be entertained, that the eyesight and motion of the organ will ever be regained. But this degree of injury, as Richter observes, cannot always be immediately detected, because the optic nerve and muscles are concealed by the conjunctiva; and, if the nature of the case were known, still it would be advisable to replace the eyeball, and endeavour to prevent the disfigurement which its loss would unavoidably produce. But, says Richter, it is necessary, especially if the parts behind the eyeball have suffered severely, to use such means as will ensure a ready escape for the matter which may possibly form. Though Richter offers the opinion, it is difficult to conceive how the violence of the injury of the conjunctiva, muscles, and nerve, can ever render it most prudent not to reduce the part, until after suppuration has taken place. Richter thinks, that a surgeon may the more readily make up his mind to this conduct, as many cases have proved that the eyeball, even after being dislocated from the orbit a long while,

has been easily replaced. In other instances, the parts which connect the eye with the orbit may be so torn and injured, that it will be most adviseable to extirpate the organ.

Richter maintains, however, that this should never be done when there is the least chance of saving the eye. If the bones in the orbit be fractured, the reduction must not be made until the indications which this complication presents, have been fulfilled.

When, says Richter, the instrument, with which the eye has been pushed out of its socket, is blunt and thick, like a finger, a stick, a foil, &c. the eyeball itself always sustains a violent contusion, which brings on vehement inflammation, and lessens or destroys all hope, that, after the reduction, the eyesight will be restored. Sometimes, in these cases, an extravasation of blood in the orbit occurs, the iris is lacerated, the cornea burst, and a part of the humours of the eye discharged. Although, under such circumstances, it is scarcely to be expected that the eyesight can be recovered, yet, it is proper to reduce the eye, because, should the organ be destroyed by suppuration, or the loss of its humours, the deformity may be obviated by an artificial eye, which is not the case, when the eye has been cut away. It is also to be considered, that the mischief often seems to be worse than it really is, and the eyesight is sometimes regained contrary to all expectation.

After the reduction of the eye, the first care of the surgeon should be to prevent and diminish inflammation. In some cases, the inflammation is slight; while, in others, especially when the eyeball has been severely struck, it is extremely violent. All the usual antiphlogistic means, both general and topical, are to be employed, and, of the latter, Richter says, astringents are the best, as the inflammation arises from the contusion and stretching, which the parts have suffered. The possible consequences of inflammation, such as suppuration, opacity of the cornea, &c. are to be treated according to the rules laid down in other parts of this dictionary. (See particularly *Cornea*, *Opacity of*; *Hypopyum*; *Ophthalmia*.) In general, the sight is restored in proportion as the inflammation is diminished. Should this not happen, after the ophthalmia has been entirely removed, the surgeon must try what effect such remedies, as stimulate the nerves, will have upon the optic nerve. An account of the most eligible medicines, for this purpose, will be found in the article, *Amaurosis*.

3. The third cause of exophthalmia is a preternatural tumour in the orbit, or neighbouring parts. The swelling, as it enlarges, gradually pushes the eyeball out of its socket. The tumours, which may be formed in the orbit, are of several kinds. The principal, however, are encysted swellings, which contain either fat, an aqueous fluid, a pappy substance, or a thick matter. Sometimes, the cellular substance in the orbit is affected with induration and swelling, so as to force

the eye partly or completely out of this cavity.

According to Mr. Travers, adipose swellings occupy the interspace of the recti muscles, emerge between the globe and the orbital circumference, and have an oblong figure. When the conjunctiva is freely divided, the fatty mass is easily drawn forwards with a hook, and dissected out. (*Synopsis of Diseases of the Eye*, p. 225.)

An abscess in the orbit may cause a protrusion of the eyeball. (*Pellier*.) Exostoses in the orbit may have the same effect. In the records of surgery may be found many examples, in which the displacement of the eye was produced by a tumour, that grew out of the frontal sinus. (See *Langenbeck's Neue Bibl. B. 2*, p. 247.) In some cases, in consequence of suppuration in the antrum, the lower part of the orbit is raised, and the eye forced out of its place. Fungous diseases of the antrum are very liable to occasion the same mischief. (See *Parisian Chirurgical Journal*, Vol. 1, p. 104, &c.)

Not long ago, Langenbeck extracted from the sinus frontalis of a girl, a large hydatid, which had forced the outer table considerably forwards, and depressed the orbital process of the os frontis so far, that the eyeball was propelled as low as the extremity of the nose. After the front of the sinus had been perforated, and the hydatid removed, there was a cavity left two inches and a half in depth. (*Neue Bibl. B. 2*, p. 247, *Hanover*, 1819.) My friend Mr. Lawrence some time ago mentioned to me a remarkable case, which presented itself at the London Eye Infirmary: it was an exophthalmia, which arose from a collection of hydatids in the orbit, and was cured by making an incision, and afterward promoting their discharges. In all these examples, the eyeball is displaced from the orbit gradually, and vision is at length impeded. Instances, however, are on record, where the sight was never lost, though the eye was protruded for years. (See *Richter's Chirurg. Bibliothek. 4. Band. 2 Stack*, p. 243, *White's Cases in Surgery*, p. 135.) In an instance lately reported, the sight was not at all lessened, and the iris retained its natural mobility. (*Langenbeck, Neue Bibl. B. 2*, p. 245.)

Experience proves, also, that after the reduction, the motion of the eye, and power of seeing may be regained, in cases where the eye has been gradually pushed out of the orbit, and been displaced a considerable time, even as long as several years, during all which period vision was lost. (*Acrell; Brocklesby in Med. Obs. and Inquiries*, Vol. 4.) Langenbeck relates a very curious case of exophthalmia from a steatoma in the orbit, where, though vision was entirely prevented during the displacement, the pupil was of its regular shape, and the iris capable of motion: after the extirpation of the tumour, the eyesight became so good, that the patient could discern the smallest objects. (*Neue Bibl. B. 2*, p. 240.) In order to reduce the eye into its natural position, it is necessary to remove the cause, by which its pro-

trusion is occasioned. Suppuration and fungous tumours in the antrum must be treated according to directions laid down in the article *Antrum*. After the cure of such diseases, the antrum is often reduced to its natural dimensions, and in this circumstance, the orbit may become so wide, that the eyeball will return into it again. Should this not happen, the extirpation of the organ will be proper. The induration and swelling of the cellular substance in the orbit, may be sometimes dispersed by means of mercury.—(*Louis, sur Plusieurs Maladies du Globe de l'Œil, in Mém. de l'Acad. Royale de Chirurgie, T. 13, Ed. 12mo.*) When such treatment fails, we are recommended to extirpate the eye. (*Richter Anfangsgr. der Wundarzn, B. 3, p. 413.*) Exostoses, situated in the anterior part of the orbit, may sometimes be removed. The continental surgeons generally advise us to expose the tumour by an incision, and to apply caustic, or the actual cautery to it, in order to kill the protuberant part of the bone, and make it exfoliate. In this country, most practitioners would prefer the employment of cutting instruments for removing such exostoses. When, however, the tumour lies deeply in the orbit, it cannot be got at, and if it should resist the effect of mercurial medicines and mezeon, we are directed to extirpate the eye. (*Richter op. et loco cit.*) Abscesses in the orbit ought to be opened, and after this has been done, the eye generally returns into its proper position. (*Pellier.*) When encysted tumours in the orbit admit of being extirpated in the customary manner, the plan should be adopted; but, when this cannot be done, Richter's advice may be followed, which is to open them, press out the contained matter, and afterward extract the cyst. Considerable difficulty, however, frequently attends every effort to remove the whole cyst, and unless this be done, a permanent cicatrization cannot be expected. (*See Travers's Synopsis, p. 225.*)

On account of the vicinity of the brain, and the communication between the parts within the orbit and the dura mater, the extirpation of tumours from that cavity is not exempt from risk of fatal consequences, as two cases recently published by Langenbeck, fully prove. (*Neue Bibl. B. 2, p. 241—244.*) A young lady was referred to Mr. Lawrence and myself this spring, (1821,) by Mr. Maul of Southampton, for advice, respecting a tumour occupying the inner and upper portion of the orbit, and attended with a degree of exophthalmia, constant exacerbation at the period of the menses, and occasionally double vision. (*See Diplopia.*) We refrained from advising any immediate attempt at extirpation, the swelling being so firm and immovable, that the disease was suspected to be partly of a bony nature. However, on seeing this case about a fortnight afterward, I was surprised to find the tumour not more than half its former size, and all the firm and (what was conceived to be) bony induration below the superciliary

ridge of the os frontis gone, as well as the exophthalmia, and derangement of vision. Some sharp bony irregularities, however, could now be most plainly felt, projecting in front of the diminished swelling.

In a late publication, a memorable case of exophthalmia is related by Mr. Travers: the globe of the eye appears to have been gradually forced upwards and outwards, and to have had its motions considerably impeded, in consequence of the orbit being partly occupied by two swellings, which were of the nature of the aneurism by anastomosis.—(*See Aneurism.*) The swellings could not have been removed, without at the same time extirpating the eye. Mr. Travers was therefore induced to try, whether applying a ligature to the carotid artery would have the effect of checking and curing the disease; an expectation, which was warranted by analogous instances, in which the growth of swellings, and their dispersion, are brought about by lessening the quantity of blood determined to them. The experiment completely succeeded; the swellings in the vicinity of the eye subsided; the patient was freed from several grievous complaints, to which she had been previously subject; and among other benefits, a cure of the exophthalmia was one result, which most interests us in the present place. The case is also highly important on other accounts, and more particularly, as confirming the fact, that the carotid artery may be tied, without any dangerous effects on the brain, and as proving, that in cases of aneurism, the surgeon should not be afraid of proceeding to such an operation. (*See Med. Chir. Trans. Vol. 2, Art. 1.*) The judgment and decision, with which Mr. Travers acted in this case, appear to me highly meritorious.

The carotid artery has also been tied by Mr. Dalrymple, surgeon at Norwich, in a case very similar to the preceding, and with equal success. (*See Med. Chir. Trans. Vol. 6, p. 111, &c.*)

When the causes of exophthalmia have been removed, the eye must be put into its natural situation. If the organ has been long displaced, the surgeon often finds the fulfilment of this indication attended with difficulty. Indeed, he is frequently obliged to employ methodical bandages for the purpose of promoting the gradual return of the eye into the orbit. Yet, even in such cases, the eyesight is often regained; but, if this should not happen spontaneously, stimulants and tonics are to be tried. (*See Amaurosis.*)

EXOSTOSIS. (From *εξ*, out, and *οστος*, a bone.) An exostosis is a tumour formed by an exuberant growth of bony matter on the surface of a bone, or as Boyer says, it is formed by the more or less considerable enlargement of a part, or the whole of a bone. (*Traité des Mal. Chir. T. 3, p. 541.*)

If bones resemble the soft parts of the body in their structure, they must resemble them in their diseases, and of course be liable to various kinds of tumours. Nay, an extraordinary increase of the size and density of all the bones of an individual has been observed, which affection ought probably also to be classed with the disease, to which surgeons usually apply the term exostosis.

The generality of writers, even the most modern, have admitted many diseases among exostoses, which ought to be considered in a very distinct light: I need only instance the *spina ventosa*.

One division of exostoses is into *true* and *false*; the former being of a truly osseous consistence, the others being more or less hollow, spongy expansions of the bones, sometimes containing a quantity of fleshy, fungous matter within the shell of the disease. Periostoses, or mere thickenings of the periosteum, are also classed among the *false* exostoses. (*Dict. des Sciences Méd. T. 14, p. 218.*) According to Mr. A. Cooper, exostoses have two different seats: by *periosteal* exostosis, this author means an osseous deposition seated between the external surface of the bone, and the internal surface of the periosteum, and firmly adherent to both; by *medullary* exostosis, he signifies a similar formation originating in the medullary membrane, and cancellated structure of a bone. The same experienced surgeon makes two other general divisions of exostoses into the *cartilaginous* and *fungous*, the first being "preceded by the formation of cartilage, which forms the nidus for the ossific deposit," while the second is a tumour softer than cartilage, yet firmer than fungus, in other parts of the body, containing spicula of bone, being of a malignant nature, and depending "upon a peculiar state of constitution and action of vessels." It is a disease similar to "fungus hæmatodes, but somewhat modified by the structure of the part in which it originates." (*Surgical Essays, Part 1, p. 155*) This last form of exostosis is probably the disease treated of in another part of this dictionary, under the title of *Osteosarcoma*.

Exostoses differ very much in respect to size. Those of the cranium are generally small and circumscribed. Exceptions occur, however, for we learn, that Sir Everard Home removed a very large tumour, which had a bony base, and was situated on the head. (*A. Cooper, Surgical Essays, Part 1, p. 156.*) The largest *true* exostoses met with are such as are formed upon the long

bones. In the history of surgery may be found numerous cases of enormous exostoses; but it is worthy of notice, that these were nearly all of them of the species termed *false*, and many of them were situated in the jaw, the clavicle, or the extremities of the long bones. Observations of this kind are abundant in l'*Histoire de l'Acad. des Sciences*; les *Mem. de l'Acad. de Chir.*; the *Sepulchretum Anatomicum*; the writings of Morgagni, &c. (*Dict. des Sciences Méd. T. 14, p. 219.*)

The bones most frequently affected with exostosis, are those of the cranium, the lower jaw, sternum, humerus, radius, ulna, bones of the carpus, and particularly the femur, and tibia. There is, however, no bone of the body, which may not become the seat of this disease. It is not uncommon to find all the bones of the cranium affected with exostosis, and the *ossa parietalia* sometimes an inch thick.

According to Mr. A. Cooper, the exostosis, which forms between the outer table of the skull and the pericranium, is of an extremely hard consistence, and generally attended with little pain, while the *fungous* exostosis, springing from the diploe of the skull, is less firm, and more vascular. It is described as being of a malignant nature, making its way through the inner table, and occasioning disease of the dura mater, and fatal effects on the brain. (*Surgical Essays, Part 1, p. 156.*)

Sometimes as Boyer remarks, the tumour is confined to a small part of the affected bone, composing a mass superadded to its surface, and of various shapes. Sometimes it rises insensibly, having no very distinct limits, and resembling a more or less regular portion of a sphere. In some instances its figure is styloid, and it projects in a greater or less degree. On other occasions, its base is rendered distinct by a pedicle, or contraction, which varies in breadth and length in different cases. In particular instances, the exostosis, though limited to the surface of a bone, occupies the whole extent of it. Thus, the whole external surface of one of the bones of the skull has been found occupied by an exostosis, while the cerebral surface of the same bone was in the natural state. The whole circumference of the femur sometimes acquires an enormous size, at the same time that the medullary surface of the same bone continues entirely unchanged. These are the *periosteal* exostoses of Mr. Cooper. In other examples, on the contrary, the two surfaces and the whole thickness of the bone are deformed by an augmentation of bulk; and when this happens in a cylindrical bone, the medullary cavity is more or less reduced, or even totally obliterated. There are a few extremely uncommon cases, in which the substance of a bone acquires great solidity, and a hardness compared to that of ivory, without any material increase of bulk. An exostosis rarely occupies the whole extent and thickness of a bone; but when this happens in a

cylindrical bone, the articular surfaces generally remain in their natural state.

The structure and consistence of exostoses present great differences. Sometimes, especially when the tumour is not very large, and it is situated on the surface of a cylindrical bone, one may trace with the eye the diverging of the osseous fibres, in the interspace of which one would say, that there is deposited a new bony substance, the organization of which is less distinct. Sometimes the tumour is entirely cellular, and formed of a few broad laminae, intercepting extensive spaces, which are filled with matter different from the medulla, and of various quality. This case is denominated the *laminated exostosis*. Sometimes the enlarged portion of bone makes a sort of hollow sphere, with thick hard walls, and the cavity of which is filled with fungous granulations more or less extensive and indolent. According to Boyer, this variety of the disease differs essentially from osteosarcoma, notwithstanding external appearances. The case here alluded to, I conclude to be the same as that which Mr. A. Cooper has named the *cartilaginous exostosis of the medullary membrane*. "In this case, the shell of the bone becomes extremely expanded, or rather the original shell is absorbed, and a new one deposited; and within this ossified cavity, thus produced, a very large mass of cartilage is formed, elastic, firm, and fibrous." It is not malignant, but often ends in a very extensive disease. (*A. Cooper, Surgical Essays, Part 1, p. 173.*)

In other instances, the tumour is perfectly solid, exceeding in consistence that of the hardest bones, and equalling that of ivory. Here, the surface is sometimes smooth, and like that of the bone in its natural state; sometimes irregular, full of little projections, and in some degree stalactitical. It is very uncommon to find a large portion of an exostosis converted into a pultaceous substance; but it is not at all unfrequent to see this substance composing part of the tumour. Lastly, it very often happens, that the same exostosis presents an assemblage of the ivory substance, and of the cellular laminated substance, the cavities of which are partly filled with a pultaceous matter, and partly with a sort of gelatinous substance.

When an exostosis is not very large, it hardly affects the surrounding soft parts; but when it has made considerable progress, the muscles become stretched and emaciated, the cellular substance is thickened, and, its layers being adherent together, a kind of confusion is produced among all the adjacent parts. Exostoses not of considerable size may, however, seriously interrupt the functions of certain organs. The action of the flexor muscles of the leg has been known to be obstructed by an exostosis in the vicinity of the knee. A similar tumour arising near the symphysis pubis need not be very large to impede considerably the functions of the urethra, as experience has proved. An exostosis in the orbit has been known to displace the eye and destroy vi-

sion. Lastly, exostoses, when situated near certain important organs, and of large size, may affect with different degrees of gravity the functions of these parts, as the brain, the lungs, &c. (See *Boyer, Traité des Mal. Chir. T. 3, p. 541—544.*)

Mr. A. Cooper has related a case, in which the eyes were pushed out of their sockets by two exostoses, which grew from the antra, and one of which destroyed the patient by making its way to the brain through the orbital process of the os frontis. (*Surgical Essays, Part 1, p. 157.*) In one instance, reported by the same author, an exostosis from the sixth or seventh cervical vertebra abolished the pulse at the wrist, by pressing upon the subclavian artery. (*P. 159.*) In another, a *cartilaginous exostosis* of the medullary membrane of the lower jaw extended so far back that it pressed the epiglottis down upon the rima glottidis, and caused such difficulty of respiration, and so much irritation, that the patient was destroyed. (*P. 175.*)

Venerereal exostoses, or nodes, are observed to arise chiefly on compact bones, and such of these as are superficially covered with soft parts, as for instance, the bones of the cranium, and the front surface of the tibia.

The causes of exostosis do not seem to be at all understood. Most writers impute the disease to internal causes, such as scrofula and lues venerea. That the latter affection is the cause of nodes, which are certainly a species of exostosis, no one will deny; but, that scrofula is ever concerned in producing any of the other kinds of exostosis must not be admitted, at least, before some evidence is adduced in support of the doctrine. Boyer, however, and all the surgeons of the continent adopt the opinion, that scrofula is sometimes a cause of the disease.

Hydatids are occasionally found within exostoses, in which circumstance the former are supposed to be the cause of the enlargement of the bone. A remarkable specimen of such a disease in the tibia is mentioned by Mr. A. Cooper. (*Surgical Essays, Part 1, p. 163.*) He refers also to a humerus, in the museum of St. Thomas's Hospital, where the shell of the bone is considerably expanded, the periosteum over it thickened, and in the seat of the cancellated structure, several hydatids, supposed to have been the cause of the enlargement of the exterior surface of the bone, as well as of the increase of its cavity. (*Vol. cit. p. 161.*) A most interesting case of a bony tumour on the forehead, containing hydatids, has likewise been recently published by Mr. R. Keate. (*Med. Chir. Trans. Vol. 10, p. 278.*)

The ease with which bony tumours form in some persons, is a curious and remarkable fact, and renders it probable, that constitutional causes here have great influence. Thus, such a blow, as in the generality of persons, would hardly excite notice, will, in others, bring on swellings of the bone, which is struck. Mr. A. Cooper adverts to a young friend of his, in whom an exostosis, which was undoubtedly caused by a blow,

is growing on the metacarpal bone of the little finger. (*loc. cit.*) I remember, that Mr. Abernethy mentions, in his lectures, his having seen a boy from Cornwall, who was so excessively afflicted with an apparent predisposition to exostoses, or an exuberant deposition of bony matter, that a very trifling blow would occasion a bony swelling on any bone of his body. His ligamentum nuchæ was ossified, and prevented the motion of his neck; the margins of his axillæ were also ossified, so that he was, as it were, completely pinioned. Besides all this, the subject in question had numerous other exostoses on various parts of his body. Mr. Abernethy gave, in this case, muriatic and acetic acids, with a view of dissolving the lime, which this gentleman thought might be too abundant in the system; but, even if this theory had been correct, and the acids capable of the chymical action intended, after passing into the circulation, how could they be expected to dissolve only the redundant depositions of phosphat of lime, and at the same time leave the skeleton itself undissolved?

When an exostosis depends upon lues venerea, it is almost always preceded by an acute pain, which in the beginning extends to nearly the whole of the affected bone, but afterward becomes fixed to the point where the exostosis forms, and it is most severe in the night-time. When an exostosis is caused by scrofula, says Boyer, the pain is duller, or rather it is quite inconsiderable. It is the same with the exostosis, which succeeds a blow, or contusion, without any manifest general cause. In the latter example, the pain immediately excited by the accident subsides in a few days, and the swelling occurs so slowly, that no notice is taken of it till it has attained some magnitude. (*Traité des Mal. Chir. T. 3, p. 545.*)

An exostosis constantly feels hard; but its size is various, and it may be indolent, or painful. By these signs, and its firm adhesion to the bones, it may be always distinguished from other tumours. Some exostoses cannot be ascertained before death. Such was the case in which the parietal bone was found, after death, to be three times thicker than natural. Such also was the example related in the memoirs of the Academy at Dijon, in which a person died from an exostosis on the internal side of the os pubis, which tumour prevented the discharge of the urine, or the introduction of a catheter, by its pressure on the neck of the bladder.

Exostoses may be either *acute* or *chronic*, in their progress. In the first case, which, according to Boyer, happens most commonly in the *cellular* exostosis, described by authors under the name of *laminated*, the appearance and formation of the tumour are quick; the swelling rapidly acquires a considerable size; and it is always preceded by, and accompanied with, continual violent pain, which the external and internal use of opium has little effect upon, and the intensity of which is not increased by pressure.

The pain is sometimes so severe that it occasions a good deal of symptomatic fever. Boyer, who seems not to be aware of the origin of what he terms the *cellular*, and what Mr. A. Cooper has named *fungous exostosis*, from the medullary membrane, finds difficulty in accounting for the rapid growth, and great sensibility of the tumour, considering the natural density of the bones, and the little energy of their vital properties.

In the hardest kinds of exostosis, says Boyer, the tumour is preceded by no pain, or, if any, it is very slight; the tumour grows slowly; and, although it sometimes attains a considerable size, its increase is attended with no particular sensibility, and no disturbance of the animal economy. (*Boyer, op. cit. T. 3, p. 546.*)

Our ignorance of the pathology of exostoses, particularly their causes, accounts for the imperfection of our treatment of them. With the exception of the venereal exostosis, or node, there is no species of this affection, for which it can be said, that we have any one medicine of efficacy.

Boyer, and other writers on the diseases of the bones, seem to regard some exostoses as a perfectly inorganic mass of lime, and, consequently they entertain no idea, that the absorbent vessels can possibly take away the particles of the tumour, just as the secreting arteries have laid them down. Such writers, however, are well aware, that nodes are capable of being diminished, and this can only be effected by the action of the absorbent system.

Boyer does acknowledge, indeed, that he has seen a venereal exostosis of the humerus, as well as a few other bony swellings, subside; but he represents the event as extremely rare; and he advances it as a principle, that the resolution of exostoses hardly ever happens, and that the greater part of the examples, recorded in proof of the occurrence, were nothing more than periostoses. (*P. 547.*)

When an exostosis is hard, chronic, and free from pain and alteration of the structure of the bone, it is a much more common thing for it to cease to enlarge and remain stationary during life, without producing inconvenience, provided it be so situated as not to impede the functions of any vital organ.

But, in the *cellular* exostosis of Boyer, which I take to be the same disease as the *fungous* exostosis of the medullary membrane of Mr. A. Cooper, the acute and rapid progress of the disease indicates a deeper and more serious alteration of the texture of the bone. A part of the tumour usually consists of a pulsatous, or gelatinous matter, and the rest, still endued with its natural organization, though altered by the disease, soon presents one or several cavities, in which there is suppuration. At the same time, the external soft parts, being excessively and rapidly distended, inflame, ulcerate, and leave exposed a more or less extensive portion of the tumour, the disease of which has in many cases been very wrongly supposed to be caries. It is not, observes Boyer, that the

part of the swelling denuded by ulceration is not sometimes affected with caries; but, then it exists as a complication of the original disease, and as a particularity, by no means the result of the ulceration of the soft parts, and of the exposure of the diseased bone to the contact of the air. When the soft parts are thus ulcerated, the opening contracts to a certain point, and becomes fistulous. The suppuration is always of bad quality, and in a quantity proportioned to the size of the cavity of the abscess and the strength of the patient. The fever, which commences at an early period of the disorder, assumes a slow type, and its continuance, together with the copiousness of the ichorous discharge, the irritation, &c. may bring on the patient's dissolution.

The following are the symptoms of what Mr. A. Cooper denominates the *fungous exostosis of the medullary membrane*. The disease begins with a general enlargement of the affected part of the limb, extending a considerable way around the seat of the exostosis itself. This form of the complaint mostly occurs in young persons, though Mr. A. Cooper has seen it in an individual fifty years old. "Its increase proceeds very gradually; and even when it has acquired considerable magnitude, although it produces some diminution of motion in the limb, it does not occasion pain, or prevent the patient from using it. When any pain does arise, it is of an obtuse kind, only being acute in the event of a nerve being stretched by the tumour. Thus an exostosis of the thigh bone sometimes causes great agony, by pressing on the sciatic nerve. Paleness, debility, and irregularity of the bowels, are observed to attend the early stage of the disease; and afterward the complexion becomes sallow. In the mean time, the diseased part of the limb attains an enormous size; but the skin retains its natural colour. At many points, the swelling feels hard; at others, it is so elastic as to cause the presence of fluid to be suspected; but, if an opening be made, only blood is discharged. The surface of the tumour next becomes tuberculated, and the prominences tender, and their surface is often slightly inflamed. The rest is now broken, the appetite impaired, and the bowels extremely irregular. At length, the tubercles ulcerate; the skin secretes pus; but, when the swelling itself is exposed, it discharges a bloody-coloured serum. A fungus then forms, which sometimes bleeds profusely, and, after it has risen very high, sloughing occurs, and considerable portions of the swelling are thrown off. But, although the swelling may be lessened by this process, Mr. A. Cooper has never known the disease cured by it; and, in the end, the patient is destroyed by the effects of the repeated bleeding, immense discharge, and constitutional irritation." In this disease, as in common fungus hæmatodes, tumours of a similar nature are often formed in other parts of the body, and, after the amputation of the affected bone, frequently make their appearance in organs of the greatest importance to life. The swelling is described as originating from the medullary membrane, and as

removing the muscles to the distance of three inches, or more, from the bone, so that they represent a thin layer spread over the tumour. The blood-vessels and large nerves are also similarly displaced. The tuberculated appearance of the skin, which is itself sound, is caused by projecting small masses on the surface of the tumour. Under the muscles is the periosteum, pushed to a considerable distance from the bone. A part of the swelling itself is yellow, like fat; another portion resembles brain; and a third is composed of coagulated blood with interstices filled with serum. In some parts, the white substance is found nearly as firm as cartilage; but, in general, it presents a more spongy appearance; and is interspersed with spiculæ of bone. The shell of the bone itself is in part absorbed; in some places, it is only thinner than usual; while in others it is immensely expanded, so as to form a case, like wire-work, over the tumour. The fungous granulations, proceeding from the medullary membrane itself, are exceedingly vascular, and often shoot from the cavity of the bone beyond the level of the integuments. (*A. Cooper, Surgical Essays, Part 1, p. 165—168.*)

According to Boyer, spherical exostoses, with an internal cavity, and hypersarcosis, are only attended with violent pain in the beginning, and when they have attained a considerable size, they become almost indolent. But, the successive formation of the fungosities, contained in their cavity, has the effect of distending its parietes, and rendering them thin, so that such exostoses are exposed to fractures and ulceration. This last effect may, indeed, be a consequence of the progress of the disease, and give rise to a series of consecutive symptoms, which may be compared with those which have been described in the preceding case. The spherical exostosis, however, is less dangerous, perhaps, because the disease extends less deeply. Such tumours admit of being directly attacked, and operations for the destruction of the bony shell, and of the fungous growth, which it includes, may be successfully practised; an attempt, which would certainly be useless and dangerous in the foregoing instance.

One termination of exostosis, not spoken of by writers, but which has been observed, especially in the hard and stalactitical exostosis, is that by necrosis. Tumours of this description, after acquiring a large size, have been attacked with mortification, separated from the bone, which served them as a base, and surrounded with a reproduction in every respect similar to that, with which nature surrounds sequestra formed under any other circumstances. This termination is undoubtedly the most favourable of all, because nature proceeds in it slowly, without any violent disturbance; but unfortunately, it is the least common. Art can imitate it; but her means are very inferior to those of nature. (*Boyer, Traité des Mal. Chir. T. 3. p. 547—550.*)

The hardest exostosis, which has grown slowly, and without causing severe pain, is the least dangerous of all, especially when

the constitution is sound, and the patient not of a bad habit. After the disease has attained a certain size, it may become stationary, and continue in this state, without inconvenience, during life. This is most frequently observed in the *ivory* exostosis. Without having precisely this extreme hardness, however, some exostoses which are tolerably solid, and in which the natural organization of bone is still distinguishable, are capable of undergoing a slight reduction after the removal of their cause by nature or art. Boyer states, that this sometimes happens in a few scrofulous exostoses, and particularly in such as are venereal, and not of very large size.

The *cellular* exostoses of Boyer, the *fungous exostosis* of Mr. A. Cooper, and the cases which are named *osteosarcomata*, are the most serious of all, especially when the texture of the bone is considerably altered, and the disease is in a state of ulceration. The rapid formation of the disease, the violent shock which it imparts to the constitution, and the hectic disturbance which it excites, generally bring the patient into imminent danger, and commonly leave no other resource but that of amputating the limb.

The treatment of exostoses is to be considered in a medical and surgical point of view. When any general cause of the disease is known, or suspected, such cause is to be removed by those means which experience has proved to be most efficacious. Thus Boyer recommends mercurial and antiscrofulous remedies, &c. according to the nature of the case.

Whatever may be the species of exostosis, or the nature of its cause, relief, says Boyer, may be derived from the outward use of opium, whenever the disease is attended with severe pain. He speaks favourably of the application of a linseed-meal poultice, made with a decoction of the leaves of night-shade and henbane, to which a strong solution of opium has been added. But he thinks that an antiphlogistic plan, with bleeding, is hardly ever admissible, because it weakens the patient too much in so tedious a disease, and can only be a palliative, incapable of curing, or preventing the ravages of the disorder.

When there is no pain, or it has been appeased, during or after any general method of treatment, which may have been indicated, the surgeon may try resolvent applications, particularly soap and mercurial plasters, volatile liniment, bathing in water containing a small quantity of soda, or potassa, hydro-sulphurated washes, &c. Boyer acknowledges, however, that the progress of exostoses can scarcely ever be checked by any general methodical treatment. The muriatic and acetic acids have been administered, but without effect; nor am I acquainted with any remedies which possess efficacy, excepting mercury, which we know will rarely answer, except in cases of nodes. In the commencement of any deep-seated disease in a bone, however, Mr. A. Cooper thinks, that the best medicine for internal exhibition,

is the oxymuriate of quicksilver in small doses, together with the compound decoction of sarsaparilla. (*Surgical Essays, Part 1, p. 169.*) Boyer is firmly of opinion, that with the exception of recent small exostoses, the nature of which is even doubtful, the resolution of such tumours is almost impossible. A slight diminution of the swelling, and its becoming perfectly indolent, are the most favourable changes which can be hoped for, whether they occur spontaneously, or are the fruit of surgical assistance. (*Traité des Mal. Chir. T. 3, p. 554—557.*)

Whether any exostoses might be lessened by keeping open a blister over them, for a considerable time, is a point, perhaps, worthy of further investigation. It is certain, that such applications tend to diminish venereal nodes, after they have been lessened as much as they can be by mercury; and we also know, that blisters, kept open, promote the absorption of the dead bone in cases of necrosis. In the local treatment, Mr. A. Cooper approves of the use both of leeches and blisters, a discharge from the latter being kept up with equal parts of the mercurial and savin ointments. (*Surgical Essays, Part 1. p. 169.*)

When exostoses merely occasion a deformity, and no pain, nor inconvenience, from the pressure which they produce on the neighbouring parts, it is certainly most advisable not to undertake any operation for their removal; for, as Boyer has truly observed, in by far the greater number of instances, the local affection is much less to be dreaded, than the means used for removing it.

Caustics and the cautery have occasionally been applied to exostoses; but they mostly do mischief. Boyer mentions an unfortunate woman, who had some caustic applied to an exostosis at the inside of the tibia; but which, instead of removing the tumour, caused a necrosis, of which she was not well two years afterward. In a few instances, however, after the removal of fungous, or cartilaginous exostoses, of the interior of a bone with cutting instruments, the application of the cautery has prevented a reproduction of the diseased mass, as we find exemplified in a case recorded by Mr. A. Cooper, where such a disease of the jaw was thus extirpated. (*Surgical Essays, Part. 1, p. 158.*) The bold and successful manner also in which the hydatid exostosis of the head was attacked with the saw, caustics, and the actual cautery, by Mr. R. Keate, is particularly entitled to the attention of the surgical practitioner. (*Med. Chir. Trans. Vol. 10, p. 288, &c.*) As far as my information extends, no attempt to stop the progress, and effect the cure of a fungous exostosis, by tying the main artery of the limb, has ever yet succeeded. Two cases, proving the inefficacy of this practice, are detailed by Mr. A. Cooper. (*Vol. cit. p. 170.*)

As the *fungous exostosis* of the medullary membrane is evidently connected with a state of the constitution, analogous to what prevails in fungous hæmatodes, (see this word)

the permanent success of amputation should never be too boldly premised; but, as no medicines have any material power over the disease, and the operation is the only chance of relief, it ought to be advised.

Cartilaginous exostoses of the medullary membrane may sometimes be extirpated by removing their outer bony covering, and then cutting away the cartilaginous matter closely from the bony surface to which it is attached. Sometimes, as I have noticed, these measures are followed by the use of the actual cautery.

Periosteal exostoses are also either *cartilaginous*, or *fungous*, which latter are attended with less general swelling of the limb, and are more prominent than fungous exostoses of the medullary membrane. Ulceration, bleeding, sloughing, and great discharge ensue, and unless some operation be performed, the patient loses his life. (*A. Cooper, Surgical Essays, Part 1, p. 180.*)

The *cartilaginous exostosis*, between the *periosteum* and bone, arises from inflammation of the *periosteum*, and subjacent part of the bone, and a deposition of firm cartilage, adherent to both these surfaces, takes place. In this substance bony matter is secreted, which is first thrown out from the original bone. As the cartilage increases in bulk, the quantity of phosphate of lime augments, and fresh cartilage is constantly deposited upon the outer surface of the tumour. On dissection;—1st, the *periosteum* is found thicker than natural; 2dly, immediately below the *periosteum*, cartilage; and 3dly, ossific matter, deposited within the latter, from the shell of the bone, nearly to the inner surface of the *periosteum*. When the growth of such a swelling ceases, and the disease is of long standing, the exterior surface consists of a shell of osseous matter, similar to that of the original bone, and communicating with its cancelli, in consequence of the primitive shell having been absorbed. (*A. Cooper's Surgical Essays, Part 1, p. 186.*) The *periosteal cartilaginous exostoses* constitute the indolent, very hard forms of the disease. In their early stage they may sometimes be checked by small doses of mercury, the decoction of sarsaparilla, and the *emplastrum ammoniaci cum hydrargyro*. (*Vol. cit. p. 196.*) When large, or troublesome, they may be sawn away, as Mr. A. Cooper states, without danger, if the disease be well discriminated from the fungous swelling.

When exostoses are productive of much pain and injure the health, and their situation admits of their being safely removed, with the aid of suitable saws, or even with that of a gouge and mallet; the operation may be undertaken. Many tumours of this kind, however, have bases so very extensive and deep, that, when situated on the limbs, amputation becomes preferable to any attempt made to saw or cut away the exostoses, and preserve the members on which they are situated.

In removing an exostosis, its base must be as freely exposed by the knife as circumstances will allow, and to this part a small fine saw

may be applied. In cutting away some exostoses, the flexible saw, described by Dr. Jeffray, of Glasgow, (see *Amputation*), will be found useful. Mr. Hey's saws are now so well known to the profession, that I scarcely need recommend them to be remembered in the present cases. Mr. Machell, a surgeon in London, has invented a saw, well calculated for cutting a bone at a great depth, without injuring the muscles. It is a small, fine, perpendicular wheel-like saw, turned by means of a handle connected with machinery. It is highly commended by Mr. A. Cooper, who has given a drawing of it in his *Surgical Essays, Part 1*. An orbicular saw, invented and used by Professor Graefe, of Berlin, likewise merits particular notice on account of its ingenuity. (See *C. G. E. Schwalb de Serra Orbiculari, 4to. Berol. 1819.*) A strong pair of bone-nippers will also be useful.

EXTIRPATION. (from *extirpo*, to eradicate.) The complete removal or destruction of any part, either by cutting-instruments, the action of caustics, or the application of a ligature.

EXTRACTION. (from *extraho*, to draw out.) The taking extraneous substances out of the body. Thus bullets and splinters are said to be *extracted* from wounds; stones from the urethra, or bladder.

Surgeons also sometimes apply the term, *extraction*, to the removal of tumours out of cavities, as for instance, to the taking of cartilaginous tumours out of the joints; they seldom speak of extracting any diseased original part of the body; though they do so in one example, viz. the cataract.

EXTRACTION OF THE CATARACT. See *Cataract*.

EXTRAVASATION. (from *extra*, out of, and *vas*, a vessel.) A term applied by surgeons to the passage of fluids out of their proper vessels, or receptacles. Thus when blood is effused on the surface, or in the ventricles of the brain, it is said, that there is an *extravasation*.

When blood is poured from the vessels into the cavity of the peritoneum, in wounds of the abdomen, or when the contents of any of the intestines are effused in the same way,

surgeons call this accident an *extravasation*. The urine is also said to be *extravasated*, when, in consequence of a wound, or of sloughing, or ulceration, it makes its way into the cellular substance, or among the abdominal viscera. When the bile spreads among the convolutions of the bowels, in wounds of the gall bladder, this is a species of extravasation.

In wounds of the thorax, an extravasation of blood also frequently happens in the cavity of the pleura. Large quantities of blood are often extravasated in consequence of vessels being ruptured by violent blows: in the scrotum, on the shoulder, and under the scalp, this effect is observed with particular frequency.

In the articles, *Head*, *Injuries of*, and *Wounds*, I have treated of extravasations of blood in the cranium, chest, and abdomen.

EYE, CALCULUS IN THE INTERIOR OF. Scarpa has dissected an eye, which was almost entirely transformed into a stony substance. It was taken from the body of an old woman, and was not above half as large as the sound one. The cornea appeared dusky, and behind it the iris, of a very singular shape, was distinguishable, being concave, and without any pupil in its centre. The rest of the eyeball, from the limits of the cornea backward, was unusually hard to the touch.

On making an incision, Scarpa found the sclerotica and choroides almost in their natural state, and a small quantity of limpid fluid issued from the anterior chamber of the aqueous humour. Beneath the choroides, two hard calculous concave plates presented themselves, united together by means of a complete membranous substance. One was situated forward; the other backward: the latter occupied the bottom of the eye; the former the situation of the corpus ciliare and crystalline lens.

Scarpa made an incision, through the compact membrane, which joined together the margins of the two calculous bodies. He found in the cavity, instead of the vitreous humour, some drops of a glutinous bloody fluid, and in the longitudinal direction of this cavity, a little soft cylinder, which, extending forward from the bottom of the eye, along the great axis of this organ, was inserted into a cartilaginous, elastic substance, situated in the centre of the front calculous body, precisely where, in the natural state, it is customary to find the lens and its capsule, which were entirely wanting.

The posterior surface of the iris had formed a firm adhesion to the middle of the cartilaginous substance, situated in the centre of the front calculus. Hence, the iris, when beheld on the side next the cornea and anterior chamber, appeared as it actually was, concave in the middle.

The optic nerve, which had degenerated into a mere thread, entered the sclerotica and choroides, as well as the centre, or bottom, of the posterior calculous body, and lost itself in the little soft cylinder, which, as was explained, proceeded to be inserted

in the cartilaginous substance, situated in the middle of the anterior calculus, or the place naturally occupied by the lens and its capsule. The greater part of this little cylinder was, according to appearance, nothing else than the membrane of the vitreous humour, destitute of fluid, shrivelled, and changed into a compact substance. Haller met with a similar case. (See *Obs. Pathol. Oper. Min. Obs.* 15.) Fabricius, Hildanus, Lancisi, Morgagni, Morand, Zinn, and Peller, make distinct mention of calculi in the interior of the eye. (*Scarpa sulle Malattie degli Occhi. Venezia, 1802.*) Ossifications of the capsule of the lens, of that of the vitreous humour, and of, what was supposed to be, the hyaloid membrane are noticed by Mr Wardrop. (*Morbid Anatomy of the Human Eye, Vol. 2, P. 128. 8vo. Lond. 1818.*)

EYE, CANCER, AND EXTIRPATION OF. One of the well-known characters of carcinoma in general is to attack persons advanced in age, rather than children and young subjects. Hence, an observation made by the experienced Desault, that cancer of the eye is most frequent in childhood, could not but appear a position inconsistent with the usual nature of the disease in general. Yet, how was this statement to be contradicted, while it was confirmed by the testimony of Bichat himself, who says, that more than one-third of the patients on whom Desault operated in the Hôtel Dieu for cancer of the eye, were under twelve years of age? Here truth and accuracy, as in many other questions relative to disease, would never have been attained without the aid of morbid anatomy, whereby distempers, which bear a superficial resemblance to each other, while they are in reality of a totally different nature, are prevented from being confounded together. Now when Scarpa even goes further than Bichat, and asserts, that in twenty-four individuals, affected with what is called carcinoma of the eye, twenty of those, at least, are children under twelve years of age, this declaration, considered with the acknowledged propensity of cancer, on all other occasions, to attack old rather than young subjects, might have remained a mysterious anomaly in the history of disease, had not the valuable investigations of Mr. Wardrop proved beyond all doubt, that the afflicting disease which rendered it necessary for so many young subjects to undergo a severe operation, was not true cancer, but what is now denominated by modern surgeons, *fungus hæmatodes*. (*Obs. on Fungus Hæmatodes. 8vo. Edinb. 1809.*) As Scarpa observes, this author has afforded a solution of the question, by showing, from careful observation, founded on pathological anatomy, that the morbid change of structure in the eyeball of a child, commonly called carcinoma, is not in reality produced by cancer, but by another species of malignant fungus, to which the epithet hæmatodes is applied; a disease, indeed, equally, and, with regard to the eye, more formidable and fatal, than cancer, but distinguished from it by peculiar characters, which not being confined to age, sex, or part

of the body, attacks the eyeball both of the infant and adult. (*Scarpa, Trans. by Briggs, P. 502. Ed. 2.*)

According to Scarpa, and indeed, the sentiments of several other surgeons of the present day, cancer is always preceded by scirrhus, or a morbid induration of the part affected. As the disorganization increases in this hard scirrhus substance, an ichorous fluid is formed in cells within it, and afterward extends towards the external surface of the tumour, causing ulceration of the investing parts. The compact, and apparently fibrous mass is then converted into a malignant fungous ulcer, of a livid, or cineritious colour, with edges everted, and irregularly excavated, and with a discharge of acrid, offensive sanies. The scirrhus, composing the base of the malignant fungus, instead of increasing in size, now rather diminishes, but retains all its original hardness, and, after rising a certain way above the ulcerated surface, is destroyed at various points by the same ulcerated process, from which it originated. And, if any part of the livid fungous sore seem disposed to heal, it is a deceitful appearance, as, in a little time, the smooth points are again attacked by ulceration. To relate in this place all the differences between cancer and fungus hæmatodes of the eye, would be superfluous, as the subject is considered in a future article (See *Fungus Hæmatodes*;) but, I may briefly advert to a few remarkable points of diversity; 1st. The primary origin of fungus hæmatodes is generally in the retina, especially, that point at which the optic nerve enters the cavity of the eye. 2dly. True cancer of the eyeball, when it begins on any part of the organ itself, instead of commencing as fungus hæmatodes at the deepest part of the eye, originates on its surface in the conjunctiva; and, as far as present evidence extends, if we except the lachrymal gland, this membrane is the only texture, connected with the eye, ever primarily affected with carcinoma. (*Scarpa on Diseases of the Eye, p. 526, Ed. 2; and Travers, Synopsis of the Diseases of the Eye, P. 99.*) 3dly. Cancer of the eye, as Scarpa truly observes, is less destructive than fungus hæmatodes, and that for two important reasons. In the first place, because carcinoma begins on the exterior parts of the eye, so that whatever relates to the origin and formation of the disease is open to observation; and secondly, because the cancerous fungus of the eye, on its first appearance, is not actually malignant, but becomes so in process of time, or from improper treatment, previously to which period good surgery may be employed with effect. In this light, Scarpa views many excrescences on the conjunctiva and anterior hemisphere of the eye, which appear in consequence of a straphyloma of the cornea, long exposed to the air and ulceration; those which arise from relaxation and chronic inflammation of the conjunctiva; from ulceration of the cornea, neglected or improperly treated;

from violent ophthalmia, not of a contagious nature, treated in the acute stage with astringent and irritating applications; from suppuration of the eye, rupture of the cornea, and wasting of the eyeball; or from blows, or burns on the part. Nothing, says Scarpa, is more probable, than that all these ulcerated fungi were, on their first appearance, not of malignant character, or certainly not cancerous, and that many of them were not actually so at the time of a successful operation being done.

Now, in the opinion of the same valuable author, there is no criterion as yet known of the precise time, when a sarcoma of the eye changes from the state of a common ulcerated fungus to that of carcinoma; for, the exquisite sensibility, darting pains, rapidity of growth, colour, and ichorous discharge, are not an adequate proof of cancer. The symptom, however, on which he is inclined to place the greatest dependence, as a mark of the change in question, is the almost cartilaginous hardness of the malignant ulcerated fungus, which induration, he asserts, is not met with in the benign fungus, and never fails to precede the formation of cancer. (See *Scarpa on the Eye, Transl. by Briggs, Ed. 2, p. 511—513.*)

4thly. The last difference of fungus hæmatodes from cancer of the eye, here to be noticed, is the pulpy softness of the whole of the diseased mass, in the first of these diseases; a character completely opposite to the firm, almost cartilaginous consistence of the carcinomatous fungus.

Before describing the operation of removing an eye, affected with malignant disease, the following corollaries, drawn by Scarpa, should be recollected. 1. The complete extirpation of the eye, for the cure of fungus hæmatodes, although performed on the first appearance of the disease under the form of a yellowish spot, deeply seated in the eye, is useless, and rather accelerates the death of the patient.

2. The exterior fungous excrescence of the eye, commonly called carcinoma, beginning on the conjunctiva, and anterior hemisphere, while it is soft, flexible, and pulpy, although accompanied with symptoms, similar to those of carcinoma, is not actually this disease, nor does it become malignant, and strictly cancerous, until it is rigid, hard, coriaceous, warty, and, in every respect, scirrhus.

3. The inveterate fungous excrescence, hard to the touch in all its parts, covered with ulcerated warts, which has involved the whole of the eyeball, optic nerve, and surrounding parts, and rendered the bones of the orbit carious, and contaminated the lymphatic glands behind the angle of the jaw, and, in the neck, is incurable.

4. On the contrary, the partial, or total extirpation of the eye will succeed, when attempted before the external fungous excrescence has changed from the state of softness to that of a scirrhus, warty, and carcinomatous hardness. (*Vol. cit. p. 526.*)

The operation of removing the eye was

first performed in the sixteenth century by Bartisch, a German practitioner, who employed a coarsely constructed instrument, shaped like a spoon, with cutting edges, and by means of which the eye was separated from the surrounding parts, and taken out of the orbit. This instrument was too broad to admit of ready introduction to the deep contracted part of the orbit, so that, when it was used, either a part of the disease was likely to be left behind, or the thin bones of the orbit to be fractured in the attempt to pass it more deeply into that cavity. Fabricius Hildanus became acquainted with these inconveniences by experience, and, in order to avoid them, devised a sort of probe-pointed bistoury; a better instrument, but not free from objections, and forgotten for near a century afterward; surgeons continuing to use sometimes the cutting spoon, sometimes various kinds of hooks. Muys, Bartholine, &c. afford examples of operations so performed. Bidloo made use of scissors, and a pointed bistoury.

A lancet seemed to Lavauguyon sufficient for extirpating the eye, and he is the first French surgeon who has spoken of this operation. All the surgeons of that country considered the operation as useless, cruel, and dangerous, until St. Ives mentioned, that he had done it with success. Heister preferred operating with the bistoury alone. Several English surgeons have used a sort of curved knife, an engraving of which is given in B. Bell's system; but, in dissecting the tumour, this instrument was regarded by Louis as less convenient than a straight bistoury.

Thus far the plans of operating, advised by authors, were not guided by any fixed rules. Louis endeavoured to lay down such rules, and for a long while his method was mostly adopted in France. It consists in dividing the attachments of the eye to the eyelids; then those of the small oblique muscle; next, those of the great oblique muscle; then those of the levator palpebræ superioris, varying, according to their insertions, the manner of holding the knife. The eyeball is afterward detached, and the four straight muscles, and optic nerve, divided with a pair of scissors.

This way of operating, founded upon anatomical principles, seems at first glimpse to offer a method, in which, as Louis remarks, each stroke of the instrument is guided by the knowledge of the parts. But, it is to be noticed, that these parts, being altered by disease, most commonly do not present the same structure and relations, which they do in the natural state; and that the flattened, lacerated, destroyed muscles, on their being confused with the eye itself, cannot serve, as in lithotomy, for the foundation of any precept relative to the operation. Besides, why use both the knife and scissors? The latter instrument is obviously useless, though Louis seems to think the operation cannot be done without it. The inclination of the outer side of the orbit will

always allow a bistoury to be carried to the bottom of this cavity, so as to divide from above downwards, the optic nerve, and muscular attachments.

Guided by the above principles, Desault, after having practised, and taught the method of Louis, returned to Heister's advice, who directs only a bistoury to be employed. To have an exact idea of the mode of operating, which is always easy and simple with this one instrument, we must suppose the carcinoma to be in three different states. 1. When the tumour hardly projects out of the orbit, so that the eyelids are free. 2. When it is much larger, projects considerably forward, and pushes in this direction the healthy eyelids, which are in contact with it, together with a portion of the conjunctiva, which invests them, and is now detached from them. 3. When, in a much more advanced period, the eyelids participate in the cancerous state. In the first case, the eyelids must be separated from the eye, by cutting through the conjunctiva, where it turns to be reflected over the globe of the eye. In the second instance, the eyelids and conjunctiva, which are in contact with the diseased eye, must be dissected from it. In the third, these parts must be cut away, together with the eye. (*Euvres Chir. de Desault, T. 2.*)

After the above observations, and the additional information on the subject contained in the 1st vol. of the 4th Edition of the *First Lines of the Practice of Surgery*, I shall conclude this article with a few brief directions.

When the eyeball is exceedingly enlarged, it is necessary to divide the eyelids at the external angle, in order to facilitate the operation. The surgeon can in general operate most conveniently when he employs a common dissecting knife, and when his patient is lying down with his face exposed to a good light. In cutting out a diseased eye, it is necessary to draw the part forwards, regularly as its surrounding attachments are divided, in order that its connexions, which are still more deeply situated, may be reached with the knife. This object cannot be very well accomplished with the fingers, or forceps, and, therefore, most surgical writers recommend us, either to introduce a ligature through the front of the tumour, (see *Travers, Synopsis, p. 308.*) or to employ a hook, for the purpose of drawing the part in any direction, during the operation, which the necessary proceedings may require. When the eyelids are diseased, they must be removed; but, if prudence sanctions their being preserved, this is an immense advantage. The eye must not be drawn out too forcibly, before the optic nerve is divided, and care must be taken not to penetrate any of the foramina, or thin parts of the orbit, with the point of the knife, for fear of injuring the brain. Great care should also be taken to leave no diseased parts behind, in the orbit. The hemorrhage may be stopped by filling the orbit with scraped

lint, and applying a compress and bandage. It is constantly advisable to remove the lachrymal gland, as this part seems to be particularly apt to be the source of such inveterate fungous diseases, as too often follow the operation.

Mr. Travers, with a straight double-edged knife, freely divides the conjunctiva and oblique muscles, so as to separate the eyeball and lachrymal gland from the base of the orbit. Drawing the eye then gently forwards with the ligature, he introduces a double-edged knife, "curved breadthwise" at the temporal commissure of the lids, for the purpose of dividing the muscles, vessels, and nerves, by which the globe remains attached. The hemorrhage he represses with a small bit of fine sponge put into the orbit, and a light compress, applied over the eyelids, and supported with a bandage. The sponge, he says, should not be suffered to remain longer than the following day, when a soft poultice in a muslin bag may be substituted for the compress. He approves of giving an opiate at bed-time, and joins the late Mr. Ware in condemning the practice of cramming the orbit with lint, or charpie, and leaving it to be discharged by suppuration. (*Synopsis of the Diseases of the Eye*, p. 308.)

For a few days after the operation, antiphlogistic treatment is proper. Sometimes fungous granulations continually form in the orbit, notwithstanding they are repeatedly destroyed; and sometimes the disease in the orbit extends even to the brain, and produces fatal consequences. When malignant fungous excrescences grow from the cornea alone, it is clearly unnecessary to extirpate the whole eyeball.

For information relating to the subjects of this article, consult particularly *Mémoire sur plusieurs Maladies du Globe de l'Œil; ou l'on examine particulièrement les cas qui exigent l'extirpation de cet organe, et la Mé-*

thode d'y procéder; par M. Louis, in Mém. de l'Acad. de Chirurgie, Tom. 13, p. 262, Edit. in 12mo. C. F. Kultchmeid, Programma de oculo ulcere canceroso laborante feliciter extirpato, &c. Jenæ. 1748. EYE, DISEASES OF. See *Amaurosis; Cataract; Cornea; Encanthis; Exophthalmia; Fungus Hæmatodes; Gutta Serena; Hemeralopia; Iris; Hydrophthalmia; Hypopium; Leucoma; Nyctalopia; Ophthalmia; Pterygium; Pupil, Closure of; Staphyloma, &c. &c.*

EYELIDS, DISEASES OF. See *Ectropium; Lagophthalmus; Hordeolum; Ptosis; Trichiasis; and Tumours Encysted.* In the examination of the interior of the upper eyelid, a modern very convenient plan is now pursued, which is to evert the part over a probe, which is to be placed just across the upper edge of the cartilage of the tarsus, which is then to be suddenly inclined outwards, when the whole inner surface of the lid will be exposed, the part continuing in this everted state until replaced by the surgeon.

F.

FEVERS, SURGICAL. Under this head may be comprehended two species of fever, viz. the *inflammatory* and the *hectic*, which are particularly interesting to surgeons, because frequently attendant on surgical disorders.

In treating of inflammation, I have mentioned, that a febrile disturbance of the constitution is attendant on every considerable inflammation. In the present article, some account will be offered of the particulars of this disorder.

The fever about to be described is known and distinguished by several names; some calling it *inflammatory*; some *symptomatic*; and others *sympathetic*. It is sometimes idiopathic; that is to say, it occasionally originates at the same time with the local inflammation, and from the same causes. (*Burns.*) In other instances, and indeed we may say

in all ordinary surgical cases, it is symptomatic; or, in other words, it is produced, not directly by the causes which originally produced the inflammation, but in consequence of the sympathy of the whole constitution with the disturbed state of a part.

The idiopathic inflammatory fever is said to be always preceded by chilliness. The symptomatic, or sympathetic inflammatory fever, sometimes takes place so quickly, in consequence of the violence of the exciting cause, or of the local inflammation, that no preceding coldness is observable. If, however the local inflammation be more slowly induced, and consequently operate more gradually on the system, then the coldness is evidently perceived. The symptomatic fever, induced by scalding, or burning a part, is quickly produced, and we have very little time to attend to the earliest period of its formation. On the other hand, the sympto-

matic fever, induced by wounds, is excited more slowly, and the period of its formation is longer. This fever is not produced, when the inflammation only affects parts in a slight degree; but it makes its appearance if the local inflammation be considerable, or if it affect very sensible parts. (*Burns.*)

The degree in which this fever is excited does not altogether depend upon the absolute quantity or violence of the inflammation; but in a great measure upon the degree of the local inflammatory action, compared with the natural power and action of the part affected. Parts in which the action is naturally low, are extremely painful when inflamed, and the system sympathizes greatly with them. Hence, the constitution is very much affected when tendons, bones, or ligaments, are the parts inflamed. Severe inflammation of a large joint, every one knows, is apt to excite the most alarming, and even fatal derangement of the system. When very sensible parts are inflamed, as for instance the eye, the symptomatic fever is generally more considerable than it would be were it to arise from an equal quantity and degree of inflammation in a less sensible organ.

In common parts, as muscles, cellular membrane, skin, &c. the symptoms will be acute; the pulse strong and full, and the more so if the inflammation be near the heart; but, perhaps not so quick as when the part is far from it. The stomach will sympathize less, and the blood will be pushed farther into the small vessels. (*Hunter.*)

If the inflammation be in tendinous, ligamentous, or bony parts, the symptoms will be less acute, the stomach will sympathize more, the pulse will not be so full, but perhaps quicker; there will be more irritability, and the blood not being propelled so well into small vessels, it will forsake the skin. (*Hunter.*)

It seems to be a material circumstance, whether the inflammation is in the upper, or lower extremity; that is, far from, or near the heart, for the symptoms are more violent, the constitution more affected, and the power of resolution less, when the part inflamed is far from the source of the circulation, than when near it, even when the parts are similar, both in texture and use. (*Hunter.*)

If the heart, or lungs, are inflamed, either immediately, or affected secondarily, by sympathy, the disease has more violent effects upon the constitution than the same quantity of inflammation would have if the part affected were not a vital one, or one with which the vital parts did not sympathize. If the part be such as the vital ones readily sympathize with, then the sympathetic action of the latter will affect the constitution, as in an inflammation of the testicle. (*Hunter.*) In such cases, the pulse is much quicker and smaller, and the blood is more sily than if the inflammation were in a common part, such as muscle, cellular membrane, and skin. (*Hunter.*)

When the stomach is inflamed, the pa-

tient feels an oppression and dejection through all the stages of the inflammation; the pulse is generally low and quick, and the pain obtuse, strong, and oppressing; such as the patient can hardly bear. If the intestines are much affected, the same symptoms take place, especially if the inflammation be in the upper part of the canal; but if only the colon be affected, the patient is more roused, and the pulse is fuller than when the stomach alone is inflamed. When the uterus is inflamed, the pulse is extremely quick and low. When the inflammation is either in the intestines, testicle, or uterus, the stomach generally sympathizes. In inflammation of the brain, the pulse varies more than in the same affection of any other part; and perhaps we must, in this instance, form a judgment of the complaint, more from other symptoms than the pulse. (*Hunter.*)

When inflammation is situated in a part, not very essential to life, and occasions the general affection of the system, called inflammatory fever, the pulse is fuller and stronger than common, and the blood is pushed farther into the extreme arteries than when the inflammation is in a vital part. The patient, after many occasional rigours, is at first rather roused. The pulse is as above described, when the constitution is strong and not irritable; but if this be extremely irritable and weak, as in many women who lead sedentary lives, the pulse may be quick, hard, and small, at the commencement of the inflammation, just as if vital parts were concerned. The blood may also be sily; but it will be loose and flat on the surface. (*Hunter.*)

We may set down the ordinary symptoms of the inflammatory fever, occurring in consequence of local inflammation in common parts and in a healthy habit, as follows: The pulse is frequent, full and strong; all the secretions are diminished; the patient is vigilant and restless; the perspiration is obstructed, and the skin is hot and dry; the urine is high-coloured, and small in quantity; the mouth is parched, and the tongue furred; an oppressive thirst is experienced; with disturbance of the nervous system; loss of appetite and sleep; and in some cases, delirium.

TREATMENT OF INFLAMMATORY FEVER.

Upon this part of the subject very little is to be said; for as in almost every instance the febrile disturbance of the system is produced, and entirely kept up by the local inflammation, it must be evident, that the means employed for diminishing the exciting cause, are also the best for abating the constitutional effects. Hence it very seldom happens that any particular measures are adopted expressly for the fever itself; as this affection is sure to subside in proportion as the local inflammation is lessened or resolved. But when the febrile disturbance is considerable, and the inflammation itself is also considerable, the agitated state of the system may have in its turn a share in keep-

ing up, and even increasing the local affection, and should be quieted as much as possible. However, in these very instances, in all probability we should be led to a more rigorous adoption of the antiphlogistic plan of treatment, by an abstract consideration of the state of the local inflammation itself, without any reference to that of the constitution. Indeed the increased action of the heart and arteries, and the suppression of the secretions, require the employment of antiphlogistic means, and antimonials, the very same things which are indicated for the resolution of the local inflammation itself. Bleeding, purging, cold drinks, low diet; the exhibition of the antimonium tartarizatum, James's powder, or the common antimonial powder; and bathing the feet and body in warm water, are measures which have the greatest efficacy in tranquillizing the constitutional disturbance implied by the term inflammatory fever. But I think it right to repeat, that it is hardly ever necessary to have recourse to such an evacuation as general bleeding, merely on account of the fever; as this is only an effect which invariably subsides in proportion as the local cause is diminished.

As Dr. Thomson has remarked, "the inflammatory fever, succeeding to external injuries, or to surgical operations, undergoes a kind of natural crisis by the appearance of suppuration. In these instances therefore, unless when the patient is strong and in full health, when the disease is seated in an organ of much importance to life, or is in danger of spreading, as is the case in all inflammations of the membranes lining the three great cavities of the body, the lancet ought to be used with caution. For we may, by too free a detraction of blood, produce a sudden sinking of the powers of life, and convert the existing constitutional symptoms into fever of a different type or character. But in all cases of inflammation, in which any doubt arises with regard to the farther general detraction of blood, it may, I believe, be laid down as a general rule, that it is safer to employ local than general blood-letting." (*Lectures on Inflammation*, p. 170.)

HECTIC FEVER.

The *sympathetic*, or *symptomatic* fever, already described, is an *immediate* affection of the constitution, in consequence of some local disorder; hectic fever is a *remote* effect. When hectic fever is a consequence of local disease, it has commonly been preceded by inflammation and suppuration; but there is an inability to produce granulation and cicatrization: and the cure, of course, cannot be accomplished. The constitution may now be said to be oppressed with a local disease, or irritation, from which it cannot deliver itself.

A distinction should be made between hectic fever, arising entirely from a local complaint in a good constitution, which is only disturbed by too great an irritation, and hectic fever, arising principally from the

badness of the constitution; which does not dispose the parts to heal. In the first species, it is only necessary to remove the part (if removeable,) and then all will do well; but in the second, nothing is gained by a removal of the part, unless the wound, made in the operation, is much less, and more easily put into a local method of cure; by reason of which, the constitution sinks less, under this state and the operation together, than under the former disease. Here the nicest discrimination is requisite. (*Hunter*.)

Owing to a variety of circumstances, hectic fever comes on at very different periods after the inflammation, and commencement of suppuration. Some constitutions having less powers of resistance than others, must more easily fall into this state.

Hectic fever takes its rise from a variety of causes, which have been divided into two species, with regard to diseased parts; viz. parts called vital, and others not of this nature. Many of the causes of hectic fever, arising from diseases of the vital parts, would not produce this constitutional affection, if they were in any other part of the body; such, for instance, is the formation of tumours, either in, or so as to press upon, a vital part, or one whose functions are immediately connected with life. Scirrhi in the stomach, and mesenteric glands; diseased lungs, liver, &c. very soon produce hectic fever.

When hectic fever arises from a disease of a part that is not vital, it commences sooner or later, according as it is in the power of the part to heal, or continue the disease. If the part be far from the source of the circulation, the fever will come on sooner, with the same quantity of disease. When the disease is in parts which are not vital, and excites hectic fever, it is generally in situations where so much mischief happens, as to affect the constitution, and where the powers of healing are little. This is the case with diseases of many of the joints. We must also include parts which have a tendency to such specific diseases, as are not readily cured in any situation.

Although hectic fever commonly arises from some incurable local disease of a vital part, or of an extensive disease of a common part, yet it is possible for it to be an original disease in the constitution, without any local cause whatever, that we know of.

Hectic is a slow mode of dissolution: the general symptoms are those of a low, or slow fever, attended with weakness. But there is rather weak action, than real weakness; for upon the removal of the hectic cause, the action of strength is immediately produced, and every natural function is re-established, however much it may have been previously impaired.

The particular symptoms are debility; a small, quick, and sharp pulse; the blood forsakes the skin; loss of appetite; frequently, a rejection of all aliment from the stomach; wasting; a great readiness to be thrown into sweats; spontaneous perspirations, when the patient is in bed; pale-co-

loured, and very copious urine; and often a constitutional purging.

Hectic fever has been imputed to the absorption of pus into the circulation; but no doubt, much exaggeration has prevailed in the doctrine, which ascribes to this cause many of the bad symptoms, frequently attacking persons who have sores. When suppuration takes place in particular parts, especially vital ones, hectic fever almost constantly arises. It also attends many inflammations before suppuration has actually happened, as in cases of white swelling of the large joints. The same quantity and species of inflammation and suppuration in any of the fleshy parts, especially such as are near the source of the circulation, have in general no such effect. Hence, in the first instances, the fever is only an effect on the system, produced by a local complaint, that has a peculiar property.

The constitution sympathizes more readily with diseases of vital organs, than with those of any other parts; their diseases are also in general more difficult of cure, than the same affections of parts, which are not vital. All diseases of bones, ligaments, and tendons, affect the constitution more readily, than those of muscles, skin, cellular membrane, &c.

When the disease is in vital parts, and is such as not to kill, by its first constitutional effects, the system then becomes teased with a complaint, which is disturbing the *necessary actions of health*. In the large joints, a disease continues to harass the constitution, by attacking parts which have no power, or rather, no disposition to produce salutary inflammation and suppuration. Thus, the system is also irritated by the existence of an incurable disease. Such is the theory of the cause of hectic fever.

If the absorption of matter always produced the symptoms above described, how could any patient who has a large sore, possibly escape hectic; for there is no reason to suppose, that one sore can absorb more readily than another. If absorbed matter occasioned such violent effects as have been commonly ascribed to it, why does not venereal matter do the same? We often know that absorption is going on, by the progress of buboes. A large one, just on the point of bursting, has been known to be absorbed, in consequence of a few days' sea-sickness. The person continued at sea for four and twenty days afterward; yet no hectic symptoms followed, but only the specific constitutional effects, which were of a very different description.

When the cavities of veins are inflamed, matter is sometimes formed within these vessels, and cannot fail to get into the circulation; yet, hectic symptoms do not arise. Also very large collections of matter, produced without visible inflammation, as many abscesses of the scrophulous kind, are wholly absorbed, in a very short time, but no bad symptoms are the consequence, (Hunter.)

We may conclude, therefore, that the ab-

sorption of pus has no share in occasioning hectic fever. Many arguments might be adduced to expose the absurdity of the doctrine; but, here it will be sufficient to refer the reader to what Mr. Hunter has said farther on the subject, in his work on inflammation.

It is much more probable, that hectic fever arises from the effect, which the irritation of a vital organ, or other parts, such as joints, has on the constitution, when either incurable in themselves, or are so for a time to the constitution. (Hunter.)

TREATMENT OF HECTIC FEVER.

There is no method of curing the consequences above related. All relief must depend on the cure of the cause, (viz. the local complaint) or on its removal.

Tonic medicines have been recommended, on account of the evident existence of great debility. Antiseptics have also been given, in consequence of the idea that, when pus is absorbed, it makes the blood disposed to putrefy. For these reasons, bark and wine have been exhibited. In most cases, bark will only assist in supporting the constitution. Until the cause is removed, however, there seems no prospect of curing a disorder of the constitution. It is true, tonic medicines may make the system less susceptible of the disease, and also contribute to diminish the cause itself, by disposing the local complaints to heal. When, however, the hectic fever arises from a specific disease, such as the venereal, though bark may enable the constitution to bear the local affection better, than it otherwise could do, yet, this medicine can never remove the syphilitic mischief. (Hunter.)

No medicine, not even bark itself, has any direct power of communicating strength to the human constitution. All that can be done, in the treatment of hectic fever, when it is thought inexpedient, or impracticable, to remove the morbid part, is to combat particular symptoms, and to promote digestion. It is by bringing about the latter object that bark in these cases is useful. The infusion of cinchona being more likely to agree with the stomach, than the decoction, or powder, should generally be preferred. Nourishing food, easy of digestion, should be frequently taken, in small quantities at a time. Nothing is more prejudicial to a weak constitution, than overloading the stomach. Wine may also be given, but not too freely, and, not at all, if it should create heartburn, as it sometimes does in hectic patients. Madeira is less apt, than port, to have this disagreeable effect. In these cases, it is likewise often found useful to administer gentle cordial aromatic draughts. But, of all medicines, opium is perhaps the most valuable to those who are afflicted with hectic fever; it alleviates pain, procures sleep, and checks the diarrhoea, which so frequently contributes to hasten the patient's dissolution.

When the local complaint, connected with

this fever, is totally incurable, it must, if possible, be removed by a manual operation. Thus, when a diseased joint keeps up hectic fever, and seems to present no hope of cure, amputation must be performed. But, when the local disease is attended with a chance of cure, provided the state of the constitution were improved, the surgeon is to endeavour to support the patient's strength. Great discretion, however, must be exercised, in deciding how long it is safe to oppose the influence of an obstinate local disease over the system, by the power of medicine; for, although some patients, in an abject state of weakness, have been restored to health by a removal of the morbid part, many have been suffered to sink so low, that no future treatment could save them from the grave. Clemency in the practice of surgery does not consist so much in delaying strong and vigorous measures, as in boldly deciding to put them in execution, as soon as they are indicated.

When hectic fever arises from local diseases in parts, which the constitution can bear the removal of, the morbid part should be taken away, if it cannot be cured, consistently with the advice already given. When the disease arises from some incurable disease in an extremity, and amputation is performed, all the abovementioned symptoms generally cease, almost immediately after the removal of the limb. Thus, a hectic pulse, at one hundred and twenty, has been known to sink to ninety in a few hours after the removal of the hectic cause. Persons have been known to sleep soundly the first night afterward, who had not slept tolerably for several preceding weeks. Cold sweats have stopped immediately, as well as those called colliquative. A purging has immediately ceased, and the urine begun to drop its sediment. (*Hunter.*)

FICATIO, or FICUS. (a fig.) A tubercle about the anus, or pudenda, resembling a fig.

FINGERS, ABSCESSSES OF. See *Whitlow*.

FINGERS, Amputation of. See *Amputation*.

FINGERS, Necrosis of. In these cases, the surgeon is to endeavour to extract the exfoliating portions of bone, immediately they become loose. For this purpose he is justified in making such incisions, as will enable him to fulfil the object in view. Until the process of exfoliation is sufficiently advanced, he can do little more, than apply simple dressings, and keep the part in a clean quiet state.

When the separation of the dead pieces of bone will certainly destroy the utility of the finger, and convert the part into an inconvenient, stiff appendage to the hand; or, when the patient's health is severely impaired by the irritation of the disease, the termination of which cannot be expected, within a moderate space of time, amputation is proper. It is a truth, however, that many fingers are amputated, which might be preserved, and surgeons ought to consider well, before presuming to remove parts,

which, when curable, may become of the greatest consequence, in regard to the perfection of the hand. The bread of many persons, it is well known, depends on the unimpaired state of certain fingers. These remarks are offered, because I have seen several surgeons, fond of seizing every opportunity of cutting their fellow-creatures, remove fingers, which might have been usefully saved, either by allotting a little more time for the exfoliation or by making incisions, and cutting out the dead piece of bone.

FINGERS, Dislocations of. See *Dislocation*.

FINGERS, Fractures of. See *Fracture*.

FINGERS SUPERNUMERARY. The instances of children born with a smaller number of fingers, than natural, are more rare, than cases in which the number is greater, than usual. Of the latter malformation, examples were noticed in times of great antiquity. Thus, in the 1st Book of Chronicles is the following notice of such an occurrence: "There was war at Gath, where was a man of great stature, whose fingers and toes were four and twenty, six on each hand, and six on each foot." (*Chap. xx. Verse 6.*) Ann Boleyn, so celebrated for her beauty, and her misfortunes, had six fingers on her right hand. Pliny, the naturalist, speaks of two sisters, who had six fingers upon each of their hands. In the Memoirs of the Royal Academy of Sciences for 1743, is the account of a child, which was shown at one of the meetings, and had six toes on each foot, and the same number of fingers on each hand. In each foot, there was six metatarsal bones, and the left hand an equal number of metacarpal bones, but in the right hand, there were only five, the outer one of which had two articular surfaces, one for the little, and the other for the supernumerary finger. In the Copenhagen Transactions, T. Bartholine has inserted the description of a very curious skeleton: on the right hand, there were seven fingers; on the left six; and besides these circumstances, the thumb was double. On the right foot, there were eight toes; on the left, nine; the right metatarsus consisting of six bones; the left, of seven. Saviard speaks of a still more curious case: he saw a new-born infant at the Hôtel Dieu at Paris, which had ten fingers on each hand, and ten toes on each foot: the phalanges seemed, as if they were all in a broken imperfect state. (*Obs. de Chir.*) The example of the greatest number of fingers and toes is recorded by Voight; including the thumb, there were thirteen fingers on each hand, and twelve toes on each foot. (*Mag. für das neueste der Naturkunde, 3 B, p. 174.*) Individuals are occasionally born with two thumbs, on the same hand. (*Panarolus. Pentec. 3, Obs. Obs. 4—8.*)

Since allowing the redundant number of fingers to remain would keep up deformity, and create future inconvenience, the surgeon is called upon to amputate them. The redundant fingers are sometimes with, sometimes without a nail; are seldom more nu-

nerous than one upon each hand; are generally situated just on the outside of the little fingers; and, as far as my observation extends, are incapable of motion, in consequence of not being furnished, like the rest of the fingers, with muscles. The phalanges are also mostly imperfectly formed, or deficient. The best plan is to cut off supernumerary fingers with a scalpel, at the place where they are united to the other part of the hand. The operation should be performed, while the patient is in the infant state, that is to say, before the superfluous parts have acquired much size, and while the object can be accomplished with the least pain. The incisions ought to be made, so as to form a wound with edges, which will admit of being brought together with strips of adhesive plaster. As soon as the dressings are applied, the hemorrhage will almost always cease, without a ligature.

FISSURE, (from *findo*, to cleave asunder.) A very fine crack in a bone is so called.

FISTULA, in surgery, strictly means a sore, which has a narrow orifice, runs very deeply, is callous, and has no disposition to heal. The name is evidently taken from the similitude, which the long cavity of such an ulcer has to that of a pipe or reed. A fistula commonly leads to the situation of some disease keeping up suppuration; and from which place the matter cannot readily escape. No technical term has been more misapplied than this; and no misinterpretation of a word has had worse influence in practice, than that of the present one. Many simple, healthy abscesses, with small openings, have too often been called *fistulous*; and, being considered as in a callous state, the treatment pursued has in reality at last rendered them so, and been the only reason of their not having healed.

FISTULA IN ANO. See *Anus*.

FISTULA LACHRYMALIS. In correct language, this term can be applied only to one case, viz. that in which there is an ulcerated opening in the lachrymal sac, unattended with any tendency to heal, and from which opening a quantity of puriform fluid is from time to time discharged, especially when the lachrymal sac is compressed. Such has been the confusion, however, prevailing respecting the nature of the diseases of the lachrymal passages, and so great has been the force of ancient custom, that down to the present time, the generality of British, as well as foreign surgeons, imply by the expression, *fistula lachrymalis*, several forms of disease, totally different from each other, and to only one of which the name is at all applicable. In order not to assist in perpetuating this absurd and erroneous plan, from which nothing but mistakes and ignorance can result, I shall follow the example, pointed out by Beer, Schmidt, and our countryman, Mr. McKenzie, and consider the various forms of disease, to which the lachrymal passages are subject, not under the head of *fistula lachrymalis*, but under the more sensible title, *Lachrymal Organs, Diseases of the*.

VOL. I.

"FISTULÆ IN PERINÆO. As Mr. A. Cooper has justly observed, incisions in the urethra generally heal with great facility; a fact, amply proved by the common result of the lateral operation; but, when apertures are formed in the urethra, either from diseased states of the constitution and the part together, or of the latter alone, and when they are accompanied with any considerable destruction of the sides of the urethra, and of the corpus spongiosum, they are mostly very difficult of cure. (*Surgical Essays, Part 2, p. 211.*)

When the methods recommended for the removal of strictures (See *Urethra, Strictures of*) have not been attempted, or not succeeded, nature endeavours to relieve herself by making a new passage for the urine, which, although it often prevents immediate death, yet, if not remedied, is productive of much inconvenience and misery to the patient through life. The mode, by which nature endeavours to procure relief, is by ulceration on the inside of that part of the urethra which is enlarged, and situated between the stricture and the bladder. Thus the urine becomes applied to a new surface; irritating the part, and occasioning the formation of an abscess, into which the urine has access; and when the matter is discharged, be it by nature, or by art, the urine passes through the aperture, and generally continues to do so, whilst the stricture remains. (*A. Cooper, Surgical Essays, Part 2, p. 212.*)

The ulceration commonly begins near, or close to the stricture, although the stricture may be at a considerable distance from the bladder. The stricture is often included in the ulceration, by which means it is removed; but, unluckily, this does not constantly happen. The ulceration is always on the side of the urethra, next to the external surface.

The internal membrane and substance of the urethra having ulcerated, the urine readily gets into the loose cellular membrane of the scrotum and penis, and diffuses itself all over those parts; and as this fluid is very irritating to them, they inflame and swell. The presence of the urine prevents the adhesive inflammation from taking place; it becomes the cause of suppuration wherever it is diffused, and the irritation is often so great that it produces mortification, first in all the cellular membrane, and afterward in several parts of the skin; all of which, if the patient live, slough away, making a free communication between the urethra and external surface, and producing what are termed *fistulæ in perinæo*, though it is plain enough to every surgeon, who knows the correct meaning of the word *fistula*, that a recent opening, produced in the perineum by ulceration or sloughing, ought not to be called a fistula, immediately it is formed, and at least, not until it has acquired some of the characters, specified in our explanation of the term *fistula*.

According to Mr. Hunter, when ulceration takes place further back, than the por-

tion of the urethra, between the glans penis and membranous part of the canal, the abscess is generally more circumscribed.

The urine sometimes insinuates itself into the corpus spongiosum urethræ, and is immediately diffused through the whole, even to the glans penis, so as to produce a mortification of all those parts. A fatal instance of this kind is reported by Mr. C. Bell. (*Surgical Obs. Vol. 1. p. 98.*)

Although the ulceration of the urethra may be in the perinæum, yet the urine generally passes easily forwards into the scrotum, which contains the loosest cellular substance in the body; and there is always a hardness, extending along the perinæum to the swelled scrotum, in the track of the pus. (*Hunter.*)

Mr. A. Cooper is of opinion, that, as soon as the abscesses, which are the forerunners of the fistulæ, can be plainly felt to contain a fluid, it is the best practice to open them with a lancet. The extensive destruction of parts by ulceration, will thus be prevented; the place not unfrequently then heals up expeditiously without any fistulous orifice being left, and a tendency to those dangerous extravasations of urine is also prevented, which, if the abscesses are not opened early, often prove destructive to life. (*A. Cooper, Vol. cit. p. 212.*)

Ulceration can only be prevented by destroying the stricture; but when the urine is diffused in the cellular membrane, the removal of the stricture will generally be too late to prevent all the mischief, although it will be necessary for the complete cure. Therefore, an attempt should be made to pass a bougie, for perhaps the stricture may have been destroyed by the ulceration, so as to allow this instrument to be introduced. When this is the case, bougies must be almost constantly used, in order to procure as free a passage as possible. In these cases, Mr. A. Cooper expresses a preference to metallic bougies, the size of which is to be gradually increased, until their diameter exceeds the natural diameter of the passage. In some instances, however, he says, that it will be necessary to introduce a pewter catheter, of large size, and to allow it to remain in the bladder, so as at once to act upon the stricture, and hinder the urine from passing through the preternatural opening. In this manner a permanent cure may often be effected. Although this experienced surgeon agrees with most surgeons of the present day, respecting the general inexpediency of employing caustic for the removal of a stricture, under the preceding circumstances, yet he admits, that instances do present themselves, in which, from long neglect, the urethra, and the parts, surrounding the stricture, are so altered in structure, that no instrument can be passed through the obstruction, without danger, and where the slower action of caustic is safer, than the use of a metallic bougie. (*Surgical Essays, Part 2, p. 213.*) The experience of modern surgeons tends to prove, however, that there are some cases which

form exceptions to the plan of employing bougies, or catheters, though a fistulous opening may have occurred in the passage. These cases are the examples, in which the apertures in the urethra are the consequence of ulceration and abscess, unaccompanied by stricture, and taking place in a bad constitution, and perhaps only preceded by a slight discharge from the urethra. Here bougies would increase the tendency to ulceration, and aggravate the local and constitutional irritation. (*A. Cooper, p. 216.*)

While we are attempting to cure the stricture, antiphlogistic measures, particularly bleeding, are to be adopted. The parts should be exposed to the steam of hot water; the warm bath made use of; opium and turpentine medicines given by the mouth, and in clysters; with a view of diminishing any spasmodic affection. But, as Mr. Hunter observes, all these proceedings are often insufficient; and, therefore, an immediate effort must be made, both to unload the bladder, and to prevent the further effusion of urine, by making an opening in the urethra, somewhere beyond the stricture, but the nearer to it the better.

Introduce a director, or some such instrument, into the urethra, as far as the stricture, and make the end of it as prominent as possible, so as to be felt; which, indeed, is often impossible. If it can be felt, it must be cut upon, and the incision carried on a little farther, towards the bladder, or anus, so as to open the urethra beyond the stricture. This will both allow the urine to escape, and destroy the stricture. If the instrument cannot be felt, at first, by the finger, we must cut down towards it; and, on afterward feeling it, proceed as above.

When the stricture is opposite the scrotum, as the opening cannot be made in this situation, it must be made in the perinæum, in which case there can be no direction given by an instrument, as one cannot pass sufficiently far, and the only guide is our anatomical knowledge. The opening being made, proceed as directed in the cure of a false passage. (*See Urethra, False passage of.*) In whichever way the operation is done, a bougie, or a catheter, which is better, must afterward be introduced, and the wound healed over it.

When the inflammation, from the extravasation of urine is attended with suppuration and mortification, the parts must be freely scarified, in order to give vent both to the urine and pus. When there is sloughing, the incisions should be made in the mortified parts.

Sometimes, when the urethra is ulcerated, and the cellular membrane of the penis and prepuce is so much distended, as to produce a phymosis, it is impossible to find the orifice of the urethra.

Frequently the new passages for the urine do not heal, on account of the stricture not being removed: and even when this has been cured, they often will not heal, but become truly fistulous, and produce fresh inflammations and suppurations, which often

burst by distinct openings. Such new abscesses and openings often form, in consequence of the former ones having become too small, before the obstruction in the urethra is removed.

Such diseases sometimes bring on intermittent disorders, which do not yield to bark; but cease as soon as the fistulæ and disease of the urethra have been cured.

In order to cure fistulæ in perinæo, unattended with the above described urgent symptoms, the urethra must be rendered as free as possible, and this alone is often enough; for, the urine finding a ready passage forwards, is not forced into the internal mouth of the fistulæ, so that these heal up. The cure of the strictures, however, is not always sufficient, and the following operation becomes indispensable.

The sinuses are to be laid open in the same manner as other sinuses, which have no disposition to heal. In doing this, as little as possible of the sound part of the urethra must be opened. Hence, the surgeon must direct himself to the inner orifice of the fistulæ, by means of a staff, introduced (if possible) into the bladder, and a probe passed into one of the fistulous passages. The probe should be first bent, that it may more readily follow the turns of the fistulæ. When it can be made to meet the staff, so much the better; for then the operator can just cut only what is necessary.

When the fistula is so straight, as to admit of a director being introduced, this instrument is the best. When neither the probe nor the director, can be made to pass as far as the staff, we must open the sinuses as far as the first instrument goes, and then search for the continuation of the passage, for the purpose of laying it open. The difficulties of this dissection, however, in the thickened, diseased state of the parts in the scrotum and perinæum, are such as can only be duly appreciated by a man, who has either made the attempt himself, or seen it made by others. I have myself seen one of the first anatomists in London fail in two instances to trace the continuation of the urethra, and baffled in the endeavour, therefore, to pass an instrument from the orifice of that passage into the bladder. The difficulty and confusion, arising from the hardened, enlarged state of the parts, which are to be cut, have been well depicted by Mr. C. Bell. (*Surgical Obs. Vol. 1, p. 129.*)

Having divided the fistulæ as far as their termination in the urethra, a catheter should be introduced, and worn, at first, almost constantly. This is better than a bougie, which must be frequently withdrawn to allow the patient to make water, and it often could not be introduced again without being entangled in the wounds.

In many cases, the employment of the catheter should not be continued after a certain period. At first, it often assists the cure; but, in the end, it may obstruct the healing, by acting at the bottom of the wound, as an extraneous body.

Hence, when the sores become stationary, let the catheter be withdrawn, and introduced only occasionally. And even after the sores are well, it will be prudent to use the bougie, in order to determine whether the passage is free from disease.

When fistulæ in perinæo have been laid open, the wounds are to be at first dressed down to the bottom as much as possible, which will prevent the reunion of the parts first dressed, and make the granulations shoot from the bottom, so as to consolidate the whole by one bond of union. (*Hunter on the Venereal Disease, Edit. 2.*) Additional observations upon this subject, and, in particular, the opinions of Desault, will be found in the article *Urinary Abscesses and Fistulæ*. Mr A. Cooper's practice in cases, where a considerable portion of the urethra has been destroyed, will be hereafter noticed. (See *Urethra*.)

FISTULA, SALIVARY. (See *Parotid Duct*.)

FLUCTUATION. (from *flucto*, to float.) the perceptible motion communicated to any collection of purulent matter, or other kind of fluid, by applying the fingers to the surface of the tumour, and pressing with them alternately, in such a manner, that the fingers of one hand are to be employed in pressing, or rather in briskly tapping upon the part, while those of the other hand remain lightly placed on another side of the swelling. When the ends of one set of fingers are thus delicately applied, and the surgeon taps, or makes repeated pressure with the fingers of the other hand, the impulse, given to the fluid, is immediately perceptible to him, and the sensation, thus received, is one of the principal symptoms, by which practitioners are enabled to discover the presence of fluid in a great variety of cases. Great skill in ascertaining by the touch the presence of fluid in parts, or being endued with the *tactus eruditus*, as it is termed, distinguishes the man of experience as remarkably, perhaps, as any quality that can be specified.

When the collection of fluid is very deeply situated, the fluctuation is frequently exceedingly obscure, and sometimes not at all distinguishable. In this circumstance, the presence of the fluid is to be ascertained by the consideration of other symptoms. For example, in cases of hydrops pectoris and empyema, surgeons do not expect to feel the undulation of the fluid in the thorax with their fingers; they consider the patient's difficulty of breathing, the uneasiness attending his lying upon one particular side, the œdema of the parietes of the chest, the dropsical affection of other parts, the more raised and arched position of the ribs on the affected side, the preceding rigours, fever, and several other circumstances, from which a judgment is formed, both with regard to the presence and the peculiar nature of the fluid.

FOMENTATION. By a fomentation, surgeons commonly mean the application of flannel or towels, wet with warm water, or some medicinal decoction. In the practice

of surgery, fomentations are chiefly of use in relieving pain, and inflammation, and in promoting suppuration, when this is desirable. Some particular decoctions, however, are used for fomentations, with a view of affecting by means of their medicinal qualities, scrofulous, cancerous, and other sores, of a specific nature. I shall merely subjoin a few of the most useful fomentations in common use.

FOMENTUM AMMONIÆ MURIATÆ.

R. Fomenti Communis ℥ij. Ammon. Mur. ℥j. Spirit. Camph. ℥ij.

Just before using the hot decoction, add to it the ammonia muriata, and spirit. Said to be of service to some indolent ulcers; and, perhaps, it might be of use in promoting the absorption of some tumours, and suppuration in others.

FOMENTUM CHAMÆMELI. R. Lin.

contusi ℥j. Chamæmeli ℥ij. Aq. Distillat. ℥vj. Paulisper coque, et cola. A fomentation in very common use.

FOMENTUM CONII. R. Fol. Conii.

recent. ℥j. vel. Fol. Conii. exsicc. ℥ij. Aq. Comm. ℥ij. Coque usque reman. ℥ij. et cola. Sometimes applied to scrofulous, cancerous, and phagedenic ulcers.

FOMENTUM GALLÆ. Gallæ Contusæ

℥ss. Aq. Ferventis ℥ij. Macera per horam. et cola. Used for the prolapsus ani, and sometimes employed, as a cold application, in cases of hemorrhoids.

FOMENTUM PAPAVERIS ALBI. R.

Papav. Alb. Exsicc. ℥iv. Aq. Pur. ℥vj. Bruise the poppies, put them in the water, and boil the liquor, till only a quart remains, which is to be strained. This fomentation is an excellent one, for very painful inflammations of the eyes, and for numerous ulcers, and other diseases, attended with intolerable pain.

FORCEPS, an instrument much employed in surgery for a variety of purposes, and having accordingly various constructions. The general design, however, of surgical forceps is to take hold of substances, which cannot be conveniently grasped with the fingers; and, of course, the instrument is always formed on the principle of a pair of pincers, having two blades, either with, or without handles, according to circumstances. The smallest forceps is that which is employed in the operation of extracting the cataract, and which is useful for removing any particles of opaque matter from the pupil, after the chief part of the crystalline lens has been taken away.

Another forceps of larger size, is that used for taking up the mouths of the arteries, when these vessels require a ligature, in cases of hemorrhage. This instrument is also frequently employed for taking dressings off sores, removing pieces of dead bone, foreign bodies from wounds, and, particularly, for raising the fibres, which are about to be cut, in all operations, where careful dissection is required. This forceps resembles that which is contained in every case of dissecting instruments, and is often called

the *artery*, or *dissecting* forceps, from its more important uses.

Neither of the foregoing forceps is made with handles; each opens by its own elasticity; and the ends of the blades only come into contact, when pressed together by the surgeon.

The following kinds of forceps are constructed with handles, by means of which they are both opened and shut:

1. The common forceps, contained in every pocket-case of surgical instruments, and used for removing dressings from sores, extracting dead pieces of bone, foreign bodies, &c.

2. Larger forceps, employed for extracting polypi.

3. Forceps of different sizes and constructions, used in the operation of lithotomy, for taking the stone out of the bladder, or for breaking the calculus, when it is too large to be extracted in an entire state.

***FRACTURE.** (from *frango*, to break.)

Is a solution of continuity of one, or more bones, produced in general by external force; but occasionally, by the powerful action of muscles, as is often exemplified in the broken patella.

The subject of fractures is so interesting a branch of surgery, and the accidents themselves so frequent and important, that the little which English surgeons have done for the improvement of this part of their profession cannot but cause equal surprise and regret. Mr. Pott, it is true, made many excellent observations on the treatment of fractures in general; and his remarks on compound fractures in particular are in some respects the best which are extant; but what surgeon will now presume to defend the weak arguments upon which he has founded the doctrine of paying unqualified attention to the relaxation of the muscles, as if this were an object which should constantly supersede every other consideration, and invariably regulate the posture of the limb? I have no hesitation in declaring my own belief, that the doctrine and practice recommended by Mr. Pott, in regard to fractured thighs, have done considerable harm, and the more so, as coming from a man who was deservedly looked upon as one of the best and most experienced judges of surgical practice. Many a surgeon in this country implicitly believed every thing which was asserted by so able a master, and the very observations, which some years ago were here considered to be the glory of their author, and the pride of English surgery, are now exposed by the surgeons of neighbouring countries, as specimens of our wrong precepts and bad practice. M. Roux, in fact, has had but too much room for animadversion upon this subject. We have not only not made a single improvement of consequence in the treatment of any particular fracture, but the generality of our surgical writers have given the most faulty and imperfect account of the diagnosis, and every thing else relating to these accidents. What is worse, a view of our practice con-

veys no better opinion of this part of our surgery. Observe the care and neatness, with which a French surgeon applies the bandages, and splints, and consider how well every indication is accomplished by his apparatus, and you will find great cause both for admiration and imitation. On the other hand, see the slovenly way, in which an English surgeon generally puts on the splints and roller, and the unscientific method, in which he usually treats a fractured thigh, or clavicle, and you cannot fail to be ashamed of the comparison. This was a matchless opportunity for M. Roux to draw a parallel in favour of French surgery, and of course he has not neglected it, many pages of his work being devoted to an explanation of the many improvements Desault made; the little, or rather the nothing, which we have done; and the errors to which we unfortunately still adhere. (See *Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, p. 173, &c.) It is to be hoped, however, that the period has now arrived, when we shall give to the study of fractures the time, the attention, and the importance, which it claims; and when even the young hospital pupil will not be convinced, that his lecturer by one or two cursory discourses can have done justice to the subject.

In this article, my plan is to follow the arrangement pursued by Boyer, in his "*Traité des Maladies Chirurgicales*, T. 3." I shall first speak of fractures in general, and allot separate sections to the consideration of, 1. Their differences; 2. Their causes; 3. Their symptoms; 4. Their prognosis; 5. Their treatment; 6. The formation of callus.

The subject will then conclude with a full account of the symptoms, causes, and treatment of the fractures of particular bones.

1. Differences of Fractures.

The differences of fractures depend upon what bone is broken; what portion of it is fractured; the direction of the fracture; the respective position of the fragments; and, lastly, upon circumstances accompanying the injury, and making it simple, compound, or variously complicated.

1. *In respect to the bone affected.* Sometimes it is one of the broad bones, as the scapula, the sternum, or the os ilium.— Sometimes it is a short bone, like the os calcis; but, far more commonly it is one of the long bones. The situation and functions of the broad bones render their fractures unfrequent. The bones of the skull are the only exception to this remark, for they are often broken; but here the assistance of the surgeon is required less for the solution of continuity itself, than for the affection of the brain, and the extravasation of blood, with which the case is apt to be combined. Fractures of the short bones are still more unusual, because these bones, being nearly equal in their three dimensions, are capable of greater resistance,

and are not much within the reach of external violence. Besides, most of them are but little exposed to the operation of outward force, by their situation, or functions. Hence, unless limbs are crushed, fractures of short bones are generally caused by the action of the muscles, which also frequently breaks the patella, olecranon, and os calcis. The long bones, which serve as pillars, or arches of support, or levers, are by the very nature of their functions, particularly liable to fractures.

2. *In respect to the part of the bone broken.* Bones may be fractured at different points of their length. Most commonly, their middle portion is broken, and, in this circumstance, they usually break like a stick, which has been bent beyond its extensibility by a force applied at each end of it. Sometimes the fracture occurs more or less near the extremities of the bone, which is always an unfavourable event, as will be explained in considering the prognosis. Lastly, the bone is sometimes broken in several places, and the injury may be produced by two different causes, which have operated successively, or simultaneously, upon the broken parts of the bone; or it may be occasioned by one single cause, which has acted at the same moment upon several points of it. These distinctions of fractures, deduced from their particular situation, (says Boyer) are not merely scholastic refinements; they have truly an important influence over the prognosis and treatment, as will be hereafter seen.

3. *In respect to the direction, in which the bone is broken.* A bone may be fractured in various ways, and the fracture receives different names, according to its direction in regard to the axis of the bone. Thus, fractures are distinguished into *transverse* and *oblique*. The obliquity renders the surface of the injury larger, and materially increases the difficulty of maintaining the ends of the bone in contact, after they have been set. Oblique fractures are subject to considerable variety, which depends upon the degree of their obliquity, and whether they are partly oblique and partly transverse. When a bone is broken in different places, at once, and divided into several fragments, or splinters, the fracture is termed *comminuted*.

Duverney admitted another class of fractures, viz. *longitudinal*. (See *Traité des Maladies des Os*, T. 1, p. 167.) But J. L. Petit regarded this species as only imaginary, because he conceived that any blow which was capable of breaking a bone longitudinally, would much more readily cause a transverse fracture. For the same reason, Louis absolutely rejected the possibility of longitudinal fractures, and this sentiment has been the prevailing one up to the present day.

The following case, however, is related by Levéillé, in order to prove the possibility of longitudinal fractures. This surgeon amputated the thigh of an Austrian soldier who was put under his care in the year 1800, in

consequence of being struck by a ball in the lower third of the leg, at the battle of Marignano. The soldier had walked several miles after receiving the injury, before he arrived at Pavia. The wound appeared simple, and likely to heal as soon as the injured portion of the tibia had exfoliated. The event turned out otherwise, and the thigh was amputated.

Levéille has preserved the tibia, upon which the impression of the ball may be distinguished, and from this point, run several longitudinal and oblique lines, which extend from the lower third towards the upper head of the tibia, and pass through the whole thickness of the parietes of the medullary canal. They are acknowledged to be really longitudinal fractures, by Dubois, Chauffrier, Duméril, Deschamps, and Roux, who were appointed by the Ecole de Médecine to inquire into the fact. (*Levéille, Nouvelle Doctrine Chir. T. 2, p. 158.*)

In a foregoing article of this dictionary, I mentioned that, in several of the cases of fractured thigh bones from gun-shot violence, which were under the care of Dr. Cole and myself in Holland, the bone was split longitudinally to the extent of seven or eight inches. (See *Amputation.*) The fact, however, that bullets and other balls do produce longitudinal fractures, is now universally admitted; and were there any doubt upon the subject, a specimen sent to England by my friend Dr. Cole would soon remove it. Boyer, who a few years ago denied the possibility of longitudinal fractures, in his late work remarks:—"On trouve néanmoins, à la suite des plaies d'armes à feu, les os fendus suivant leur longueur, jusques dans leurs articulations,"—but he is correct when he adds, that such instances afford no proof of the possibility of a simple longitudinal fracture. (See *Traité des Maladies Chir. T. 3, p. 10.*)

4. *In regard to the respective position of the fragments.* These differences are highly important to be understood, because, as Boyer remarks, the treatment of fractures consists almost entirely in remedying, or preventing the displacement of the fragments. It is not to be supposed, however, that such displacement is an absolutely essential symptom of all fractures, for it seldom exists in members composed of two bones, when only one of them is broken. Neither does it constantly happen in every fracture of the neck of a bone, as is exemplified in certain fractures of the neck of the thigh-bone, the fragments of which sometimes change their relative situation only when the patient tries to walk, or the limb is imprudently moved about. Fractures of the leg are also observed, in which there is neither a displacement of the fragments, nor an alteration in the shape of the limb, especially when the tibia alone is fractured near its upper part, where it is very thick. When the ulna alone is broken at its upper part, there is hardly ever any displacement. The corresponding surfaces of the fragments having a large extent cannot

be separated, or can only be so with difficulty. The fibula also resists the causes, which tend to produce displacement. But it is a symptom which almost invariably occurs when both bones of the leg, or fore-arm, are fractured together; as also in fractures of limbs which contain only one bone, on account of the little extent of the surfaces of the fracture, and the great number of muscles, which tend to displace them.

The displacement may happen in respect to the diameter, length, direction, or circumference, of the bone.

In respect to the diameter. Transverse fractures are the only cases, in which this kind of displacement is observed. The two fragments may either be in contact at a part of their surfaces, or they may not be in contact at all. In the latter circumstance, the limb is shortened by the ends of the fracture slipping over each other.

In respect to length. This mode of displacement, in which the ends of the broken bone ride more or less over each other, constantly occurs in oblique fractures, and sometimes in transverse ones, when the displacement in the direction of the diameter of the bone has been such that the surfaces of the fracture are no longer in contact. It will be hereafter explained, that whenever the limb is shortened in fractures of the extremities, it is the lower fragment which is displaced.

We may refer to the species of displacement here spoken of, that which takes place in fractures of the patella, olecranon, and os calcis; but with this difference, that the fragments, instead of riding over each other, separate from each other in the direction of the length of the bone, and continue separated by an interspace more or less considerable.

In respect to the direction of the bone. In this kind of displacement, the two fragments form an angle more or less prominent, and the bone appears arched. It is principally observed in comminuted fractures. It may also happen in simple fractures; for instance, in the leg, when the limb in a strait posture does not lie upon a surface exactly horizontal, and the heel is lower than the rest of the leg. The angular projection is then anterior. On the contrary, it would be posterior if the heel were too much raised.

In respect to the circumference of the bone. This displacement occurs when the lower fragment performs a rotatory movement, while the upper one continues motionless. Thus, in fractures of the neck of the femur, if the foot is badly supported by the apparatus, its weight, together with that of the limb, and the action of the muscles, inclines it outward, and turns the lower fragment in the same direction.

Besides the simple displacements above described, there are others of a more complicated nature, which happen in several directions at once. For example, such is the displacement which is observed in a fracture of the thigh-bone, when the lower

fragment is drawn upward and inward, while the foot is turned outward.

Let us next consider the causes producing the displacement of fractures.

The bones being only passive instruments of loco-motion, possess not, in their own organization, any cause of the change of situation which takes place; but yield to the impulse of external bodies, the weight of the member, and the action of the muscles.

The displacement may be produced by an external force, either at the moment when the fracture happens, and by the very action of the fracturing cause itself; or it may be caused by the weight of the body when the fracture precedes the fall; or lastly, it may be brought on by some other external force, acting on the fragments, sooner or later, after the occurrence of the injury.

The outward violence, which is productive of a fracture, operates sometimes directly on the situation of the breach of continuity; sometimes on parts more or less distant from this place. In both cases, the action of the force is not confined to the production of the fracture, but is partly spent in causing a displacement of the fragments.

Falls are the most usual causes of fractures. But sometimes, the fall does not happen till after the leg, or thigh, is actually broken. The weight of the body then produces the displacement, by pushing the upper fragment against the soft parts, which are more or less lacerated. This is what happened to Ambrose Paré. This celebrated surgeon, being kicked by a horse, endeavoured to get out of the way; but he instantly fell down, and the two bones of his left leg, which had been fractured, being impelled by the weight of the body, not only passed through the skin, but even through his stocking and boot. Boyer has seen a case nearly similar in a young man about twenty years of age, who, in a standing posture, was struck on the middle of the thigh with the pole of a carriage, which fractured the femur. The patient fell down, and in the fall the upper fragment was not only driven through the muscles and integuments, but also through his breeches.

The weight of the limb itself may produce displacement according to the direction, or circumference of the bone, as already detailed. The disturbance of the limb, also, in lifting the patient, and carrying him to his bed, may sometimes alter the relative situation of the fragments, and cause them to be displaced.

But of all the causes of the displacement of fractures, the action of the muscles is the common and most powerful one. Among those muscles which surround a fractured bone, some are attached to it throughout its whole length, and are equally connected with both the fragments. Some arise from the bone above, and are inserted either into that, which is articulated with the lower fragment, or into the lower fragment itself. Lastly, there are others, which come from a point more or less distant, and terminate in the upper fragment. The muscles round the

thigh bone furnish examples of these three arrangements. The triceps is attached to the bone its whole length. The biceps, semi-membranosus, and semi-tendinosus, come from the pelvis, and are inserted into the leg, a part, with which the lower fragment is articulated, and all the motions of which it follows. The great head of the biceps is inserted into this fragment itself. Lastly, the iliacus, psoas, pectineus, &c. come from the loins and pelvis, and are attached to the femur, not far from its upper end.

The muscles which are attached to both fragments, contribute very little to their displacement. They may, however, draw them to the side on which they are situated, and thus change the direction of the limb. The triceps, especially its middle portion, acts in this manner in fractures of the femur, and renders the thigh convex anteriorly. The coraco-brachialis tends to produce the same effect, when the humerus is broken below its middle.

The displacement is principally owing to such muscles as are affixed to the lower fragment, or part with which this fragment is articulated. Suppose the humerus to be broken between its upper end and the insertion of the great pectoral. This muscle, aided by the latissimus dorsi and teres major, will draw the lower fragment inward, and displace it by drawing it to the inner side of the upper fragment, which remains motionless. In fractures of the neck of the thigh bone, the upper fragment, included within the capsular ligament, affords attachment to no muscle. All those, which are affixed to the lower fragment, pull it upward and backward, in which direction the displacement is inevitable. In all fractures, the lower fragment follows every movement made by the part of the limb with which it is articulated, and, consequently, the muscles which are attached to the bones of this last part of the limb, become a powerful cause of displacement. Thus, in a fracture of the thigh bone, the biceps, semi-tendinosus, and semi-membranosus, draw the leg, and with it the lower fragment, upward, inward, and backward, so as to make the lower end of the fracture ascend at the inside of, and rather behind the upper one, the extremity of which then projects forward and outward. In a fracture of the leg, the gastrocnemius, soleus, and peronei muscles, acting upon the foot, pull the lower fragments of the tibia and fibula, and draw them to the outer and posterior side of the upper fragments. For, here, as well as every where else, the strongest muscles, in producing the displacement, draw towards their own side the end of the fracture, on which they operate. And as the posterior muscles of the leg are far more numerous and powerful than those on the front of the limb; while those on its outside are not antagonized by any others; the displacement must happen in the direction backward and outward. Whenever therefore a bone is fractured at a given point, an anatomical know-

ledge of the muscles will enable one to determine *à priori* in what direction the displacement will occur, if no means be taken to impede it, and it proceed altogether from this particular cause.

Lastly, the muscles, which are attached only to the upper fragment, may sometimes displace it. In a fracture of the thigh, situated immediately below the little trochanter, the psoas and iliacus muscles together carry forward the extremity of the upper fragment, which elevates the integuments, and forms a more or less considerable projection near the fold of the groin. But, it is to be observed, that, in general, the displacement of the upper fragment is not common, and that it is the lower one which is drawn out of its proper position.

The manner in which the displacement of fractures is effected by the action of muscles, explains one circumstance, which frequently attends these cases, especially fractures of the thigh, clavicle, and leg. This is a rising, a projection of the upper fragment, or that which is nearest the trunk. One might believe, at first sight, that such projection is formed by the upper fragment, which, abandoning its natural situation rises over the lower one. But on the least reflection, it becomes manifest, that the upper end of the fracture projects only because the lower one is displaced and drawn towards that side on which the strongest muscles are situated. Thus, in practice, in order to make the *rising end of the bone*, (as it was termed) disappear, it is only necessary to reduce the lower fragment into its natural place. If instead of doing this, pressure is made on the projecting part, the design fails; and if the plan be still more forcibly pursued and continued, inflammation and sloughing of the integuments and other soft parts, are likely to be the unfortunate consequences.

5. *In respect to circumstances, with which fractures are accompanied.* The most important division of fractures is into *simple* and *compound*.

By a *simple fracture*, surgeons mean a breach in the continuity of one or more bones, without any external wound, communicating internally with the fracture, and caused by the protrusion of the ends of the broken bone, or bones. By a *compound fracture*, they signify the same sort of injury of a bone, or bones, attended with a laceration of the integuments, which laceration is produced by the protrusion of one, or both ends of the fracture.

The dangerous nature of compound fractures will be fully explained in the sequel of this article, and we have already adverted to the subject in speaking of *Amputation*.

Fractures are said to be *complicated*, when they are attended with diseases, or accidents, which render the indications in the treatment more numerous, and require the employment of different remedies, or the practice of sundry operations for the accomplishment of the cure.

Thus, fractures may be complicated with

severe degrees of contusion, wounds of the soft parts, the injury of large blood-vessels, a dislocation, or disease, such as the scurvy, rickets, lues venerea, &c. which are said to retard the formation of callus, and render the cure more backward.

The complication of fracture with dislocation happens but seldom, and it cannot occur, unless the luxation has taken place first, or has been produced at the same time with the fracture, and by the same cause. When once the fracture has happened, the fragments are not sufficiently within the grasp of external force, and are too moveable to admit of the bone being dislocated.

A patient with fracture may be attacked by an acute disease, which may render the treatment more troublesome, and the cure slower.

2. Causes of Fractures.

The causes of fractures are divided into *predisposing* and *remote*.

In the first class are comprehended, the situation and functions of the bones, the age of the patients, and their diseases. Superficial bones are more easily fractured than those which are covered by a considerable quantity of soft parts. The functions of some bones render them more liable to be fractured than others; thus the radius, which supports the hand, is more liable to be fractured than the ulna. The clavicle, which serves to keep the shoulder in its proper position, and support on its arched extremity all the motions of the upper extremity, is particularly subject to be broken. The gradual increase of the quantity of the phosphate of lime, in the structure of the bones, makes them brittle, in proportion as we advance in years, and in old age, the proportion of the inorganized to the organized part is so great, that the bones are fractured by the slightest causes. In childhood, the fibrous and organized part bears a greater proportion to the earth, and the bones being, consequently, more elastic and flexible, are not so easily broken, as in old age.

Lues venerea, arthritis, cancer, rachitis, scurvy, and scrofula, says Levéillé, predispose to fractures. B. Bell mentions two venereal patients, of whom the hardest and largest bones were completely broken by the ordinary action of the muscles of the limb. Fabricius Hildanus quotes from Sarazin, a physician of Lyons, the case of a gouty patient, sixty years of age, who, in putting on his glove, broke his arm; the fracture having been ascertained three days afterward to be situated above the elbow. Desault used often to speak of a nun of Salpêtrière, whose arm was broken as a person was handing her out of a carriage. Louis, who was vexed that no union took place, was not a little surprised to find her thigh bone experience the same fate one day as she was changing her posture in bed. It was then that Louis learned that this lady had a cancer in her right breast. Levéillé as-

tures us, that he has observed similar cases in the Hôtel Dieu.

According to this last writer, the history of two girls is related by Buchner, one of whom died rickety at the age of sixteen, having broken the femur a short time before her death; and the other, after taking the breast very well for two years, and thriving for a time, became affected with rachitis, and met with the same accident as she was merely running along the street. (*Nouvelle Doctrine Chir. Tom. 2, p. 163.*)

Many extraordinary instances of fractures from the morbid softness and fragility of the bones are upon record. Suffice it here, to refer to the Philosophical Transactions; *Mém. de l'Acad. Royale des Sciences*; *Act. Hafniens.*; *Ephem. Nat. Cur. Dec. 1, Ann. 3, Obs. 112*; Gooch's *Chirurgical Works*, Vol. 2; Saviard's *Observations Chirurgicales*, p. 274, &c. (See also *Fragilitas and Mollities Ossium*.)

On the subject of fractures, produced by the scurvy, Levéillé recommends us to peruse Marcellus Donatus; Saviard's *Observations*; Heyne de *Morbis Ossium*; Poupert's *Works* inserted in the *Mém. de l'Acad. de Sciences*, 1699; and the *Treatise* published at Verona, in 1761, by Jean de Bona.

Paré, Platner, Callisen, and several other writers, set down cold, as a predisposing cause of fractures. This doctrine has originated from these injuries being more frequent in the winter time, and is quite erroneous, since, in cold countries, the greater number of falls, which happen in winter, is a circumstance that fully explains why fractures are then more common than in summer.

The remote cause of fractures is external force, variously applied, in falls, blows, &c. In particular instances, the bones are broken by the violent action of the muscles attached to them; this is almost always the case with the fractured patella. The olecranon and os calcis have likewise been broken by a violent contraction of the muscles inserted into them. With respect to the heel, Petit records two instances, one of which was communicated to him by Poncelet, and the other seen by himself in Madame La Presidente de Boissière, who met with the accident in walking a gentle pace in the court of the Hôtel de Soubise. When the injury happens in leaping, or falls from a high situation, Levéillé thinks it more probable, that a portion of the os calcis is torn off by the powerful action of the muscles of the calf, than that it is broken by any blow immediately on the part. He states, that Desault used frequently to cite two examples of this kind, one of which is recorded in his *Œuvres Chirurgicales*.

Whether the long bones can be fractured by the mere action of the muscles, is yet an unsettled point. In the Philosophical Transactions, a fracture of the humerus is ascribed to this cause, and Botentuit saw the same accident produced by striking a shuttlecock with a battledore. According to De-beaumarchef, as a man was descending a

ladder at a quick rate, his heel got entangled in an opening, and he made a violent exertion to avoid falling. The consequence was a fracture of the lower third of the leg. Curet informs us, that a cabin-boy, aged seventeen, made a considerable effort to keep himself from being thrown down by the rolling of the ship, as he was making water. The femur was fractured by the powerful action of the muscles of the thigh. The lad had no fall, and, with some difficulty, supported himself on the other limb, till he received assistance.

We are told, says Lavéillé, by Poupée Desportes, that a negro, about twelve or thirteen years old, was seized with such violent spasmodic contractions of the muscles of the lower extremities, that the feet were turned backward, and the neck of each thigh bone was fractured, the ends of the broken bones also protruding through the skin upon the outside of the thigh. A cure was effected, after an exfoliation. We read also, in the *Mélanges des Curieux de la Nature*, that, during a fit of epilepsy, a child, ten years old, had its left humerus and tibia broken, and that upon opening the body, other solutions of continuity were observed. Doctor Chamseru recollects having assisted, at his father's house, in dressing a child, eleven or twelve years old, that had broken the humerus in throwing a stone a considerable distance. (*Levéillé, Nouvelle Doctrine Chir. T. 2, p. 164, 166.*)

Richerand, however, positively denies, that a long bone, when healthy, can ever be broken by the mere contraction of the muscles. (*Nosogr. Chir. T. 3, p. 12, Edit. 4.*)

For my own part, making all due allowance for the inaccuracy of some of the reports made by writers, I think the possibility of the long bones being broken by the violent action of the muscles is sufficiently proved. I have never seen but one example of the occurrence; but, it was a very unequivocal one. I once attended for the late Mr. Ramsdens, an exceedingly strong man, at Pentonville, who broke his os brachii in making a powerful blow, although he missed his aim and struck nothing at all. The whole limb was afterward affected with vast swelling and inflammation. This man, I remember, was also visited by Mr. Welbank, of Chancery-lane. According to Nicod, the greater number of fractures of long bones, by mere muscular action, are preceded by pains in the broken limbs, and, in one of the cases, published by this author, not only was this circumstance remarked, but an abscess and exfoliation of a portion of the fractured humerus ensued. In another instance, reported by this gentleman, the clavicle, in a state of preternatural fragility from disease, was fractured in an effort to carry the arm far behind the back. After the reunion of the fracture, an abscess took place, and a piece of the bone exfoliated. (*Annuaire Med. Chir. des Hôpitaux de Paris, p. 494—98, &c. 4to. Paris. 1819.*)

3. Symptoms of Fractures.

Some of the symptoms of fractures are equivocal. The pain, and inability to move the limb, commonly enumerated, may arise from a mere bruise, a dislocation, or other cause. The crepitus: the separation and inequalities of the ends of the fracture, when the bones is superficial; the change in the form of the limb; and the shortening of it; are circumstances, communicating the most certain information; and the crepitus, in particular, is the principal symptom to be depended upon. The signs of fractures, however, are so exceedingly various, according to the bones, which are the subject of injury, that it cannot be said, that there is any one, which is invariably attendant on such cases, and characteristically confined to them. The writers of systems of surgery usually notice loss of motion in the injured limb, deformity, swelling, tension, pain, &c. as forming the general diagnosis of fractures. However, it is easily comprehensible by any one, acquainted with anatomy, that numerous fractures cannot prevent the motion of the part, nor occasion outward deformity; and every surgeon must know, that though, at first, there may be pain in the situation of a fracture, no swelling and tension take place till after a certain period.

When, therefore, a limb is broken, and the event is not manifest from the distortion of the part, it is proper to trace, with the fingers, the outlines of the suspected bone: if it be the tibia, let the surgeon examine with his fingers, whether any inequality can be discovered along the anterior surface, and along the sharp front edge of that bone. If it be the clavicle, let him trace the superficial course of the bone, in the same attentive manner. Whether any unusual pain occurs, or any unnatural irregularity appears, let him try, if a grating, or crepitus, cannot be felt, on endeavouring to make one end of the suspected fracture rub against the other. When the humerus, or the os femoris, is the subject of inquiry, a crepitus is felt almost as soon as the limb is touched, and, in the case of the broken thigh, there is a considerable shortening of the extremity, except in a few cases of fractures, completely transverse. But, when there are two bones, as in the leg and the fore-arm, and only one is broken, the other continues to prevent the limb from being shortened, and thrown out of its natural shape, so that a crepitus can only be felt by a very careful examination with the fingers. The difficulty of the diagnosis is increased, when the surgeon is consulted late, and great swelling has come on. Where is the surgeon, says Boyer, that has not sometimes hesitated to deliver an opinion in certain cases of this description? (*Traité des Malad. Chir.* 3, p. 27.)

When the injured limb is shortened, the surgeon, before pronouncing that such change proceeds from the riding of the fragments over each other, must be sure, that the bones are not dislocated, and that the limb is not naturally shorter, than the

other, or in consequence of a previous fracture, that has been badly set.

In comparing the length of the lower extremities, one should place the pelvis in an horizontal position, and put the two anterior superior spines of the ossa ilium in the same line; for, if these processes are not on a level, the limb, towards which the pelvis inclines, will seem longer than the opposite member.

The practitioner, who is well acquainted with the conformation of the limbs, and particularly with the mutual relations of the eminences of the bones to each other, will readily perceive the alterations produced by a fracture. Whenever, in consequence of a fall, or a blow, a limb becomes concave at a part, where it ought to be convex; or straight, et vice versa; the change of shape and direction must proceed from a fracture with displacement. The inner edge of the great toe, when the leg rests on an horizontal surface, should correspond with the inner edge of the knee-pan. If this natural relation be altered; if the inner edge of the great toe correspond with the outer edge of the knee-pan, there can be no doubt of the existence of a fracture of both bones of the leg. (*Boyer, Vol. cit. p. T. 3, p. 25.*)

I am aware, that considerable harm, and great unnecessary pain, have been occasioned in the practice of surgery, by too much solicitude to feel the grating of fractured bones, and, whenever the case is sufficiently evident to the eyes, the practitioner who gives way to this habit, at the expense of torture to the unfortunate patient, ought, in my opinion, to be severely censured. A fracture is an injury, necessarily attended with a great deal of pain, and followed by more or less swelling and inflammation; and to increase these evils by roughly, or unnecessarily handling the part, is ignorantly cured, (if I may use the expression) unsurgical.

In some kinds of fractures, the broken bone is so surrounded with thick fleshy parts, that it is difficult to feel a crepitus, or ascertain the existence of the injury. Some fractures of the neck of the thigh bone, unattended with much retraction of the limb, are instances illustrative of this observation.

4. Prognosis of Fractures.

The Prognosis of fractures varies, according to the kind of bone injured, what part of it is broken, the direction of the breach of continuity, and what other mischief complicates the case. Fractures of bones, which have many strong muscles inserted into them, are more difficult of cure, than those of other bones, which have not so many powers attached to them, capable of disturbing the fragments.

A fracture of the middle part of the long bone, is less dangerous, than a similar injury near a joint. Fractures near joints may occasion a false ankylosis. Thus, in a fracture of the thigh-bone, near the condyles, the inflammation and swelling extend to the knee-joint, which is affected with a

degree of stiffness that continues for a long while, and sometimes cannot be entirely cured during life. Besides, the inflammation of the joint is attended with more severe symptoms, in consequence of the contusion having been more violent. In a fracture near an articulation, it is to be observed, also, that the splints have no command over the short fragment, so that it is often difficult to prevent displacement. Hence, a fracture of the neck of the thigh-bone is considered a worse case, than a similar injury of the body of the bone.

When a bone is fractured in several places, the case is more serious, and the difficulty of cure much augmented. But, the accident is still worse, when a limb is fractured in two different places at once; as, for instance, in the thigh and leg. Here it is almost impossible to reduce the fracture of the thigh, and maintain the reduction well, so as to preserve the natural length of the limb. (*Boyer, Traité des Mal. Chir. T. 3. p. 29.*)

Oblique fractures are more troublesome, and difficult of cure, than transverse ones, because an oblique surface does not resist the retraction of the lower portion of the broken bone, and consequently it is very difficult to keep the ends of the fracture duly applied to each other.

Fractures complicated with violent contusion of the soft parts, or with a wound rendering them compound, are much more dangerous, than others free from such accidents. The bad symptoms, which render compound fractures so dangerous, are of many kinds: hemorrhage; violent and extensive inflammation of the limb, with extreme pain, delirium, and fever; large abscesses; gangrene; &c. Fractures of the leg are generally more serious, than similar injuries of the upper extremity. The wound of a large artery may add considerably to the danger of a fracture.

In a debilitated old man, a fracture is less likely to end well, than in a healthy child, or strong young subject. In extreme old age, the cure of a fracture is always more difficult, and sometimes impossible. (*Boyer, T. 3, p. 32.*) The scurvy certainly retards the formation of callus; but, it is not true that pregnancy always prevents the union of fractures. Some years ago, I attended for Mr. Ramsdens, a woman in a court, leading out of St. Paul's Church-yard, who broke both bones of her leg, when she was seven months gone with child. Her pregnancy, however, did not appear to be at all unfavourable to the cure, as she got quite well in the usual time. "It is not generally settled," says a modern writer, "whether pregnancy should be accounted a complication. I have, as well as some other practitioners, seen a pregnant woman get well of a simple fracture in the ordinary time." (*Leveillé, Nouvelle Doctrine Chir. T. 2, p. 159.*) And in another place he says, "*Contre l'opinion de Fabrice de Hilden, l'expérience m'a prouvé que, chez les femmes grosses, le cal était aussi prompt à se former, que chez toute autre personne.*" (*Op. cit. Tom. 2. p.*

172.) The experience of Boyer also tends to prove, that pregnancy is not unfavourable to the union of fractures. (*See Traité des Mal. Chir. T. 3, p. 32.*)

The cases in which fractures remain disunited, will be considered in a future section of the present article.

5. Treatment of Fractures in general.

The general treatment of fractures embraces three principal indications. The first is to reduce the pieces of bone into their natural situation. The second is to secure and keep them in this state. And the third is to prevent any unpleasant symptoms likely to arise, and relieve them when they have come on.

The first indication is only applicable to cases attended with displacement; for when the fragments are not out of their relative position, the surgeon must strictly refrain from all avoidable disturbance of the limb. His interference should then be limited to putting up the fracture, resisting the accession of all unfavourable symptoms, and removing them, if possible, after they have taken place.

6. Of the Reduction of Fractures.

The means employed for the reduction of fractures in general, are chiefly three, viz. *extension*; *counter-extension*; and *coaptation*, or *setting*. But as Boyer remarks, these means should vary according to the species of displacement; and surgical writers have generalized too much in representing them all three as necessary for the reduction of every kind of fracture. In fact, there are several cases, in which extension and counter-extension are positively useless: of this nature are fractures of the patella and olecranon, where the displacement consists of a separation of the fragments. Here the reduction may be accomplished, by putting the limb in a position, in which the muscles attached to the upper part of the bone are relaxed, and then pushing the upper fragment into contact with the lower.

Extension signifies the act of pulling the broken part in a direction from the trunk, with a view of bringing the ends of the fracture into their natural situation. By counter-extension, surgeons imply the act of making extension in the opposite direction, in order to hinder the limb, or even the whole body, from being drawn along by the extending power, which would then be unavailing.

It was formerly recommended to apply the extending force to the lower fragment, and the counter-extension to the upper one. Such practice, indeed, was advised by Mr. Pott, and is still generally preferred in this country; but upon the continent, it has been abandoned. The objections alleged against it by Boyer are; first, that it is frequently difficult and sometimes impossible, to take hold of the two fragments; as, for example, when the neck of the thigh-bone is broken. Secondly, that by applying the extension and counter-extension to the broken bone

itself, most of the muscles, which surround it, are compressed, and such compression produces in these organs a spasmodic contraction, which often renders the extension and counter-extension useless, and sometimes even hurtful. (*Traité des Mal. Chir. T. 3, p. 34.*) The French surgeons, therefore, apply the extending force to that part of the limb, which is articulated with the lower fragment, and the counter-extension to that which is articulated with the upper. For instance, in a fracture of the leg, the extending means act upon the foot, and the counter-extending upon the thigh; and in a fracture of the thigh, the extension is applied to the leg, while the counter-extending power fixes the pelvis.

One circumstance must here occur to the mind of the surgical reader. In this country, it is properly inculcated, that one of the first principles to be attended to in the reduction of fractures, is to put the limb in such a position as will relax the most powerful muscles connected with the broken bone; because these muscles principally impede the reduction, and disturb the ends of the fracture. But in the French mode of making the extension and counter-extension, how can this grand principle be observed? If the extending and counter-extending means are not to be applied to the broken bone itself; but to others, which are articulated with it, the limb must of necessity be kept in a straight posture at the time of reducing the fracture; for, were the member placed in a half-bent state, the extension and counter-extension, as practised by the continental surgeons, would not be in the same line. If, therefore, it be advantageous to bend the limb at the time of reducing a fracture, the French mode of practising extension and counter-extension must be relinquished. I am not, however, one of those surgeons, who are entirely blinded with the idea of the possibility of relaxing the whole of the muscles, connected with the broken bone, by merely bending the limb. On the contrary, I am perfectly convinced with Desault, that in general, what is gained by the relaxation of some muscles, is lost by the tension of others. But where it is possible to relax by a certain posture the set of muscles most capable of preventing the reduction and disturbing the coaptation of a fracture, that posture I would select. Thus, in a fracture of the leg, the strong muscles of the calf undeniably possess this power, and the bent position, which relaxes them, appears to me therefore the most judicious and advantageous, not only during the reduction, but during the whole treatment of the case. A few years ago, I had under my care, in the military hospital at Cambray, a fracture of the tibia and fibula, which was at first treated in the straight posture. The gentlemen who assisted me, reduced the fragments, and made them lie tolerably well. But every time the bandage was opened, the bones were always found displaced again. Finding that this inconvenience went on for two or three weeks, we resolved to lay the limb on its outside, in the

bent position. Not the least trouble was afterward experienced in keeping the fragments reduced. Unless, therefore, the situation of a wound, abscess, or some particular reason indicate an advantage or convenience from the straight posture, I always reduce a fractured leg in the best position, which will be hereafter described. Here, therefore, I consider the French mode of making the extension and counter-extension as generally inadmissible.

I was also formerly of opinion, that the bent position of the limb on its side, as advised by Mr. Pott, was the best for fractured thighs; but this sentiment has subsequently appeared to me erroneous, and it gives me pleasure to have this opportunity of declaring my entire conversion to the principles and practice adopted in these cases by Desault, and other eminent continental surgeons. The considerations which have led me to this change, will be related in speaking of fractured thighs. If then the straight posture be advantageous in cases of broken thighs, I think it will be universally allowed, that the parts of the limb, recommended by the French surgeons for the application of the extension and counter-extension, are the most proper.

The evils and difficulties formerly encountered in setting fractured limbs, undoubtedly proceeded in a great measure from the violent extension and counter-extension practised by our ancestors. As they were ignorant of the utility of relaxing the muscles, which displaced the ends of the broken bone, they had no means, but the employment of actual force, to effect the reduction. Since, however, the excellent instructions, contained in Mr. Pott's remarks on fractures, have received all the attention due to them, practitioners have generally been careful, in the reduction of fractures, to incapacitate the muscles as much as possible by relaxing them, and thus the necessity for the employment of violent extension and counter-extension is effectually removed.

It is difficult to lay down rules, respecting the precise degree of force which should be used in making extension; for it must vary in different cases, according to the species of displacement, and the number and power of the muscles concerned in producing it. In transverse fractures, displaced only according to the diameter of the bone, a very moderate extension suffices, as it is merely practised with a view of lessening the friction of the surfaces of the fracture, which are always more or less rough. But whatever be the direction of the fracture, when the fragments ride over each other, the extension and counter-extension must constantly be such as to remove the shortening of the limb, and overcome the force of those muscles, which, after all attention has been paid to their relaxation, still oppose the reduction. Extension, however, ought never to be practised in a violent and sudden way; but in as gradual a manner as possible, the utmost care being taken not to shake, nor even move the limb any more than can be avoided. When the practitioner extends a

broken member all at once violently, he excites the muscles to strong spasmodic action, and there is some danger of lacerating them, because their fibres are not allowed the requisite time to yield to the force, which elongates them. The extension is to begin in the direction of the lower fragment, and be continued in that, which is natural to the body of the bone.

In every case of fracture with displacement, as soon as the necessary extension has been made, the surgeon is to endeavour to place the ends of the broken bone in their natural situation: this is termed *coaptation*, or *setting*. This operation is to be undertaken in different ways, according to the species of displacement, and the practitioner can almost always execute it by acting upon the lower fragment, without applying his fingers directly to the fracture itself, in order to regulate the contact of the extremities of the bone. When, however, it is judged necessary for this purpose to touch the broken part itself, it should be done with the utmost gentleness, so as to avoid pressing the soft parts against the points and splinters of bone.

Although the reduction of fractures may in general be accomplished with tolerable facility, it sometimes happens, that the first attempts fail. This is occasionally ascribable to the employment of too much force, and too little management, in making the extension; so that the muscles are irritated, and act so powerfully, that the design of the surgeon is completely frustrated. Here, the grand means of success is putting the limb into such a position, as will relax the most powerful muscles, which oppose the reduction. Sometimes, however, the irritable and convulsive state of the muscles is not the effect of any wrong mode of proceeding on the part of the surgeon; but arises from the alarm, pain, and injury, caused by the accident itself. Here relaxing the muscles as much as possible is also the most likely method of removing the difficulty. In short, now that the utility of paying attention to this principle is universally known in the profession, a fracture is hardly ever met with, which cannot be immediately reduced; particularly if a copious bleeding be premised when the patient is a strong muscular subject. This evacuation, indeed, will also prove for other reasons highly beneficial, where the limb is much contused and swollen, and the tendency to inflammation is great.

7. Of the means for keeping Fractures reduced.

After the bones have been put into their natural situation, time alone would complete their cure, were there not in the muscles a continual propensity to displace the ends of the fracture again. In cases of fracture, these organs are often affected with involuntary spasmodic action, by which the broken part would certainly be displaced, were no measures taken to maintain the extremities of the broken bone in contact. Besides, the patient in easing himself, coughing, sneez-

ing, &c. must unavoidably subject the limb to a degree of motion by which the coaptation would be altogether destroyed. Hence, the necessity of employing means for fixing the broken limb so effectually, that it may continue perfectly motionless during the whole time requisite for the union of the fracture. This second indication is sometimes troublesome and difficult, and, as Boyer observes, it is in this part of the treatment, that the surgeon has an opportunity of evincing his skill and experience. The means employed for the fulfilment of this indication are, an advantageous position; quietude; bandages; splints; and various kinds of apparatus.

In the treatment of all fractures, the position of the part, and indeed of the whole body, is a thing of material importance. Whenever the case is a fracture of the lower extremities, the patient should lie strictly in bed, until the callus is completely formed. It is likewise an advantage not to have the bed much more than a yard wide, because the surgeon and assistants can then more conveniently get at any part of the limb. Feather beds are a great deal too soft and yielding: a horsehair mattress is far preferable. Boyer, indeed, is so impressed with the utility of letting the patient lie upon a surface, which will not sink, that he recommends two mattresses to be used, and a board to be laid under the upper one, from the hip to beyond the patient's foot. (*Traité des Mal. Chir.* p. 39, Vol. 3.)

The most favourable position for a fractured limb, is that, in which all the muscles, passing over the fracture, and extending either to the lower fragment, or to that part of the limb which is articulated with it, are equally relaxed. The injured limb should also have firm support at every point, and its position ought to be regulated so that not only this object be carefully fulfilled, but at the same time the chance of displacement from the action of the muscles, or the weight of the body, or part itself, may be diminished as much as possible.

The natural, or rather the most easy position of the limb, is that which is usually chosen by a person who reposes himself, or who is sleeping; for then all motion is suspended, and every part assumes that posture which is most congenial to it. In this condition, the limbs are not extended, nor yet entirely bent; but only in a moderate state of flexion. Hence, Boyer remarks, that a half-bent position of the limbs, is that which is most natural, and that in which all the muscles enjoy an equal degree of relaxation, and, consequently, that it is, generally speaking, the best for fractures. This posture, as Boyer observes, which was recommended by Hippocrates and Galen, has been highly extolled by Pott, who appears to have exaggerated its advantages. Considered in a general way, it is without contradiction preferable to every other position of the limb; but its employment should be liable to exceptions, as will be noticed in treating of parti-

cular fractures. (See *Boyer, Traité des Mal. Chir. T. 8, p. 40.*)

In whatever position a broken limb is placed, (says this writer,) it should bear throughout its whole length equally and perpendicularly upon the surface on which it lies, and not be only partially supported. When, for example, only the extremities of a fractured limb rest upon the bed, the weight of the limb itself will make it bend in the situation of the fracture. The limb will also be rendered crooked, if the broken part be supported, while the extremities of the limb (especially the inferior) sink lower by their own weight. The displacement of the fracture is not the only inconvenience arising from the limb being laid upon a surface where it is not every where equally well supported. The parts which do bear on this surface, experience a painful degree of pressure, which, if long continued, is apt to produce inflammation, and even sloughing of the integuments. Thus, in fractures of the leg, gangrene of the heel has sometimes arisen entirely from this cause. Such inconveniences may be prevented by laying a fractured limb on a surface of corresponding form; that is to say, on a surface which is depressed where the limb has projections, and rises where it presents depressions. The surface should not be so hard as to annoy the patient, but yet it ought to be sufficiently firm not to yield to the weight of the limb and apparatus. According to Boyer, the best pillows for the support of broken limbs, are stuffed with chaff of oats, a substance which he describes as far preferable to feathers, because it more readily admits of being pushed from the place where the limb is prominent to another situation where the member presents a depression, or hollow; and it has the advantages of being less heating than feathers, and less apt to spoil.

In whatever position fractured limbs are placed, they ought to be kept perfectly quiet during the whole time requisite for the union. If the broken bone be moved while the callus is forming, the surfaces of the fracture rub against each other, and the process is disturbed; and, indeed, sometimes by repeatedly moving the limb, the consolidation of fractures is entirely prevented, or, at least, rendered very slow and difficult.

In order to maintain the limb in the right position, and in a state of quietude, and to preserve the fragments in proper contact with respect to each other, the surgeon is to caution the patient to avoid moving at all more than can be helped, and every cause likely to subject the limb to any kind of shock, or concussion, is to be removed. But, in particular, it will be necessary to apply a retentive apparatus, usually consisting of some application to the skin itself, bandages, splints, tapes, straps, and buckles, soft pads, &c. (See *Boyer, Traité des Mal. Chir. T. 3, p. 42.*)

Upon the subject of the dressings, bandages, &c. which ought to be applied to fractures, no surgeon has written better than Mr. Pott.

"The intention (says he) in applying any kind of external medicine to a broken limb, is, or ought to be, to repress inflammation, to disperse extravasated blood, to keep the skin lax, moist, and perspirable, and at the same time to afford some, though a very small degree of restraint or confinement to the fracture, but not to bind or press; and it should also be calculated as much as possible to prevent itching, an herpetic eruption, or an erysipelatous efflorescence. At St. Bartholomew's hospital, we use a cerate made by a solution of litharge in vinegar, which, with soap, oil, and wax, is afterward formed into such consistence as just to admit being spread without warming.

"This lies very easy, repels inflammation, is not adherent, comes off clean, and very seldom, if ever, irritates, or causes either herpes or erysipelas. But let the form and composition of the application made to the limb be what it may, one thing is clear, viz. that it should be put on in such manner, as that it may be renewed and shifted as often as may be necessary, without moving the limb in any manner: it being certain, that when once a broken thigh or leg has been properly put to rights, and has been deposited properly on the pillow, it ought not ever to be lifted up or moved from it again without necessity, until the fracture is perfectly united; and it is true, that such necessity will not very often occur."

Such application having been made as the surgeon thinks right, the next thing to be done is to put on a proper bandage.—That formerly used was what is commonly called a roller. This was of different lengths according to the surgeon's choice, or as it was used in the form of one, two, or more pieces.

"By such kind of bandage three intentions are aimed at, and said to be accomplished, viz. to confine the fracture, to repress or prevent a flux of humours, and to regulate the callus, (see *Duverney*;) but whoever will reflect seriously on this matter, will soon be convinced, that although some sort of bandage is necessary in every simple fracture, as well for preserving some degree of steadiness to the limb, as for the retention of the applications, yet none, nor either of these three ends can be answered merely, or even principally, by bandage of any kind whatever: and therefore, if this should be found to be true, that is, if it should appear, that whatever kind of deligation be made use of, it cannot be a principal, but only an accessory kind of assistance, and that in a small degree, and very little to be depended upon, it will follow that such kind of bandage as is most difficult to be applied with justness and exactitude, such as is soonest relaxed and out of order, such as stands most frequently in need of renewal, and, in such renewal, is most likely to give pain and trouble, must be more improper and less eligible, than one which is more easily applied, less liable to be out of order, and which can be adjusted without moving the limb, &c.

"The best and most useful bandage for a simple fracture of the leg or thigh, is what is

commonly known by the name of the eighteen-tailed bandage, or rather one made on the same principle, but with a little difference in the disposition of the pieces. The common method is to make it so, that the parts which are to surround the limb make a right angle with that which runs lengthways under it; instead of which, if they are tacked on so as to make an acute angle, they will fold over each other in an oblique direction, and thereby sit more neatly and more securely, as the parts will thereby have more connexion with and more dependence on each other. In compound fractures, as they are called, every body sees and acknowledges the utility of this kind of bandage preferably to the roller, and for very obvious and convincing reasons, but particularly because it does not become necessary to lift up and disturb the limb every time it is dressed, or every time the bandage loosens.

"The pain attending motion in a compound fracture, the circumstance of the wound, and the greater degree of instability of parts thereby produced, are certainly very good reasons for dressing such wound with a bandage which does not render motion necessary; but I should be glad to know what can make it necessary, or right, or eligible, to move a limb in the case of simple fracture? what benefit can be proposed by it? what utility can be drawn from it? When a broken bone has been well set, and the limb well placed, what possible advantage can arise from moving it? surely none; but, on the contrary, pain and probable mischief. Is it not the one great intention, to procure union? Can moving the limb every two or three days contribute to such intention? must it not, on the contrary, obstruct and retard it? Is not perfect quietude as necessary toward the union of the bone, in a simple as in a compound fracture? It is true, that in the one there is a wound which requires to be dressed, and the motion of the limb may in general be attended with rather more pain than in the other; but does motion in the simple fracture give ease, or procure more expeditious union?

"Every benefit then which can be supposed to be obtained from the use of the common bandage or roller, is equally attainable from the use of that which I have just mentioned, with one additional, and, to the patient, most invaluable advantage, viz. that of never finding it necessary to have his leg or thigh once, during the cure, removed from the pillow on which it has been properly deposited. In short, to quit reasoning and speak to fact, it is the constant practice at St. Bartholomew's, and attended with all possible success. We always use the eighteen-tailed bandage; and never move the limb to renew or adjust it." (*Pott's Remarks on Fractures, &c.*)

In France, an universal preference is given to Scultetus's bandage in every instance where we employ the eighteen-tailed one, from which it chiefly differs in being composed of separate pieces admitting of removal, so that when a part of the bandage is

soiled, it can be taken away, without disturbing the whole of the dressings. The clean pieces are first stitched to those which are about to be removed, and then they are drawn under the part. In cases of compound fracture, where the bandage is soiled with the discharge in a very short time, and must be often removed, certainly Scultetus's bandage is the best, particularly as it possesses all the recommendations peculiar to that of the eighteen-tailed kind. (*Boyer, Traité des Mal. Chir. T. 3, p. 46.*)

With respect to the general objects and uses of bandages in cases of fracture, I ought to notice one design of them, which is strongly inculcated in the modern French schools: namely, that of "benumbing the irritability of the muscles" by the compression resulting from their regular and even application to the whole of the member. In describing the treatment of particular fractures, I shall have occasion to advert to the examples in which a moderate general compression of the muscles may be attended with utility.

"The parts of the general apparatus for a simple fracture, which come next in order, (observes Mr. Pott,) are the splints;" which are unquestionably the most efficient of all the applications made to a broken limb, with a view of keeping the ends of the fracture steady and in a proper state of contact. Without them, the surgeon would in vain endeavour to maintain the reduction.

"Splints," says Pott, "are generally made of pasteboard, wood, or some resisting kind of stuff, and are ordered to be applied lengthways on the broken limb; in some cases three, in others four; for the more steady and quiet detention of the fracture.

"That splints, properly made and judiciously applied, are very serviceable, is beyond all doubt; but their utility depends much on their size, and the manner in which they are applied.

"The true and proper use of splints is to preserve steadiness in the whole limb, without compressing the fracture at all. By the former they become very assistant to the curative intention; by the latter they are very capable of causing pain and other inconveniences; at the same time that they cannot, in the nature of things, contribute to the steadiness of the limb.

"In order to be of any real use at all, splints should, in the case of a broken leg, reach above the knee and below the ankle; should be only two in number, and should be so guarded with tow, rag, or cotton, that they should press only on the joints, and not at all on the fracture.

"By this they become really serviceable; but a short splint, which extends only a little above and a little below the fracture, and does not take in the two joints, is an absurdity, and, what is worse, it is a mischievous absurdity.

"By pressing on both joints, they keep not only them but the foot steady; by pressing on the fracture only, they cannot retain it in its place if the foot be in the smallest degree displaced; but they may, and fre-

quently do, occasion mischief, by rudely pressing the parts covering the fracture against the edges and inequalities of it.

"In the case of a fractured os femoris, if the limb be laid in an extended posture, one splint should certainly reach from the hip to the outer ankle, and another, (somewhat shorter) should extend from the groin to the inner ankle. In the case of a broken tibia and fibula, there never can be occasion for more than two splints, one of which should extend from above the knee to below the ankle on one side, and the other splint should do the same on the other side. (See *Remarks on Fractures and Dislocations*, in *Pott's Chirurgical Works*, Vol. 1, p. 298, &c. Edit. 1808.)

Assalini strongly disapproves of the employment of all tight bandages, and of covering the whole of a broken limb with splints. He was called to a gentleman of rank at Paris, who had broken the knee-pan transversely. He laid the limb upon a concave splint, which was adapted in shape to the under surface of a part of the leg and thigh. No bandage was used, merely two leather straps, which crossed upon the knee, and included the fractured bone. A perfect bony union was thus easily effected. Assalini afterward extended the use of a concave splint, applied under the limb, to fractures of the leg and thigh. In the first of these cases, however, only the thigh is received in the hollow splint, and from this two branches, or lateral splints, go along the leg. The apparatus has also a kind of sole for the support of the foot. As this simple contrivance is fastened with a very few straps, and no plasters or bandages are used, the surgeon has constantly a view of the whole front of the limb, and of the fractured part of it, which Assalini thinks a great advantage. In compound fractures, he puts no other dressings on the wound but linen compresses, which are kept continually wet with cold water. (*Manuale di Chirurgia, parte prima*, 1812.) For further observations on the subject, see *Splint*.

In oblique fractures of the thigh, and sometimes even in those of the leg, the difficulty of accomplishing by the ordinary means a cure free from deformity, and especially without a shortening of the limb, has led to the idea of employing continual extension. This expression implies the operation of a bandage, or machine, which continually draws the fragments of the broken bone in contrary directions, at the same time that it restrains them from gliding over each other, and maintains them in contact during the whole time necessary for their union. In England this practice has long been relinquished. It appears to have been chased away by the dazzling theory of relaxing every muscle in such manner as to render it incapable of displacing an oblique fracture; a theory with which the surgeons of this country were but too much blinded by the persuasive eloquence of the late Mr. Pott. Desault saw at once, however, every inconsistency in the doctrine of relaxing the

muscles so as to incapacitate entirely the whole set connected with a broken thigh; and he never ceased to inculcate in his school, that, in such cases, the assistance of the mechanical apparatus applied to the limb was the main thing by which the shortening of the limb was to be prevented. When we consider the treatment of fractured thighs, we shall find, that the best apparatus for these cases partly produces its good effect by continual, though moderate extension. Perhaps, also, these are the only instances in which an advantageous position will not generally do away all occasion for this method, to which many surgeons appear to entertain strong but highly exaggerated objections.

By means of continual extension, (observes Boyer) we not only succeed in uniting the fracture, while the limb preserves its natural length, but we afford the part a steadiness which is singularly favourable to the formation of the callus.

In order to derive from continual extension the utmost benefit, and render the method as little painful as possible, and supportable during the whole time of treatment, the machines and bandages, according to Boyer, should be constructed and applied conformably to the following rules.

We should avoid compressing the muscles which pass over the situation of the fracture, and the elongation of which organs is necessary to restore to the limb the length which it has lost by the gliding of the fragments over each other.

With this view, the extending power ought to be applied to that part of the limb which is articulated with the lower head of the fractured bone; and the counter-extending force to that which is articulated with the upper head. If these powers were applied to the broken bone itself, the muscles passing over the fracture would suffer such compression as would excite spasm, and render the continual extension ineffectual and even hurtful.

The extending and counter-extending force ought to be divided upon as large surfaces as possible.

The reason of this rule is obvious. The pressure of external bodies on parts is less painful in proportion as the surface pressed upon is extensive, and the operation supported at once by numerous points. On this principle, a narrow band creates stronger and more painful pressure than a broad one; and hence the rollers, and other pieces of the apparatus for making the extension and counter-extension, should be as wide as possible.

The powers, making continual extension, should act according to the direction of the axis of the broken bone.

The continual extension should be practised in as slow, gradual, and insensible a manner as possible.

The muscles easily yield to a force which stretches them, when such force acts slowly, and is very gradually increased, according to the shortness of the limb and the power

of the muscles producing the displacement. But if one were all on a sudden to begin with making violent extension, the rough forced elongation of the muscles would excite such a spasmodic action of them, as would frustrate every attempt to restore the natural length of the limb. And if, in order to fulfil this purpose the extending force were increased in a ratio to the resistance of the muscles, there would be danger of lacerating these organs, because their fibres would not have time enough to yield.

Lastly; the parts upon which the extending and counter-extending force acts should be defended; and the compression, made by the tapes or other pieces of the bandage and apparatus, ought to be equalized.

These indications may be fulfilled by covering the parts on which the tapes and bandages press, with tow or wool pads; and by filling up all the depressions of the limb with the same soft substances, so as to give it a circular form. The bandages will then not hurt the most projecting parts, on which they would make a strong and injurious degree of pressure, if the depressions were not artificially filled up.

By observing these rules, says Boyer, continual extension may always be borne even by the most delicate and irritable patients; and the important advantage will be obtained of curing the fracture, with the proper length of the limb preserved. (*Traité des Mal. Chir. T. 3, p. 56, 59.*)

8. *Means for preventing and removing the unfavourable Symptoms liable to arise from Fractures.*

After having reduced the fracture; applied a suitable apparatus for maintaining the reduction; and put the part in an advantageous position; the practitioner is to attend to the third indication in the treatment, viz. the prevention and removal of any unfavourable symptoms.

With the exception of a few simple fractures of the upper extremity, it is proper in all cases to allow for the first few days only very low diet, broths, tea, &c. When the patient is young and strong, and the swelling and inflammation are likely to be considerable, venesection should be practised. In other circumstances, it may in general be dispensed with, because it is well known, that for the quick formation of the callus, by which the fracture is to be united, strength and a vigorous circulation are highly favourable. The patient may be permitted to drink as often, and as much as he likes, of any cooling acid beverage. A very low diet is only to be continued the first few days, unless great inflammation arise; for experience proves that the method, when too much prolonged, has bad effects, and tends, on the same principle as bleeding, to retard the union of the fracture.

Costiveness is to be averted by the use of clysters and mild aperient medicines. It must be confessed, that, in fractures of the lower extremity, the disturbance of the limb caused by the patient's being obliged to

move himself, after taking a purgative, is seriously objectionable; but, perhaps, in all, and certainly in some habits, a neglect to open the bowels soon after the accident, would have still more pernicious consequences. In order, however, to lessen the disturbance, a bed-pan should be carefully introduced under the patient. Here, also, I feel it my duty to recommend to the notice of the profession a very complete fracture-bed invented by my friend, Mr. Earle. One great convenience of this bed, the cost of which is moderate, is to enable the patient to void his feces without the slightest change of position or disturbance; an object effected by the simple contrivance of a little kind of trap, opening under the bed, out of which a small portion of the mattress admits of being withdrawn, and a tin receptacle is placed for the reception of what is voided from the bowels and bladder. Some other advantages of this apparatus will be hereafter briefly mentioned.

With respect to external applications, we should carefully avoid using all such plasters and ointments as irritate the skin or create a disagreeable itching; for they sometimes bring on erysipelas. The emplastrum saponis in common use is the best for all simple fractures, and it is the best, rather because it does no harm than because it does any essential good. It is, generally speaking, a good plan for the first few days to wet the bandages with cold water; for in this way, the tendency to inflammation and swelling may be considerably lessened. The surgeon, however, should recollect, that the bandage shrinks when wet, and may become so tight as to do harm, if not attended to. Solutions of the acetate of lead, and other salts, make bandages stiff and hard; and as they are perhaps not more efficacious than cold water alone, the latter is sometimes preferred in cases of fracture.

When a fracture is well set, the position of the part right, and the bandage and splints neither too tight nor too slack, the less the broken bone is moved, and the less the apparatus and dressings are disturbed, the better. Sometimes, however, the practitioner is obliged to take off the splints, and undo the bandage, in order to ascertain that the ends of the fracture lie in even contact. Were he to leave the splints on the part ten days, or a fortnight, without ever being sure of this important point, he might find, when too late for alteration, that the fracture was in a state of displacement, and the limb seriously deformed. Hence a strong reason for employing the eighteen-tailed bandage, which admits of being opened without disturbing the limb, or even without lifting it from the surface upon which it has been deposited.

In fractures of the lower extremities, particularly of the legs, it sometimes happens, the first two or three nights after the reduction, that the limb is affected with convulsive spasms and cramps, which make the patient start out of his sleep, and displace the

ends of the bone, which must be again reduced.

When the callus has acquired some firmness, the patient should still keep the part or limb quiet, until the union is perfectly consolidated. And, in fractures of the lower extremity, even after the union has proceeded so far, that the splints admit of being left off, the patient ought not to venture to get out of bed, or bear upon the limb, till several more days have elapsed.

All fractures, however simple and well treated they may be, are constantly followed by weakness and stiffness of the limb. These unpleasant consequences are the greater, the more violently the limb has been contused, the nearer the fracture is to a joint, and the longer the part has remained motionless, and without exercise. The stiffness always affects the inferior joint of the broken bone, much more than the superior. For the relief of these effects of fractures, it is customary to employ friction, liniments, emollient relaxing applications, cold washes and bathing; but, sometimes, notwithstanding such remedies, the member does not quickly recover its strength, but continues stiff and weak for a year, or even a longer time. The most effectual plans for the prevention of this state should therefore be resorted to early. These consist in making the joints, nearest the fracture, execute slight motions, as soon as the union is sufficiently advanced, not to be in danger of interruption from this practice. A great deal of caution, however, is necessary in moving the part, and it is safer for the surgeon to superintend the business himself, than leave it to the patient or others. One of the best proceedings also for the hinderance of much weakness and stiffness in the limb after a fracture, is to discontinue the splints and tight bandages, immediately the state of the callus will allow. The manner, in which their pressure retards the circulation, and prevents the action of the muscles, is one of the principal causes of the stiffness of the limb, and, consequently, the sooner they can be safely left off, the sooner will the patient regain the free use of the limb.

In France, the chief division of fractures is into *simple* and *complicated*, which last includes among many varieties the cases, which we name *compound*. We shall here briefly notice a few of the complications, and the particular treatment which they require.

Fractures (says Boyer) are always attended with a certain degree of contusion, which is constantly more severe in cases where the violence has acted directly on the situation of the fracture. But, such contusion can only be regarded as a complication of the accident, when it exists in so violent a degree as to demand a different treatment from that which is employed in simple fractures.

In this circumstance, the splints and bandage should be applied rather slackly, and the latter ought to be wet with cold water, or some resolvent lotion. The patient is to

be bled more or less freely, according to his age, the state of his constitution, and violence of the contusion. The next day, the splints and bandage should be opened; a thing highly necessary to be observed; for, where it has been neglected, the limb has been known to mortify, in consequence of the swelling having rendered the bandage too tight, so that the circulation was impeded. (*Boyer, Traité des Mal. Chir. T. 3, p. 63—64.*)

In cases where the contusion is very great, but unattended with a wound of the integuments, the tension and swelling may be so intense, that the cuticle is detached, forming vesicles filled with yellowish serum. These vesicles may deceive an inexperienced surgeon, and lead him to imagine that the limb is threatened or actually affected with gangrene. They ought to be punctured, and covered with pledgets of simple ointment. Here some practitioners apply emollient poultices under the apparatus; but, there is some inconvenience in their use, and it may be questioned, whether cold lotions are not generally better.

In simple fractures, it does not often happen, that a large artery is wounded; but, when the injury does occur, and a diffused aneurism takes place, the surgeon is to expose the vessel by an incision, and apply a ligature above and below the opening. We are to be careful, however, before resorting to the operation, that the tumour is not a venous extravasation, which may almost always be dissipated by resolvent applications.

Fractures are sometimes complicated with a dislocation. Here, if possible, the luxation should invariably be reduced before the fracture is set. The possibility of reducing the dislocation (says Boyer) depends upon the species of articulation, the situation of the fracture, and other circumstances of the case. When it is a ginglymoid joint, when the ligaments are lacerated, and the swelling is not considerable, the luxation may be reduced easily enough; but, when it is an orbicular joint, surrounded by numerous muscles; and when the fracture is near the articulation, and situated below the dislocation; the reduction of the latter is impossible. The attempt indeed would be injurious, because the necessary extension could not act upon the upper fragment, and were it to operate upon the lower, it could only have the effect of painfully stretching the muscles, and perhaps lacerating them. The fracture, therefore, should be at first attended to, and after its firm union, an endeavour may be made to rectify the dislocation. Boyer conceives, that there will be more probability of success, when care is taken to move the limb gently, as soon as the state of the callus will permit it. He also recommends the employment of emollient relaxing applications. He confesses, however, that the attempt rarely succeeds after the perfect union of the fracture. There are, it is true, examples, in which old dislocations may be reduced; but, these are cases, which

are not complicated with a fracture, an accident, which always renders the muscles and ligaments so stiff, that they cannot yield to the extension requisite for the reduction. "I do not know, (says Boyer,) that a luxation, complicated with fracture, has ever been reduced, when the nature of the joint, and the circumstances of the case, prevented the treatment from beginning with the reduction of dislocation." (*Traité des Mal. Chir. T. 3, p. 79.*)

COMPOUND FRACTURES.

What Mr. Pott has said upon these cases is, with one or two exceptions, to which I shall advert, the essence of good surgery, not in the least deteriorated, as a few other parts of his precepts have been, by the more mature instructions of time and experience, or by that growing state of surgical science, which, fostered by genius and observation, is continually bringing to light new facts.

"In a compound fracture," says Mr. Pott, "the first object of consideration is, whether the preservation of the fractured limb can, with safety to the patient's life, be attempted; or, in other words, whether the probable chance of destruction, from the nature and circumstances of the accident, is not greater than it would be from the operation of amputation. Many things may occur to make this the case. The bone, or bones, being broken into many different pieces, and that for a considerable extent, as happens from broad wheels, or other heavy bodies of large surface, passing over, or falling on such limbs; the skin, muscles, tendons, &c. being so torn, lacerated, and destroyed, as to render gangrene and mortification the most probable and most immediate consequence; the extremities of the bones forming a joint being crushed, or as it were comminuted, and the ligaments, connecting such bones, being torn and spoiled, are, among others, sufficient reasons for proposing and for performing immediate amputation. Reasons, which (notwithstanding any thing that may have been said to the contrary) long and reiterated experience has approved, and which are vindicable upon every principle of humanity, or chirurgic knowledge.

"When a surgeon says, that a limb, which has just suffered a particular kind of compound fracture, ought rather to be cut off, than that any attempt should be made for its preservation, he does not mean by so saying, that it is absolutely impossible for such limb to be preserved at all events; he is not to be supposed to mean so much in general, though sometimes even that will be obvious; all that he can truly and justly mean is, that from the experience of time it has been found, that the attempts to preserve limbs so circumstanced, have most frequently been frustrated by the death of the patients, in consequence of such injury; and that from the same experience it has been found, that the chance of death from amputation is by no means equal to that arising from such kind of fracture.

"Every man knows, that apparently desperate cases are sometimes cured; and that limbs so shattered and wounded, as to render amputation the only *probable* means for the preservation of life, are now and then saved. This is an uncontroverted fact, but a fact which proves very little against the common opinion; because every man of experience also knows, that such escapes are very rare, much too rare to admit of being made precedents, and that the majority of such attempts fail.

"This consideration relative to amputation is of the more importance, because it most frequently requires immediate determination; every minute of delay is, in many instances, to the patient's disadvantage; and every short space of time indeed, frequently makes all the difference between probable safety and fatality. If these cases in general would admit of deliberation for two or three days, and during that time such circumstances might be expected to arise, as ought necessarily to determine the surgeon in his conduct, without adding to the patient's hazard, the difference would be considerable; the former would not seem to be so precipitate in his determination, as he is frequently thought to be; and the latter, being more convinced of the necessity, would submit to it with less reluctance. But, unhappily for both parties, this is seldom the case; and the first opportunity having been neglected or not embraced, we are frequently denied another. Here therefore, the whole exertion of a man's judgment is required, that he may neither rashly and unnecessarily deprive his patient of a limb, nor, through a false tenderness and timidity, suffer him to perish, by endeavouring to preserve such limb. Some degree of address is also necessary upon such occasions, in order to convince the patient, that what seems to be determined upon hastily and with precipitation, will not safely admit of longer deliberation.

"The limb being thought capable of preservation, the next consideration is the reduction of the fracture. The ease or difficulty attending this, depends not only on the general nature of the case, but on the particular disposition of the bone with regard to the wound.

"If the bone be not protruded forth, the trouble of reducing and of placing the fracture in a good position, will be much less than if the case be otherwise: and in the case of protrusion or thrusting forth of the bone or bones, the difficulty is always in proportion to the comparative size of the wound, through which such bone has passed. In a compound fracture of the leg or thigh, it is always the upper part of the broken bone, which is thrust forth. If the fracture be of the transverse kind, and the wound large, a moderate degree of extension will in general easily reduce it; but if the fracture be oblique, and terminates, as it often does, in a long sharp point, this point very often makes its way through a wound no longer than just to permit such extension.

In this case, the very placing the leg in a straight position, in order to make extension, obliges the wound or orifice to gird the bone tight, and makes all that part of it, which is out of such wound, press hard on the skin of the leg underneath it. In these circumstances, all attempts for reduction in this manner will be found to be impracticable; the more the leg is stretched out, the tighter the bone will be begirt by the wound, and the more it will press on the skin underneath.

"Upon this occasion, it is not very unusual to have recourse to the saw, and by that means to remove a portion of the protruded bone.

"I will not say that this is always or absolutely unnecessary or wrong, but it most certainly is frequently so. In some few instances, and in the case of extreme sharp-pointedness of the extremity of the bone, it may be, and undoubtedly is right: but, in many instances, it is totally unnecessary.

"The two most proper means of overcoming this difficulty are, change of posture of the limb, and enlargement of the wound. In many cases, the former of these, under proper conduct, will be found fully sufficient; and where it fails, the latter should always be made use of. Whoever will attend to the effect, which putting the leg or thigh (having a compound fracture and protruded bone) into a straight position always produces; that is, to the manner in which the wound in such position girds the bone, and to the increased difficulty of reduction thereby induced, and will then, by changing the posture of such limb from an extended one, to one moderately bent, observe the alteration thereby made, in both the just-mentioned circumstances, will be satisfied of the truth of what I have said, and of the much greater degree of ease and practicability of reduction in the bent, than in the extended position; that is, in the relaxed than in the stretched state of the muscles." Reduction being found impracticable, either by extension or change of posture, Mr. Pott recommends an enlargement of the wound.

"If the bone be broken into several pieces, and any of them be either totally separated, so as to lie loose in the wound, or if they be so loosened and detached, as to render their union highly improbable, all such pieces ought to be taken away; but they should be removed with all possible gentleness, without pain, violence, or laceration, without the risk of hemorrhage, and with as little poking into the wound as possible. If the extremities of the bone be broken into sharp points, which points wound and irritate the surrounding parts, they must be removed also. But the whole of this part of the treatment of a compound fracture should be executed with great caution; and the practitioner should remember, that if the parts surrounding the fracture be violated, that is, be torn, irritated, and so disturbed as to excite great pain, high inflammation, &c. it is exactly the same thing to the patient, and to the event of the case, whether such violence be the

necessary consequence of the fracture, or of the unnecessary, and awkward manner of poking into, and disturbing the wound. The great objects of fear and apprehension in a compound fracture, (that is, in the first or early state of it) are pain, irritation, and inflammation; these are to be avoided, prevented, and appeased by all possible means, let every thing else be as it may be; and although certain things are always recited, as necessary to be done, such as removal of fragments of bone, of foreign bodies, &c. &c. yet it is always to be understood, that such acts may be performed without prejudicial or great violence, and without adding at all to the risk or hazard necessarily incurred by the disease.

"Reduction of, or setting a compound fracture, is the same as in the simple; that is, the intention in both is the same, viz. by means of a proper degree of extension to obtain as apt a position of the ends of the fracture, with regard to each other, as the nature of the case will admit, and thereby to produce as perfect and as speedy union as possible.

"To repeat in this place what has already been said under the head of Extension would be tedious and unnecessary. If the arguments there used for making extension with the limb so moderately bent as to relax the muscles, and take off their power of resistance, have any force at all, they must have much more when applied to the present case; if it be allowed to be found very painful to extend, or to put or to keep on the stretch, muscles which are not at all, or but slightly wounded, and only liable in such extension to be pricked and irritated, it is self-evident, that it must be much more so when the same parts are torn and wounded." After a few additional observations, in praise of the good effects of relaxing the muscles, Mr. Pott proceeds:—

"The wound dilated, (if necessary) loose pieces removed, (if there were any) and the fracture reduced in the best possible position, the next thing to be done is to apply a dressing."

When Mr. Pott wrote on this subject, the plan of bringing the edges of the wound together with adhesive plaster, in cases of compound fracture, had not been established; and the advantage of this mode of dressing in the first instance was not duly known. I do not mean the practice of drawing the edges of the wound forcibly together with strips of plaster, nor of encircling and compressing the part with the same; but only the method of applying two or three short pieces of plaster, so as lightly and gently to retain the opposite sides of the wound in contact, and afford them an opportunity of uniting by the first intention. Now, although such attempt will frequently fail, on account of the wound being generally in a contused, irregular, and lacerated state, the chance of success should be taken, because the experiment at all events will occasion no harm, and if it answer, it will change the case at once from a fracture with an open wound to

one, which has no external communication, or, as might almost be said, from a compound into a simple fracture. Some of the following directions, therefore, given by Mr. Pott, I consider in the present state of surgery as only applicable when the wound has suppurated.

"The dressing necessary in a compound fracture, is of two kinds, viz. that for the wound, and that for the limb. By the former, we mean to maintain a proper opening for the easy and free discharge of gleet, sloughs, matter, extraneous bodies, or fragments of bone, and this in such manner, and by such means, as shall give the least possible pain or fatigue, shall neither irritate by its qualities, nor oppress by its quantity, nor by any means contribute to the detention or lodgment of what ought to be discharged. By the latter, our aim should be the prevention or removal of inflammation, in order, if the habit be good, and all other circumstances fortunate, that the wound may be healed, by what surgeons call the first intention, that is, without suppuration or abscess; or, that not being practicable, that gangrene and mortification, or even very large suppuration may be prevented, and such a moderate and kindly degree of it established as may best serve the purpose of a cure. The first, therefore, or the dressing for the wound, can consist of nothing better, or indeed so good, as soft dry lint, laid on so lightly as just to absorb the sanies, but neither to distend the wound, or be the smallest impediment or obstruction to the discharge of matter. This lint should be kept clear of the edges, and the whole of it should be covered with a pledget spread with a soft easy digestive. The times of dressing must be determined by the nature of the case; if the discharge be small or moderate, once in twenty-four hours will be sufficient; but if it be large, more frequent dressing will be necessary, as well to prevent offence, as to remedy the inconveniences arising from a great discharge of an irritating sharp sanies.

"The method of treating the limb, with a view to the prevention of such accidents and symptoms, as pain, inflammation, and laceration of parts, are likely to produce, is different with different practitioners; some using from the very first, relaxing, greasy applications; others applying medicines of very different nature. Both these may be right conditionally, that is, according to different circumstances in the case, but they cannot be equally so in the same circumstances.

"When from neglect, from length of time passed without assistance, from misconduct or drunkenness in the patient, from awkwardness and unhandiness in the assistants, or from any other cause, a tension has taken possession of the limb, and it is become tumid, swollen, and painful, Mr. Pott admits, that a warm cataplasm is the most proper application that can be made: immediate union is impossible, and every thing which can tend toward relaxing the tense, swollen, and irritable state of the parts concerned,

must necessarily be right. But when the parts are not in this state, the intention seems to be very different. To relax swollen parts, and to appease pain and irritation by such relaxation, is one thing; to prevent inflammatory defluxion and tumefaction, is certainly another; and they ought to be aimed at by very different means. In the former, a large suppuration is a necessary circumstance of relief, and the great means of cure; in the latter it is not, and a very moderate degree of it is all that is required. The warm cataplasm, therefore, although it be the best application that can be made use of in the one case, is certainly not so proper in the other, as applications of a more discutient kind, such as mixtures of spirit. vini, vinegar and water, with the muriate of ammonia, liquor ammoniæ acetatæ, liquor plumbi acetatis, and medicines of this class, in whatever form the surgeon may choose. By these, in good habits, in fortunately circumstanced cases, and with the assistance of what should never be neglected, (I mean *palebotomy**) and the general antiphlogistic regimen,) inflammation may sometimes be kept off, and a cure accomplished, without large collections or discharges of matter, or that considerable degree of suppuration, which though necessary in some cases, and almost unavoidable in others, are and must be rather promoted and encouraged, than retarded, or prevented, by warm relaxing applications of the poultice kind.

"Compound fractures in general require to be dressed every day; and the wounded parts not admitting the smallest degree of motion without great pain, perfect quietude becomes as necessary as frequent dressing.

"The common bandage therefore (the roller) has always in this case been laid aside, and what is called the eighteen-tailed bandage substituted very judiciously in its place.

"Splints of proper length, which reach from joint to joint, comprehend them both, and are applied on each side of the leg only, are very useful both in the simple and in the compound fracture, as they may, thus applied, be made to keep the limb more constantly steady and quiet than it can be kept without them."

Mr. Pott then enters into the consideration of the posture of the limb, which "is so principal a circumstance, that without its concurrence every other will be fruitless. The points to be aimed at are, the even position of the broken parts of the bone, and such disposition of the muscles surrounding them, as is most suitable to their wounded, lacerated state, as shall be least likely to irritate them, by keeping them on the stretch, or to produce high inflammation, and at best large suppuration."

According to Mr. Pott, these cases, of all others, require at first the most rigid observance of the antiphlogistic regimen: pain is to be appeased, and rest obtained, by ano

* At present, bleeding is not frequently practised except on young plethoric persons, and out of large cities.

dynes; inflammation is to be prevented or removed, by bleeding and aperient medicines. —And during the first state or stage, the treatment of the limb must be calculated, either for the prevention of inflammatory tumefaction, by discutients; or, such tumour and tension having already taken possession of the limb, warm fomentation, and relaxing and emollient medicines are required.

"If these, according to the particular exigence of the case, prove successful, the consequence is, either a quiet easy wound, which suppurates very moderately, and gives little or no trouble; or a wound, attended at first with considerable inflammation, and that producing large suppuration, with great discharge, and troublesome formation and lodgment of matter. If, on the other hand, our attempts do not succeed, the consequence is gangrene and mortification.

"These are the three general events or terminations of a compound fracture, and according to these must the surgeon's conduct be regulated.

"In the first instance, he has indeed nothing to do but to avoid doing mischief, either by his manner of dressing, or by disturbing the limb. Nature let alone, will accomplish her own purpose; and art has little more to do than to preserve the due position of the limb, and to take care that the dressing applied to the wound proves no impediment.

"In the second stage, that of formation and lodgment of matter, in consequence of large suppuration, all a surgeon's judgment will sometimes be required in the treatment both of the patient and his injured limb. Enlargement of the present wound, for the more convenient discharge of matter;* new or counter-openings for the same purpose, or for the extraction of fragments of broken or exfoliated bone, will very frequently be found necessary, and must be executed. In the doing this, care must be taken, that what is requisite be done, and no more; and that such requisite operations be performed with as little disturbance and pain as possible.

Previous to large suppuration, or considerable collections and lodgments of matter, evacuation by phlebotomy, an open belly, and antiphlogistic remedies, as well as the free use of anodynes, and such applications to the limb as may most serve the purpose of relaxation, are the remedies, which Mr. Pott advises for the relief of the swelling, induration, and high inflammation, attended with pain, irritation, and fever. "But the matter having been formed and let out, and the pain, fever, &c. which were symptomatic thereof, having disappeared, or ceased, the use and purpose of such medicines and such

applications cease also, and they ought therefore to be discontinued. By evacuation, &c. the patient's strength has necessarily (and indeed properly) been reduced; by cataplasm, &c. the parts have been so relaxed as to procure an abatement or cessation of inflammation, a subsidence of tumefaction, and the establishment of a free suppuration; but these ends once fairly and fully answered, another intention arises, which regards the safety and well-doing of the patient nearly, if not full as much as the former; which intention will be necessarily frustrated by pursuing the method hitherto followed. The patient now will require refection and support, as much as he before stood in need of reduction; and the limb, whose indurated and inflamed state hitherto required the emollient and relaxing poultice, will now be hurt by such kind of application, and stand in need of such as are endued with contrary qualities, or, at least, such as shall not continue to relax. Good, light, easily digested nutriment, and the Peruvian bark, will best answer the purpose of internals; the discontinuation of the cataplasms, and the application of medicines of the corroborating kind, are as necessary with regard to externals."

"Every body who is acquainted with surgery knows (says Mr. Pott) that, in the case of bad compound fracture, attended with large suppuration it sometimes happens, even under the best and most judicious treatment, that the discharge becomes too great for the patient to sustain; and that, after all the fatigue, pain, and discipline, which he has undergone, it becomes necessary to compound for life by the loss of the limb†. This, I say, does sometimes happen under the best and most rational treatment; but I am convinced that it also is now and then the consequence of pursuing the reducing, the antiphlogistic, and the relaxing plan too far. I would therefore take the liberty seriously to advise the young practitioner to attend diligently to his patient's pulse and general state, as well as to that of his fractured limb and wound; and when he finds all febrile complaint at an end, and all inflammatory tumour and hardness gone, and his patient is rather languid than feverish, that his pulse is rather weak and low than hard and full, that his appetite begins to fail, and that he is inclined to sweat, or purge, without assignable cause, and this in consequence of a large discharge of matter from a limb which has suffered great inflammation, but which is now become rather soft and flabby, than

* "It is a practice with some, from a timidity in using a knife, to make use of bolsters and plaster-compresses for the discharge of lodging matter. Where another, or a counter-opening can conveniently and safely be made, it is always preferable, the compress sometimes acting diametrically opposite to the intention with which it is applied, and contributing to the lodgment by confining the matter; besides which, it requires a great degree of pressure to make it efficacious, than a limb in such circumstances generally can bear."

* "It is surprising how large and how disagreeable a discharge will be made for a considerable length of time, in some instances, from the detention and irritation of a splinter of bone. If therefore such discharge be made, and there be neither sinus nor lodgment to account for it, and all other circumstances are favourable, examination should always be made, in order to know whether such cause does not exist, and if it does, it must be gently and carefully removed."

† After the bones had united, Mr. Pott never found it necessary to amputate a limb for a compound fracture, on account of the too great discharge.

hard and tumid; that he will in such circumstances set about the support of his patient, and the strengthening of the diseased limb *totis viribus*; in which I am from experience satisfied, he may often be successful, where it may not be generally expected that he would. At least, he will have the satisfaction of having made a rational attempt; and if he is obliged at last to have recourse to amputation, he will perform it, and his patient will submit to it, with less reluctance, than if no such trial had been made."

According to Mr. Pott, gangrene and mortification are sometimes the inevitable consequences of the mischief done to the limb at the time that the bone is broken; or they are the consequences of the laceration of parts, made by the mere protrusion of the said bone. They are also sometimes the effect of improper or negligent treatment; of great violence used in making extension; of irritation of the wounded parts by poking after, or in removing fragments or splinters of bone; of painful dressings; of improper disposition of the limb, and of the neglect of phlebotomy, anodynes, evacuation, &c.

"When such accident, or such disease, is the mere consequence of the injury done to the limb, either at the time of, or by the fracture, it generally makes its appearance very early; in which case also, its progress is generally too rapid for art to check. For these reasons, when the mischief seems to be of such nature that gangrene and mortification are most likely to ensue, no time can be spared, and the impending mischief must either be submitted to or prevented by early amputation. I have already said, that a very few hours make all the difference between probable safety and destruction. If we wait till the disease has taken possession of the limb, even in the smallest degree, *the operation will serve no purpose but that of accelerating the patient's death*. If we wait for an apparent alteration in the part, we shall have waited until all opportunity of being really serviceable is past. The disease takes possession of the cellular membrane surrounding the large blood-vessels and nerves, some time before it makes any appearance in the integuments; and will always be found to extend much higher in the former part, than its appearance in the latter seems to indicate. *I have more than once seen the experiment made of amputating, after a gangrene has been begun, but I never saw it succeed; it has always hastened the patient's destruction.*"

"As far therefore as my experience will

enable me to judge, or as I may from thence be permitted to dictate, *I would advise that such attempt should never be made*; but, the first opportunity having been neglected, or not embraced, all the power of the chirurgic art is to be employed in assisting nature to separate the diseased part from the sound; an attempt which now and then, under particular circumstances, has proved successful, but which is so rarely so, as not to be much depended upon.

"If the parts are so bruised and torn, that the circulation through them is rendered impracticable, or if the gangrene is the immediate effect of such mischief, the consequence of omitting amputation, and of attempting to save the limb is, as I have already observed, most frequently very early destruction: but, if the gangrenous mischief be not merely and immediately the effect of the wounded state of the parts, but of high inflammation, badness of general habit, improper disposition of the limb, &c. it is sometimes in our power so to alleviate, correct, and alter these causes, as to obtain a truce with the disease, and a separation of the unsound parts from the sound. The means whereby to accomplish this end must, in the nature of things, be varied according to the producing causes or circumstances: the sanguine and bilious must be lowered and emptied; the weak and debilitated must be assisted by such medicines as will add force to the *vis vitæ*; and errors in the treatment of the wound or fracture must be corrected; but it is evident to common sense, that for these there is no possibility of prescribing any other than very general rules indeed. The nature and circumstances of each individual case must determine the practitioner's conduct.

"In general, inflammation will require phlebotomy and an open belly, together with the neutral antiphlogistic medicines; pain and irritation will stand in need of anodynes, and the Peruvian bark, joined, in some cases and at some times, with those of the cooling kind, at others with the cordial, will be found necessary and useful. So also tension and induration will point out the use of fomentation and warm relaxing cataplasms, and the most soft and lenient treatment and dressing."

Mr. Pott then offers many just observations against stimulating antiseptic applications to the wound and scarification of the limb, as practised while the gangrene is forming. The custom of using stimulating dressings to bad compound fractures first began in cases produced by gunshot, and had its foundation in the opinion, that gunshot wounds were poisonous, and that the mortification in them was the effect of fire; a doctrine and practice now completely exploded. "A gunshot wound (says Pott) whether with or without a fracture, is a wound accompanied with the highest degree of contusion, and with some degree of laceration; and every greatly contused and lacerated wound requires the same kind of treatment which a gunshot wound does,

* In the article *Gunshot Wounds*, however, the reader will find, that there is a species of gangrene, arising from external violence, and totally unconnected with constitutional causes, where the surgeon should deviate from the common rule of deferring amputation, until the mortification has ceased to spread. A memoir "*Sur la Gangrène Traumatique*," which was published a few years ago by Baron Larrey, contains the most decisive facts in regard to the propriety of such practice. (See his *Mém. de Chir. Militaire*, T. 2.) And the experience of Mr. Lawrence tends also to confirm the truth of Larrey's Observations. (See *Med. Chir. Trans.* Vol. 6, p. 184, &c.)

as far as regards the soft parts. The intention in both ought to be to appease pain, irritation, and inflammation."

"Scarification, in the manner, and at the time, in which it is generally ordered and performed, has never appeared to me to have served any one good purpose. When the parts are really mortified, incisions made of sufficient depth will give discharge to a quantity of acrid and offensive ichor; will let out the confined air, which is the effect of putrefaction: and thereby will contribute to unloading the whole limb; and they will also make way for the application of proper dressings. But while a gangrene is impending, that is, while the parts are in the highest state of inflammation, what the benefit can be which is supposed or expected to proceed from scratching the surface of the skin with a lancet, I never could imagine; nor, though I have often seen it practised, do I remember ever to have seen any real benefit from it. If the skin be still sound, and of quick sensation, the scratching it in this superficial manner is painful, and adds to the inflamed state of it; if it be not sound, but quite altered, such superficial incision can do no possible service; both the sanies and the imprisoned air are beneath the *membrana adiposa*; and merely scratching the skin in the superficial manner, in which it is generally done, will not reach to, or discharge either.

"From what has been said, it will appear, that there are three points of time, or three stages, of a bad compound fracture, in which amputation of the limb may be necessary and right; and these three points of time are so limited, that a good deal of the hazard or safety of the operation depends on the observance or nonobservance of them.

"The first is immediately after the accident, before inflammation has taken possession of the parts. If this opportunity be neglected or not embraced, the consequence is either a gangrene or a large suppuration, with formation and lodgment of matter. If the former of these be the case, the operation ought never to be thought of, till there is a perfect and absolute separation of the mortified parts.* If the latter, no man can possibly propose the removal of a limb, until it be found, by sufficient trial, that there is no prospect of obtaining a cure without; and that, by not performing the operation, the patient's strength and life will be exhausted by the discharge. When this becomes the hazard, the sooner amputation is performed the better. In the first instance, the operation ought to take place before inflammatory mischief is incurred; in the second we are to wait for a kind of crisis of

such inflammation; in the third, the proportional strength and state of the patient, compared with the discharge and state of the fracture, must form our determination." (*Pott's Remarks on Fractures.*)

6. *Of the Formation of Callus, the Consolidation of Fractures, and of the Cases in which they remain without Union.*

In the treatment of fractures, the whole business of the surgeon consists in putting the displaced extremities of the bone into their natural situation again; in keeping them in this situation by means of a suitable apparatus; in endeavouring to avert unfavourable symptoms, and in adopting measures for their removal, when they have actually occurred. The consolidation of a broken bone is (strictly speaking) the work of nature, and is effected by a process, to which a state of perfect health is above all things propitious.

This consolidation of a broken bone, which is analogous to the union of wounds of the soft parts, is termed the *formation of the callus*, and the new uniting bony substance itself is named *callus*.

1. *Of the Time requisite for the Formation of the Callus, and of general circumstances, which favour, retard, or even completely prevent it.*

Surgical writers have been absurdly anxious to specify a determinate space of time, which should be allowed for the formation of the callus, as if this process always went on in different cases with the same uninterrupted regularity. Forty days were often fixed upon as necessary for the purpose. This prejudice is not only false, but dangerous, inasmuch as patients have been thereby induced to suppose themselves cured, before they were so in reality, and have consequently moved about too boldly, and thus run the risk of occasioning deformity, or a new fracture. As Boyer observes, it is impossible to determine precisely, and in a general way, the period requisite for the cure, because it differs according to a variety of circumstances. All we know is, that the callus is usually formed between the twentieth and seventieth day, sooner or later, according to the age and constitution of the patient, the thickness of the bone, the weight which it has to support, the state of the patient's health, &c.

1. *Age.* Fractures are consolidated (*ceteris paribus*) with more ease and quickness in young subjects, than in adults, or old persons. In general, also, the callus forms more speedily in proportion as the individual approaches to infancy. In two children, whose arms had been broken in difficult labours, De la Motte saw the humerus united in twelve days, by a very simple apparatus. In fact, at this period of life, every part has a tendency to grow and develope itself, and the vitality of the bones is more active, their vascularity greater, their gelatinous substance more abundant. On the contrary, in advanced age, the parts have lost all disposition to development, the vascularity of the bones

* Compound fractures are cases of external violence. Now as the mortification proceeds from the injury, and may not be connected with any internal cause, it is an example of what Larrey calls the "*Gangrene Traumatique*," and the question whether the surgeon ought to be governed by the old maxim of delaying amputation, until the spreading of the mortification has ceased, yet remains unsettled. Were the patient of a sound constitution, and not too far gone, I should not fear to imitate Larrey, and amputate though the mortification were actually in a spreading state.

is in a great measure obliterated, and (to use the expression of Boyer) their vitality is annihilated under the mass of phosphate of lime, which accumulates in them.

It has been asserted, that in early infancy the callus is generally produced in excess, and may cause deformity by its redundancy. But experience does not confirm the truth of this statement. The real cause of deformity always proceeds from the fracture either being badly set, or not kept properly reduced, or else from the part being moved about before the callus has acquired a due degree of firmness.

2. *Constitution.* A fracture is united much sooner in a strong healthy person, than a weak unhealthy subject. Sometimes, the consolidation is prevented by some inexplicable unknown cause, nothing wrong being remarkable either in the constitution or the part. Ruysch and Van Swieten met with several cases of this kind, in which the patients were apparently quite healthy and judiciously treated.

3. *Thickness of the Bone, and weight which it has to support.* The bones are thicker and larger in proportion as they have a greater weight to bear, and as the muscles inserted into them are more powerful. It is observed, *ceteris paribus*, that the larger the bones are, the longer is the time requisite for their union. Thus a broken thigh-bone is longer in growing together again, than a fractured tibia; the tibia longer than the humerus, the bones of the fore-arm, clavicle, ribs, &c.

As the callus remains a good while softer than the rest of the bone, it follows that if the newly united bone has to bear all the weight of the body in walking, the patient should defer this exercise longer. Hence, one reason why fractures of the arm are sooner cured than those of the tibia, and why six or seven weeks at least are necessary in the treatment of a broken thigh-bone, which of itself has to support in progression all the weight of the trunk.

4. *State of Health.* Fractures unite with more quickness and facility when the patient enjoys good health. The scurvy has a manifest and powerful effect in retarding the consolidation of fractures, and even in causing the absorption of the callus several years after its formation, so that a bone becomes flexible again at the point where it was formerly broken. In Lord Anson's Voyage, this phenomenon is particularly recorded. (See p. 142, *Edit. 15 in 8vo.*) Langenbeck is acquainted with several cases, in which the callus at the end of eight weeks became again soft, and the bone flexible, in consequence of the patients being attacked with fevers, or erysipelas. (*Neue Bibl. B. 1, P. 90.*) Cancer, lues venerea, and rickets, are also stated by surgical writers to obstruct and sometimes hinder altogether the formation of callus.

Fabricius Hildanus has cited two cases, which tend to prove that the union of fractures is retarded by pregnancy. (*Cent. 5. Obs. 87. Cent. 6. Obs. 68.*) Alanson has also related a case, in which the union, which

had been delayed during pregnancy, took place after delivery; (*Med. Obs. and Inq. Vol. 4, No. 37.*) and Werner has published an account of a fracture of the radius in a pregnant woman, where the cure was apparently retarded for a long time by this circumstance, and though the union took place previously to delivery, the callus was not very firm till after that event. (*Richter, Bibl. B. 11, P. 591.*) From the facts, however, mentioned in a preceding page of this article, there can now be no doubt, that pregnancy frequently does not prevent the formation of callus in the ordinary time, though the observation of Mr. Wardrop is true, that many instances have been observed of bones being fractured during pregnancy, and never showing any disposition to unite till after delivery. (*Med. Chir. Trans. Vol. 5, p. 359.*)

Besides the remarks made here and in a foregoing page on the causes preventing the union of fractures, a few additional observations on the same subject will be introduced in the sequel of this article, when we speak of the modes of attempting the cure of old disunited fractures.

2. Of some local Circumstances necessary for the Consolidation of Fractures.

As Boyer has well explained, three local circumstances are necessary to obtain a firm callus, without deformity. 1. The two fragments must be possessed of sufficient vascularity. 2. The surfaces of the fracture must correspond. 3. They must be kept in a completely motionless state.

The two fragments must be sufficiently vascular. If one of them should be too scantily supplied with blood, the fracture would be incapable of union. This (says Boyer) is what happens in certain fractures of the neck of the femur, where the head of this bone is entirely detached, and the ligamentous substance, which is reflected over its neck, and serves as its periosteum, is totally lacerated, as well as the vessels which ramify upon it. Hence, the upper fragment lodged in the cotyloid cavity no longer receives from the vessels sent to it through the ligamentum teres, a sufficiency of blood for the process of the formation of callus. This is especially likely to be the case, when the patient is far advanced in years, and the vessels considerably lessened in diameter. An adequate circulation must therefore exist in both portions of bone; for without it the attempt at union will fail.

The surfaces of the fracture must correspond exactly. This circumstance is not absolutely necessary for the consolidation of the fracture; but without it, the formation of the callus is always slow and difficult. For instance, in a transverse fracture of the thigh-bone, the fragments after being displaced according to the thickness of the bone, may undergo a second displacement according to its length, by passing beyond each other. The surfaces of the fracture are then not at all in contact, and the portions of bone only touch each other by their sides, which being covered by the periosteum, can

unite but difficultly. Here, at the end of the second month, the union will frequently have made but little progress; nor can the cure be accomplished without deformity and shortening of the limb.

The fragments must be retained in a completely motionless state. This condition is so essential to the formation of callus, that if the ends of a fracture were daily moved, they could not unite. The two extremities of the bone would then heal separately, just like the sides of a wound which have not been put in contact. The ends of a fracture, however, which cicatrize separately, do not (according to Boyer) always become smooth, nor is there ordinarily any capsular ligament formed. (*Traité des Mal. Chir. T. 3, p. 86.*)

3. *Different Opinions on the Formation of Callus.*

As Boyer remarks, perhaps no subject has excited more discussion, than the formation of callus. The ancients ascribed it to the extravasation of a gelatinous fluid, which was called the osseous juice, and which becoming hard, served to unite the ends of the broken bone, just as glue serves to unite two pieces of wood. Hence, in order to favour the production of callus, they were in the habit of recommending their patients to eat abundantly of every sort of viscid farinaceous aliment, the glutinous parts of animals, and especially osteocolla, of which Fabricius Hildanus relates miracles.

But if these accounts were true, callus must be inorganic; or else one would be compelled to admit, that the inspissation of an inorganic fluid was capable of producing an organized substance: which is an absurdity. Besides, observation demonstrates, that callus is an organized matter, like the substance of the bone itself, which it resembles, and that, when subjected to anatomical and chymical experiments, it exhibits all the appearances of the proper substance of bones.

According to Duhamel, callus is formed by the periosteum, which he regards as the organ of ossification. When a bone is fractured, (says this naturalist) the periosteum of the two fragments first grows together, and then swells, and forms a circular rising round the fracture. The thickened membrane is converted into a gelatinous substance, which soon becomes a cartilaginous matter. In this, vessels develop themselves, and different points of ossification commence, which multiply and unite. Thus, when every part of the periosteum near the fracture is hardened and ossified, this membrane is changed, as it were, into a sort of clasp, which extends over the two fragments, and holds them together.

It was objected to Duhamel's theory, that if a bone be slit longitudinally in the situation of a former fracture, the fragments are observed to have their substances blended completely together, and not simply to lie in contact in the manner of two pieces of

wood placed end to end, and kept in contact by means of a clasp. Duhamel, with a view of obviating this difficulty, supposes that the periosteum elongated itself from the circumference towards the centre of the bone, and that such continuation of this membrane underwent the same changes, as that portion which was contiguous to the fracture, and thus served to unite the ends of the fragments, between which it was interposed. He admits, also, in some cases, that the internal periosteum, or medullary membrane, may furnish productions extending between the ends of the fracture, like the continuation of the external periosteum, with which they become connected. Lastly, he supposed, that, in young subjects, whose bones had not acquired their full degree of hardness, the cartilaginous part was capable of extension, and that in cases of fracture, it contributed to the more perfect union of the fragments.

The system of Duhamel was opposed by Haller and Dethleef, who, after a long series of well-performed experiments, came to the conclusion, that the callus was formed by a gelatinous juice, which exudes from the extremity of the fractured bone, particularly from the medullary texture, and is effused all about the fracture; that such juice is organized, forms a cartilage, and at length ossifies.

But, as Boyer justly remarks, whatever difference there may seem to be betwixt this doctrine, and that of Duhamel, it is merely in the mode of explaining the facts. All these observers noticed the same phenomena; and all the experiments of Dethleef accorded perfectly well with those of Duhamel. Both found, during the first days, immediately after the fracture, a lymph extravasated between the fragments, and a small tumour in the situation of the fracture. Both also remarked, that this tumour became softer, and that it afterward formed a gelatinous, then a cartilaginous, and lastly a bony substance, which composed the uniting medium. But, Duhamel contends, that the cartilage is produced by the periosteum, while Haller and Dethleef argue, that it is the production of the extravasated lymph.

Professor Boyer thinks, that Duhamel imputes too much to the periosteum; but, that Haller and Dethleef were also wrong, if they supposed, as Fongeroux alleges, that an unorganized lymph could produce an organized substance by inspissation. (See *Le Second Mémoire sur les Os, par M. Bordenave, recueilli et publié par M. Fongeroux, p. 124.*) It appears to Boyer much more natural to believe, that the gelatinous lymph already contains the rudiments of organization, which become visible as they are developed; just as it is usually believed, that the rudiments of all our organs are contained in the transparent mucilage, of which the embryo seems to consist.

The experiments of Duhamel and Dethleef were carefully repeated by Bordenave, who ascertained several new and interesting

facts. The result was the same in regard to the phenomena observed; but the explanation of them was different.

Instead of attributing the formation of callus to the periosteum, like Duhamel; or to the extravasation of lymph, like Dethleef; Bordenave conceived, that broken bones unite again by a process analogous to that, which nature employs for the union of the divided soft parts. His inference is principally founded on two facts generally admitted; 1st, that there is in the bones a vascular texture, designed to maintain the circulation in them; 2dly, that such texture dilates when fractures are uniting, as appears from the swelling in the situation of the fracture, without which swelling, there could be no union. Bordenave further remarks, with Haller and Dethleef; 1st, That callus, at the commencement of its formation, appears to consist of a glutinous fluid effused from the ruptured vessels. 2dly, That this substance afterward assumes the form of cartilage, to which certain vessels are distributed, which deposit the bony matter, and thus begin the generation of callus. 3dly, That the particles of bone, being all joined together, the callus changes into a porous substance, which in time becomes solid and compact, like the substance of bones.

Doubtless (says Boyer) we shall always remain ignorant of the process, which nature employs for the union of the bones, as well as for that of the soft parts. Every theory, which can be invented on this point, will only be conjectures more or less probable. However, if this author were to adopt any system exclusively, he expresses that he should prefer that of Bordenave.

The mechanism of nature, in the formation of callus, must be analogous to that which she adopts in the union of wounds. The principal difference seems to be, that in the union of a fracture, the vessels after a time deposit the phosphate of lime. The vessels of the periosteum, medullary membrane, and probably also those of the soft parts in the immediate vicinity of the fracture, first effuse coagulating lymph. This gradually becomes vascular, and in proportion as the vessels acquire the power of secreting earthy matter, it is by degrees converted into new bone, termed *callus*, which from being at first soft and flexible, at length becomes firm and unyielding, and fit for constituting the future bond of union between the two extremities of the fracture.

The observations made by Baron Larrey, lead him to reject as entirely erroneous, the doctrine, which refers the production of callus to the periosteum, and he adopts the opinion, that the union and reparation of bones are the work of their own vessels. He adverts to examples, in which after the use of the trephine in young subjects, the perforation becomes more or less closed by new bone, thrown out from the circumference towards the centre. Here, says he, the ossification assuredly can neither be referred to the pericranium, nor the dura-ma-

ter. The first of these membranes has been extensively destroyed, and, if the second were concerned, a vertical substance, shutting up the opening, would be apparent. In further support of his opinions, Baron Larrey cites the well-known celerity, with which fractures of the lower jaw unite, on account of the great vascularity of that bone, and he believes, with Mr. A. Cooper, that if the ends of a fracture do not touch in consequence of loss of substance, the intervening space remains unfilled up by new bone; a position, which seems rather repugnant to what has been said concerning the mode of reparation after the use of the trephine.

Larrey has often seen the superficial layers of the tibia exfoliate, after a necrosis produced by a cause, which had destroyed the whole of the periosteum on the front surface of that bone, as is sometimes the case in hospital gangrene. He has seen these layers replaced by red vascular granulations, disposed in parallel lines, which granulations soon ossified, that is to say, phosphate of lime was substituted for the vermilion colour of the vessels, and gave the new-formed substance the appearance and consistence of bone. Lastly, this substance was covered with a new cellular membrane, derived from the adjacent textures; but, in the place of the cicatrix, a depression always remained, proportioned to the loss of substance. If the formation of callus depended on the periosteum, Larrey argues that the broken patella could never unite by bone, as it is often found to do, when the fragments are kept closely in contact. Here he contends, that the union is the result of the work and inosculation of the vessels belonging to the substance of the fragments themselves. Lastly, he adverts to preparations, in which the vessels of callus have been actually injected by the celebrated Soemerring. (*See Journ. Complém. du Dict. des Sciences Méd. T. 8, p. 107, &c. Svo. Paris, 1820.*)

From experiments, instituted by Breschet and Villermé, it would appear, that the union of broken bones is not exclusively owing to the effusion of a particular fluid, which concretes and gradually changes into an osseous substance; nor to the ossification of the swollen and elongated periosteum; nor, in the majority of instances, to granulations produced from the surfaces of the fracture; but, it is frequently dependent upon all these circumstances together, or at least several of them; and, in every case, it is the result of a series of changes, observable in the soft parts immediately adjoining the fracture, in the periosteum, in the medullary structure, in the cavities and very texture of the bones themselves, and in the substance intervening between the two fragments. In simple fractures, the following are stated to be the principal circumstances remarked during the process.

1. Extravasation and coagulation of a small quantity of blood between the ends of the fracture, which blood escapes from torn, or ruptured vessels.

2. A fluid, at first of a viscid quality, effused and secreted, as it were, between the periosteum and the bone, and likewise exuding from the surfaces of the fracture, and the soft parts.

3. A gradual increase in the quantity and consistence of the preceding substances blended together, forming every day a stronger and stronger connexion between the parts; then their change to a red intermediate substance between the fragments, and between the bone and the periosteum, to a substance which is at first soft, but in the end acquires the characters of bone.

4. At the fractured part, a reunion of the periosteum, and soft parts, which are equally indurated and confused together, with the intermediate substance between the fragments.

5. A diminution, and then an obliteration, of the medullary cavity, at first by a cartilaginous, and then a bony deposition.

6. Successive ossification of the whole of the swelling, composing the callus, and of the substance between the fragments, preceded by a fibrous and cartilaginous state.

7. The return of the soft parts around the fracture, and then of the periosteum, to their natural state.

8. After the union of the surfaces of the fracture, the medullary cavity and texture are gradually re-established, and the swelling, formed by the callus, always diminishes.

But, in compound fractures, besides these circumstances, the production of granulations from the surfaces of the bone is also to be taken into the account. (See *Dict. des Sciences Med.* T. 38, P. 436.) This difference from what happens in the process of union of simple fractures is also particularly noticed by Mr. Wilson: "from the parts being exposed (in a compound fracture,) the first bond of union, viz. the coagulable lymph of the blood is removed, or destroyed before it can become vascular. Inflammation in consequence of the injury comes on, suppuration takes place, and, when the parts are healthy, granulations arise. These granulations from the broken extremities of the bone soon assume the ossifying disposition, and when they come in contact with each other unite." (*On the Skeleton, Diseases of the Bones, &c.* P. 233, Seco. Lond. 1820.) It is a curious fact, that broken cartilages are united by means of bone; a circumstance, which has often been noticed in respect to the cartilages of the ribs.

Whatever may be the process, by which callus is formed, it is during the first two or three weeks after the fracture, that the fragments undergo the changes, which promote their reunion. But, it is between the twentieth and thirtieth, and especially between the thirtieth and fiftieth days, that nature labours effectually in consolidating the callus. Hence, at this period, our care to retain the ends of the fracture in exact contact and perfectly at rest should be redoubled; for though there are a few instances, in which deformity really proceeds from irregular os-

sifications, it is almost always a fact, that the deformity originates from the fracture being disturbed and not kept properly reduced. (*Boyer, Traité des Mal. Chir.* T. 3, p. 86, &c.)

4. Of the Conduct to be adopted at the ordinary Period of the Consolidation of Fractures; and of the Treatment of False Joints.

When the requisite time for a broken bone to become firmly united has elapsed, it is proper to examine carefully and cautiously the place of the fracture, in order to learn whether the callus has acquired a suitable degree of strength. If the bone should be found to bend in the least at the injured part, the callus is not sufficiently strong, and the limb should be immediately put up in the apparatus again, with a view of preventing a new fracture, or, at all events, deformity.

For the same reason, the patient should not be allowed to make use of his limb, immediately the fracture has united. In fractures of the lower extremity, he ought to use crutches, and only let the weight of the trunk by degrees bear upon the injured limb. From neglect of this precaution, the callus has been known to be absorbed, the limb to be shortened, and the patient become a cripple. An accidental slip may also produce the fracture again; for, notwithstanding the assertion of writers, the callus, so far from being firmer than the rest of the bone, is not so strong till after a certain time. (*Boyer, T. 3, p. 93.*)

If, when the necessary time for the completion of the union has expired, the callus is not yet firm, we must examine; 1st, The relative position of the fragments, and the consistence of the callus. 2dly, The causes, which may have retarded its consolidation.

That the state of the constitution has considerable influence over the process by which broken bones are reunited, is unquestionable. Schmucker found the formation of callus, even in the most simple fractures, sometimes delayed eight months, and in one example more than a year; but the patients were all of them unhealthy subjects. (*Vermischte Chir. Schriften*, 1 B. p. 26.)

There are certain indescribable constitutions, in which bones, more particularly, however, the os brachii, will not unite again after being broken. These temperaments are also very various; at least I inter so from two subjects, to whom I paid particular attention. One was a strong, robust man, whose chief peculiarity seemed to be his indifference to pain: the ends of his broken humerus were cut down to, turned out, and sawn off, by Mr. Long, in St. Bartholomew's hospital, and the limb was afterward put in splints, and taken the greatest care of; but no union followed. The other case was a broken tibia and fibula, which remained disunited for about four months; but afterward grew together. The latter subject was a complete instance of hypochondriasis. I have since seen a woman, under Sir James Earle, in the above hospital, whose os brachii did not unite in the least, though it had been broken

several months. Every attempt to move the bone occasioned excruciating torture. The woman died of some illness in the hospital, and on dissecting the arm, the cause of the fracture not having united was found to arise from the upper, sharp, pointed extremity of the lower portion of the broken bone having been forcibly drawn up by the muscles, and penetrated the substance of the biceps, in which it still remained. I am indebted to Mr. Henry Earle for the account of the appearance on dissection, and I do not know that this kind of impediment to the union of a fracture has been noticed by any earlier writer than Mr. Charles White, who appears to have conceived the possibility of the occurrence. (*Cases in Surgery*, p. 70, Edit. 1770.)

The causes of fractures remaining disunited will, according to Richerand, be found to depend, either upon the broken ends of the bone not being properly in contact; the limb having been moved too much; the advanced age of the patient; or upon a general inertia and languor of the constitution. (*Nosographie Chir.* Tom. 3, p. 37, Edit. 2.)

It is observed by Larrey, that the gunshot wounds of the extremities, complicated with fracture, especially with that of the humerus, received by the soldiers of the French army in Syria, were almost all followed by the formation of accidental joints. The two fragments of the broken bone continued moveable, their asperities and projecting angles having been destroyed by friction, and their ends being rounded and covered with a cartilaginous substance, so as to facilitate the motions, which the patients executed in various directions, in an imperfect manner, and without pain. Larrey acquaints us, that many invalids were sent back to France with such infirmity.

"I ascribe," he says, "the causes of these accidental articulations:

"1. To the continual motion to which the wounded soldiers were exposed after their departure from Syria, till their arrival in Egypt, in consequence of their having been obliged either to walk this journey on foot, or to be carried it on beasts.

"2. To the bad quality of the food, and the brackish water, which the men were under the necessity of drinking in this painful journey.

"3. To the state of the atmosphere of Syria, almost entirely destitute of vital air, and impregnated with pernicious gases, issuing from the numerous marshes near which we were a long while stationed.

"All these causes may have prevented the formation of callus, either by diminishing the quantity of the phosphate of lime, or moving the bones out of that state of coaptation in which they should constantly lie in order to unite.

"Bandages, embrocations, rest, and regimen, proved quite ineffectual."—(*Larrey Mém. de Chir. Mil.* T. 2, p. 131, 132. *Langenbeck. N. Bibl. B. 1.* p. 81.)

The presence of an ulcer, a sinus, loose splinters of bone, a necrosis, or other suppu-

rating disease, near a fracture, is a circumstance that often appears seriously to retard, or completely to prevent the formation of callus. How frequently have I noticed, in cases of compound fracture, that, while the wound suppurates largely, and while there are spiculæ and dead portions of bone unextracted, no solid union takes place; but that as soon as the wound, ulcer, or sinus admits of being healed, and the suppuration ceases, the callus begins to form in the most favourable manner. Schmucker relates a case, illustrating the truth of these observations, where the tibia and fibula were broken so obliquely, that the ends of the fracture could not be made to lie well, a necrosis of a portion of the tibia followed, and no callus was formed at the end of eight months, when a sinus on each side of the leg still continued. This eminent surgeon now laid the sinuses open, and extracted the dead pieces of bone, by which means the impediment to the formation of callus was removed, and the fracture, which had till then remained loose and moveable, became firmly united in two months. (*Vermischte, Chir. Schrift.* 1 B. p. 25, 26.)

False or preternatural articulations, which occur in cases of fracture without union, have been generally supposed to resemble common joints. According to Boyer, this opinion is incorrect. The ends of the fracture, which are sometimes rounded, and sometimes pointed, are connected together by a cellular and ligamentous substance. But their surfaces are not covered by a smooth cartilaginous matter, nor is there constantly a capsular ligament. "I am convinced of this fact, by the dissection of several ununited fractures, the fragments of which are preserved in my museum." (*Boyer, T. 3, p. 94.*) And in another place, the same Professor, speaking of these false joints, remarks: "I repeat that I have never found, in their structure, any thing which could be compared with an articulation; neither capsular ligament, nor smooth cartilaginous surfaces. On the contrary, I have invariably found in the false joints of the thigh-bone and humerus, which I have had opportunities of dissecting, a fibrous ligamentous substance extending from one fragment to the other, and it is very probable, that, with some modifications, it is the same with all the other cases which I have not seen.

"But in the fore-arm, the ends of the fracture may assume a structure which bears a greater resemblance to an articulation. This is what happened in an example, which was communicated to Bayle by Sylvestre, in the *Republique des Lettres*, Juillet 1685 p. 718, &c. A similar case is recorded by Fabricius Hildanus. Obs. 91 Centur. 3." (*Boyer, Traité des Mal. Chir.* T. 3, p. 101—103.)

On this subject, Langenbeck observes, that the edges of the fragments heal, and resemble those of a harelip. "When the parts are incessantly moved, the end of one fragment becomes excavated in the form of an articular cavity. I have in my possession (says he) a lower jaw, and an olecranon, the frac-

tures of which are not united. For the connecting medium, nature has provided a white substance, resembling ligament. In a male patient, I have also seen an articular connexion established in the body of the thigh-bone, subsequently to a fracture." (*Neue Bibl. B. 1, p. 93*) When a capsule is formed, it is alleged not to be of a ligamentous nature. (*Bichat, Anatomie Générale, T. 3, p. 191.*)

In the Hunterian Collection may be seen a false joint in the bones of the fore-arm, where the resemblance to a natural articulation was greater than what Boyer has seen in other situations.

A valuable dissertation on false joints has been published by Reisseisen, entitled "*De Articulationibus analogis, quæ fracturis ossium superveniunt*;" but I am sorry that it has not been in my power to meet with a copy of it.

A false joint in the arm, or fore-arm, does not absolutely prevent the motion of the limb, which may yet be of considerable use; but when the disease is in the thigh, or leg, the member cannot support the weight of the body, and the patient is unable to walk without crutches.

The diversity of causes which may be concerned in preventing the union of fractures, plainly shows, that the treatment should be different in different cases.

When the want of union is ascribable to the ends of the fracture not being in a state of coaptation, and to their having been moved about too frequently, the obvious indications are, to set the fracture better, and to take adequate measures for keeping its extremities in contact and perfectly motionless.

If the union has been prevented by a portion of muscle or other soft part, getting between the ends of the bone, the only means of affording a chance of union, would be cutting through the integuments, removing the displaced soft parts, and placing the ends of the bone in contact (*Wardrop in Med. Chir. Trans. Vol. 5, p. 360.*)

When the advanced age of the patient seems to be the cause of the union not taking place, the application of the proper apparatus is to be continued a considerable time, since experience proves, that in old subjects the cure of fractures often requires many months. In such examples, also, tonic and cordial medicines, with a nutritive diet, are highly proper.

When several months have elapsed since the accident, and there is reason to apprehend that a preternatural joint is formed, a variety of plans have been proposed and practised.

The most ancient method of treatment is that of forcibly rubbing the ends of the fracture against each other, so as to make them inflame, and take on a disposition to form callus. This plan was recommended by the late Mr. John Hunter, and has had the approbation of many other distinguished modern practitioners. Mr. Hunter used even to advise us, in the case of a disunited frac-

ture of the leg, or thigh, to let the patient get up, and attempt to walk with the splints on the limb, so that the requisite irritation might be produced. The idea of exciting a degree of inflammation in the situation of the fracture, certainly appears rational, and I believe the practice has been attended with a limited degree of success. Mr. White records an example, in which he cured a broken thigh on this principle, a strong leather case having been made for the limb. (*Cases in Surgery, p. 75.*) The method is spoken of in Celsus: *si vetustas occupavit, membrum extendendum est ut aliquid lædatur: ossa inter se manu dimovenda, ut concurrendo exasperentur. et ut si quid pingue est, eradatur, totumque id quasi recens fiat; &c.*

The foregoing treatment, however, is only likely to answer before a new joint, or at all events a ligamentous fibrous connexion, is completely formed, and when the limb has hitherto been kept entirely motionless.

When the case is old, and there is every cause for believing that a preternatural articulation, or fibrous ligamentous connexion has taken place, we are advised to cut down to the ends of the bone, rasp or saw them off, and then treat the limb just as if the case were a recent compound fracture.

This bold practice was first suggested by Mr. C. White: "Robert Elliot, of Eyham, in Derbyshire, a very healthful boy, nine years old, had the misfortune about midsummer, in the year 1759, by a fall, to fracture the humerus, near the middle of the bone. He was immediately taken to a bone-setter in that neighbourhood, who applied a bandage and splints to his arm, and treated him as properly," says Mr. White, "as I suppose he was capable of for two or three months. His endeavours, however, were by no means productive of the desired effect, the bones not being at all united. A surgeon of eminence, in Bakewell, was afterward called in; but as he soon found he could be of no service to him, and as the case was very curious, he advised the lad's friends to send him to the Infirmary at Manchester. He was accordingly brought thither the Christmas following, and admitted an in-patient. Upon an examination, we found it to be a simple oblique fracture, and that the ends of the bone rode over each other: his arm was become not only entirely useless, but even a burthen to him, and not likely to be otherwise, as there was little probability that it could ever unite, it being now six months since the accident happened.

"Amputation was therefore proposed as the only method of relief: but I could not give my consent to it, for as the boy was young, and had a good constitution, it was hardly possible that it could be owing to any fault in the solids or fluids, but that either nature was disappointed in her work by frequent friction, while the callus was forming, or rather, that the oblique ends of the bone, being sharp, had divided a part of a muscle, and some portion of it had probably insinuated itself betwixt the two ends of the bone, preventing their union. Whichever of these

might be the case, I was of opinion," continues Mr. White, "that he might be relieved by the following operation, viz. by making a longitudinal incision down to the bone, by bringing out one of the ends of it, which might be done with great ease as the arm was flexible, and cutting it off, either by the saw or cutting-pincers, then by bringing out the other, and cutting off that likewise, and afterward by replacing them end to end, and treating the whole as a compound fracture.

"The objections made by the other gentlemen concerned, to this proposal, were, first, the danger of wounding the humeral artery by the knife. Secondly, the laceration of the artery by bringing out the ends of the bones. And, thirdly, that we had no authority for such an operation. As to the first, that was easily obviated, by making the incision on the side of the arm, opposite to the humeral artery. The place of election appeared to me to be at the external and lower edge of the deltoid muscle, as the fracture was very near to the insertion of that muscle into the humerus; the danger of wounding the vessel not only being by that means avoided, but after the operation, while the patient was confined to his bed, the matter would be prevented from lodging, and the wound be easily come at, to renew the dressings. The second objection will not appear to be very great, when we consider that in compound fractures the bone is frequently thrust with great violence through the integuments, and seldom attended with laceration of any considerable artery; and as this would be done with great caution, that danger would appear very trifling. The third and last objection is no more than a general one to all improvements.

"This method which I have been proposing," says Mr. White, "was at last resolved upon, and I assisted in the operation, which was performed by a gentleman of great abilities in his profession, on January 3, in the present year (1760.) The patient did not lose above a spoonful of blood in the operation, though the tourniquet was not made use of. When the operation and dressings were finished, the limb was placed in a fracture box, contrived on purpose, the lad confined to his bed, and the rest of the treatment was nothing different from that of a compound fracture.

"The wound was nearly healed in a fortnight's time, when an erysipelas came on, and spread itself all over the arm, attended with some degree of swelling; this by fomentations, and the antiphlogistic method, soon went off, and the cure proceeded happily, without any other interruption. In about six weeks after the operation the callos began to form, and is now quite firm. The arm is as long as the other, but somewhat smaller, in consequence of such long continued bandages; he daily acquires strength in it, and will soon be fit to be discharged." (*Cases in Surgery*, p. 69, &c.)

In another instance of a broken tibia,

which continued disunited an extraordinary length of time, Mr. White practised an operation, somewhat similar to the foregoing one, with complete success. He made a longitudinal incision, about four inches in length through the integuments, which covered the fracture. By the application of a trephine, he cut off the upper end of the bone, and as the lower end could not be easily sawn off, he contented himself with scraping it. In the course of the subsequent treatment, he had occasion to take off, with the cutting-pincers, a small angle of tibia, and to touch the lower part of the bone with the butter of antimony, as well as to introduce the same caustic between the extremities of the fracture, in order to destroy a substance which intervened. A trifling exfoliation followed. In twelve weeks the bone was firmly united. (*Op. cit.* p. 81, 82.)

Besides Mr. White's cases, there are now some other instances upon record, where the operation which he first proposed, has succeeded. In the year 1813, Langenbeck operated upon a humerus in the foregoing manner, and the result was perfectly successful. The ununited fracture was situated at the insertion of the deltoid. (*Neue Bibl. B. 1*, p. 95.) Mr. Rowlands, of Chester, by a similar operation, cured a fractured thigh, which had lost all disposition to unite. (See *Med. Chir. Trans. Vol. 2*, p. 47.) Viguerie, surgeon to the Hôtel Dieu, at Toulouse, has also practised Mr. White's operation with success. (See *Larrey, Mém. de Chir. Militaire*, T. 2, p. 132.)

On the other hand, the operation has frequently failed. In the instance in which I saw it executed on the humerus by Mr. Long, in St. Bartholomew's Hospital, it did not answer, though the ends of the bone were most fairly sawn off, and the case treated with particular care and skill. Boyer states that he once performed the same operation in a similar case; but that it had not the desired effect; (*Traité des Mal. Chir. T. 3*, p. 110.) Dr. Physic, of New-York, when he was a student in 1785, saw this proceeding unsuccessfully adopted in a case, where the humerus remained disunited. (See *Medical Repository*, Vol. 1, New-York, 1804.) Besides these examples, I have heard of others, in which Mr. Cline and other practitioners have tried the experiment with no better success. What is still more discouraging, the operation has sometimes proved fatal. (*Richerand, Nosogr. Chir. T. 3*, p. 39. Edit. 2. *Larrey, Mém. de Chirurgie Militaire*, T. 2, p. 132.)

The difficulties, the danger, and the frequent ill success of the foregoing operation, rendered another mode of treatment extremely desirable, when Dr. Physic, of New-York, suggested the plan of introducing a seton through the preternatural joint, with a view of exciting inflammation, and bringing about an union of the bone. This suggestion promises to be a considerable improvement in modern surgery. Dr. Physic had an opportunity of performing the new

operation on the 18th December, 1802, in an example of disunited humerus, twenty months after the occurrence of the accident. "Before passing the needle (says Dr. Physic) I desired the assistants to make some extension of the arm, in order that the seton might be introduced, as much as possible, between the ends of the bone. Some lint and a pledget were applied to the orifices made by the seton needle, and secured by a roller. The patient suffered very little pain from the operation. After a few days, the inflammation, (which was not greater than what is commonly excited by a similar operation through the flesh of any other part) was succeeded by a moderate suppuration. The arm was now again extended, and splints applied. The dressings were renewed daily for twelve weeks, during which time no amendment was perceived; but, soon afterward, the bending of the arm at the fracture was observed not to be so easy as it had been, and the patient complained of much more pain, than usual, whenever an attempt was made to bend it at that place. From this time, the formation of the new bony union went on rapidly, and on the 4th of May, 1803, was so perfectly completed, that the patient could move his arm in all directions, as well as before the accident happened. The seton was now removed, and the small sores occasioned by it healed up entirely in a few days. On the 28th of May, 1803, he was discharged from the hospital perfectly well, and he has since repeatedly told me, his arm is as strong as ever it was." (*Physic. in Medical Repository, Vol. 1. New-York.*)

On this subject an interesting memoir was read by Laroche to the Ecole de Médecine at Paris (Germinal, an 13.) It was entitled, "*Dissertation sur la non réunion de quelques fractures, et en particulier de celles du bras, et sur un moyen nouveau de guérir les fausses articulations qui en résultent.*" The author of this production affirms that, when he was at Augsburg, he saw Baron Percy, then with the army of the Rhine, pass a seton through the imperfectly healed cicatrix of a compound fracture of the thigh, which fracture seemed to have lost all disposition to unite. The method answered so well, that in two months the patient was able to walk without crutches. The French assert, that this operation was done when no knowledge of Dr. Physic's case had reached France.

Mr. Brodie has also successfully employed the seton in a case of ununited broken thigh. The patient was a boy, about 13. (See *Med. Chir. Trans. Vol. 5, p. 387, &c.*) In this country, the same operation has been practised for the cure of a disunited humerus by Mr. Stansfield, of Leeds. (See *Op. cit. Vol. 7, p. 103, &c.*) It appears, also, that Mr. Charles Bell applied the method to a fracture of the leg, at the time when Roux was in England. The patient was a child six years old, and the broken bone had continued without union three years. The case had been originally mistaken by some un-

skilful surgeon for a mere contusion. Roux knew not whether the operation succeeded or not. (*Parallèle de la Chir. Angloise, &c. p. 195.*)

We are not to expect, however, that Dr. Physic's new operation will succeed in every instance. Like most other surgical means, it is liable to occasional failures, among which, I believe, we must include the attempt made on a disunited thigh by Mr. Wardrop, (See *Med. Chir. Trans. Vol. 5, p. 365.*) though a partial amendment is mentioned. Mr. Hutchinson was also obliged to take out the seton, in a case of ununited humerus, and no cure was effected. (See *Practical Obs. p. 162.*) Another instance of failure has likewise been mentioned to me.

FRACTURES OF THE OSSA NASI.

These bones, from their situation, are much exposed to fractures. The fragments are sometimes not deranged; but most frequently, they are depressed. In order to replace them, the surgeon must pass a female catheter, a ring-handled forceps, or any such instrument, into the nostrils, and using it as a lever, push the fragments outwards: while with the index finger of the left hand, he prevents them from being pushed out too far. When the fragments are disposed to fall inwards again, some authors advise supporting them with an elastic gum cannula, or lint, introduced into the nostril; but I am inclined to believe with Mr. C. Bell, that no tubes can be employed so as to support the broken bones; and when these have been replaced, they will not readily change their position, as they are acted upon by no muscles. (See *Operative Surgery, T. 2, p. 222*.)

Besides, as Delpech remarks, since the tubes cannot reach the fragments, they cannot support them, and they must be attended with all the inconvenience of foreign bodies placed in contact with parts already inflamed, or about to become so. (*Précis des Mal. Chir. T. 1, p. 222.*)

As fractures of the ossa nasi are the result of falls, and direct blows on the face, the soft parts are always either very much contused or wounded.

Fractures of the ossa nasi are sometimes attended with very dangerous symptoms; depending either upon the concussion of the brain, produced by the same blow, which caused the fracture; or on the cribriform lamella and the crista galli of the os ethmoides being driven inwards so as to injure and compress the brain. This last danger, however, some modern surgeons consider as void of foundation, and whenever the symptoms indicate an affection of the brain, the nature of the case is referred to the intimate connexion between the bones of the nose and the os frontis. (*Delpech, Précis des Mal. Chir. T. 1, p. 221, 8vo. Paris, 1816.*)

When there are symptoms of pressure on this organ, (see *Head, Injuries of*.) and the ossa nasi are much depressed, the surgeon must immediately raise them, and endeavour

to draw gently forwards the perpendicular process of the os ethmoides, which is connected with the cribriform lamella and crista galli. Perhaps, a pair of closed common forceps introduced into each nostril, might best enable the surgeon to do what is necessary. Bleeding and the antiphlogistic treatment are always proper; for, the vicinity of the eye renders it liable to become inflamed; and when there are symptoms of injury of the brain, extravasation, &c. the necessity of such practice is still more strongly indicated.

FRACTURES OF THE LOWER JAW.

This bone is sometimes fractured near the chin; but seldom so as to produce a division of the symphysis, the solution of continuity generally happening between this part and the insertion of the masseter. In other instances, the fracture occurs near the angles of the jaw, that is to say, between the insertion of the masseter and the root of the coronoid process. The bone may also be broken in two places at the same time; in which event the middle portion is extremely difficult to keep right, because many of the muscles, which draw the lower jaw downwards, are attached to that part.

The condyles and coronoid processes are also sometimes broken; the former the most frequently.

Fractures of the lower jaw may be either perpendicular to its basis, oblique, or longitudinal: of the latter, examples have been known in which a portion of the alveolar process with the teeth in it was detached from the rest of the bone.

The soft parts are generally contused and wounded. J. L. Petit mentions one case, in which the bone was broken, and the coronoid process quite denuded, by the kick of a horse.

Fractures of the lower jaw are subject to displacement in the following way. When the fracture is near the symphysis, the side on which the processus innominatus is situated is drawn downward and backward by the sub-maxillary muscles, while the other fragment is supported by the muscles which close the jaw. When the fracture is more backward, the displacement occurs in the same way, but not so easily. When the bone is fractured in two places, the middle portion is always pulled downwards and backwards by the muscles attached to the chin, while the two lateral pieces are kept up by the levator muscles. When the ramus of the jaw is broken, the masseter, being attached to both pieces, prevents any considerable degree of displacement. When the neck of the condyle is fractured, the pterygoideus externus may pull the condyle forwards.

When a blow is received on the lower jaw, or the bone is injured by a fall, or by the pressure of some heavy body; when an acute pain is experienced in the part, and an inequality can be felt at the basis of the bone; when some of the teeth, correspond-

ing to that inequality, are lower than the others; and when a crepitus is perceptible on moving the two pieces of the jaw on each other; there can be no doubt of a fracture. When the gums are lacerated, or the bone denuded by a wound, the case is (if possible) still more manifest.

Fractures of the rami and condyles produce great pain near the ear, particularly when the jaw is moved; and a crepitus may also be felt.

Fractures of the lower jaw, whether simple or double, are easily set, by pushing the displaced part upward, and a little forward, and then pressing on the basis of the bone, so as to bring it exactly on a level with the portion which has preserved its natural position. Indeed, the correctness of the reduction can always be rightly judged of by attending to the line which the base of the jaw ought to form, and observing that the arch of the teeth is as regular as nature will allow. The maintenance of the reduction, however, is difficult; and can only be well executed by supporting the lower jaw, and keeping it applied to the upper one. As the latter indication cannot be properly fulfilled in persons whose teeth are very irregular, it is sometimes necessary to interpose an even piece of cork between the teeth on each side of the mouth, and against this cork the lower jaw is to be kept up with the bandage presently noticed, while the aperture left between the incisores in the situation where no cork is placed, allows food and medicines to be introduced with a small spoon.

As soon as the fracture is set, the surgeon should adapt some thick pasteboard, previously wet and softened with vinegar, to the outside of the jaw, both along its side and under its basis. Over this moistened pasteboard a bandage with four tails is to be applied, the centre being placed on the patient's chin, while the two posterior tails are to be pinned to the front part of a nightcap, and the two anterior ones fastened to a part of the same cap more backward. When the pasteboard becomes dry, it forms the most convenient apparatus imaginable for surrounding and supporting the fracture. A piece of soap-plaster may now be applied to the skin underneath, which will prevent any ill effects of the hardness and pressure of the pasteboard.

Until the bone is firmly united, the patient should be allowed only such food as does not require mastication, and it may be given by means of a small spoon introduced between the teeth. Broths, soups, jellies, tea, and other slops, appear most eligible.

In order to keep the middle portion of the bone from being drawn downwards and backwards towards the larynx, it is frequently necessary to apply tolerably thick compresses just under and behind the chin; which are to be well supported by the bandage already described.

I need hardly state the necessity of enjoining the patient to avoid talking, or moving the jaw more than can possibly be avoided.

When the condyle is fractured, as it is in-

cessantly drawn forward by the action of the pterygoideus externus, and, on account of its deep situation, cannot be pressed back, the lower portion must, if possible, be pushed into contact with it. For this purpose, the bandage must be made to operate particularly on the angle of the jaw, where a thick compress should be placed.

Compound fractures of the lower jaw are to be treated on the same principles as similar injuries of other bones. If possible, the external wound should be healed by the first intention; and, when this attempt fails, care must be taken to keep the wound clean by changing the dressings about once in three days; but not oftener, lest the fracture suffer too much disturbance. It is observed, that compound fractures of the jaw, and even simple ones, which are followed by abscesses, are particularly liable to be succeeded by troublesome and tedious exfoliations.

In very bad fractures, in which all motion of the jaw must have the most pernicious effect, I consider it prudent to administer every kind of nourishment in a fluid form, through an elastic gum catheter, introduced through one of the nostrils down the oesophagus.

FRACTURES OF THE VERTEBRÆ.

On account of the shortness and thickness of these bones, they cannot be broken without considerable violence. The spinous processes, which project backwards, are the most exposed to such injury; for they are the weakest parts of the vertebræ, and most superficially situated. The violence, which is great enough to break the bodies of the vertebræ, must produce a greater or less concussion, or other mischief, of the spinal marrow; from which accident much more perilous consequences are to be apprehended than from the injury of the bones, abstractedly considered. The displaced pieces of bone may press on the spinal marrow, or even wound it, so as to occasion a paralytic affection of all the parts, which derive their nerves from the continuation of this substance below the fracture.

As the mere concussion of the spine may occasion symptoms which very much resemble those usually occurring, when the vertebræ are fractured, the diagnosis is generally obscure. Perhaps an inequality in the line of the spinous processes may be observed. The lower extremities, the rectum, and bladder, are generally paralytic; the patient is afflicted with retention of the urine and feces, or with an involuntary discharge of the latter. (*Boyer.*)

Fractures of the spinous processes, without other serious mischief, are not dangerous; and are the only instances of fractures of the vertebræ which admit of being detected with certainty.

Any attempt to set fractures of the bodies of the vertebræ, even were they known to exist, would be both useless and dangerous. General treatment can alone be employed. Cupping will tend to prevent inflammation in the situation of the injury. When the pa-

tient is affected with a flatulent distention of the abdomen, vomiting, hiccough, &c. the belly may be rubbed with camphorated liniment, and purgative clysters and antispasmodics given.

If requisite, the urine must be drawn off with a catheter. When the bladder, rectum, and lower extremities are paralytic, it is common to rub the back, loins, sacrum, and limbs, with liniments containing the tinctura lyttæ. (*Boyer.*) With respect to the external and internal use of stimulants, however, it can never be judicious, when there is reason to apprehend much inflammation of the injured parts; and as for the idea of thus restoring the nervous influence, there can be little chance of success, the cause of its interruption being here of a mechanical nature. (*Delpech, Mal. Chir. T. 1, p. 222.*)

Some authors recommend trepanning, or cutting out a portion of the fractured bone, when the compression of the spinal marrow, or its injury by a splinter, is suspected; but, exclusively of the difficulty of that operation, on account of the great depth of the intervening soft parts, the indication is never sufficiently evident to authorize it. (*Boyer.*)

Some cases published by Mr. C. Bell tend to prove, that the danger to be apprehended from injuries of the vertebræ, is the same as that which accompanies injuries of the brain. Hence he joins the generality of practitioners in recommending general and local bleeding, and keeping the patient perfectly quiet. And, with respect to operations for the removal of fragments of bone, it is his decided belief, that an incision through the skin and muscles covering the spine, and the withdrawing of a portion of the circle of bone which surrounds the marrow, would be inevitably fatal, the membranes of that part being particularly susceptible of inflammation and suppuration. And, even if a sharp spicula of fractured bone had run into the spinal marrow, and caused palsy of the lower parts of the body, Mr. C. Bell thinks that exposing the medulla to extract the fragment would so aggravate the mischief, that inflammation, suppuration, and death, would be the inevitable consequences. (*Surgical Obs. Vol. 1, p. 157.*) The same author describes inflammation of the spinal marrow as "attended with an almost universal nervous irritation, which is presently followed by excitement of the brain; in the mean time, matter is poured into the sheath of the spinal marrow, and either by its pressure causing palsy, or by its irritation disturbing the function of the part, so as to be attended with the same consequences. The excitement of the brain being followed by effusion, death ensues." (*P. 159.*) Cases are also referred to, where palsy of the lower extremities comes on several months after an injury of the spine, owing to thickening of the membrane of the medulla, or disease of the latter parts itself. Here Mr. C. Bell recommends perseverance in local bleeding and deep issues. (*P. 160.*)

A fracture of the upper cervical vertebræ, or of the processus dentatus, is always suddenly fatal. In such cases, the immediate paralysis of the diaphragm is said to be the cause of instantaneous death. (See also *L. T. Soemmering, Bemerkungen über Verrenkung und Bruch des Rückgraths*, 8vo. Berlin, 1793. *F. A. F. Cuenotte, Diss. Med. Chir. Sistens Casum Subluxationis vertebræ Dorsi cum Fractura complicata, post factam repositionem et varia dira symptomata Duodecima demum Septimana funestæ*. Argent. 1761.)

FRACTURES OF THE STERNUM.

The sternum is not frequently broken, and the reason of this fact is imputed to the position of this bone, resting, as it were, upon the cartilages of the ribs, to the several pieces of which it continues to be formed until advanced age, and to its spongy texture. When the accident does occur, it is from the direct application of external violence to the injured part, and hence the fracture is always accompanied with great contusion, or even a wound of the integuments, and more or less injury of the thoracic viscera. As Boyer remarks, the sternum, in consequence of the elasticity of the cartilages of the ribs, may be readily propelled backward by pressure in this direction, and the result is an actual change in the form, and a real diminution of the chest. Now, since this cavity is always accurately filled by its contents, these alterations cannot happen in a considerable and sudden manner, without a risk of the thoracic viscera being contused, and even ruptured. Thus, when the sternum has been fractured by violent blows on the chest, the heart and lungs have been found severely contused, and sometimes lacerated; and there will always be greater danger of such mischief, when the fracture is attended with depression of one or more of the fragments. In some cases, a large quantity of blood is effused in the cellular membrane of the anterior mediastinum, and, in others, the accident is followed by inflammation, and suppuration in the same situation, and necrosis of the broken part of the bone. Since the lungs are also liable to be ruptured by the same force which causes the fracture, or wounded by the depressed pieces of bone, emphysema may become another complication, as we see exemplified in a case related by Flajani. (*Collezione d'Observ. &c. di Chir. T. 3, p. 214, 8vo. Roma, 1802.*)

A fracture of the sternum is rendered obvious by the inequalities perceptible, when the surface of the bone is examined with the fingers; by a depression, or elevation of the broken pieces; a crepitus and an unusual moveableness of the injured part in respiration. In many cases, the fracture may be seen, the soft parts being torn, or otherwise wounded. The breathing is difficult, and almost always accompanied with cough, spitting of blood, palpitations, and inability to lie on the back. According to the observations of Petit and Baldinger, several of

these latter symptoms may continue with less intensity, a long while after the fracture is cured. (*Léveillé Nouvelle Doctrine Chir. T. 2. p. 243.*)

Fractures of the sternum, when mere solutions of continuity, only require common treatment; viz. a piece of soap-plaster to the situation of the injury, a roller round the chest, quietude, and bleeding, and a low regimen, with a view of preventing, what may be considered as the most dangerous consequence, inflammation of the parts within the chest.

In cases, attended with great depression of the fractured bone, the necessary incisions should be made, in order to raise with an elevator the portions of the bone driven inward, or to extract with forceps any loose splinters, which seem to be similarly circumstanced. However, it is not often necessary to trephine the sternum, either to raise a depressed portion of the bone, or to give vent to extravasated fluid. In the first of these circumstances, I believe with Mr. C. Bell, that the formal application of the trephine can never be right, or necessary, though the surgeon may be called upon to extract loose splinters. (*See Operative Surgery, Vol. 2, p. 218.*) Such an operation, however, may occasionally be proper when abscesses form under the sternum, or the bone is affected with necrosis, and the natural separation of the diseased parts is likely to occupy a considerable time.

Fractures of the sternum are more frequently produced by gunshot violence, than any other cause, and, in these cases, there are generally many splinters requiring extraction. At the battle of Marengo, the French general Champeux received such a wound, with which he lived nearly a month; the injury was attended with so many splinters, that when they were removed, the pulsations of the heart were visible to a considerable extent. (*Léveillé, Vol. cit. p. 244.*)

The ensiform cartilage, when ossified in old subjects, is liable to fracture. Little more, however, can be done in such a case, than relaxing the abdominal muscles by raising the thorax and pelvis, and then applying a piece of soap-plaster and a roller over the part, for the purpose of keeping it steady. When the blow has been violent, the patient should always be bled.

FRACTURES OF THE RIBS.

These generally happen near the greatest convexity of the bones, several of which are often broken together. The first rib being protected by the clavicle, and the lower ribs being very flexible, are less liable to be fractured, than the middle ones.

When the spicula of a fractured rib is beaten inward, it may lacerate the pleura, wound the lungs, and cause the dangerous train of symptoms attendant on emphysema. (*See Emphysema.*)

A pointed extremity of the rib, projecting inwards, may also cause an extravasation of blood; or, by its irritation, produce inflammation in the chest. A fracture, which is

not at all displaced, is very difficult to detect, particularly in fat subjects; and, no doubt, is very frequently never discovered. The surgeon should place his hand on the part where the patient seems to experience a pricking pain in the motions of respiration, or where the violence has been applied. The patient should then be requested to cough, in which action the ribs must necessarily undergo a sudden motion, by which a crepitus will often be rendered perceptible. All the best practitioners, however, are in the habit of adopting the same treatment, when there is reason to suspect a rib to be fractured, as if this were actually known to be the case by the occurrence of a crepitus, or the projection of one end of the fracture; which, indeed, in the instances which are displaced, makes the nature of the accident sufficiently plain.

A broken rib cannot be displaced either in the direction of the diameter of the bone, or in that of its length. The ribs being fixed posteriorly to the spine, and anteriorly to the sternum, cannot become shortened. Nor can any of the broken pieces become higher, or lower than the other, because the same muscles are attached to both fragments, and keep them at an equal distance from the neighbouring ribs. The only possible displacement is either outward or inward. (Boyer.)

Simple fractures of the ribs, free from urgent symptoms, require very simple treatment. The grand object is to keep the broken bones as motionless as possible. For this purpose, after a piece of soap-plaster has been applied to the side, and over it proper compresses, a broad linen roller is to be firmly put round the chest, so as to impede the motion of the ribs; and compel the patient to perform respiration chiefly by the descent and elevation of the diaphragm. A scapularly will prevent the bandage from slipping downwards. When the fractured part is depressed inward, the compresses should be placed on the anterior and posterior part of the bone. As a roller is apt to become slack, many surgeons, with good reason, prefer a piece of strong linen, large enough to surround the chest, and laced with pack-thread, so as to compress the ribs in the due degree.

When there is reason from the symptoms to think the lungs injured, or disposed to inflame, copious and repeated bleedings should be practised. Indeed, as peripneumony is always liable to succeed the accident, and is a most dangerous occurrence, every person free from debility, either having a broken rib, or supposed to have such, should always be bled in the first instance. The spermaceti mixture, with opium, is an excellent medicine for appeasing any cough, which may disturb the fracture, and give the patient infinite pain.

[FRACTURES OF THE SACRUM.]

Although more superficial than the other bones of the pelvis, the sacrum is less frequently fractured; a fact, explicable, as Boyer

has remarked, by its thickness, its spongy texture, and the advantageous way in which it supports the weight and efforts of the whole trunk. For the sacrum to be broken, the violence must be very great, like that resulting from the fall of a very heavy body, or the passage of a carriage wheel on the convex side of the bone, or a fall from a great height on that part. On the other hand, fractures of the sacrum, when they do happen, are more serious than those of the ossa innominata, because, in addition to the great degree of contusion and laceration, with which they in common with the latter cases are complicated, there is almost always great damage done to the sacral nerves; a kind of injury, which may have fatal consequences. Hence retention of urine, inability to retain this fluid, involuntary discharge of the feces, paralysis of the lower extremities, &c. Another principal danger also depends upon the injury, which the pelvic viscera may have suffered from the same violence which broke the bone.

When the fracture is situated at the upper part of the sacrum, which seldom happens on account of the thickness of the bone in that situation, there is no displacement, unless the bone is smashed, and the fragments are driven inwards by the same force which produced the fracture, a case, which always implies severe injury of the external and internal soft parts. But when the fracture occupies the lower portion of the bone, where it is less thick, the inferior fragment may be displaced inwards, towards the rectum. And, as Boyer observes, fractures of the higher part of the bone are not in general easily detected. (*Traité des Mal. Chir. T. 3, p. 152.*)

When the violence has been such as to make it probable, that it has extended its effects to the pelvic viscera, every means in the power of art must be adopted for the prevention of inflammation. In particular, copious bleeding should be practised, and, if necessary, repeated. Leeches should also be applied to the vicinity of the sacrum, and the parts kept cool with the *lotio pumbi acetatis*. Any difficulty either in the expulsion, or retention of the urine and feces, will likewise claim immediate and constant attention. (See *Urine Retention of; Incontinence of, &c.*) With regard to the particular means for promoting the union of the fractured sacrum, quietude is the most important, and, after the risk of inflammation is over, all that can be done is to apply a piece of the emplastrum saponis to the part, and put a roller round the pelvis, or a T bandage.

FRACTURES OF THE OS COCCYGIS.

Though much slighter than the sacrum, it is less frequently broken, because less exposed to external force, and is capable of a degree of motion, by which it eludes the effect of violence. But, in elderly persons, in whom the different pieces of the os coccygis are connected by ankylosis, a fall on the buttock may fracture this bone. The accident is known by the moveableness of the

fragments, and the acute pain produced when the thighs are moved, the fragments being then disturbed by the action of the glutei muscles, some of whose fibres are attached to them. (*Boyer, T. 3. p. 160.*)

The treatment of fractures of the os coccygis consists in enjoining quietude, employing discutient, or emollient applications, according to the particular state of the soft parts, and taking blood away from the patient; adopting the antiphlogistic regimen, and enjoining the patient to avoid lying on his back, or sitting down. He should also avoid walking, so as to put the glutei muscles into action, which would disturb the broken bone. All formal attempts at reduction are not only useless in respect to the fracture, but highly injurious to the soft parts, which are not in a state to bear handling without ill effects.

FRACTURES OF THE OSSA INNOMINATA.

The situation and shape of the ossa innominata, and the thickness of the soft parts by which they are covered, explain why they are but seldom fractured. When such accidents happen, they are generally produced by the passage of heavy carriage wheels over the pelvis, falls from great heights, the kick of a horse, &c. and are always attended with considerable contusion of the external soft parts, and sometimes with great injury of the pelvic viscera. The anterior superior spinous process of the ilium is sometimes broken off by the kick of a horse. (*Boyer.*)

The two ossa innominata may be broken together; but commonly one of them is thus injured. Most frequently, the fracture takes place in the upper expanded portion of the bone, known under the name of the ilium, though sometimes it happens either in the ischium, or the os pubis. The solution of continuity may be limited to one part of the bone, or extended to several parts of it; and there may be a greater or lesser number of fragments, and these attended, or not, with displacement. In many instances, in which the pelvis has been violently jammed between two bodies, or run over by a heavy carriage, the bones of the pelvis, besides being fractured, are dislocated, some interesting examples of which accident have been recently published. (*A. Cooper's Surgical Essays. Part 1. p. 49, &c.*)

During my apprenticeship at St. Bartholomew's Hospital, several instances occurred, in which the os ilium, os ischium, and os pubis, were found fractured on opening the bodies after death; and, when the great violence necessary to produce the accident is considered, we cannot wonder that the injured state of the pelvic viscera should frequently prove fatal. Fractures of the ossa innominata are unavoidably attended with more or less contusion of the soft parts on the outside of the pelvis, and when the violence has been very great, the pelvic viscera may be seriously bruised, crushed, or lacerated; and the large nerves, contained in the pelvis, or the spinal marrow itself, inju-

red: hence, extravasation of blood in the cellular membrane of the pelvis, ecchymoses deeply situated even in the substance of the muscles, or other organs, injury of the kidneys; complete loss of motion, a paralysis of the lower extremities; discharge of blood, or a black bilious matter by vomiting, or stool either immediately, or at more or less distant periods from that of the accident; retention of urine; fever; painful tension of the abdomen, from inflammation of the peritoneum and bowels; the formation of abscesses, which are sometimes of great extent; sloughing; and death. (*Boyer, Traité des Mal. Chir. T. 3, p. 154.*)

As the same author has observed, the violence, occasioning a fracture of the ossa innominata, may produce a displacement of the fragments, and carry them more or less away from their natural situation. When the pubes, or ischium, is broken, the splinters may be propelled into the canal of the urethra, or even through the bladder, and give rise to extravasation of the urine, or by merely compressing these organs, this may cause more or less interruption of their functions. But, unless the fragments be displaced by the same force, which caused the fracture, they can hardly be drawn out of their place by any other circumstance, since they are retained by the muscles being attached to both fragments, and by surrounding ligamentous expansions.

Owing to the deep situation of fractures of the pelvis, and to there being no displacement, nor mobility of the fragments, the diagnosis is sometimes attended with great difficulty. A suspicion of the accident may be entertained, when the pelvis has suffered great violence, the patient experiences great agony, and all motion of the trunk and lower extremities is difficult and painful. Under these circumstances, if the fracture should be in the ilium, especially its upper and front portion, or in the os pubis, the mobility of the fragments, or even a crepitus, may be distinguished in a thin subject, if when he is lying horizontally, with his thighs and legs bent, and his head and chest elevated, the projecting part of the os innominatum be taken hold of, and an attempt be made to move the fragments in opposite directions. In this business, however, one caution is given by Boyer, viz. not to mistake the crepitation of an emphysema, often attending large extravasations of blood, for the grating of the fractured bone.

In cases, in which the fracture affects a part of the os innominatum very deeply placed, and it is limited to a single point of the os pubis, or the ischium, so that no detached moveable fragment has been produced, the exact nature of the case is rarely made out with certainty, before the patient's death, and the dissection of the parts.

Fractures of the ossa innominata may be generally deemed cases, accompanied with serious danger. When the fragments are displaced, and do not admit of being rectified again, the disorder arising from this cause, may have fatal consequences. And

as Boyer observes, even when such displacement does not exist, these fractures are not the less to be apprehended, on account of the injury, which the spinal marrow and the nerves, vessels, muscles, and viscera within the pelvis are likely to have sustained. These complications, which are almost inseparable from the fracture, may prove indeed directly fatal, or destroy the patient at a period more or less remote from the time of the accident. Sometimes, however, the fracture is not extensive, and the violence, which produced it, has not caused any very serious injury of the soft parts: but examples of this kind are uncommon.

In these last cases, which are the most simple, a cure of the fracture may be easily effected by means of rest; a position in which all the chief muscles attached to the pelvis, are relaxed; discutient applications; and a roller, or T bandage. (*Boyer, Traité des Mal. Chir. T. 3, p. 156.*) The grand indication is to obviate the consequences of inflammation of the parts within the pelvis, and even of the peritonæum and abdominal viscera, by copious and repeated blood-letting. Any complaints, respecting the evacuation of the urine and feces, must also receive immediate attention. When there is great contusion, and the bones are very badly broken, the patient cannot move nor go to stool, without suffering the most excruciating pain. To afford some assistance in such circumstances, Boyer, in a particular case, passed a piece of strong girth web under the pelvis, and, collecting the corners into one, fastened them to a pulley suspended from the top of the bed. This enabled the patient to raise himself with very little efforts, so that a flat vessel could be placed under him. It appears to me, that a bed, constructed on the principles recommended by the late Sir James Earle, might be of infinite service in these cases, as well as in many others, particularly compound fractures and paralytic affections from diseased vertebræ. (*See Observations on Fractures of the Lower Limbs; to which is added, an account of a contrivance to administer cleanliness and comfort to the bed-ridden; by Sir J. Earle, 1807.*) Mr. Earle has also exerted his mechanical ingenuity with great success in the invention of a bed, admirably well calculated for the treatment of fractures, and other cases, in which it is an object of high importance, to enable the patient to empty the bowels without changing his position.

Sometimes, notwithstanding the rigorous adoption of antiphlogistic measures, abscesses cannot be prevented from forming in the pelvis; particularly, when there are detached splinters driven inwards. These collections of matter should be opened, as soon as a distinct fluctuation can be felt. The splinters may wound the urethra or bladder, and cause an extravasation of urine. Desault extracted a splinter, which had had this effect, from the bottom of a wound, made for the discharge of the effused urine. In these cases, a catheter should be kept introduced, in order to prevent the urine from collecting in

the bladder, and afterward insinuating itself into the cavity of the abdomen. (*Chopart.*) The possibility of mistaking a fracture of the acetabulum for a dislocation of the thigh-bone, and the differences of these cases, as explained by Mr. A. Cooper, have been mentioned in the article *Dislocation*.

FRACTURES OF THE THIGH.

The os femoris is liable to be broken at every point, from its condyles to its very head; but it is at the middle third of this extent, that fractures mostly occur. The fracture is sometimes transverse, but more frequently oblique. The latter direction of the injury makes a serious difference in the difficulty of curing the case, without future deformity or lameness. Sometimes the fracture is comminuted, the bone being broken in more places than one; and sometimes the case is attended with a wound, communicating with the fracture, and making it what is termed *compound*. As Petit remarks, however, the thigh-bone is less seldom broken into several pieces, than other bones more superficially situated.

A fractured thigh is attended with the following symptoms; a local acute pain at the instant of the accident; a sudden inability to move the limb; a preternatural mobility of one portion of the bone; sometimes a very distinct crepitus, when the two ends of the fracture are pressed against each other; deformity, in regard to the length, thickness, and direction, of the limb. The latter change, viz. the deformity, ought to be accurately understood; for, having a continual tendency to recur, especially in oblique fractures, our chief trouble in the treatment is to prevent it. (*Desault, par Bichat, T. 1, p. 181.*)

Almost all fractures of the thigh are attended with deformity. When this is considered, in relation to length, it appears, that, in oblique fractures, the broken limb is always shorter than the opposite one; a circumstance denoting, that the ends of the fracture ride over each other. We may also easily convince ourselves, by examination, that the deformity is owing to the lower end of the fracture having ascended above the upper one, which remains stationary. What power, except the muscles, can communicate to the lower portion of the fractured bone, a motion from below upwards? At one end, attached to the pelvis, and, at the other, to this part of the bone, the patella, the tibia, and fibula, they make the former insertion their fixed point, and drawing upward the leg, the knee, and the lower portion of the thigh, they cause directly, or indirectly, the displacement in question. In producing this effect, the triceps, semitendinosus, semi-membranosus, rectus, gracilis, sartorius, &c. are the chief agents.

For the purpose of exemplifying the power of the muscles to displace the ends of the fracture, mention is made, in Desault's works by Bichat, of a carpenter, who fell from a scaffold, and broke his thigh. The

limb, the next day, was as long as the other; but the man had a complete palsy of his lower extremities, and could not discharge his urine. The moxa was applied, the muscles soon regained their power, and then the shortening of the limb began to make its appearance.

Besides the action of muscles, there is another cause of displacement. However firm the bed may be, on which the patient is laid, the buttocks, more prominent than the rest of the body, soon form a depression in the bedding, and thence follows an inclination in the plane on which the trunk lies, which, gliding from above downward, pushes before it the upper end of the fracture, and makes it ride over the lower one. The muscles, irritated by the points of bone, increase their contraction, and draw upward the lower part of the bone; and, from this double motion of the two ends of the fracture in opposite directions, their riding over each other results. (*Desault, par Bichat, T. 1, p. 183, 184.*)

Transverse fractures are less liable to be displaced in the longitudinal direction of the bone, because, when once in contact, the ends of the fracture form a mutual resistance to each other; the lower end, drawn upward by the muscles, meets with resistance from the upper one, which being itself inclined downward by the weight of the trunk, pushes the former before it, and thus both retain their position in relation to each other.

The deformity of a fractured thigh, in the transverse direction, always accompanies that which is longitudinal; but, sometimes, it exists alone. This is the case, when, in a transverse fracture, the two ends of the bone lose their contact; one being carried outward, the other inward; or, one remaining in its place, while the other is separated. The upper end of the fracture is not now, as in the foregoing instance, motionless in regard to the muscular action; the contraction of the pectineus, psoas, iliacus internus, and upper part of the triceps, draws it from its natural direction, and contributes to displace it.

The deformity of the limb, in regard to its direction, is either the consequence of the blow, which produced the fracture, or, what is more common, of the ill-directed exertions of persons who carry the patient. Thus we see, that an injudicious posture bends the two portions, so as to make an angle.

Whatever may be the kind of deformity, the lower end of the fracture may retain the natural position in which it is placed, or else undergo a rotatory motion on its axis outward, which is very common, or inward, which is more unusual. This rotation always aggravates the displaced state of the fracture, and should be attended to in the reduction. (*Desault, par Bichat, T. 1, p. 185.*)

Every one at all initiated in the surgical profession knows, that there are two very different methods of treating fractured thighs. In one, which was recommended and prac-

tised by Desault, and is still universally preferred in France, the limb is kept in a straight extended position. In the other, the limb is laid upon its side, with the knee bent, a mode, which was extolled by the celebrated Mr. Pott, and since his time has found many partisans in this country. To these two positions for fractured thighs may now be added that, in which the patient lies upon his back, with his thigh and leg in the bent position, supported on two oblique planes, or surfaces, the apex, or angle of which is beneath the ham. This last position, however, has been more particularly recommended for fractures of the neck of the femur, though, if it be advantageous for them, I see no reason for not giving it a fair trial in other fractures of that bone.

That Mr. Pott has lost sight of certain advantages of the straight position; that he was blind to the imperfections of the bent posture; and that he exaggerated the power, which we have of relaxing all the muscles of a limb by position; few reflecting surgeons of the present day will be inclined to deny.

Were we to resign the privilege of thinking for ourselves, and implicitly to mould our opinions, according to any authority, however high, we should often fall into very avoidable errors. Were we to believe the literal sense of several passages in Mr. Pott's remarks upon fractures, we should suppose it possible and practicable to relax at once, by a certain posture of the limb, every muscle connected with a fractured bone. In the first vol. of his works, page 389, edit. 1783, he observes, in speaking of what must best answer the purpose of incapacitating the muscles from displacing the fracture: "Is it not obvious, that putting the limb into such position as shall relax the whole set of muscles, belonging to, or in connexion with, the broken bone, must best answer such purpose?" and, in the next page, "What is the reason why no man, however superficially acquainted with his art, ever finds much trouble in setting a fractured os humeri? is it not because both patient and surgeon concur in putting the arm into a state of flexion, that is, into such a state as relaxes all the muscles surrounding the broken bone?" Also in page 393, he continues, "Change of posture must be the remedy, or rather the placing the limb in such manner as to relax all its muscles." That to have all the muscles relaxed in cases of fracture would be desirable, were it also practicable, every one will admit; but the possibility of accomplishing it, so long as different muscles have different uses, different situations, and different attachments to the bones, every one must grant to be no more than visionary. For instance, do not the patient and surgeon, in the case of fractured os humeri, adverted to above, rather concur in putting the fibres of the triceps and anconeus into a state of tension, at the same moment that they relax the biceps and brachialis internus?

The position of the fractured os femoris,

says Mr. Pott, should be on its outside, resting on the great trochanter; the patient's whole body should be inclined to the same side; the knee should be in a middle state between perfect flexion, or extension, or half bent; the leg and foot, lying on their outside also, should be well supported by smooth pillows, and should be rather higher in their level than the thigh; one very broad splint of deal, hollowed out and well covered with wool, rag, or tow, should be placed under the thigh, from above the trochanter quite below the knee; and another somewhat shorter should extend from the groin below the knee on the inside, or rather in this posture on the upper side. The bandage should be of the eighteen tail kind, and when the bone has been set, and the thigh well placed on the pillow, it should not without necessity, (which necessity in this method will seldom occur) be ever moved from it again, until the fracture is united; and this union will always be accomplished, in more or less time, in proportion as the limb shall have been more or less disturbed. (Pott.)

Here only two splints are mentioned; the surgeons of the present day usually employ four. After placing the patient in a proper position, the necessary extension is to be made. Then the under-splint, having upon it a broad soft pad, and an eighteen-tailed bandage, is to be laid under the thigh, from the great trochanter to the outer condyle. The surgeon, before applying the soap plaster, laying down the tails of the bandage, and putting on the other three splints, is to take care that the fracture lies as evenly as possible.

In the position for a fractured thigh, Mr. Pott, we find, directs the leg and foot to be rather higher in their level than the thigh; with what particular design, I have not myself been able to make out. Whoever meditates upon the consequence of elevating the leg and foot above the level of the thigh, in the bent position, will know, that it is to twist the condyles of the os femoris more outward than is natural. When a patient is placed, according to Mr. Pott's direction, upon a common bed, the middle soon sinks so much that the leg becomes situated very considerably higher than the thigh, and I am disposed to think that this is one cause, why so many broken thighs are united in so deformed a manner, that the foot remains permanently distorted outward. The great propensity of the triceps, and other muscles to produce this effect, may also serve to explain the frequency of the deformity. It is not merely the depression of the middle of the bed which is disadvantageous: as the weight of the patient's body falls more upon one side of the bed, than the other, in the bent position of the limb, unless the sacking be tight and the mattress very firm, it happens, that such a declivity is formed, as to render it exceedingly difficult, if not impracticable, to make the patient continue duly upon his side. It cannot be enjoined too forcibly, that fractured thighs should always

be laid upon beds not likely to sink much. When this happens, no rational dependence can be put in the efficacy of the bent position, and, as Desault has explained, the same thing is hurtful also in the straight posture.

The most enthusiastic advocates for the bent position must allow, that it leaves the leg and foot too moveable and unsupported, and that though it may relax the muscles, which have the most power to disturb the coaptation of a fractured thigh, it yet leaves a mass of muscle unrelaxed, quite sufficient to displace the ends of the bone. Hence, practitioners should endeavour to improve the apparatus employed, so that it may make a permanent resistance to the action of the muscles, and in the straight position such resistance may certainly be practised with most effect and convenience.

The whole tenor of Mr. Pott's observations on fractures would lead one to suppose, that from the moment a muscle is partially relaxed, it becomes incapable of acting on, or displacing a fracture. But, if this were correct, (which it cannot be) we should not have the power of completely bending, or extending our limbs; for as soon as the set of muscles, designed for this purpose, were partly relaxed by the half-flexion, or half-extension of the joint, they would be deprived of all further power. Therefore, in addition to the arguments to be brought against the bent posture, arising from its not actually relaxing all the muscles connected with the broken bone, we are also to take into the account the fact, that the partial relaxation of any muscle by no means incapacitates it from acting.

In the earlier editions of this Dictionary, I expressed a preference to Mr. Pott's method of treating broken thighs. More mature reflection, however, and subsequent experience, have made me a convert to the sentiments of Desault on this subject. The terrible compound fractured thighs, which I had under my care in the campaign in Holland in the year 1814, could not have been at all retained by any apparatus put merely upon the thigh itself. The superiority of long splints, extending the whole length of the limb, was in these cases particularly manifest. With such splints, which maintain steady the fracture itself, the knee, leg, ankle, and foot, your patient may, in fact, even be removed upon an emergency from one place to another, without any considerable disturbance of the broken part. But, how could this be done in the bent position, with short splints, merely applied to the thigh, affording no support to the leg, and not confining the motions of the knee, and foot?

There are some excellent remarks on the treatment of fractured thighs in *Les Œuvres Chirurgicales de Desault par Bichat*. It is observed, that, if we compare the natural powers of displacement with the artificial resistance of almost every apparatus, we shall find, that the disproportion between such forces is too great to let the former

yield to the latter. The action of the muscles, however, which is always at first very strong, may afterward be gradually diminished by the extension exercised on them. A power incessantly operating can effect, what another greater power temporarily applied, cannot at once accomplish, and the compression of circular bandages tends also to lessen the force of the muscles.

Desault cured in the Hôtel Dieu an immense number of fractured thighs, without any kind of deformity. It was particularly to the well-combined employment of extension and compression of the muscles, that such success was owing. The advantage of keeping the muscles a long while extended, in order to diminish their power, is especially evident in the reduction of certain dislocations, as those of the shoulder, in which we often cannot succeed till the muscles have been kept on the stretch for a greater or lesser time. The fracture of the patella and olecranon equally demonstrates the utility of compression for the same purpose; as when the muscles are not compressed by the bandage, they draw upward the fragment of bone with double or triple force.

Against reducing fractured thighs in the bent posture, Desault entertained the following objections: the difficulty of making the extension and counter-extension, when the limb is so placed; the necessity of then applying them to the fractured bone itself, instead of a situation remote from the fracture, as, for example, the lower part of the leg; the impossibility of comparing with precision the broken thigh with the sound one, in order to judge of the regularity of its shape; the irksomeness of this position long continued, though it may at first seem most natural; the inconvenient and painful pressure of a part of the trunk on the great trochanter of the affected side; the derangement, to which the limb is exposed when the patient has a motion; the difficulty of fixing the leg firmly enough to prevent the effect of its motion on the thigh-bone; the manifest impossibility of adopting this method, when both thighs are fractured; lastly, experience in France having been little in favour of such posture.

Also, what is gained by the relaxation of some muscles, is lost by the tension of others. For such reasons, (certainly strong ones,) Desault abandoned the bent position, and always employed the straight one, which was advised by Hippocrates, and all the Greek physicians.

Petit, Heister, and Duverney, recommend applying the extending means just above the condyles of the os femoris. Dupouy was one of the first to remark, that this practice rendered it necessary to employ very great force, and that it would be better to make the extension from the foot. Fabre takes into consideration also the inconvenience of the pressure, made on the muscles, which, irritating and stimulating them to action, multiplies the obstacles to setting the fracture. For nearly similar motives, Desault espoused their doctrine,

introduced it at the Hôtel Dieu, and the success which he experienced from the practice, contributed materially to its more extensive adoption.

Desault, as we have stated, preferred the straight posture, and laid his patients on surfaces, not likely to sink with the weight of the body. The feather beds, formerly in common use at the Hôtel Dieu, had this inconvenience; for these, in cases of fractures, Desault substituted a firm, tolerably hard mattress, which did not allow the continual change of posture to occur, which a soft bed does. The object of every apparatus being to keep the ends of the fracture from being displaced, the mechanism of every contrivance, for this purpose, should be directed against the causes of the displacement. These are, 1. the action of the muscles, drawing upward the lower end of the fracture; 2. the weight of the trunk propelling downward the upper end. Hence, every apparatus, intended to prevent displacement of a thigh fractured obliquely, should, 1. draw and keep downward the lower end of the fracture; 2. carry and maintain upward the upper end of the fracture, and the trunk, which is above it. This principle is of general application, and only subject to a few exceptions in transverse fractures, attended merely with displacement in the direction of the diameter of the limb, or else none at all. 3. There must also be in the apparatus a resistance to the rotation of the lower portion of the broken bone, so as to keep the limb steady, even in case of any sudden motion.

If we compare the operation of the different pieces of our apparatus with the above indications, we shall find, that without permanent extension, they are not very effectual. With regard to bandages, whether a roller or eighteen-tailed bandage, be used, they all have one common mode of operating; they press the muscles towards the ends of the fracture, so as to make them form a kind of natural case for the fracture, and thus they make lateral resistance against the parts. In this manner, bandages materially aid in preventing displacement sideways, and are particularly useful in transverse fractures. But, what is there to hinder the two inclined surfaces of an oblique fracture from slipping one over the other? What power is there to keep the limb from receiving the effects of accidental shocks? Is the pelvis kept back? Is the action of the muscles resisted? The latter is indeed somewhat diminished by the pressure, and this is the chief use of the bandage: but, will such compression be enough to prevent the longitudinal displacement of the broken bone, especially, if the bandage be applied slackly, as some advise?

These remarks apply also to compresses; *petit moyen contre une grande cause.*

Splints are useful in firmly fixing the limb, and guarding it from the effects of accidental shocks, or of contractions of the muscles. They operate more powerfully than bandages, in preventing lateral displacement;

and hence, they suffice for transverse fractures, without permanent extension. They also resist the rotation of the thigh outward, or inward. But when the breach of continuity is oblique, will they hinder the ends of the bone from gliding over each other, and the consequent shortening of the limb? They obviously could only do so, by the friction of the different pieces of the apparatus, especially the tapes, which fasten it, and then, to make the resistance effectual, they must be tied so tightly as to create danger of mortification. Will the splints prevent the trunk from descending, and propelling before it the upper end of the fracture? Will they hinder the action of the muscles on the lower end? Will they, in short, fulfil all the above indications? Their chief use is to prevent lateral displacement, and keep the limb steady. Hence, they should extend along the leg, as well as the thigh, which cannot fail to be disturbed whenever the lower part of the limb is allowed to move.

The pads serve principally to keep the limb from being galled by the splints, and their action in preventing displacement of the fracture must be but trivial.

According to Desault, the ordinary pieces of apparatus, which do not execute any permanent extension, may suffice for transverse fractures; but they are always ineffectual, when the division is oblique, because they do not fulfil the twofold indication of drawing downward the lower end of the fracture, and keeping the other one upward.

Desault ascertained that the object particularly to be aimed at, was such a disposition that the foot, leg, thigh, and pelvis, should constitute but one whole; so that, though the different parts thereof might be drawn in different directions, yet they would still, with respect to one another, preserve the same mutual relation. He invented the following apparatus to answer these purposes.

A strong splint, long enough to extend from the ridge of the os ilium to a certain length beyond the sole of the foot, is a principal part of this apparatus: this splint should be two inches and a half broad, each of its extremities being pierced in the form of a mortice, and terminating in a semicircular niche. It is applied to the exterior side of the thigh, by means of two strong linen bands, each being more than a yard long.

The middle part of one of these bands is to be applied to the inside of the thigh, at its upper part; its ends are brought to the exterior side of the thigh, passed through the mortice, and knotted on the semicircular niche. Compresses are to be previously placed under the middle part of the band, in order to prevent any disagreeable pressure; as well as on the tuberosity of the ischium, which Desault considered as the principal point of action of this band. The inferior part of the leg is next covered with compresses, on which the middle part of the

second band is placed: the extremities of this band cross on the instep and upper part of the foot, then on the sole, after which they are conveyed outward, and one end passed through the mortice and knotted with the other on the niche, with such a degree of force as to pull the inferior portion of the femur downward, and push the splint upward, and by this means, the pelvis, and superior portion of the fractured bone. On the internal side of the limb is placed a second splint, which extends from the superior part of the thigh, to a certain distance beyond the foot. A third is placed on the anterior part of the limb from the abdomen to the knee. The superior extremities of the anterior and exterior splints are fixed by means of a bandage passed round the pelvis. A band, the middle part of which is placed under the sole of the foot, and the extremities crossed on its superior surface, and fastened to the splints, operates with them in preventing the foot from moving.

Before applying the apparatus, Desault covered the whole limb with compresses, wet with a solution of the acetite of lead. Over these, Scultetus's bandage was put, and a roller round the foot, all wet with the same lotion. For more particulars, the reader is referred to the *Parisian Chirurgical Journal*, Vol. 1; *Œuvres Chir. de Desault par Bichat*, T. 1; *Rosalino Giardina Memoria sulla Fratture, con alcune Modificazioni all' Apparato di Desault*. Svo. Palermo, 1814. *Boyer, Traité des Maladies Chir.* T. 3; *Richerand, Nosogr. Chir.* T. 3, Edit. 4. Boyer's apparatus for fractured thighs is described in the 2d vol. of the *First Lines of the Practice of Surgery*, ed. 4.

Instead of the position advised by Pott, or that recommended by Desault and Boyer, Mr. C. Bell prefers the posture, in which the patient lies upon his back, with the limb supported in the bent attitude by means of a wooden frame. This machine is simple enough, consisting of boards, ten or eleven inches in breadth, one reaching from the heel to the ham, the other from the ham to the tuberosity of the ischium. Under the knee-joint, they are united at an angle, while a horizontal board connects their lower ends together. Thus they form two sloping surfaces, to which cushions are adapted, and over which the limb can be placed in an easy bent position. Near the edge of the inclined boards, holes are made, furnished with pegs. After the bone has been set, a long splint is applied from the hip to the side of the knee, and another along the inside of the thigh. (See *Operative Surgery*, Vol. 2, p. 189.) I entertain a very favourable opinion of this mode of placing fractured thighs. However, the foregoing apparatus does not sufficiently secure the leg and foot from motion, though with the aid of a roller and a foot-board, this advantage might easily be obtained. The fracture apparatus, devised by my friend Mr. Earle, is excellently calculated for this mode of treatment, with these additional recommendations, that the obliquity of the two

surfaces, on which the limb reposes, can be altered as occasion may require; there is a foot-board for the support of the foot, and a contrivance, by which the patient is enabled to have stools, without moving himself or changing his posture in the slightest degree.

Fractures of the Neck of the Thigh-bone.

These accidents are infinitely more frequent, than dislocation of the thigh-bone, and are divisible into two kinds: first, that in which the neck of the bone is broken within the capsular ligament; and secondly, that in which the fracture happens externally to this ligament, either through the root of the neck of the bone, or through the trochanter major. (*A. Cooper, Surgical Essays, Part 2, p. 30.*)

The neck of the thigh-bone may be fractured either by a fall on the great trochanter, the sole of the foot, or the knee. According to Desault, the first accident produces the injury much more frequently, than the two latter. Of thirty cases, which were seen by Desault, four-and-twenty arose from falls on the side. All those inserted by Sabatier in his interesting Memoir, were the result of a similar accident. These statements, however, do not exactly coincide with the experience of Mr. A. Cooper, who observes, that in London, the accident is most commonly produced by a person slipping off the edge of the foot pavement. According to this eminent surgeon, a fracture of the neck of the thigh-bone, within the capsular ligament, seldom happens but at an advanced period of life, and the reason of the facility, with which the injury takes place in old persons, he ascribes to the interstitial absorption, which that part of the femur undergoes in individuals past a certain age, whereby it becomes shortened, and altered in its angle with the shaft of the bone. Mr. A. Cooper admits, however, that the accident is frequently caused by a fall upon the trochanter major. (*Surgical Essays, Part 2, p. 35, 36. Also Larrey, Journ. Complém. T. 8, p. 98, 8vo. Paris. 1820.*) Fractures of the neck of the thigh-bone are said to be more common in women, than men. (*J. Wilson on the Skeleton, &c. p. 245.*)

The division is seldom oblique, almost always transverse; the neck being sometimes, in the latter case, wedged in the body of the bone, as Desault found in several instances; a model of one of which, in wax, is preserved in the collection of *L'Ecole de Santé*, and the natural specimen of which was in the possession of Bichat. The fracture of the neck of the thigh-bone is sometimes complicated with that of the trochanter major.

The diagnosis is occasionally so difficult, that the best informed practitioners cannot always detect the accident with certainty. At the instant of the fall, an acute pain is felt, (sometimes a crack is distinctly heard) and a sudden inability to walk occurs; and the patient cannot raise himself from the ground. The latter circumstance, however,

is not invariable. In the fourth vol. of the *Mem. de l'Acad. de Chirurgie*, a case is related, in which the patient walked home after the accident, and even got up the next day. Desault published a similar example. The locking of one end of the fracture in the other, may offer an explanation of this circumstance. The dissections made by Dr. Colles, have recently led to another discovery, viz. that sometimes the solution of continuity does not extend completely through the neck of the femur. (See *Dublin Hospital Reports, Vol. 2.*) Three cases proving this are there adduced; a fact, which at once explains the ability of some patients to walk directly after the injury, and the absence of all retraction of the limb.

A shortening of the limb almost always takes place; but this symptom is more or less striking, according as the breach of continuity is out of the cavity of the orbicular ligament, which then cannot keep the bone from being retracted; or as the extremity of the fracture is confined by this ligament. The action of the muscles drawing upward the lower end of the fracture, the weight of the trunk in propelling downward the pelvis and upper end of the fracture, are the two causes of the shortening of the limb. In general, a slight effort suffices for the restoration of the natural length of the limb; but the shortness recurs almost as soon as the extension ceases. "This evidence of the nature of the accident continues," as Mr. A. Cooper correctly remarks, "until the muscles acquire a fixed contraction, which enables them to resist any extension, which is not of the most powerful kind." (*Surgical Essays, Part 2, p. 31.*) Goursault and Sabatier remark, that sometimes the shortening of the member does not take place till a long while after the accident. In opposition to the common belief, that the limb is shortened, Baron Larrey asserts, that the member is at first actually lengthened. (*Journ. Complém. T. 8, p. 99.*) This statement I have never seen confirmed, and it is contradicted by daily experience. And to prove how widely Larrey differs from Mr. A. Cooper, the following passage will suffice. "In order to form a still more decided judgment of this accident (says the latter writer) after the patient has been examined in the recumbent posture, let him be directed to stand by his bed-side, supported by an assistant, so as to bear his weight upon the sound limb. Immediately he does this, the surgeon observes most distinctly the shortened state of the injured leg, the toes resting on the ground, but the heel not reaching it, the everted foot and knee, and the diminished prominence of the hip." (*Surgical Essays, Part 2, p. 34.*) A swelling is observable at the upper and front part of the thigh, always proportioned to the retraction, of which it appears to be an effect.

The projection of the great trochanter is almost entirely effaced. Directed upwards and backwards, this eminence becomes ap-

proximated to the crista of the os ilium; but, if pushed in the opposite direction, it readily yields; and, when it has arrived at its natural level, the patient becomes capable of moving his thigh.

The knee is a little bent. Abduction of the limb always occasions acute pain, and it is noticed by Mr. A. Cooper, that the rotation inwards is particularly painful, because the broken extremity of the bone then rubs against the capsular ligament. (*Vol. cit. p. 33.*) If, while the hand is placed on the great trochanter, the limb is rotated on its axis, this bony projection may be felt revolving on itself, as on a pivot, instead of describing, as in the natural state, the segment of a circle, of which the neck of the femur is the radius. This symptom, which was particularly noticed by Desault, is very manifest when the fracture is situated at the base of the neck, less so when at its middle; and it is not very perceptible when the breach is near the head of the bone. In the rotatory motions, the lower fragment, rubbing against the upper one, produces a distinct crepitus, which, however, is not an invariable symptom, as Larrey would lead one to suppose.

As Mr. A. Cooper observes, no crepitus can be felt while the patient is lying upon his back with the limb shortened; but, if the leg be drawn down, it may sometimes be distinguished, especially when the limb is rotated inwards. (*Surgical Essays, Part 2, p. 34.*)

The toes are usually turned outward; a position which Sabatier considers as the inevitable effect of the fracture, though Paré and Petit noticed, that it did not constantly occur. Two cases, adduced by these illustrious surgeons, were not credited by M. Louis; but the experience of Desault fully confirmed the possibility of the limb not being always rotated outwards. And, as Mr. A. Cooper has remarked, three or four hours generally elapse before the turning of the limb outward is rendered most obvious by the fixed contraction of the muscles. (*Surgical Essays, Part 2, p. 32.*)

The position of the toes outward is commonly, and I believe correctly, imputed to the rotator muscles. Bichat conceived, however, that if this doctrine were true, such position ought always to exist; and he reminds us, that all the muscles, which proceed from the pelvis to the trochanter, are, with the exception of the quadratus, in a state of relaxation, by the approximation of the femur to their point of insertion; and that the contracted muscles would not allow the foot to be so easily turned inward again. Hence, Bichat thought it probable, that the weight of the foot itself may pull the limb into the position, in which it is commonly found. On the other hand, it is remarked by Mr. A. Cooper, that any one may satisfy himself, that the rotation of the limb outwards is in part owing to the muscles, by feeling the resistance, which is made to rotation inwards, which resistance, however, he

thinks may in some measure depend upon the length of the portion of the neck of the femur, which remains attached to the trochanter major, and rests against the ilium. (*Surgical Essays, Part 2, p. 32.*)

It follows from the preceding account, that none of the symptoms of a fracture of the neck of the thigh-bone are exclusively characteristic; that each, considered separately, would be insufficient, and that their assemblage can alone throw light on the diagnosis. In every instance of doubt, however, the safe course must be pursued, and the apparatus applied, which, though useless, is not dangerous, should the injury not exist, and is indispensably necessary when it does. (*Desault, par Bichat, T. 1, p. 219—226.*)

It was at one time supposed, that fractures of the neck of the thigh-bone could not be cured, without some shortening of the limb, and lameness. Ludwig, Sabatier, and Louis, broached this doctrine, and imputed the circumstance to the destruction of the neck of the bone. That this sometimes happens has been well ascertained. A late Surgical visiter to Paris informs us, that, in several specimens, which he examined in different museums, whether imperfect union, or no union at all, had followed the fracture, this absorption of the neck of the bone had taken place to a great extent, and in some to so great an extent, that the articulating surface of the bone, which plays in the acetabulum, rested between the trochanters, consolidated to the body of the bone by ligamentous union, and the thickening of the surrounding parts, whilst all the intervening neck of the bone was absorbed. (*See Sketches of the Medical School of Paris, by J. Cross, p. 90.*) M. Roux has also nearly always found the neck of the femur shortened and deformed after its reunion. (*Parallèle de la Chir. Angloise avec la Chir. Francoise, p. 178.*) Desault, however, is said to have rarely met with instances of lameness from such a cause in his practice.

A question, that has lately been much agitated, is, whether reunion by bone ever follows cases, in which the fracture is entirely within the capsule, and the head of the bone insulated, except at its attachment to the acetabulum by the round ligament? The French surgeons decide in the affirmative, and pretend actually to demonstrate the fact by preparations in their museums. M. Roux, indeed, was good enough to send over a specimen to Mr. A. Cooper, with the hope of producing conviction; but, this eminent surgeon still remains unconvinced, because the traces of reunion in the preparation appear to him to indicate a sort of fracture, where the internal fragment still retained some connexion with the capsular ligament. (*Roux Parallèle de la Chirurgie Angloise, &c. p. 179, 180.*) In fact, it was a case, in which the fracture had happened at the junction of the cervix with the trochanter. And Mr. A. Cooper in his last valuable publication distinctly states, that, in all the ex-

minations which he has made of *transverse fractures of the cervix femoris, within the capsular ligament, he has never met with a bony union, or of any which did not admit of motion of one bone upon the other.* (*Surgical Essays, Part 2, p. 39*) By this eminent surgeon, the want of bony union is referred to the fragments not being in contact and duly pressed against each other and to the little action in the head of the bone separated from the cervix, "its life being supported solely by the ligamentum teres, which has some few vessels ramifying from it to the head of the bone." For the particular appearances found in the dissection of these cases, I must refer to the statements of Dr. Colles. (*Dublin Hospital Reports, Vol. 2,*) and to Mr. Cooper's own account, from which it seems, that "no ossific union is produced; that nature makes slight attempts for its production upon the neck of the bone, and upon the trochanter major; but scarcely any upon the head of the bone; and that, if any union is produced, it is by ligament only." (*Vol. cit. p. 46.*) Mr. Wilson's observations are all in confirmation of the same explanation; (*On the Skeleton, p. 247.*) and he adverts to two preparations, in the museum of the College of Surgeons, which have been supposed to be proofs of a bony reunion of the neck of the femur, subsequently to a fracture within the capsular ligament; but (says Mr. Wilson) "I have very attentively examined these two preparations, and cannot perceive one decisive proof in either of the bone having been actually fractured." One of these cases is that, which was published last year by Mr. Liston in the *Edinb. Med. and Surgical Journ.* Lastly, Dr. Colles of Dublin dissected several cases, in which the neck of the femur had been broken: in one, where the injury was within the capsular ligament, "no effort of nature had been made to create a reunion between the two pieces of the fracture, and the stability of the limb had depended upon the strength of those ligamentous bands, by which each piece was connected with the capsular ligament of the joint, aided, no doubt, by the extraordinary thickness, which the capsular had acquired." (*Dublin Hospital Reports, Vol. 2, p. 336.*) In the two first instances, reported by this author, "The broken surfaces moved on each other, and were converted into a state approaching to ivory. No attempt had been made to reunite the fracture, and the pieces of bone were held in apposition only by new ligamentous productions from the capsular ligament, which were inserted into the external surfaces of each piece." In No. 3, there had been a slight attempt made at reunion. In No. 7, 8, and 9, we observed a phenomenon, which, I believe, is now for the first time mentioned, a fracture of only part of the bone. No 6 presented us with that mode of reunion, which some have supposed the most perfect, of which this fracture is susceptible. While No. 10 and 11 exhibit a mode of reunion, very little inferior to callus in point of firmness, but very different in its na-

ture, and which I conceive is peculiar to the fracture of the neck of the femur." Dr. Colles also found, that, in all these cases (except, perhaps, No. 5) the capsular ligament was not lacerated. In every instance, however, there was an increased thickness of the capsule, and a removal of all, or the greater part of the neck of the bone. "Although the ligamentous bands seem, in a majority of instances, to have proceeded from the capsular ligament, yet, it is evident from No. 6, that these may arise merely from the broken surfaces of the bone; for, in this case not a single fibre was attached to the capsular ligament, the new bond of union being covered by the reflected portion of the synovial membrane or periosteum of the neck. We have an illustration of this in Ruysch. Tab. 1, Ches. 9." In No. 10 and 11, the fragments were united by a cartilaginous substance. In No. 7, 8, and 9, the unbroken portion of the neck was so softened, that it more resembled cartilage than bone, and, in this state, "it was laid down upon the fractured surface, and united to it." (*Dr. Colles in Dublin Hospital Reports, Vol. 2, p. 353—355.*) In the museum of the Ecole de Médecine at Paris, there are some preparations, which the professors exhibit at their lectures, in order to prove, that bony union may succeed a fracture of the neck of the femur. These specimens were carefully examined by Mr. Cross; but, none of them proved to him, that bony union ever follows where the head of the bone becomes insulated, except its attachment to the pelvis by the ligamentum teres. (*Sketches of the Medical Schools at Paris, p. 93.*) On the other hand, Boyer observes, that experience fully proves the possibility of uniting such fractures of the neck of the thigh bone, as are situated within the capsular ligament; but, he acknowledges, that there are certain circumstances, which may prevent this desirable event. "From all that has been hitherto said on the prognosis of a fracture of the neck of the femur, we may conclude, (says Boyer) that this fracture is more serious, than that of any other part of the same bone, because the difficulty of keeping it reduced is greater. That it may in general be reunited, especially in young healthy subjects; but, more easily, when it is situated near the base of the neck, than near the head of the bone. That the languid vitality of one of the fragments and the impossibility of ascertaining whether the coaptation be exact, make the cure slow, and the time necessary for their consolidation uncertain. That the neglect of means adapted to maintaining the limb in its proper length, and natural straightness, and the fragments sufficiently motionless, may cause them to unite by an intermediate substance. Lastly, that the situation of the fracture near the head of the femur; the complete laceration of the elongation of the capsule investing the neck of the bone; the great age of the patient; and, particularly, the constitution labouring under some diathesis, which affects the osseous system; may render the cure absolutely im-

possible; that, in this circumstance, one of the fragments is more or less destroyed by the friction of the other against it, and in the joint a disease is formed, which tends to carry off the patient." (*Boyer, Traité des Maladies Chirurgicales, T. 3. p. 284.*) This professor lays much stress on the complete laceration of the continuation of the capsule over the neck of the bone, as an occurrence preventive of union. But, he thinks it does not frequently happen, because the capsular ligament hinders much displacement of the fragment. (*Op. cit. p. 278.*) As for Baron Larrey, he appears to entertain no doubt of the possibility of uniting fractures of the neck of the femur within the capsular ligament, and concludes his tract on this subject with the case of General Fririon, who was perfectly cured, after a supposed injury of this description. (*See Journ. Complém. Tom. 8, p. 118.*)

How is this discordance between the most experienced French and English surgeons to be reconciled and accounted for? After the very numerous and careful dissections, which have been performed by Mr. A. Cooper and Dr. Colles, with the view of ascertaining the state of the joint, after fractures of the neck of the thigh-bone, little doubt can be entertained, that, where the fracture is transverse and within the capsular ligament, a bony reunion, if not absolutely impossible, is at least so rare an occurrence as not to be calculated upon. The difference of the French surgeons upon this question is to be ascribed to their not having duly discriminated from the foregoing kind of case, either fractures extending more or less in the direction of the axis of the neck of the bone, or other fractures external to the capsular ligament. How much, however, the safety of the practitioner's reputation will depend upon the prognosis which is given, must be quite evident: for in the transverse fracture within the capsule, lameness is sure to follow, though its degree cannot at first be exactly estimated. (*A. Cooper, Surgical Essays, Part 2, p. 51.*)

The following circumstances are enumerated by this author, as forming a criterion of the fracture being external to the capsular ligament. 1. The injury frequently happens in young persons; indeed, it is said, that, when the patient is under fifty, the fracture is generally on the outside of the capsule, and capable of ossific union. 2. Whilst the internal fracture happens from very slight causes, this is produced by severe blows, falls from considerable heights, or by the passage of a carriage-wheel over the pelvis. 3. The crepitus is in general more readily felt, in consequence of their being less retraction of the limb. 4. The trochanter is displaced forwards nearer the spine of the ilium, than natural. 5. The pain of the accident is greater, than when the fracture is within the capsule. 6. The limb is generally less shortened. 7. The limb admits of being rotated with greater facility, there being no remnant of the cervix capable of making re-

sistance by coming in contact with the ilium. (*Vol. cit. p. 53.*)

Having spoken of the nature of fractures of the neck of the thigh-bone, within and without the capsular ligament, I come next to the consideration of the proper practice to be adopted. In the first description of the injury, as no osseous union can be expected, ought we to endeavour to keep the fragments as nearly in a state of apposition as possible, and subject the patient to rest and confinement, with the view of promoting the other modes of union, so well pointed out in Dr. Colles's paper? Or should we, as Mr. A. Cooper does, avoid confining the patient to any long, or continued extension, "as being likely to be productive of ill-health, without the probability of producing union?" Yet it appears both from this gentleman's own statements, and from those of Dr. Colles, that, though a bony union cannot be effected, other connecting means may be established, and the more perfect these are, the less will be the subsequent lameness. As long, therefore, as these facts are incontrovertible, I should be disposed to recommend surgeons to do every thing in their power to keep the limb quiet, and in a desirable posture, for a due length of time. Whether for this purpose, Boyer's apparatus, with the limb in the straight posture; or the apparatus with two inclined surfaces, with the limb in the bent position, and the patient on his back; or lastly, Hagedorn's ingenious and scientific treatment, as explained in the second vol. of the *First Lines of Surgery*, should be preferred, time and experience must determine. Mr. A. Cooper merely places one pillow under the whole length of the limb, and puts another across under the patient's knee, so as to keep the limb in an easy bent position. In a fortnight, or three weeks, the patient is allowed to sit upon a high chair, and in a few more days, he begins to take exercise upon crutches. After a time, these are laid aside, a stick substituted for them, and in a few months this assistance may be dispensed with. At the end of the treatment, a shoe must be worn with a sole of equal thickness to the diminished length of the limb. (*Surgical Essays, Part 2, p. 50.*)

In the treatment of such fractures of the neck of the femur, as are situated on the outside of the capsular ligament, Mr. A. Cooper prefers the position in which the patient lies on his back, with the injured limb in a bent posture, supported on what is termed the double inclined plane, the kind of instrument already spoken of as being sometimes employed by Mr. C. Bell. When the limb has been placed over this machine, in an easy bent position, a long splint, reaching above the trochanter major, is applied to the outer side of the thigh, and fastened to the pelvis with a strong leather strap, so as to press one portion of bone towards the other. The lower part of the splint is also fastened to the outside of the knee with a strap. The limb is to be kept as quiet as possible for eight weeks, at the end of which time the patient may leave his bed, if the attempt

should not cause too much pain; but the splint is to be continued another fortnight. (*Surgical Essays, Part 2, p. 59.*) Desault's apparatus has been described in the foregoing columns, and those of Boyer and Hagedorn are explained and represented in the 2d Vol. of the First Lines of Surgery.

Larrey, who disapproves of the plan of continued extension, has lately proposed a particular apparatus for fractures of the neck of the femur: but as it appears to me very inferior to other methods already mentioned, I shall here merely refer to the *Journ. Compl. T. 8, p. 116*, where a description of it may be found.

I am glad to find the number of advocates for Pott's method of treatment annually diminishing. Indeed, the bad effects and painful consequences of having the whole weight of the trunk operating upon the fractured ends of the bone, which are often not properly in contact, are too obvious to need any comment. Yet this injudicious pressure is made in the bent position, which also forbids the use of long effective splints, and all assistance from moderate continued extension.

A fracture of the neck of the thigh-bone may be complicated with a dislocation of the head of the bone. (See J. G. Haase, *De Fractura colli Ossis Femoris, cum Luxatione Capitis ejusdem ossis conjuncta*, Lips. 1798.) For further information relative to fractures of the neck of the femur, the following authors may be consulted. C. G. Ludwig, *de Collo Femoris ejusque Fractura Programma*, Lips. 1755. OBLIQUE FRACTURES OF THE EXTERNAL, OR INTERNAL CONDYLE OF THE FEMUR INTO THE JOINT.

In these cases, Mr. A. Cooper prefers the straight position, because the tibia presses the extremity of the broken condyle into a line with that which is not injured. The limb is to be put in the extended posture upon a pillow, and evaporating lo-

tions and leeches are to be used for the removal of the swelling and inflammation. "When this object has been effected, a roller is to be applied around the knee, and a piece of stiff pasteboard, about sixteen inches long, and sufficiently wide to extend entirely under the joint, and to pass on each side of it, so as to reach to the edge of the patella, is to be dipped in warm water, and applied under the knee, and confined by a roller. When this is dry, it has exactly adapted itself to the form of the joint, and this form it afterward retains, so as best to confine the bones. Splints of wood or tin may be used on each side of the joint; but they are apt to make uneasy pressure. In five weeks, passive motion of the limb may be gently begun, to prevent anchylosis." (*Surgical Essays, Part 2, p. 101.*) This author afterward describes a compound fracture of the external condyle, a portion of which was after a time extracted, and the case ended so favourably, that the patient, who was a boy, was able to bend and extend the leg without pain.

For fractures just above the condyles, Mr. A. Cooper recommends the bent position, without which, he says, deformity is sure to follow. He advises the limb to be placed over the double inclined plane, and a roller applied round the lower portion of the femur. (p. 103.)

FRACTURES OF THE PATELLA.

This bone is most frequently broken transversely, and the accident may be occasioned either by the action of external bodies, or by that of the extensor muscles. In the latter case, the fall is subsequent to the fracture, and, as Camper has remarked, it is mostly only an effect of it. For instance, the line of gravity of the body is, by some cause or another, inclined backward; the muscles in front contract to bring it forward again; the extensors act on the patella; this breaks, and the fall ensues. That it is the action of the muscles, and not the fall, which usually breaks the knee-pan, is well ascertained. Sometimes the fracture occurs, though the patient completely succeeds in preventing himself from falling backward, as we find exemplified in two cases lately reported by Mr. A. Cooper. (*Surgical Essays, Part 2, p. 85.*) A soldier broke his patella in endeavouring to kick his serjeant; the olecranon has been broken in throwing a stone. In the operating theatre of the Hôtel Dieu both the knee-pans of a patient were broken by the violent spasms of the muscles, which followed an operation for the stone. The force of the muscles occasionally ruptures the common tendon of the extensor muscles; or, what is more frequent, the ligament of the patella. Of these cases, Petit, Desault, and Sabatier, met with examples. When the patella is broken longitudinally, the cause is always outward violence. (*Œuvres, Chir. de Desault T. 1, p. 252.*)

A transverse fracture of the patella may also originate from a blow, or fall, on the

part; but, in common cases, it is produced by the violent action of the extensor muscles of the leg. It is only of late years, however, that the true mode, in which the bone is usually broken, has been understood. As Boyer observes, for the production of a transverse fracture of the knee-pan, the extensor muscles of the leg need not act with a convulsive force, their ordinary action being strong enough to produce the effect in question, when the body is inclined backward, and the patient is in danger of falling upon his occiput. In this state, the thigh being bent, the extensor muscles of the leg contract powerfully, in order to bring the body forwards, and prevent the fall backwards; and the patella, whose posterior surface then rests only by a point against the forepart of the condyles of the femur, is placed between the resistance of the ligament binding it to the tibia, and the action of the extensor muscles. A fracture now happens the more easily, because, by the flexion of the knee, the line of the extensor muscles, and that of the ligament of the patella, are rendered oblique, with respect to the vertical axis of this bone, which is bent backwards at the point, where it rests upon the condyles. (*Traité des Mal. Chir. T. 3, p. 322.* C. Bell's *Operative Surgery, Vol. 2, p. 201, 8vo. Lond. 1809.* A. Cooper's *Surgical Essays, Part 2, p. 86.*) By violent spasmodic action of the extensor muscles, however, the patella may be broken transversely, while the limb is perfectly straight. A very singular case is mentioned by Mr. A. Cooper, where a patella, which had been formerly broken, and united by ligament, was again divided into two portions, in consequence of the destruction of the uniting medium by ulceration. (*Vol. cit. p. 100.*) A case is also on record, where the ligamentous uniting substance was so incorporated with the skin, that when the latter happened to be lacerated, the knee-joint was laid open, and amputation became necessary. (*C. Bell, Op. Surgery, Vol. 2, p. 204.*)

In transverse fractures, there is a considerable separation between the two fragments of the bone, very perceptible to the finger, when the hand is placed on the knee. This separation is not occasioned equally by both portions; the upper one, embraced by the extensor muscles, is drawn upward very forcibly by these powers, which the patella no longer resists; while the inferior portion, being merely connected with the ligament below, is not moved by any muscle, and can only be displaced by the motions of the leg, to which it is attached. Hence, the separation is least when the limb is extended, being then only produced by the upper fragment; greatest, when the limb is bent, because both pieces contribute to it; and it may be increased, or diminished, by bending the knee more or less.

As Boyer has particularly noticed, the laceration, or not, of the tendinous expansion, upon the front of the patella, makes a material difference in these cases, because it is a part of great importance in the cure.

According to this author, a portion of it in simple fractures of the patella generally escapes laceration, and the separation of the fragments is then not very considerable; but violent action of the extensor muscles, the fall subsequent to the fracture, or bending the knee too much, may separate the pieces of bone far from each other, and rupture the tendinous expansion. (*Traité des Mal. Chir. T. 3, p. 328.*) According to Mr. A. Cooper, "when the ligament is but little torn, the separation will be but half an inch; but under great extent of injury, the bone is drawn five inches upwards, the capsular ligament, and tendinous aponeurosis covering it, being then greatly lacerated." (*Surgical Essays, Part 2, p. 84.*)

The upper portion of bone may be moved transversely, and pain is thus excited, but no crepitus can be felt, as the two pieces of bone are not sufficiently near each other. When the swelling of the knee, consequent to fractures of the patella, is very great, the symptoms of the injury may be more or less obscured. However, in consequence of the inability of the extensor muscles to move the leg, except in a few cases where the fracture is very low, the patient cannot stand without difficulty, and is nearly quite unable to walk.

In the treatment of a fractured patella, the chief indications are to overcome the action of the extensor muscles of the leg, and to keep the fragments as near each other as possible, partly by a judicious position of the limb, and partly by mechanical means. The first indication is fulfilled by relaxing the above-mentioned muscles; 1st, by extending the leg; 2dly, by bending the thigh on the pelvis, or, in other words, raising the femur, so that the distance between the knee and anterior superior spinous process of the ilium may be as little as possible, which object, however, will also require the body to be raised, and the pelvis somewhat inclined forwards. In short, as Richter long ago advised the patient should be almost in a sitting posture, the trunk forming a right angle with the thigh. (*Bibl. Chir. B 6, p. 611, Gottingen, 1782.*) 3dly, The muscles are to be compressed with a roller. The second indication, or that of placing and maintaining the fragments in contact, or as nearly so as circumstances will allow, is in a great measure already answered by the above recommended position of the limb and trunk; but it is not perfectly fulfilled, unless the upper portion of the bone be also pressed towards the lower fragment, and mechanically held in this situation by the pressure of an apparatus or bandage. And, in pushing the upper fragment towards the lower one, the surgeon should always be careful that the skin be not depressed and pinched between them.

Having described the principles which ought to be observed, I do not know that any great utility would result from a detail of the various methods of treating a broken patella preferred by different surgeons. In the 2d vol. of the *First Lines of Surgery*

may be found a description of the plan and apparatus employed by Baron Boyer. Desault's practice, which was related in the last edition of this Dictionary, I now omit, as not being exactly such as modern surgeons would adopt; not from any of his principles being erroneous, but because his apparatus is more complicated than necessary.

After putting the patient in bed upon a mattress, and in the desirable posture, with the limb confined, supported, and raised, as above directed, upon a well-padded hollow splint, Mr. A. Cooper applies at first no bandage to the knee, but covers it with linen wet with a lotion composed of liq. plumbi acet. dilut. ℥v. and spir. vin. ℥j. If, on the succeeding day or two, there be much tension, or ecchymosis, leeches should be applied, and the lotion continued; but the employment of a bandage is not to commence until the tension has subsided; for Mr. A. Cooper assures us, that he has seen the greatest suffering, and such swelling as threatened gangrene, produced in these cases by the too early use of a roller. Instead of a circular bandage, placed above and below the broken bone, and drawn together with tape, &c. so as to bring the upper fragment towards the lower one, this experienced surgeon prefers the following method. A leather strap is buckled round the thigh, above the broken and elevated portion of bone, and from this circular piece of leather, another strap passes under the middle of the foot, the leg being extended, and the foot considerably raised. This strap is brought up to each side of the patella, and buckled to the leather band already applied to the lower part of the thigh. It may also be fastened to the foot, or any part of the leg, with tapes. The limb is to be confined in this position five weeks, if the patient be an adult, and six if advanced in years. Then a slight passive motion is to be begun, and to be gently increased, from day to day, until the flexion of the knee is complete. (*Surgical Essays, Part 2, p. 91.*) But, although the impropriety of making any constriction of the knee with a bandage, while the skin is swelled and inflamed, must be obvious, the surgeon ought to be apprised, that such swelling and inflammation ought not to occasion the least delay in placing the limb in the right posture, and pressing the upper fragment towards the lower one. Mohrenheim ascribes the lameness so frequent formerly after this fracture, partly to the custom of not thinking of bringing the pieces of bone together until the swelling had subsided, and partly to the fashion of bending the joint too soon, with a view of preserving its motion. But, says he, nothing can be clearer than that it is most advantageous to attend to the union of the fracture first, and to the flexibility of the joint afterward. (*Beobachtungen, 2 B. 8vo. 1783.*) Boyer has likewise remarked, that the uniting substance is apt to yield, and become lengthened by bending the knee too early, and he therefore never allows this motion

to be performed before the end of two months. When the ligamentous substance is long, and the patient very slow in regaining the use of the extensor muscles, he should sit every day on a table, and endeavour to bring them into action, and as this increases, a weight may be affixed to the foot, as Hunter, Sheldon, &c. recommend.

Nothing keeps the leg more surely extended than a long, broad, excavated splint, with a suitable pad applied to the posterior part of the thigh and leg, and fixed there with a roller, while the thigh itself is to be bent by raising the whole limb, from the heel to the top of the thigh, with pillows, which, of course must form a gradual ascent from the tuberosity of the ischium to the foot.

The broken patella is almost always united by means of a ligamentous substance, instead of bone.

However, that an osseous union may follow a transverse fracture of the patella, and still more frequently a perpendicular one, is a fact of which there is now not the slightest doubt. Thus, Lallement has published an unequivocal specimen of a transverse fracture united by bone, with the history of the case, and the appearances after the death of the patient from some other affection. (*Boyer, Traité des Mal. Chir. T. 3, p. 355, &c.*) In the collection of Dr. William Hunter, there is one well-marked instance of the bony union of a transverse fracture of the patella, and other examples have been seen in the dead subject by Mr. Wilson. (*On the Structure, Physiology, &c. of the Skeleton, p. 240.*) The reason why transverse fractures of the patella, do not commonly unite by callus, is not owing to the want of power in this bone to produce an osseous connecting substance; for, as Larrey has several times noticed, if the fragments are kept in perfect contact by means of a suitable apparatus, their bony reunion becomes so complete, that scarcely any vestige of the injury can afterward be traced. (*Journ. Complém. T. 8, p. 114.*) Indeed, it is a fact on which Larrey dwells, as affording a proof that callus is produced not by the periosteum, but by the vessels of the bones themselves. And what must add strength to the purport of the foregoing remarks is, the consideration that perpendicular or longitudinal fractures of the patella, which are not liable to any displacement from the action of the extensor muscles of the leg, readily admit of bony union. (*Wilson on the Structure and Physiology, &c. of the Skeleton, p. 239.*) This is a statement which, I think, could not be rendered doubtful by any experiments made on animals, without the advantages of quietude and proper treatment. Yet, there are other facts related, which prove that both in longitudinal and transverse fractures a ligamentous union is generally produced, when the fragments are separated; but if these are not drawn asunder, an osseous union takes place. Thus, in one case, reported by Mr. A. Cooper, one-third of the patella was separated from the rest of this bone, and had united by ligament, a free

motion being left between the fragments. (*Surgical Essays, Part 2, p. 94.*) The same gentleman divided the patella longitudinally in a dog, without extending the division into the tendon above, or the ligament below, so that the fragments could not be separated. In three weeks, a close bony union was the result. (*P. 95.*) A case is also related, in which a gentleman fractured the patella transversely, and the lower portion likewise perpendicularly. The transverse fracture united, as usual, by ligament; the perpendicular one, by bone. (*P. 96.*)

The incorrect notions, formerly entertained, respecting the inconveniences of an exudation and projection of the callus into the joint after a fracture of the patella, and especially when the fragments are kept in contact, were long ago refuted by Pott and Sheldon. (*Pott's Chir. Works, Vol. 1, p. 332, Ed. of 1808. Sheldon's Essays on the Fracture of the Patella, &c. 8vo. Lond. 1789.*) On the contrary, as Mr. A. Cooper particularly remarks, "the internal articular surface of the bone preserves its natural smoothness." (*Essays, Part 2, p. 86.*) How such doctrine of a superabundant callus could ever be reconciled with the doubts about a bony union ever being possible, appears difficult of explanation.

Pott, and some others, thought that there being commonly an interspace afterward between the two pieces of the patella, with a certain length of the connecting substance, might be advantageous in the motion of the joint; but Desault, Boyer, Mr. A. Cooper, Sir J. Earle, and others, have always found that the greater the distance between the two pieces of the bone, the greater is the difficulty afterward in walking up a rising, or over an unequal ground.

In the treatment of a longitudinal, or perpendicular, fracture of the patella, the leg should be kept extended, leeches used, and a cold lotion applied. After a few days, a roller is to be put round the limb, and then a laced knee-cap, with straps buckled round the limb above and below the patella. (*A. Cooper, Vol. cit. p. 96.*) The experience of Dupuytren confirms the fact, that a longitudinal fracture of the patella is soon well consolidated. (*Annuaire Med. Chir. de Paris, p. 98, 4to. Paris, 1819.*) Compound fractures of the patella frequently terminate in the death of the patient, unless amputation be done early. The injury, however, does not invariably lead either to the loss of life or limb. I saw a case in St. Bartholomew's hospital last summer (1820,) under Mr. Vincent, where the patella was broken to pieces, and the opening so extensive, that the fingers readily passed into the joint; yet, after a tedious confinement, the formation of abscesses, and the separation of several fragments of bone, the patient recovered with a stiff joint. In general, however, I believe, with Mr. A. Cooper, that in compound fractures of the patella, if the laceration be extensive, or the contusion very considerable, amputation will be required:

but, if the wound be small, the patient not irritable, and no sloughing of the integuments, or ligament, likely to occur, it will be best to try to save the limb. (*Vol. cit. p. 99.*) The wound should be reunited as speedily as possible, and advantage taken of evaporating lotions, perfect rest in a desirable posture, a very low regimen, leeches, venesection, and saline opening medicines. Since writing the above remarks, I have seen another case of bad compound fracture of the patella in St. Bartholomew's hospital, where it has been about a month. No fragments of bone have yet been removed, but a good deal of matter issues daily from the wound. The case must be regarded as in a very precarious state, though if hectic symptoms should not lower the patient too much, the limb will probably be saved.

In addition to the works already cited, consult *D. H. Meibomius de Patellæ Osse, ejusque Læsionibus, et Curatione, Franck. 1697. P. Camper, Diss. de Fracturâ Patellæ, et Olecrani, 4to. Hagæ Comit. 1789. Buirer in v. Siebold Chiron. 3, 1, p. 64.*

FRACTURES OF THE LEG

May be transverse or oblique. The first case is alleged to be most common in children. Experience proves, that the two bones of the leg are much more frequently broken together, than singly; a fact ascribed by Boyer to the strength of the knee and ankle joints. (*Traité des Mal. Chir. T. 3. p. 360.*) The direction of an oblique fracture of the tibia is found to be pretty constantly from below upwards, and from within outwards, the end of the upper fragment mostly presenting itself under the skin at the front and inner part of the leg. In these cases, the longitudinal displacement of the fracture is less constant, than the horizontal and angular. However, when it does happen, the inferior fragments are drawn outward and backward, whilst the superior project internally and forward. The angular displacement may be produced either by the action of the posterior muscles of the leg, or the weight of the body, and, in both cases, the angle projects forwards. But it may be directed posteriorly, if the heel be too much raised. A rotatory displacement, most commonly happening in the direction outwards, is produced by the inclination of the foot, and if this be turned too much inwards the rotatory displacement will be in that direction. A longitudinal displacement cannot take place in transverse fractures, on account of the considerable extent of the surfaces of bone; but, in oblique fractures, the inferior fragments are almost always drawn upward by the action of the posterior muscles of the leg, in which position of the parts, the lower ends of the superior fragments project forwards, and may be felt by the hand. Sometimes, however, when the solution of continuity is obliquely downward and outward, the anterior projection will be produced by the lower pieces. In both kinds of displacement, the pointed ends of

the bones may tear and penetrate the integuments, and cause a compound fracture.

The usual symptoms, denoting a fracture of both bones of the leg, are a change in the direction and shape of the limb, pain, and incapability of walking or bearing upon the limb, mobility of the fractured pieces, and a distinct crepitus.

Fractures near the knee are not very subject to displacement, on account of the thickness of the tibia at that part; but they are more dangerous than those of the middle of the bone, because often followed by ankylosis of the knee-joint. Fractures, close to the ankle, are still more dangerous. Oblique fractures are very difficult of management, and when their displacement is upward and outward, the integuments are in danger of being torn by the projecting points of the superior portion of the tibia. (Boyer.) To bad compound fractures of the leg most of the observations are applicable, already delivered on compound fractures in general.

When the size of the tibia is compared with that of the fibula, and the close connexion of these bones to each other is remembered, an opinion might be formed, that the first could never be broken without the second. Experience, however, proves the contrary. And reasons for this fact, as Boyer remarks, may be deduced from the consideration, that the tibia is the bone which supports the weight of the body, and that it is situated at the forepart of the limb, simply covered by the skin, and much exposed to the effects of violence. (*Traité des Mal. Chir. T. 3, p. 373.*) When the tibia alone is broken, the fracture is said to be generally transverse.

If the injury happens near the knee, the great extent of the fractured surfaces prevents any considerable displacement of the fragments; and the fibula acting as a support on the external side, contributes also to this effect. Boyer, however, has seen one instance, in which the tibia was broken by the kick of a horse, and the fragments displaced in the direction of the axis of the bone, which displacement could not be rectified, so that the bone remained permanently arched at the part.

The absence of displacement often renders the diagnosis of fractures of the tibia very difficult, and the difficulty is further increased by the little pain and inconvenience produced by such a fracture, with which persons have been known to walk.

Whenever there is reason to suspect the accident, in consequence of a blow or a fall on the leg, the part should be minutely examined. The fingers are to be moved along the anterior side of the tibia, the slightest inequality in which may be easily perceived, on account of its being covered only by the skin; and the motion of the pieces may be perceived, by grasping the opposite ends of the bone, and pushing them in contrary directions. However, this motion, and the crepitus, are very indistinct, on account of the fibula not allowing the fractured por-

tions to be sufficiently moved on one another.

In a review of the position and strength of the two bones of the leg, it will appear that the tibia supports alone the whole weight of the body, every shock directed in the axis of the limb, and many kinds of force applied also in the transverse direction, without operating upon any particular point. Hence, the frequency of fractures of the tibia; and if the fibula is generally broken at the same time, the latter injury is but subsequent to the other, and takes place because this slender bone is not capable of bearing the weight of the body, the impulse of external violence, and even the action of the muscles, after the tibia has given away. (*Dupuytren Annuaire Med. Chir. des Hôpitaux de Paris, p. 15. 4to. Paris, 1819.*) On the other hand, as the same distinguished surgeon remarks, the fibula being principally designed as a support for the outside of the foot, it is particularly when this function is to be executed, and its lower end has to make resistance to efforts made in that direction, that it is fractured; and if the lower part of the tibia is also sometimes broken by the same force, it is almost always consecutively, and not by the effect of a direct and simultaneous action upon the two bones. (P. 17.) All fractures of the fibula, however, are not caused in the preceding manner; and Dupuytren concurs with Boyer, Mr. C. Bell, and all the best writers on this subject, in dividing these cases into two kinds; first, those in which the force is applied directly to the bone itself; secondly, the more important and serious cases, in which the force operates upon the fibula, through the medium of the foot. With respect to the first class of cases, the situation of the fibula on the outer side of the leg, a situation which would seem to expose it much to external violence; its slenderness; the interspace left between it and the tibia at the middle part of the leg; and the way in which each end of it rests upon the latter bone; would lead one to expect that its middle portion must often be broken; yet the case is less frequent than might be apprehended. And, as Dupuytren observes, there are two reasons for this fact; viz. the protection which the fibula receives from the peronæi muscles, and the rarity of circumstances capable of producing a fracture by a direct cause. These fractures, which are usually attended with deformity, and in some cases, even do not hinder the patient from bearing upon the foot, cannot for the most part be ascertained, unless attention be paid to the manner in which the accident was produced, and to the presence of ecchymosis, and of more or less pain in the part which has been struck, or pressed upon; together with a degree of irregularity of the fibula, perceptible by the fingers, and a more or less distinct moveableness and crepitus of the ends of the fracture.

The usual causes of this sort of fracture are blows on the fibula, gunshot wounds, the fall of heavy bodies on the outside of the

leg, or the passage of them over the same part. The foot is generally twisted, neither inwards nor outwards, and in most instances, the accident is easily cured by means of rest, without being accompanied by any of the symptoms so often complicating other fractures of the fibula, produced by distortion of the foot. (*Dupuytren, Vol. cit. p. 40.*) A striking analogy may be remarked between fractures of the central part of the fibula and those of the corresponding portion of the ulna, and this in respect to causes, symptoms, treatment, and consequences. Fractures of the middle of the ulna, like those of the body of the fibula, are always occasioned by blows or falls on the fractured part, or by violence applied directly to the bone. Such fractures are scarcely ever attended with any deformity in the limb, incapacity of moving it, or displacement of the fragments; and just as some individuals are able to walk with a broken fibula, others, notwithstanding a fracture of the ulna, are found capable of using their fore-arm nearly as well as if it were free from injury. The latter case, like that of a fracture of the fibula, can only be known by the recollection of the way in which the hurt was received, the pain, ecchymosis, irregularities, motion, and crepitus, which last effects are also not very obvious so high up the bone. Like fractures of the body of the fibula, those of the body of the ulna only require rest and discutient applications, and very seldom the bandages, &c. necessary in the treatment of fractures of both bones of the fore-arm, or those of the radius alone. (*Vol. cit. p. 50.*)

Fractures of the fibula from an *indirect* cause may happen from the foot being violently twisted, either inwards or outwards. In both instances, the cause of the fracture is a change in the direction of the line, in which the weight of the body is transmitted. In the first case, the said line, instead of following, as it commonly does, the axis of the tibia, and falling upon the astragalus, crosses the lower end of the tibia, and the ankle joint, obliquely from within outwards, and after passing across the malleolus externus, extends to the outside of the member. The parts then supporting the weight of the body are the malleolus externus, and the lower end of the tibia, besides which state of parts, the same malleolus is subjected to the traction of the external lateral ligaments, which operate with great force in consequence of those ligaments being now nearly at a right angle with the lower end of the fibula, while this process itself is in contact with the astragalus, which is propelled from within outwards by the tibia. The latter bone, being thicker and stronger than the fibula, generally resists, and if the malleolus internus sometimes happens to break, it is secondarily, as an effect of the displacement of the foot outwards.

In the other example, where the foot is twisted outwards, the centre of gravity of the body, instead of following its usual course, obliquely crosses the lower end of the fibula, the ankle-joint, and the malleolus

internus, and falls on the ground at a greater or lesser distance from the inner edge of the foot. On the one side, the internal lateral ligaments and malleolus, and on the other, the lower end of the fibula, are then the parts which have to bear the weight of the whole body, and the force of the muscles; and they are also the parts which are torn and fractured; first, the internal lateral ligaments, or the malleolus; and secondly, the lower portion of the fibula. (*Annuaire, Méd. Chir. de Paris, 1819, p. 66-67.*) Some of the symptoms of a fracture of the fibula, from an *indirect* cause, depend upon the fracture of that bone, and others upon the dislocation of the foot. They are divided by Dupuytren into two kinds; viz. *presumptive*, and *characteristic*. The first are, the way in which the patient received his hurt; a noise, or sort of crack heard by him at the instant of the injury; a fixed pain at the lower part of the fibula; a difficulty, or inability of walking; more or less swelling round the ankle, especially about the malleolus externus, and lower portion of the fibula. The *characteristic symptoms* are, an irregularity and unnatural moveableness of some point of the lower end of the fibula; a crepitus, which can be more or less distinctly felt by pressing upon and moving the part; mobility of the whole foot transversely, or horizontally; a facility of bringing the lower end of the fibula towards the tibia by pressure; a change in the point of incidence of the axis of the limb upon the foot; distortion of the foot outwards, and sometimes backwards; rotation of the same part upon its axis from within outwards; an angular depression, more or less manifest at the outer and lower part of the leg; projection of the internal malleolus; disappearance of almost all these symptoms, as soon as reduction is effected by a force applied to the foot; and their immediate recurrence when such force is discontinued, particularly if the limb be in the extended posture. (*Vol. cit. p. 68.*)

In considering the varieties of simple fracture of the fibula, the first to which Dupuytren adverts, is that in which the bone is broken *more than three inches above the extremity of the malleolus externus*; a case, neither accompanied nor followed by any displacement of the foot, and almost always produced by the direct application of violence to the broken part of the bone.

A second variety of simple fractures of the fibula is when the bone has been broken, either by direct or indirect force, within three inches from the end of the malleolus externus, and when the foot is not displaced, though much displacement is possible, and, indeed, often arises from the slightest effort, or movement made by the patient. The most frequent point of injury is about two inches and a half above the extremity of the outer malleolus. This is generally the place of a fracture, caused by a twist of the foot outwards; but, the accident may happen lower down, as is commonly seen, when the

fracture is occasioned by a twist of the foot inwards.

These fractures of the fibula, abstractedly viewed, are not of much importance in themselves; but, with reference to the manner in which they facilitate the dislocation of the foot, they are very serious.

Among the most frequent complications of fractures of the fibula, are the rupture of the internal lateral ligaments, the detachment of the point of the inner malleolus, and fracture of the lower part of the tibia. When these injuries originate from a violent twist of the foot outwards, they precede the fracture of the fibula; but, when they are caused by a twist inwards, they follow the breaking of that bone. (*Dupuytren, Vol. cit. p. 96.*)

Besides distortion of the foot outwards, or inwards, as attending certain fractures of the fibula, another complication may be dislocation of the foot backwards, produced by the action of the muscles of the calf, and not by the same causes which broke the bone. However, whenever the malleolus internus has not given way, the dislocation is incomplete, and the foot is inclined outwards as well as backwards. In the complete luxation, as Dupuytren remarks, the bent posture is found exceedingly advantageous, though he admits, that it will not always answer for maintaining the reduction.

TREATMENT OF FRACTURES OF THE LEG.

As in cases of fractured thighs, the practitioner may adopt either a bent or a straight position of the limb; in this country, surgeons mostly follow Mr. Pott's advice, and select the first one, of which alone I shall treat. That the bent position is, generally speaking, the most advantageous for a broken leg, I am well convinced. The strong muscles of the calf of the leg are the powers, which tend to displace the ends of the fracture, and their relaxation is a thing of the first-rate importance. It is quite different in the thigh, where the muscles are so numerous, that the attempt to relax by any position of the limb, all such as have the power of displacing the fragments would be in vain. I am ready to acknowledge, however, that in the bent posture, the apparatus is defective, inasmuch as it does not keep the knee-joint from moving; but yet it is certain that such motion has not so injurious an effect upon fractures of the leg, as it has upon those of the thigh. When the case is complicated with a wound, which cannot be dressed in the bent posture of the limb, without great disturbance of the fracture, the straight position ought unquestionably to be preferred. With respect to one of Mr. Pott's objections to this position, viz. that it makes the knee stiff for a long while afterward, I suspect, that we should not lay much stress upon the circumstance, because, as Boyer has correctly observed, it is always the joint situated below the fracture, that is thus affected.

"In the fracture of the fibula only, (says Pott) the position is not of so much consequence; because by the tibia remaining entire, the figure of the leg is preserved, and extension quite unnecessary; but still, even here, the laying the leg on its side, instead of on the calf, is attended with one very good consequence, viz. that the confinement of the knee, in a moderately bent position, does not render it so incapable of flexion and use afterward, as the straight or extended position of it does and consequently, that the patient will be much sooner able to walk, whose leg has been kept in the former posture, than he whose leg has been confined in the latter.

"In the fracture of both tibia and fibula, the knee should be moderately bent, the thigh, body, and leg, being in the same position as in the broken thigh. If common splints be used, one should be placed underneath the leg, extending from above the knee to below the ankle, the foot being properly supported by pillows, bolsters, &c. and another splint of the same length should be placed on the upper side, comprehending both joints in the same manner; which disposition of splints ought always to be observed, as to their length, if the leg be laid extended in the common way, only changing the nominal position of them, as the posture of the leg is changed, and calling what is interior in one case, exterior in the other; and what is superior in one, in the other inferior.

"If Mr. Sharp's splints be made use of, there is in one of them a provision for the more easy support of the foot and ankle, by an excavation in and a prolongation of the lower or fibular splint for the purpose of keeping the foot steady." (*Pott.*)

The strong muscles of the leg being relaxed by placing the limb in the bent position, as advised by Pott, the surgeon is to make such extension as seems requisite, for bringing the ends of the fracture into even apposition. Then he is carefully to raise the leg a little way from the surface of the bed, by taking firmly hold of the limb, above and below the fracture, and elevating the broken bones together, in such a way as shall keep both the upper and lower portions as nearly as possible on the same level. At this moment, an assistant should put, exactly beneath the leg, the under splint, which has been previously made ready by covering it with a soft pad, and laying over this an eighteen-tailed bandage. The limb is now to be gently depressed, till it rests on the apparatus. The surgeon, before proceeding further, must once more observe, that the ends of the bones are evenly in contact. Being assured of this important point, he is to apply a piece of soap plaster, and lay down the tails of the bandage. Another soft pad, well filled with tow, is next to be put over the upper surface of the leg, and over that the other splint, when the straps are to be tightened.

Mr. Pott's method of treating fractures of the fibula, complicated with luxation of the

tibia, is described in the article *Dislocation*, and Dupuytren's practice in the 2d vol. of the *First Lines of the Practice of Surgery*.

In an oblique fracture of the head of the tibia, extending into the knee joint, Mr. A. Cooper recommends the straight position, in which the femur has the good effect of keeping the articular surfaces of the tibia even. A roller is to be used for pressing one fragment towards the other; a paste-board splint is also to be applied with the same view; and early passive motion of the joint is to be practised in order to prevent ankylosis.

When the fracture is oblique, but does not reach into the joint, the same author prefers placing the limb on the double-inclined plane. (*Surgical Essays*, Part 1, p. 103.)

FRACTURES OF THE SCAPULA.

As Boyer correctly observes, fractures of the scapula are not very common, a circumstance explicable by the deep and covered position of the greater part of this bone, and its great mobility. Nor can these accidents arise without considerable direct violence. However, there are some parts of the scapula, which being more superficial, and of a form more likely to be acted upon by external bodies, are more frequently fractured; such are the acromion, and inferior angle of the bone. Fractures of the coracoid process, and even of the neck of the scapula, are also mentioned; but, the instances of such accidents are not common; and though these parts of the bone may appear in the skeleton likely to be often broken, their deep situation in the living subject generally saves them. Indeed, as Boyer says, they generally require great violence to break them, and then the contusion of the soft parts is a worse injury than the fracture itself: thus, this author has seen the coracoid process broken by the blow of the pole of a carriage, and the patient lost his life from the violence at the same time inflicted upon all the soft parts about the shoulder (*Traité des Mal. Chir.* T. 3, p. 161.)

When the acromion is broken, the weight of the arm, and the contraction of the deltoid muscle, draw it downward, while the trapezius and levator scapulæ draw the rest of the bone upward and backward. When the lower angle is broken, the serratus major anticus draws it forward, while the rest of the scapula remains in its natural situation; or, if the angular portion be considerable, the teres major, and some fibres of the latissimus dorsi, contribute to its displacement forward and upward.

When the coracoid process is fractured, the pectoralis minor, coraco-brachialis, and short head of the biceps, concur in drawing it forward and downward.

When the neck of the scapula is fractured, the weight of the arm makes it drop down so considerably, as to give the appearance of a dislocation; but, the facility of lifting

the os brachii upward, the crepitus, and the falling of the limb downward again, immediately it is unsupported, are circumstances clearly marking, that the case is not a dislocation. Sometimes great pains, and a crepitus, are experienced, on moving the shoulder joint, after an accident; and yet the spine, the neck of the scapula, and all the above parts are not broken. In this circumstance, it is to be suspected, either that a small portion of the head of the os brachii, or a little piece of the glenoid cavity of the scapula, is broken off; which latter occurrence, I think, is not very uncommon.

Fractures of the acromion are attended with pain, which is increased by the motion of the arm; the form of the shoulder is changed; and the broken part which has descended, may be raised, by bringing up the elbow close to the side.

When the inferior angle is broken, the part remains motionless, while the rest of the scapula is moved; and it is so separated, that no mistake can be made. (*Boyer*.)

Fractures of the spine and body of the bone, are all attended with a crepitus; and, in the first cases, an irregularity of the injured part may generally be felt.

The prognosis of fractures of the scapula varies according to the situation of the injury, and the attendant circumstances. Fractures of the body of the bone, whatever may be their direction, are generally very simple, and readily cured. Those of the acromion and lower angle are more troublesome to keep right; but the most serious cases are fractures of the coracoid process and neck of the bone, which cannot be kept right without great difficulty, and are said to be frequently followed by a considerable stiffness of the arm, inability to raise it, its atrophy, and even paralysis. In other respects, the danger of fractures of the scapula depends less upon the solution of continuity in the bone, than the contusion of the soft parts, or injury of the thoracic viscera. However, when the fracture is comminuted, and the splinters are forced in to the subscapularis muscle, abscesses may form under the bone, and, according to Boyer, require a perforation to be made in it; (*Mal. Chir.* T. 3, p. 165.) a proceeding, which I cannot bring myself to think would ever be judicious, as making a depending opening in the soft parts must be far better practice. In military surgery, the scapula is often injured by sabre-cuts; but, as Dr. Hennen remarks, this bone, when preserved from motion, is found in these cases to unite with great readiness, and without future inconvenience. (*Principles of Military Surgery*, p. 48, Ed. 2.)

According to Boyer, when the scapula is fractured longitudinally, or transversely, it is merely necessary to fix the arm to the side by means of a bandage, which includes the arm and trunk, from the shoulder to the elbow. Thus, the motions of the shoulder, which are only concomitant with those of the arm, are prevented.

When the inferior angle is broken, and

drawn downward and forward by the serratus major anticus, the scapula must be pushed toward the fragment, by pushing the arm itself inward, downward, and forward, where it is to be kept with a roller. The fragment is also to be kept backward, as much as possible, with compresses and a roller, and the arm is to be supported in a sling.

The fractured acromion requires the arm to be so raised, that the head of the os brachii will push up the acromion, while an assistant pushes the scapula forward and downward, in a contrary direction to that of the arm. To maintain this position, a circular bandage is to be applied round the arm and body.

Desault used to apply also a small pillow under the axilla, before putting on the bandage, in order to make the head of the os brachii project more upward, on bringing the arm near the side. Compresses are to be placed on the scapula, which, by this means, and a roller, is to be kept downward and forward.

When the coracoid process is fractured, the muscles attached to it are to be relaxed, by bringing the arm forwards towards the breast, and confining it there in a sling; while the shoulder is kept downward and forward, and a compress confined just under the broken part with a roller.

The treatment of a fracture of the neck of the scapula consists in raising the shoulder to its proper height; in completely taking off the weight of the arm, by means of a proper sling, which always supports the limb from the elbow to the fingers; and in entirely preventing all motion of the arm by binding it to the trunk with a roller.

FRACTURES OF THE CLAVICLE.

This bone being long and slender, unsupported at its middle, and protected externally only by the integuments, is very often broken. Its serving to keep the scapula at a proper distance from the sternum, and as a *point d'appui* for the os brachii, every impulse of which it receives, makes its fractures still more common.

It may be broken at any part; but its middle, where the curvature is greatest, is most frequently the situation of the injury. It is not very often fractured at its scapular extremity. However, a direct force, falling on the shoulder, may break any part of the clavicle, on which it immediately acts. The soft parts, in this kind of case, will also be contused, or even lacerated.

A comminuted fracture may be thus occasioned, and if the violence be very great, the subclavian vessels and nerves may be torn. The fall of a heavy body on the shoulder often gives rise to a paralysis of the arm.

When the fracturing force is applied to the ends of the bone, as by a fall on the point of the shoulder, or on the hands, while the arms are extended, the clavicle may be very much bent, and fractured so obliquely,

that the broken portions protrude through the skin.

Fractures of this bone are usually attended with displacement of the broken ends, except when the injury takes place at the scapular extremity, and within the ligament, tying together the clavicle and coracoid process.

The external portion of the clavicle is always that which is displaced. The internal part cannot be moved out of its natural situation, by reason of the costo-clavicular ligaments, and of its being drawn in opposite directions, by the sternocleido-mastoideus, and pectoralis major, muscles. The external portion, drawn down both by the weight of the arm, and the action of the deltoid muscle, and forward and inward by the pectoralis major, is carried under the internal portion which projects over it. The broken clavicle no longer keeping the shoulder at a due distance from the sternum, the arm falls forward towards the breast. The patient finds it impossible to put his hand to his forehead, because this act makes a semicircular motion of the humerus necessary, which cannot be done while that bone has not a firm *point d'appui*. The shoulder and upper extremity may be observed to be nearer the breast, than those of the opposite side. The motion of the pieces of bone on one another may be felt, as well as the projection of the end of the internal portion. When the shoulder is moved, a crepitus may also be perceived; but this is productive of great pain, and the diagnosis is so obvious, that it is quite unnecessary.

The ancients, and many moderns, have supposed, that, in order to set a fracture of the clavicle, the shoulder must be drawn back, and fixed in that position. The patient was placed on a low stool, so that an assistant might put his knee between the shoulders, which he drew back at the same time with both hands, while the surgeon applied the bandage, which was to keep the parts in this position. But when the shoulders are thus drawn towards one another, the scapula is obviously pushed towards the sternum, and with it the external portion of the clavicle, which passes under the internal fragment.

The figure of 8 bandage has commonly been used for maintaining the parts in this position. While the assistant keeps back the shoulders, as above described, the surgeon is to apply one end of a roller to the arm-pit on the side affected, and then make it cross obliquely to the opposite shoulder, round which it is to pass, and from this to the other shoulder, about which it is to be applied in the same manner, and afterward repeatedly crossed before and behind. The tightness, with which it is necessary to apply this bandage, produces a great deal of excoriation about the arm-pits, and the effect is to make the ends of the fracture overlap each other, the very thing which it is wished to avoid. Boyer remarks, that the iron cross proposed by Heister, the corslet described by Brasdor in the *Mém. de l'Acad.*

de Chir. and the leather strap recommended by Brunninghausen, are only modifications of the figure of 8 bandage, and are not at all better.

Desault advised extension to be made, by means of the limb, which is articulated with the fractured bone. This is done by converting the humerus into a lever, by carrying its lower end forward, inward, and upward, pushing the shoulder backward, upward, and outward, and putting a cushion in the arm-pit to serve as a fulcrum.

Desault used to put in the arm-pit a hair or flock cushion, five or six inches long, and three inches and a quarter thick at its base. Two strings are attached to the corners of the base placed upward, which cross the back and breast, and are tied to the shoulder of the other arm. The cushion being thus placed in the arm-pit, and the fore-arm bent, Desault used to take hold of the patient's elbow, and carry it forward, upward, and inward, pressing it forcibly against the breast. By this manoeuvre, the humerus carries the shoulder outward, the ends of the fracture become situated opposite each other, and all deformity is removed.

An assistant is to support the arm in this position, while the surgeon, having a single-headed roller nine yards long, is to place one end of it in the arm-pit of the opposite side, and thence apply the bandage over the upper part of the arm, and across the back to the same situation. The arm and trunk are to be covered with such circles of the roller, as far down as the elbow, drawing the bandage more tightly, the lower it descends.

Compresses, dipped in camphorated spirit, are next to be placed along the fractured bone. Desault then took a second roller, of the same length as the first, and put one end of it under the opposite arm-pit, whence it was carried across the breast over the compress and fracture, then down behind the shoulder and arm, and, after having passed under the elbow, upward on the breast. Desault next brought it across to the sound shoulder, under and round which he passed it, for the purpose of fixing the first turn. He then conveyed the roller across the back, brought it over the compresses, carried it down in front of the shoulder and arm, under the elbow, and obliquely behind the back to the arm-pit, where the application began. The same plan was repeated, until all the roller was spent. The apparatus was secured by pins, wherever they promised to be useful, and the patient's hand was kept in a sling.

Boyer has invented an apparatus for fractured clavicles, which is more simple than that employed by Desault.

The cushion is to be applied under the arm. The apparatus consists of a girdle of linen cloth, which passes round the trunk on a level with the elbow. It is fixed on by means of three straps, and as many buckles. At an equal distance from its extremities are placed externally on each side two buckles, two before and two behind the arm. On the lower part of the arm, is to be laced a piece

of quilted cloth, five or six fingers broad. Four straps are attached to it, which correspond to the buckles on the outside of the girdle, and serve both to keep the arm close to the trunk, and from moving either backward or forward.

Certainly, the methods recommended by Desault and Boyer are very judicious and scientific. They are not, however, much adopted in this country, perhaps in consequence of the general aversion among English surgeons to every apparatus which is not exceedingly simple. It is to be hoped, at the same time, that, in the treatment of fractured clavicles, they will always attend to the principles which Desault and Boyer have inculcated. If they understand why the position of the arm should be such as these eminent surgeons point out, they will have no difficulty in doing what is proper, and with a cushion, sling, and a couple of rollers, they will easily maintain the proper posture.

I cannot quit this subject without cautioning surgeons never to fall into the error of supposing the rising end of a broken clavicle to be the end which is displaced. This is the one which is truly in its right situation, and which has often been made by injudicious pressure to protrude through the integuments, as I myself have seen.

FRACTURES OF THE OS BRACHII, OR HUMERUS.

This bone may be fractured at any point of its length: at its middle, either of its extremities, or above the insertion of the pectoralis major, latissimus dorsi, and teres major. The last case is termed fracture of the neck of the humerus; but that denomination has not the merit of being strictly anatomical. It is possible, however, that what is strictly called the neck of the humerus may be fractured, particularly by a gunshot wound. By neck of the humerus, we understand that circular narrowing, which separates the tuberosities from the head.

The fractures of this bone may be transverse or oblique, simple or compound. Transverse fractures of its middle part, below the insertion of the deltoid muscle, are attended with but little displacement; for the brachialis internus and the triceps, being attached posteriorly and anteriorly to both fragments, counteract one another, and admit only a slight angular displacement. When the fracture takes place above the insertion of the deltoid muscle, the inferior portion is first drawn outward and then upward on the external side of the superior. Fractures of the humerus, near its lower end, such particularly as are transverse, are not subject to much displacement: a circumstance to be attributed to the breadth of the fractured surfaces; to their being covered posteriorly by the triceps muscle, and anteriorly, by the brachialis internus, which admit only a slight angular displacement, by the inferior portion being drawn a little forward.

Oblique fractures are always attended with displacement, whatever be the part of the

bone broken. The inferior portion being drawn upward by the action of the deltoides, biceps, coraco-brachialis, and long portion of the triceps, glides easily on the superior, and passes above its lower extremity. Finally, fractures of the neck of the humerus are always attended with displacement, produced by the action of the pectoralis major, latissimus dorsi, and teres major, which being attached to the lower portion near its superior extremity, draw it first inward and then upward, in which last direction it is powerfully urged by the biceps, coraco-brachialis, and long portion of the triceps. In this case, the superior portion itself is directed a little outward by the action of the infraspinatus, supraspinatus, and teres minor, which make the head of the humerus perform a rotatory motion in the glenoid cavity.

The shortening and change in the direction of the limb, the crepitus, which may be very distinctly perceived by moving the broken pieces in opposite directions, the pain, and impossibility of moving the arm, &c. joined to the history of the case, render the diagnosis sufficiently plain.

Fractures of the neck of the humerus, however, are not so easily ascertained, and for want of attention, have been frequently confounded with luxations of that bone. Yet, the diagnostic symptoms of these two affections are very different.

When the neck of the humerus is fractured, a depression is observed at the upper part and external side of the arm, very different from what accompanies the luxation of that bone downward and inward. In the latter case, a deep depression is found, just below the projection of the acromion, in the natural situation of the head of the humerus; whereas, in fracture of the neck of that bone, the shoulder retains its natural form, the acromion does not project, and the depression is found below the point of the shoulder. Besides, on examining the arm-pit, instead of finding there a round tumour, formed by the head of the humerus, the fractured and unequal extremity of that bone will be easily distinguished. The motion of the broken portions, and the crepitus, thus produced, serve still further to establish the diagnosis. (*Boyer.*)

In a simple fracture of the body of the humerus, the prognosis is generally favourable; but fractures near the elbow are liable to be followed by more or less stiffness of the joint, often very difficult of removal.

In ordinary fractures of the os brachii, it is usual to apply two pieces of soap-plaster, which together surround the limb, at the situation where the accident has happened. Extension, if necessary, being now made by an assistant, who at once draws the lower portion of the bone downward and bends the elbow, the surgeon is to apply a roller round the limb. The external splint is to extend from the acromion to the outer condyle, and being lined with a soft pad, the wood cannot hurt the limb by pressure. The internal splint is to reach from the margins of the axilla to a little below the inner

condyle, and is to be well guarded with a pad, filled with tow, or any other soft materials.

Some surgeons are content with the application of two splints; but though the two, above described, are those on which we are to place the greatest reliance, yet, as the cylindrical form of the arm conveniently allows us completely to incase this part of the limb in splints, I consider the employment of four better; one on the outside, one in the inside, one on the front, and another on the back of the arm. These are to be carefully fixed in their respective situations by means of tape.

Throughout the treatment, the elbow and whole of the fore-arm are to be quietly and effectually supported in a sling.

FRACTURE OF THE HEAD, OR NECK OF THE OS BRACHII.

Chirurgical language here differs from that adopted by anatomists, and under the name of fracture of the neck of the humerus, is not meant, that of the circular, hardly perceptible depression, which separates the head from the tuberosities of this bone. By this expression, surgeons imply the fracture of that contracted part of the humerus, which is bounded above by these tuberosities; which below is continuous with the body of the bone; which has the tendons of the pectoralis major, latissimus dorsi, and teres major inserted below it; and which many practitioners extend even as low as the insertion of the deltoid muscle.

Indisputable facts, however, prove the possibility of the anatomical neck of the bone being fractured and C. Larbaud showed Bichat the humerus of a young man, aged 17, the head of which bone was accurately detached from its body, by a division which had obliquely interested the upper part of the tuberosities. An instance of this kind, I think, was pointed out to me this spring (1821) in St. Bartholomew's hospital. The patient was a boy, whose elbow had been strongly kept up, on the supposition, that the case was a fracture of the neck of the scapula, and consequently, the irregular end of the humerus formed a remarkable projection in front of the acromion, yet capable of being pushed back, where, however, it would not remain. When the accident is produced by a direct blow or fall on the fleshy part of the shoulder, the deltoid is sometimes contused and affected with ecchymosis. Even blood may be effused from some of the ruptured articular veins, or arteries, and form a collection, which Desault recommended to be speedily opened, though the reason of such practice, as a general thing, must be questionable, because large extravasations of blood about the shoulder are usually very soon absorbed.

The counter-fracture arises from a fall on the elbow, when this part is separated from the trunk, or else from a fall on the hand, which a natural instinct makes us ex-

tend, with the arm and fore-arm, to protect ourselves at the time of falling.

The whole of the symptoms of a fracture of the neck of the humerus sufficiently denote its existence; but it is not always an easy matter to see this whole, and here more difficulties occur in the diagnosis than in any other fracture of the humerus.

An acute pain is experienced at the moment of the fall; sometimes the noise of something breaking is heard. There is always a sudden inability to move the limb, which, left to itself, remains motionless. But, on external force being applied to the member, this readily yields, and admits of being moved with the greatest ease, in every direction.

An acute pain attends such motion, which, carried too far, may cause bad consequences, as has been observed in patients in whom the fracture has been mistaken for a dislocation.

Below the acromion a depression is remarkable, always situated lower down than that which attends a dislocation. If we place one hand on the head, while the lower part of the bone is moved in various directions with the other hand; or, if while extension is made, an assistant communicates to the bone a rotatory motion, the following circumstances are perceived. 1. The head of the humerus remains motionless. 2. A more or less distinct crepitus is felt, arising from the two ends of the fracture rubbing against each other. These two symptoms are characteristic of the accident; but the swelling of the joint may prevent us from detecting them.

Sometimes there is no displacement of the ends of the fracture, and then, as most of the symptoms are absent, the diagnosis is still more difficult. In general, however, the ends of the fracture are displaced, and in this circumstance, it is the lower one, which is out of its proper position, and not the upper one, which is of little extent, and is not acted upon by many muscles.

The displacement is generally not very perceptible, in regard to length, unless the fracture be very oblique, and its pointed spiculæ irritate the muscles, and make them contract with increased power; or unless the blow, which was very violent, continued to operate after the bone had been broken, and forced the ends of the fracture from their state of apposition. In this way, the body of the humerus has been drawn or driven upward, so as to protrude through the deltoid muscle, and integuments, far above the height of the head of the bone.

But commonly, as Petit observes, the weight of the limb powerfully resists the action of the muscles, and the displacement of the fracture is more liable to be transverse. In this circumstance, the lower end of the fracture is displaced outward or inward, and rarely in any other direction. In the most frequent case, the elbow is separated from the trunk, and cannot be brought near it without pain; and in the instance of

the bone being displaced outward, the limb has a tendency to the opposite direction.

A fracture of the neck of the humerus is not a serious event, and if, as Heister remarks, *prope caput, fractura peior, et difficilior curatur*, it is less on account of the nature and situation of the disease, than of the difficulty experienced in maintaining the ends of the fracture in contact.

The reduction usually presents but few difficulties, and the multiplicity of means formerly employed for its accomplishment, serve only to exhibit the uselessness of such resources.

Most of the machines, designed for reducing dislocations of the humerus, were applied to this kind of fracture. To such machines succeeded the use of pulleys, weights suspended to the limb, &c. useless plans, as their only tendency was to increase the natural power, which was always more than sufficient.

Petit proposes to reduce the fracture, by first placing the arm at a right angle with the body; and then making extension with the hands of an assistant, applied above the elbow; while the counter-extension is made by another assistant, who is to take hold of the fleshy part of the shoulder. This method is liable to three inconveniences. It fatigues and even pains the patient; it lessens the extending powers by bringing them near the moveable point; and it irritates such muscles as proceed from above to the lower end of the fracture, and thus increases their disposition to contract. Hence, difficulties sometimes attended the reduction, which is always simple, when the trunk being fixed, gentle extension is made on the fore-arm half bent. Desault used to accomplish the reduction in the following way.

The patient may either sit upon a chair, or the edge of a bed. The arm is to be a little separated from the trunk, and carried somewhat forward.

An assistant is to fix the trunk by drawing towards him the arm of the opposite side. This mode of making extension is preferable to that commonly employed, and which is effected by applying the hands to the upper part of the affected shoulder. The other being more distant from the resistance, there is no need for exerting so much power; and the patient's body being quite uncovered, the surgeon can conveniently apply the bandage, without disturbing the extension.

A second assistant extends the fore-arm half bent, which he makes use of as a lever, placing one hand behind the wrist for the purpose of a fulcrum. The other hand, applied to the front and middle part of the fore-arm, and making pressure upon it from above downward, represents the power. The ends of the fracture, which are to be placed in apposition, form the resistance.

The relaxation of muscles, produced by the half flexion of the fore-arm, and the position of the arm a little raised from the side, are peculiarly favourable to this mode of extension, recommended by the ancients and English. This method has also the ad-

vantage of leaving uncovered every part of the limb, to which the apparatus is to be applied.

The reduction takes place of itself, on employing a very little force, methodically directed, according as the fracture is displaced inward or outward. If the surgeon put his hands on the situation of the fracture, it is rather to examine the state of the ends of the broken bone, than to accomplish a thing seldom required, namely, what is implied by the term coaptation.

Every apparatus for the cure of fractures being only resistances, made by art to the powers causing the displacement of the broken part, it follows, that the whole should act in an inverse ratio to such powers. We have seen, that these consisted; 1. Of the action of external bodies, favoured by the extreme mobility of the arm and shoulder; 2. Of the action of the *latissimus dorsi*, *pectoralis major*, and *teres major*, which draw inward the lower end of the fracture, or, what is more common, of the deltoid, which pulls it outward; 3. Of the contractions of the muscles of the arm, which tend to draw the end of the fracture a little upwards.

Hence, 1. to render the arm and shoulder immoveable; 2. to bring either outward, or inward, the lower end of the fracture; 3. to draw downward the same; are the three indications, which every bandage, destined for a fracture of the neck of the humerus ought to fulfil. The last object merits less attention, than the two others, because the weight of the arm is alone almost sufficient for the purpose. Desault used to employ the following apparatus for the cure of fractures of the neck of the humerus.

1. Two bandages, one about five or six ells long; the other eight or ten; both about three inches wide. 2. Three strong splints, of different lengths, and between two and three inches broad. 3. A cushion or pillow, three or four inches thick at one of its ends, terminating at the other in a narrow point, and long enough to reach from the axilla to the elbow. 4. A sling to support the fore-arm. 5. A towel to cover the whole of the apparatus.

The reduction is to be effected as above explained, and the assistants are to continue the extension. Then the surgeon is to take the first roller, which is to be wet with the liq. plumbi acet. dil. and he is to fix one of its heads by applying two circular turns to the upper part of the fore-arm. The bandage is now to be rolled moderately tight round the arm upward, making each turn overlap two-thirds of that which is immediately below it. When the roller has reached the upper part of the limb, it must be doubled back a few times to prevent the folds, which the inequality of the part would create. The bandage is afterward to be carried twice under the opposite axilla, and the rest of it, rolled up, is to be brought up to the top of the shoulder, and committed to the care of an assistant.

The first splint is to be placed in front, reaching from the bend of the arm as high as

the acromion. The second, on the outside from the external condyle to the same height. The third, behind, from the olecranon to the margin of the axilla. The pillow, interposed between the arm and thorax, serves as a fourth splint, which becomes useless. An assistant applies these parts of the apparatus, and holds them on by applying his hands near the bend of the arm, in order not to obstruct the application of the remainder of the bandage.

The surgeon takes hold of the bandage again, and applies it over the splints with moderate tightness, and the bandage ends at the upper part of the fore-arm, where it began.

While the assistants continually keep up the extension, the surgeon is to place the pillow between the arm and trunk, taking care to put the thick end upward, if the fracture be displaced inward; but downward, if this should be displaced outward, which is most common. It is to be attached by two pins to the upper part of the roller.

The arm is to be brought near the trunk, and fixed upon the pillow, by means of the second roller, applied round the arm and thorax. The turns of this bandage should be rather tight below, and slackish above, if the fracture be displaced inward; but if outward, they should be slack below, and tight above.

The fore-arm is to be supported in a sling, and the whole of the apparatus is to be enveloped in a napkin, which will prevent the bandages from being pushed out of their places.

If the effect of the above apparatus in fulfilling the indications above specified is considered, we shall easily see, that they are very well accomplished. The arm, firmly fixed against the trunk, can only move with it, and then nothing displaces the lower end of the fracture, which is equally motionless. The shoulder cannot communicate any motion to the upper end of the fracture. The pillow, differently disposed, according to the direction, in which the lower extremity of the fracture is displaced, serves to keep this part in the opposite position.

Should this part of the bone project inward, the thick end of the pillow will remove it further from the chest. The bone will be kept at its distance from the side by the turns of the bandage, which, being very tight downward, will act upon the limb as a lever, the fulcrum for which will be the pillow, and the resistance, the action of the *pectoralis major*, *latissimus dorsi*, and *teres major*. Thus the bandage will have the effect of bringing the elbow nearer the trunk, and move the lower end of the fracture in the opposite direction, so that it may be here considered as an artificial muscle, directly opposing the natural ones.

When the lower end of the fracture is drawn outward, which is most commonly the case, the contrary effect will be produced, both from the pressure exercised by the bandage on the upper end of the displaced portion of the bone, and from the

situation of the elbow; which is kept outward by the thick parts of the pillow. The outer splint will also prevent the lower end of the fracture from being displaced outward, both by its mechanical resistance to the bone, and by compressing the deltoid muscle, which is the chief cause of such displacement. All displacement of the lower end of the fracture, forward, or backward, is prevented by the back splints; and as for the longitudinal displacement, which is already prevented by the weight of the limb, it is still more effectually hindered by the compression of the muscles of the arm, both by the splints and roller. (See *Œuvres Chir. de Desault, par Bichat, T. 1.*)

FRACTURES OF THE LOWER END OF THE OS BRACHII, WITH SEPARATION OF THE CONDYLES.

Fractures of the os brachii, with detachment of its condyles, seem to have escaped the notice of most authors, who have written on the diseases of the bones. The ancients have left us nothing upon the subject. Heister only mentions the fracture of the lower end of this bone, with a view of making an unfavourable prognosis. The accident, however, is not uncommon, and Desault, in particular, had frequent occasion to meet with it.

Whatever its causes may be, the two condyles are usually separated from each other by a longitudinal division which, extending more or less upward, is bounded by another transverse, or oblique division, which occupies the whole thickness of the bone. Hence, there are three different pieces of bone, and two fractures.

Sometimes, the division is more simple. Then, taking a direction outward, or inward, it crosses obliquely downward the lower end of the os brachii, terminates in the joint, and only detaches one of the condyles from the body of the bone.

In the first case, the deformity is greater, and the fractured part is more moveable. When pressure is made, either before or behind, on the track of the longitudinal fracture, the two condyles becoming further separated from each other, leave a fissure between them, and the fractured part is widened. The fore-arm is almost always in a state of pronation. On taking hold of the condyles, and moving them in different directions, a distinct crepitus is perceived.

In the second case, the separation of the condyles from each other is not so easy; but, a crepitus can always be distinguished, on moving the detached condyle. In one case, in which the external condyle was the only one broken, Desault found the limb always supine: a position, which the muscles inserted into this part are, doubtless, concerned in producing.

In both cases, an acute pain, the almost inevitable effect of bending, or extending the fore-arm; an habitual half-bent state of this part of the limb, and sometimes a subsequent swelling of it, together with more

or less tumefaction round the joint, are observable. When the blow has been very violent, or a pointed piece of the bone protrudes through the flesh, these accidents may be complicated with a wound, splinters of bone, &c.

Former writers consider the communication of a fracture with a joint, a fatal kind of complication. Swelling and inflammation of the adjacent parts; continuance of pain after the reduction; large abscesses; even mortification of the soft parts, and caries of the bones, are, according to such authors, the almost inevitable consequences of these fractures, and ankylosis the most favourable termination. Paré, Petit, Heister, Duverney, all give this exaggerated picture. However, analogous fractures of the olecranon and patella prove, that this representation is magnified beyond truth. Modern observation has dispelled the ancient doctrine of the effusion of callus into the joint, and with it one of the principal causes, assigned by authors for the symptoms so much dreaded.

The communication of the cavity of the joint with the external air might be thought to have more real influence; but, this can only occur in compound fractures, and Desault had often learned from experience, that the contact of air is not so dangerous, as has been supposed.

The general cause of all the ill consequences, seen in former times, was erroneous treatment, as may be inferred from the success which attended the extensive practice of Desault.

The detached condyles, being drawn in opposite directions by the muscles of the arm and fore-arm, commonly remain unmoved between these two powers, and are but little displaced. External force may, however, put them out of their proper situation, and they may then be displaced forward, or backward, or they may separate from each other sideways, leaving an interspace between them. Hence, the apparatus should resist them in these four directions, and this object is easily accomplished by means of four splints, kept on with a roller. The two lateral splints are particularly necessary, when the condyles are separated from the body of the bone, with an interspace between them. If one of them be still continuous with the humerus, no splint on this side will be requisite.

The apparatus need not extend as high as when the arm is fractured higher up. Of what avail in steadying the fractured part, are the circles of the bandage, applied to the body of the bone, so much above the injury? Their only utility would consist in restraining the action of the brachialis and triceps, by compressing these muscles.

On the other hand, the roller should be continued over the fore-arm, in order that the joint, according to the judicious precept of Paulus Ægineta, may correspond to the middle of the bandage, which should here be firmer than any where else. This method is also of use in producing a gentle com-

pression of the muscles implanted into the condyles.

Desault recommends having the front and back splints flexible at their middle part, which should be applied to the bend of the arm and elbow. (*Œuvres Chir. de Desault, par Bichat, T. 1*)

The detail of the reduction of the fracture and application of the roller and splints, becomes useless after what has been said. A further account may be found in the work mentioned in the preceding paragraph. The arm is to be kept in the bent position in a sling, and perfectly quiet, until it is judged advisable to begin to move the joint for the purpose of preventing an ankylosis.

FRACTURE OF THE FORE-ARM.

The fore-arm is more frequently broken than the arm, because external force operates more directly upon it than the latter part, especially in falls on the hands, which are frequent accidents.—Bichat, in his account of Desault's practice, mentions, that fractures of the fore-arm often held the first place in the comparative table of such cases, kept at the Hôtel Dieu.

We know that the fore-arm is composed of two bones, the ulna and radius. The last is much more liable to fractures than the first, because it is articulated with the hand by a large surface. All the shocks received by the latter part, are communicated to the radius. The situation of this bone more immediately exposes it to such causes as may break it; a circumstance which we may readily convince ourselves of on the first inspection. Both bones of the fore-arm may be broken at the same time, or one alone may be fractured.

FRACTURES OF BOTH BONES

May occur at the extremities, or middle of the fore-arm. They are frequent at the middle; very common below; but seldom happen at the upper part of the fore-arm, where the numerous muscles, and the considerable thickness of the ulna, resist causes which would otherwise occasion the accident. The bones are usually broken in the same line; but sometimes in two different directions. The fracture is almost always single; but in a few instances it is double, and Desault, in particular, was one day called to a patient, over whose fore-arm the wheels of a cart had passed, so as to break the bones, at the middle and lower part, into six distinct portions. The middle ones, notwithstanding they were quite detached, united very well, with hardly any deformity.

These accidents are most commonly occasioned by direct external violence; but sometimes they are produced by a counter-stroke, which is generally the case when the patient falls on his hand. But in this instance, as the hand is principally connected with the lower broad articular surface of the radius, this bone alone has to sustain almost the

whole shock of the blow, and hence, is usually the only one broken.

The symptoms indicating fractures of the fore-arm, are not likely to lead the surgeon into any mistake: motion at a part of the limb, where it was previously inflexible; a crepitus, almost always easily felt; sometimes a distinct depression in the situation of the fracture; a projection of the ends of the fracture beneath the skin, but a less common symptom; pain on moving the part; a noise sometimes audible to the patient at the moment of the accident; an inability to perform the motion of pronation and supination; and an almost constant half-bent state of the fore-arm.

There is one case, however, in which the fracture being very near the wrist-joint, similar appearances to those of a dislocation of this part may arise. But, attention to whether the styloid processes are above, or below, the deformity, will discover whether the case be a fracture or dislocation. In a fracture, the part is also more moveable, and there is a crepitus. (*Œuvres Chir. de Desault, par Bichat, T. 1.*) According to Boyer, the two cases may be distinguished by simply moving the hand, by which motion, if there be a luxation without fracture, the styloid processes of the radius and ulna will not change their situation; but, if a fracture exist, they will follow the motion of the hand.

The connexion of the two bones of the fore-arm, by the interosseous ligament, which occupies the interspace by which they are separated, and the manner in which the muscles attached to both, are inserted into them, render any displacement of the broken pieces in the longitudinal direction very difficult; and in reality, such displacement is seldom observed, and never in any considerable degree. When it does take place, it is to be ascribed to the cause of the fracture, rather than to muscular contraction. On the contrary, in the transverse displacement, the four pieces approach one another, and the interosseous space is diminished or entirely obliterated near the seat of the fracture; attended with evident deformity of the part. There is an angular displacement, which the fracturing cause always produces, either forward or backward, according to its direction.

Boyer gives the following account of the treatment of the fracture of both bones of the fore-arm.

The fore-arm is to be bent to a right angle with the arm, and the hand placed in a position between pronation and supination. The fore-arm and hand being thus placed, an assistant takes hold of the four fingers of the patient, and extends the fractured parts, while another assistant makes counter-extension by fixing the humerus with both his hands. By these means, the operator is enabled to restore the bones to their natural situation, and to push the soft parts into the interosseous space, by a gentle and graduated pressure on the anterior and posterior sides of the arm.

The bones are kept in their place by ap-

plying first on the anterior and posterior sides of the fore-arm two longitudinal and graduated compresses, the base of which is to be in contact with the arm. The depth of these compresses should be proportioned to the thickness of the arm, increasing as the diameter of the arm diminishes. In the next place, the surgeon takes a single-headed roller about six yards long, and makes three turns of it on the fractured part; he then descends to the hand by circles partially placed over one another, and envelopes the hand by passing the bandage between the thumb and index finger; the bandage is next carried upward in the same manner, and reflected wherever the inequality of the arm may render it necessary. The compresses and bandage being thus far applied, the surgeon lays on two splints, one anteriorly, the other posteriorly, and applies the remainder of the bandage over them. The compresses and splints should be of the same length as the fore-arm. It would be useless to employ lateral splints in this case, unless (what is scarcely ever to be expected or met with) a displacement should have taken place in that direction. Lateral splints would counteract the compresses and two other splints, by lessening the radio-cubital diameter of the arm, and with the action of the pronators tend to push the ends of the fracture into the interosseous space. The surgeon's attention should be particularly directed to preserve the interosseous space; for, if this be obliterated, the radius cannot rotate on the cubitus, nor the motion of pronation or supination be executed; and this object may be obtained with certainty by applying the compresses and splints in such a manner, that the fleshy parts may be forced into, and confined in the interosseous space, and by renewing the bandage every seven or eight days.

If the fracture be simple, and the contusion inconsiderable, the patient need not be confined to bed; but may walk about with his arm in a sling.

FRACTURES OF THE RADIUS

Are the most frequent of those of the fore-arm. The radius being almost the sole support of the hand, and placed in the same line with the humerus, is for both these reasons more exposed to fractures, than the ulna.

Fractures of the radius, whether transverse or oblique, near its middle part or extremities, may be caused by a fall or blow on the fore-arm, or, as happens in most cases, by a fall on the palm of the hand. When likely to fall, we extend our arms, and let the hands come first to the ground; in which case, the radius, pressed between the hand on the ground, and the humerus, from which it receives the whole momentum of the body, is bent, and, if the fall be sufficiently violent, broken more or less near its middle part. When, after an accident of this kind, pain, and difficulty of performing the motions of pronation and supination, supervene, the probability of a fracture of

the radius is very strong. The truth is fully ascertained by pressing with the fingers along the external side of the fore-arm. Also, in endeavouring to perform supination or pronation of the hand, a crepitus and a motion of the broken portions will be perceived. When the fracture takes place near the head of the radius, the diagnosis is more difficult, on account of the depth of soft parts over that part of the bone. In this case, the thumb is to be placed under the external condyle of the os humeri, and on the superior extremity of the radius, and at the same time the hand is to be brought into the prone and supine positions. If, in these trials, which are always painful, the head of the radius rests motionless, there can be no doubt of the bone being fractured. Here the causes of displacement are the same as in fractures of the fore-arm; it can never take place, except in the direction of the diameter of the bone, and is effected principally by the action of the pronating muscles. The ulna serves as a splint in fractures of the radius; and the more effectually, as these two bones are connected with one another throughout their whole length.

In general, when only the radius is fractured, no extension is requisite. During the treatment, the elbow is to be bent, and the hand put in the mid-state, between pronation and supination; that is to say, the palm of the hand is to face the patient's breast. Having reduced the ends of the fracture, when they appear to be displaced, the soap plaster is to be applied, and over this a slack roller. This bandage is, indeed, of no utility; but, it makes the limb seem to the unknowing by-standers more comfortable, than if it were omitted, and, as it does no harm, the surgeon may honestly apply it. However, no one can doubt, that tight bandages may act very perniciously, by pressing the radius and ulna together, causing them to grow to each other, or, at all events, making the fracture unite in an uneven manner. Only two splints are necessary; one is to be placed along the inside, the other along the outside, of the fore-arm. Soft pads must always be placed between the skin and the splints, in order to obviate the pressure of the hard materials, of which the latter are formed. The inner splint should extend to about the last joint of the fingers; but, not completely to the end of the nails; for, many patients, after having had their fingers kept, for several weeks, in a state of perfect extension, have been a very long time in becoming able to bend them again.

Sometimes, it may be proper to apply a compress just under the ends of the fracture, to prevent their being depressed toward the ulna too much, the consequence of which has occasionally been the loss of the prone and supine motions of the hand.

In setting a fractured radius, the hand should be inclined to the ulnar side of the fore-arm.

FRACTURES OF THE ULNA.

Fractures of this bone are less frequent,

than those of the radius, and takes place generally at its lower extremity, which is most slender, and least covered. A fracture of this bone is almost always the result of a force acting immediately on the part fractured; as, for instance, when, in a fall, the internal side of the fore-arm strikes against a hard resisting body. On applying the hand judiciously to the inside of the fore-arm, this fracture is easily ascertained by the depression at that part, in consequence of the inferior portion being drawn toward the radius by the action of the pronator radii quadratus. This displacement, however, is less considerable than what takes place in fractures of the radius. The superior portion of the ulna remains unmoved. (*J. L. Petit.*)

In this case, the assistant, who makes whatever little extension may be necessary, should incline the hand to the radial side of the fore-arm, while the surgeon pushes the flesh between the two bones, and applies the apparatus, as in the preceding case. In all fractures of the bones of the fore-arm, and, particularly, in those which are near the head of the radius, a false ankylosis is to be apprehended, and should be guarded against by moving the elbow gently and frequently, when the consolidation is in a certain degree advanced.

Fractures of the fore-arm always require the part to be kept quietly in a sling.

FRACTURES OF THE OLECRANON.

The olecranon may be fractured either at its base, or its extremity; but, the first occurrence is the most frequent. The division is almost always transverse, though occasionally oblique. The accident is very rarely produced by the action of the muscles, but almost always by external violence, directly applied to the part in a blow, or fall upon the elbow.

With regard to symptoms, the contraction of the triceps, being no longer resisted, by any connexion with the ulna, draws upward the short fragment, to which it adheres, so as to produce, between it and the lower one, a more or less evident interspace. This interspace is situated at the back part of the joint, and may be increased or diminished at will, by augmenting the flexion of the fore-arm, and putting the triceps into action, or else extending the limb. Another symptom, is the impossibility of spontaneously extending the fore-arm, the necessary effect of the detachment of the triceps from the ulna. The fore-arm is constantly half bent, the biceps, and brachialis having no antagonists. The olecranon is, more or less conspicuously, drawn up higher than the condyles of the os brachii, which latter parts, on the contrary, are naturally situated higher than the olecranon, when the fore-arm is half bent. The upper piece of bone may be moved in every direction, without the ulna participating in the motion. Besides these symptoms, we must take into the account, the considerable pain experienced, the crack sometimes distinctly heard by the patient, and the crepitus which is frequently perceptible.

The indications are to push downward the retracted portion of the olecranon, and to keep it in this position, at the same time that the ulna is made to meet it, as it were, by extending the fore-arm. According to Desault, however, the fore-arm should not be completely extended, as when the pieces of bone touch at their back part, they leave a vacancy in front, which is apt to be followed by an irregular callus, prejudicial to the free motion of the elbow. Hence, it was his practice to put the arm between the half bent state and extension. This posture, however, would soon be changed, if permanent means were not taken to maintain it. Desault, with this view, applied a splint along the forepart of the arm. But, as position evidently operates only on the lower part of the olecranon, the upper one requires to be brought near the former, and fixed there, which is, doubtless, the most difficult object to effect, because the triceps is continually resisting.

Desault used to adopt the following method: the fore-arm being held in the above position, the surgeon is to begin applying a roller round the wrist, and to continue it as high as the elbow. The skin, covering this part, being wrinkled in consequence of the extension of the limb, might insinuate itself between the ends of the fracture, and consequently it must now be pulled upward by an assistant. The surgeon is then to push the olecranon towards the ulna, and confine it in this situation with a turn of the roller, with which the joint is then to be covered, by applying it in the form of a figure of 8.

A strong splint, a little bent, just before the elbow, is next laid along the arm and fore-arm, and fixed by means of a roller. The apparatus being applied, the whole limb is to be evenly supported on a pillow.

The cure of the fractured olecranon is seldom effected by the immediate reunion of its fragments: there generally remains a greater or lesser interspace between them, which is filled up by a substance not of a bony consistence. It is true, such interspace is smaller when the fore-arm has been kept extended; but, this advantage does not at all counterbalance the unpleasant stiffness of the joint, which is the inevitable consequence of a posture so unfavourable to the functions of the limb. (*Boyer, Traité des Maladies Chir. T. 3, p. 226.*) This author cites several facts, which prove, that when the fractured olecranon is entirely neglected from the case not being understood, the fragments are still united by a ligamentous substance, and that when an interspace of half an inch is thus left between them, the strength and motion of the elbow become perfect.

Camper laid great stress upon the inutility of keeping the arm perfectly extended: he found patients recover sooner and better, when the elbow was kept half bent, and the joint gently exercised at as early a period as possible. "Agglutinationem scilicet motiri non debet chirurgus, sed sublatis tumore ac

inflammatione quiete et remediis aptis, cubitum quotidie prudenter movere, ut unio per tricipitis tendinem, seu per concretionem membranosam formetur, et os ossi non admoveatur. Verbo quemadmodum C. Celsus in *Med. Lib. 8 c. 10, § 4, p. 537*, de cubito fracto præcepit. Quod si ex summo cubito quilibet fractum sit, glutinare id vinciendo alienum est, fit enim brachium immobile, ac, si nihil aliud quam dolori occurrendum est, idem qui fuit ejus usus est." (*Camper de Fractura Patellæ, p. 66, Hagæ, 1789.*) The late Mr. Sheldon, however, does not concur with Desault and Camper, respecting the position of the limb during the treatment, but insists upon the utility of keeping the fore-arm perfectly extended. The main objection to the endeavour to effect a close bony union, is the general impossibility of doing this in such a manner, that the extremity of the olecranon will afterward adapt itself precisely to the hollow designed for its reception at the back of the humerus.

On an average, the olecranon becomes firmly united about the twenty-sixth day. (*Desault par Bichat.*)

FRACTURES OF THE CARPAL AND METACARPAL BONES, AND PHALANGES OF THE FINGERS.

The bones of the carpus, when broken, are usually crushed, as it were, between very heavy bodies, or the limb has been entangled in powerful machinery, or suffered gunshot violence. It must be obvious, therefore, that, as the soft parts are also seriously injured, these cases are generally followed by severe and troublesome symptoms, and sometimes require the performance of amputation, either immediately, or subsequently. When an attempt is to be made to save the part, the chief indications are to extract splinters of bone, and prevent inflammation, abscesses, and mortification. The parts may at first be kept wet with a cold evaporating lotion, any wound present being lightly and superficially dressed, but, afterward, as soon as all tendency to bleeding is over, emollient poultices may be applied over the dressings, instead of the lotion. The dressings themselves, however, should not be removed for the first three or four days, all unnecessary disturbance of the crushed parts being highly injurious. Should abscesses form, early openings should be practised, so as to prevent the matter from extending up the fore-arm. Duly supporting the hand and fore-arm in a sling is of the greatest importance. The metacarpal bones of the little finger and thumb are more frequently broken, than the other three. A fracture of a metacarpal bone is generally produced by violence applied directly to the part, as no force, capable of causing the accident, can well act upon the two ends of the bone so as to break it. The fracture may be simple, but, more commonly it is compound, the soft parts being wounded, and lacerated by the same violence, which has injured the bone.

In most cases, also, unless the force has operated by a very limited surface, more than one metacarpal bone is fractured. At first the same kind of treatment is requisite, as in the preceding cases, and after the inflammation has subsided, a hand-board, or splint may be employed. When the hand is very badly crushed, amputation is indicated.

In fractures of the finger bones, the treatment consists in applying a piece of soap-plaster, rolling the part with tape, incasing it in pasteboard, sometimes placing the hand on a flat splint, or finger-board, and always keeping the hand, fore-arm, and elbow, well supported in a sling.

FRÆNUM LINGUÆ. In infants, the tongue is sometimes too closely tied down, by reason of the frenum being extremely

short, or continued too far forwards. In the latter case, the child will not be able to use its tongue with sufficient ease in the action of sucking, swallowing, &c. in consequence of its point being confined at the bottom of the mouth. Though this affection is not unfrequent, it is less common than is generally supposed by parents and nurses. When the child is small, and the nurse's nipple large, it is common for her to suppose the child to be tongue tied, when, in fact, it is only the smallness of the child's tongue that prevents it from surrounding the nipple, so as to enable it to suck with facility. Mothers also commonly suspect the existence of such an erroneous formation whenever the child is long in beginning to talk.

The reality of the case may always be easily ascertained by examining the child's mouth. In the natural state, the point of the tongue is always capable of being turned upward, towards the palate, as the frænum does not reach along about a quarter of an inch of the lower part of the tongue from the apex. But, in tongue-tied children, by looking upon one side, we may see the frænum extending from the back part to the very point, so that the whole length of the tongue is tied down, and unnaturally confined.

The plan of cure is to divide as much of the frænum as seems proper for setting the tongue at liberty. The incision, however, should not be carried more extensively backward, than is necessary, lest the raninal arteries be cut; an accident, that has been known to have proved fatal. For the same reason, the scissors used for this operation, should have no points. I think the following piece of advice, offered by a modern author, may be of service to practitioners, who ever find it necessary to divide the frænum linguæ: "It is not the relations of the trunk of the lingual artery alone which the student ought to make himself acquainted with. He will do well to study the position of the arteria ranina in respect to the frænum linguæ. This information will teach him the impropriety of pointing the scissors upward and backward, when snipping the frænum, an operation, by the by, oftener performed than needed. He will learn, that the ranular artery lies just above the attachment of the frænum; so that if he would avoid it, he must turn the points of the scissors rather downward; if he do not, the artery will probably suffer." (*A. Burns, Surgical Anatomy of the Head and Neck, p. 239.*)

When an infant has the power of sucking, this proceeding should never be resorted to, even though the frænum may have the appearance of being too short, or extending too far forwards. (*Fab. Hildanus, centur. 3, Obs. 28; Petit, Traité des Mal. Chir. T. 3, p. 265, Edit. 1774.*)

Although the operation of dividing the frænum linguæ is for the most part done without any bad consequences, surgeons should remember well, that it is liable to dangers, especially when performed either unnecessarily, or unskillfully.

Besides the fatal events, which have occasionally resulted from wounding the raninal arteries, the records of surgery furnish us with proofs, that the mere bleeding from the raninal veins, and the small vessels of the frænum, may continue so long, in consequence of the infant's incessantly sucking as to produce death. In such cases, the child swallows the blood, as fast as it issues from the vessels, so that the cause of death may even escape observation. But, if the body be opened, the stomach and intestines will be found to contain large quantities of blood. (*See Dionis, Cours d'Opérations de Chirurgie, 7e Demonstration; Petit, Traité des Maladies Chir. T. 3, p. 282, &c.*)

Another accident, sometimes following an unnecessary, or too extensive a division of the frænum, consists in the tongue becoming thrown backward over the glottis into the pharynx, where it lies fixed, and causes suffocation. The observations of Petit on this subject are highly interesting. (*See Op. cit. T. 3, p. 267, &c.*)

Lastly, it should be known, that an infant's inability to move its tongue, or suck, is not always owing to a malformation of the frænum. Sometimes the tongue is applied and glued, as it were, to the roof of the mouth, by a kind of mucous substance, and in this case, it should be separated with the handle of a spatula. By this means, infants have been saved, which were unable to suck during several days, and were in imminent danger of perishing from want of nourishment. (*See Mémoires de l'Acad. de Chirurgie, T. 3, p. 16, Edit. 4to.*)

FRAGILITAS OSSIUM. A morbid brittleness of the bones.

Boyer imputes *mollities ossium* to a deficiency of lime in their structure; *fragilitas ossium* to a deficiency of the soft matter naturally entering into their texture. He states, that a certain degree of *fragilitas ossium* necessarily occurs in old age, because the proportion of lime in the bones naturally increases as we grow old, while that of the organized part diminishes. Hence, the bones of old persons more easily break than those of young subjects, and are longer in uniting again. As Mr. Wilson observes, however, they never are found so friable and fragile, as to crumble like a calcined bone, but on the contrary, they contain a large quantity of oil, a fact particularly noticed by Saillant, (*see Hist. de la Société de Med. 1776, p. 316,*) and after death dry so greasy, that they are unfit to be preserved as preparations. Their organized vascular part is diminished, but their oily animal matter is increased. (*On the Skeleton and Diseases of Bones, p. 258.*)

In persons who have been long afflicted with cancerous diseases, the bones are said

to become sometimes as brittle, as if they had been calcined. Saviard and Louis relate cases of this description. (*Obs. Chir. et Journ. de Savans*, 1691. *Obs. et Remarques sur les effets du Virus Cancereux*, Paris, 1750. *Ponteau Œuvres Posthumes*, T. 1.) Louis mentions a nun who broke her arm by merely leaning on a servant; and in the London Medical Journal an account is given of a person, who could not even turn in bed, without breaking some of his bones.

In the latter stage of syphilis, the bones are alleged to be sometimes remarkably brittle. (*Ephem. Nat. Cur. Dec. 1. Ann. 3. Obs. 112. Walther, Museum Anat. T. 2, p. 29.*)

In bad cases of scurvy, the bones occasionally become so brittle, that they are broken by the slightest causes, and do not grow together again. (*Boettcher von den Krankh. der Knochen. p. 68.*)

The fragilitas ossium of old age is incurable; that which depends on some other constitutional disease can only be relieved by a removal of the latter. (See *Boyer on Diseases of the Bones*, Vol. 2.)

This author, in one of his last works, expresses his opinion, that the doctrine of molities and fragilitas ossium being distinct different diseases, is by no means sufficiently proved by a due number of accurate observations. FUNGUS. Any sponge-like excrescence. Granulations are often called *fungous* when they are too high, large, flabby, and unhealthy.

FUNGUS HÆMATODES. (from *fungus*, and *aima*, blood.) *The Bleeding Fungus. Spongoid Inflammation. Soft Cancer. Carcinome Sanglante. Medullary Sarcoma.*

This disease, which has been accurately described only of late years, was formerly generally confounded with cancer. The public are indebted to Mr. J. Burns, of Glasgow, for the first good account of it; and the subsequent writings of Mr. Hey, of Leeds, Mr. Freer, of Birmingham, Mr. J. Wardrop, Mr. Langstaff, and others, have

made us still better acquainted with the subject.

It is unquestionably one of the most alarming diseases, incidental to the human body, because we know of no specific remedy for it; and an operation can only be useful at a time, when it is very difficult to persuade a patient to submit to it.

Indeed, when the diseased part is extirpated at an early period, a recovery hardly ever follows; for experience proves, that it is not a disease of a local nature, but almost always extends to a variety of organs and structures at the same time, either to the brain, the liver, or lungs, &c. It is of the utmost consequence to be aware of this fact, since we should otherwise be induced to attempt many hopeless operations, and deliver a prognosis, that might cause disappointment and censure. In a large proportion of patients, afflicted with fungus hæmatodes, the general disorder of the system is indicated by a peculiarly unhealthy aspect; a sallow, greenish yellow colour of the skin, which is frequently covered with clammy perspiration; constant troublesome cough; difficulty of breathing, &c.

Fungus Hæmatodes, is the name used by Mr. Hey. Mr. J. Burns has called the disease *spongoid inflammation*, from the spongy elastic feel, which peculiarly characterizes it, and which continues even after ulceration takes place. The fungus hæmatodes has most frequently been seen to attack the eyeball, the upper and lower extremities, the testicle, and the mamma. But, the uterus, ovary, liver, spleen, brain, lungs, thyroid gland, hip, and shoulder joints have also been the seat of the disease. A distemper, which presents itself in so many parts, must be subject to variety in its appearances.

FUNGUS HÆMATODES OF THE EYE.

1. When it attacks the eye, the first symptoms are observable in the posterior chamber, an appearance, like that of polished iron, presenting itself at the bottom of the eye. (*Scarpa on Diseases of the Eye, p. 505, Éd. 2.*) The pupil becomes dilated and immoveable, and, instead of having its natural deep black colour, it is of a dark amber, and sometimes of a greenish hue. The change of colour becomes gradually more and more remarkable, and, at length is discovered to be occasioned by a solid substance, which proceeds from the bottom of the eye towards the cornea. The surface of this substance is generally rugged and unequal, and ramifications of the central artery of the retina may sometimes be seen running across it. The front surface of the new mass, at length advances as far forwards as the iris, and the amber, or brown appearance of the pupil, has, in this stage, been known to mislead surgeons into the supposition of there being a cataract, and make them actually attempt couching. The disease continuing to increase, the eyeball loses its natural figure, and assumes an irregular knobby appear-

ance. The sclerotica also loses its white colour, and becomes of a dark blue, or livid hue. Sometimes, matter now collects between the tumour and the cornea. The latter membrane in time ulcerates, and the fungus shoots out. In a few instances, it makes its way through the sclerotica, and is then covered by the conjunctiva. The surface of the excrescence is irregular, often covered with coagulated blood, and bleeds profusely from slight causes. When the fungus is very large, the most prominent parts slough away, attended with a fetid sanious discharge. In the course of the disease, the absorbent glands, under the jaw, and about the parotid gland, become contaminated. On dissection, a diseased mass is found extending forwards from the entrance of the optic nerve, the vitreous, crystalline, and aqueous humours being absorbed. The retina is annihilated, and the choroid coat propelled forwards, or quite destroyed. The tumour seems to consist of a sort of medullary matter, resembling brain. The optic nerve is thicker and harder than natural, of a brownish ash-colour, and destitute of its usual tubular appearance. In other cases, the nerve is split into two or more pieces, the interspaces being filled up with the morbid growth. (Wardrop.) Nay, as Mr. Travers has stated, the optic ganglion, tractus opticus, and thalamus, have been repeatedly found diseased, and the surrounding adipose substance in the orbit affected to a considerable extent in places also where there was no direct communication with the diseased contents of the globe. (*Synopsis of the Diseases of the Eye*, p. 221.) Even the brain has been observed to share in the disease, sometimes dark red spots appearing on the dura mater; sometimes small spots, containing a fluid like cream, being found between the pia mater, and tunica arachnoides. Mr. Travers has a preparation, exhibiting a genuine example of the disease affecting the anterior right lobe of the cerebrum, and protruding the eye from its socket, while the eye itself was perfectly free from disease. (*Op. cit.* p. 223.) When the lymphatic glands at the angle of the jaw are enlarged, as they frequently are, they are also found converted into a kind of medullary matter, similar to that which composes the diseased mass in the eyeball. When the skin bursts over a diseased absorbent gland, a sloughy ulcer is produced; but, no fungus is emitted, unless the affection of the gland with fungus hæmatodes be primary. Fungus hæmatodes of the eye has been erroneously regarded as cancer by the best writers. We learn from Bichat, that more than one-third of the patients on whom Desault operated for supposed carcinoma of the eye, were under twelve years of age. Twenty out of twenty-four cases of fungus hæmatodes of the eye, with which Mr. Wardrop has been acquainted, happened to children under twelve years of age. Now, as cancer is rather a disease of aged, than young persons, and we find, from Mr. Wardrop, that fungus hæmatodes of the eye mostly affects persons

under twelve years of age, it is tolerably certain, that most of Desault's cases, reported to be cancers of the eye, were in fact the equally terrible disease now engaging our consideration. According to Mr. Travers, the only parts of the eye and its appendages, subject to be primarily attacked by cancer, are the lachrymal gland, conjunctiva, and eyelids; while the evidence of many cases has assured him, that fungus hæmatodes may originate in any texture of the eye, with the exception of the lens and cornea. (*Synopsis of the Diseases of the Eye*, p. 216, 222, and 421.) This account, however, differs from that delivered by Mr. Wardrop and Professor Scarpa, who describe the disease as first commencing in the retina, and particularly at the point, where the optic nerve enters the eye. "For, (says the latter author,) on the first appearance of the yellowish or greenish spot, the retina on examination is found to be entirely deficient, or in other words, to have degenerated into the malignant fungus. It is also found, that the choroid membrane, while the fungus hæmatodes is in its incipient state, does not appear to have suffered any remarkable alteration in its texture, and that is only at a more advanced period of the disease, that this membrane becomes thickened, and separated from its connexion with the sclerotica. The choroid membrane, even in the most advanced stage of the disorder, preserves more than all others, its natural texture." (*On the Principal Diseases of the Eyes*, p. 507, Ed. 2.) In cases of fungus hæmatodes, the sight of young subjects is generally destroyed, before the attention of parents is excited to the distemper. Frequently, however, a blow, followed by ophthalmia, precedes the growth of the diseased mass. When no external violence has occurred, the first symptom is a trivial fulness of the vessels of the conjunctiva, the iris becoming, at the same time, extremely vascular, and altered in colour, and the pupil dilated and immoveable. There is seldom much complaint made of pain; but, the child is sometimes observed to be languid and feverish. In adults, fungus hæmatodes of the eye generally comes on without any apparent cause, though sometimes in consequence of a blow. At first, the tunica conjunctiva is slightly reddened, and vision indistinct. The redness and obscurity of sight increases slowly, and an agonizing nocturnal headach is experienced, the eye bursts, and the humours are discharged.

With regard to the cure of the fungus hæmatodes of the eye, the only chance of effecting this desirable object depends upon the early extirpation of the diseased organ. It must be acknowledged, however, that most of the operations, in which the morbid eye has been removed, have hitherto proved unsuccessful, owing to a recurrence of the disease. The reason of such ill success may be imputed to the optic nerve and other parts being almost always in a morbid state, before an attempt is made to remove the eye. One case, however, described by Mr. Tra-

vers, as having its seat in the cellular texture connecting the conjunctiva to the cornea, was operated upon, and no recurrence of the disease had occurred a twelvemonth afterward. No other texture was affected more, than the contiguity and extent of the disease explained. (*Synopsis of the Diseases of the Eye*, p. 413.) The operation has always been found to fail, when the disease is advanced so far, that the posterior chamber is filled by the fungous mass. Since no internal medicines, nor external applications, afford the least hope of checking any form of the fungus hæmatodes, it is manifest, that when the distemper of the eye exceeds certain bounds, the miserable patient is placed beyond the reach of any effectual aid from surgery. In a case, however, which I saw in April, 1821, in the London Eye Infirmary, the disease formed a diseased mass as large as an orange, accompanied with enlarged lymphatic glands over the parotid. The patient was an infant. In this instance, Mr. Lawrence used as a local application, the liquor opii sedativus, prepared by Mr. Battley, which was found to lessen considerably the child's sufferings. (See particularly *Wardrop's Obs. on Fungus Hæmatodes*. *Scarpa on the Principal Diseases of the Eye*, chap. 21. *Some Cases in Saunders's Treatise on Diseases of the Eye*; and *B. Travers's Synopsis of the Diseases of the Eye*, 8vo. Lond. 1820.)

FUNGUS HÆMATODES OF THE LIMBS.

2. In the extremities, the disease begins with a small colourless tumour, which is soft and elastic, if there be no thick covering over it, such as a fascia; but otherwise it is tense. At first, it is free from uneasiness; but, by degrees, a severe acute pain darts occasionally through it more and more frequently, and at length, becomes incessant. For a considerable time, the tumour is smooth and even; but afterward, it projects irregularly at one, or more points; and the skin at this place becomes of a livid red colour, and feels thinner. In this situation, it easily yields to pressure, but instantly bounds up again. Small openings now form in these projections, through which is discharged a thin bloody matter. Almost immediately after these tumours burst, a small fungus protrudes, like a papilla, and this rapidly increases, both in breadth and height, and has exactly the appearance of a carcinomatous fungus, and frequently bleeds profusely. The matter is thin, and exceedingly fetid, and the pain becomes of the smarting kind. The integuments, for a little way round these ulcers, are red, and tender. After ulceration takes place, the neighbouring glands swell, and assume exactly the spongy qualities of the primary tumour. If the patient still survive the disease in its present advanced progress, similar tumours form in other parts of the body, and the patient dies hectic.

After death, or amputation, the tumour is found to consist of a soft substance, somewhat like the brain, of a grayish colour, and

greasy appearance, with thin membrane-like divisions running through it, and cells, or abscesses, in different places, containing a thin bloody matter, occasionally in very considerable quantity. There does not seem uniformly to be an entire cyst, surrounding the tumour; for it very frequently dives down betwixt the muscles, or down to the bone, to which it often appears to adhere. The neighbouring muscles are of a pale colour, and lose their fibrous appearance, becoming more like liver, than muscle. The bones are always carious in the vicinity of these tumours.

The distemper is sometimes caused by external violence, though in general there is no evident cause whatever. (*Dissertation on Inflammation by J. Burns*, Vol. 2.)

Mr. Hey has given several cases of the fungus hæmatodes. If I notice the most particular circumstances, relative to one of these, it will suffice to inform the reader of the form, in which this terrible affliction has presented itself in this gentleman's practice.

A young man, aged twenty-one, two years before applying to Mr. Hey, perceived a small swelling on the inside of the right knee, not far from the patella. This tumour was moveable, and did not impede the motion of the joint: it was not discoloured, but was painful, when moved, or pressed upon. It continued in this state half a year, and then the man having hurt his knee against a stone, it gradually increased in bulk, but did not exceed the size of an egg. The skin was now discoloured with blue specks, which were taken to be veins. He could still walk with ease, and follow his business.

Two months before his admission into the Leeds Infirmary, he met with a fall, and violently bent his knee, but did not strike it against any thing. The tumour began immediately to enlarge; and within a few hours, it extended half way up the inside of his thigh. About a fortnight after this accident, the skin burst at the lowest part of the tumour, and discharged some blood. A dark-coloured fungus, about the size of a pigeon's egg, here made its appearance, and a few weeks afterward, the skin burst at another part of the large tumour, and some blood was again discharged. From the fissure arose another fungus, which had increased, in the course of the last week, to the size of a small melon, and now measured eight inches from one side of its base to the other. The base of the fungus frequently bled, especially when the man allowed his limb to hang down.

The whole tumour was now of an enormous size, being nineteen inches across, when the measure was carried over the last mentioned fungus. From its highest part in the thigh to the lowest part, just below the knee, it measured seventeen inches, without including the fungus. The base of the tumour at the knee, exclusive of that part, which ran up the thigh, measured twenty-four inches in circumference. The tumour was situated on the inner side of the limb,

and was distinctly defined. The skin covering the disease, was in some places livid, and had several fissures and small ulcerations upon it; but had not burst asunder, except in the two places above described. The tumour was soft, and gave a sensation of some contained fluid, when gently pressed with the hands alternately in opposite directions. The patient said he had walked without pain in his knee, a week before his admission into the Infirmary; and he had lost very little blood in his journey to Leeds. He complained of the greatest uneasiness in the highest part of the tumour. It had become hot and painful in the night-time, for some days past. His pulse was 114 in a minute; his tongue was clean; and his appetite had been good, till the last few days. He had never felt any pulsation in the tumour.

In a consultation it was determined, that the tumour should be laid open, by cutting off a portion of the distended integuments; and that after removing the contents, if the sac should be found in a sound state, the disease should be treated as a simple wound; but if in a morbid state, amputation of the limb should be immediately performed.

A large oval piece of the integuments being removed, the tumour was found to contain a very large quantity of a substance, not much unlike coagulated blood; but more nearly resembling the medullary part of the brain in its consistence and oily nature. It was of a variegated reddish colour, in some parts approaching to white, and as blood issued from it, Mr. Hey conceived it was organized. This mass was partly diffused through the circumjacent parts in innumerable pouches, to which it adhered, and was partly contained in a large sac of an aponeurotic texture, which was connected with the capsule of the knee-joint. There was a great and universal effusion of blood from the internal surface of the sac, and from the pouches, containing this morbid mass.

Amputation of the limb was immediately performed, on finding such to be the nature of the case. Mr. Hey, unfortunately, however, left a portion of the diseased surface behind on the inner part of the thigh, and hoping that a small narrow portion of the upper part of the sac would soon become a clean sore, and not impede the cure, he made the circular incision two inches below its higher part.

On examining the amputated limb, the vastus internus was found to be brown, and much softer than the other muscles, which were healthy. There were many small portions of blood extravasated in the substance of this muscle. The sac was formed on the aponeurotic covering of the muscle, and ended below where this aponeurosis begins to cover the capsular ligament of the knee. The two fungous substances, above described, appeared to have been only extensions of the morbid mass, where this had made its way through the sac and the integuments.

The joint of the knee, and muscles of the leg, were perfectly sound.

I need not detail all the particulars after the operation. Suffice it to say, the man suffered a great deal of constitutional disorder. After a few weeks, the granulations upon the stump became good, and the cicatrization was nearly completed at the end of the sixth week, after the amputation. At this period, the small and superficial portion of the upper part of the great sac, which Mr. Hey had unfortunately left, was now healed; but a tumour, now about four inches in length, and between two and three in breadth, had gradually risen at the lower and under part of the thigh, beneath the cicatrix. This contained a soft substance, exactly similar, as far as the touch could discover, to that which had filled the large sac. This tumour became painful, and sometimes discharged a bloody serum, sometimes dark-coloured blood, through four or five small openings in the cicatrix.

Mr. Hey laid open the tumour, and removed its contents; but no advantage was gained by this proceeding. The interior surface was found to be too much diseased to produce good granulations. Blood continued to ooze out of the wound for a few days. Then the inner surface became covered with a blackish substance, which gradually extended itself, and formed a new fungus. A variety of escharotics were applied to destroy the fungus and morbid surface of the wound; but to no purpose, the growth of the fungus always exceeded the quantity destroyed. Undiluted oil of vitriol, applied freely, had very little effect.

An attempt was once more made to cut away the disease; but on examining the wound carefully, after the contained substance was removed, the muscular substance was found degenerated into a hard mass, which felt somewhat like cartilage. The adipose membrane was also diseased, and formed into large cells, which had contained the fungous substance. Hence, another amputation seemed the only resource.

After this operation, the whole surface of the stump seemed sound, except the principal artery, which was filled with a somewhat stiff matter, resembling coagulated blood, which prevented its bleeding. The inside of the vessel, on being touched with the scalpel, felt hard, and communicated a sensation, like that of scraping bone.

The man was sent home, as soon as his state would admit of it; but he died consumptive about six months afterward. Besides this instance in the thigh, Mr. Hey relates cases of fungus hæmatodes, situated in the female breast, in the leg, in the neck (extending from the jaw to the clavicle, and producing suffocation,) on the back part of the neck, on the back part of the shoulder, and at the extremity of the fore-arm, near the wrist.

"If I do not mistake, (says Mr. Hey,) this disease not unfrequently affects the globe of the eye, causing an enlargement of it, with the destruction of its internal organization."

tion. If the eye is not extirpated, the scleritis bursts at the last, a bloody sanious matter is discharged, and the patient sinks under the complaint." (P. 283.)

Besides some cases, in similar situations, to those mentioned by Mr. Hey, one is related by Mr. Burns, in which the hip-joint was the seat of this terrible affection. After detailing the progress of the case to the poor man's death, this author states that he found on dissection, the hip-joint completely surrounded with a soft matter, resembling the brain, enclosed in thin cells, and here and there cells full of thin bloody water; the head of the thigh bone was quite carious, as was also the acetabulum. The muscles were quite pale, and almost like boiled liver, having completely lost their fibrous appearance, and muscular properties. The same sort of morbid mischief was also found within the pelvis, most of the inside of the bones, on the affected side, being quite carious. An attempt had been made, before the patient died, to tap the bladder; but the trocar had only entered a cell, filled with bloody water, and situated in a mass of the soft brain-like substance.

I have already said enough, to render the description of the dreadful nature of the fungus hæmatodes tolerably complete. Little can be said of the treatment; for we know not of one medicine, that seems to have the least power of putting a stop to the disease, and we have no reason to believe, that there is ever the smallest chance even of any spontaneous amendment, much less of such a cure.

We have seen, that when the chief part of a fungus hæmatodes is cut away, and only a small portion of its cyst is left behind, that the fungus is reproduced from this part, and soon becomes as formidable, nay more formidable, than it was before, and this notwithstanding the application of the most powerful escharotics. Neither the hydrargyrus nitratus ruber, the hydrargyrus murialis, the antimonium muriatum, nor the undiluted vitriolic acid, have always been able to repress the growth of such fungus. (Hey.)

There is no remedy that has the power of checking, or removing the complaint. Friction, with anodyne balsams, sometimes gives relief in the early stages; but it does not retard the progress of the disease.

In short, the only chance of cure consists in extirpating the whole of the distempered parts, removing not only the soft, brain-like, fungous substance, but every particle of the cysts, sacs, or pouches, in which it may be contained. An operation of this kind, however, is only advisable in the early stages, while the disease is entirely local, if it ever be so, a circumstance much to be doubted; for after the neighbouring glands have become affected, the chance of recovery is almost destroyed. It is sometimes difficult, however, to persuade patients at an early period to submit to amputation, or extirpation, because the pain and inconveniences are inconsiderable; but the operation ought to be urged with all the force which a conviction of its

absolute necessity, and the fatal peril of delay, ought to inspire.

The attempts to cure the disease, by cutting it away, have been attended with such ill success, that some surgeons deem it advisable not to follow this method, but amputate the limb at once. The annexed views of the matter appear to me to be most judicious and rational. First, that if an attempt be made to cut away the tumour, and save the limb, the surgeon must be careful to remove, at the same time, a considerable quantity of the soft parts in the circumference of the swelling. Secondly, that the earlier this is done, the more likely is it to succeed. Thirdly, that, after the tumour is taken out, an attentive examination of the surface of the wound should be made, and every suspicious part or fibre be cut away. Fourthly, that, should the disease still recur, amputation ought to be instantly performed. Fifthly, that caustics should never be applied to this disease. Sixthly, that, even when one of these operations effectually extirpates the distemper of the limb, the patient's entire recovery is always rendered exceedingly uncertain, by reason of the viscera, and other invisible parts, being frequently affected, at the time of the operation, with the same sort of disease.

FUNGUS HÆMATODES OF THE TESTICLE.

3. Fungus hæmatodes of the testicle sometimes begins in its glandular part, sometimes in the epididymis. Its progress is slow, and the pain generally not severe. Nor is there, at first, any inequality or hardness of the diseased part, nor change in the scrotum. When the testicle has become exceedingly large, it feels remarkably soft and elastic, as if it contained a fluid. Hence, the case has often been mistaken for a hydrocele, and punctured with a trocar. (Wardrop; Earle in Med. Chir. Trans. Vol. 3, p. 60.) Occasionally, when the tumour is large, it is in some places hard, in others soft. The hydrocele may be known by the water beginning to collect at the bottom of the scrotum, and then ascending towards the spermatic cord, and by the swelling being circumscribed towards the abdominal ring; whereas the fungus hæmatodes begins with a gradual enlargement of the testicle itself, followed by a fulness, which extends up the spermatic cord. It is not in the slightest degree diaphanous, and is much heavier than a similar bulk of water. (Earle, *op. cit.*) As the disease advances, abscesses form, and the scrotum ulcerates; but no fungus shoots out. When the inguinal glands become contaminated, they often acquire an immense size; and when the skin over them bursts, large portions of them slough away. Fungus hæmatodes of the testicle is said to afflict young, more frequently than old subjects. On dissection, the substance of the diseased testicle is found to present a medullary, or pulpy appearance, generally of a pale brownish colour, though sometimes red. In most cases, the tunica vaginalis and tunica albuginea are

adherent together; occasionally there is fluid between them.

In an example, dissected by Mr. Lawrence, the swelling of the testicle consisted of cellular septa, filled with pulpy matter. Numerous tubercles of the disease were found in the omentum, and about the pelvis, intermixed with recently effused coagula. A mass of soft matter, equal in size to a man's head, lay on the spine, behind the aorta and vena cava; *which last vessel was closed for some extent.* The spermatic vessels could not be found. (See *Med. Chir. Trans. Vol. 8, Part 1, art. 13.*)

The only chance of a cure must be derived from a very early performance of castration, before the disease has extended to the inguinal glands, or far up the spermatic cord. Indeed, very little hope should be placed in the removal of the testicle; for fungus hæmatodes appears to be rather a constitutional than a local disease. Nearly every case on record has terminated fatally, and upon dissection, either the liver, the lungs, the brain, the mesenteric glands, or other internal parts, have been found affected with the same disease. In one case, dissected by Mr. Lawrence, tubercles of a similar structure to the disease in the axilla, were found in the lungs, heart, and, in short, in nearly all the thoracic and abdominal viscera, though the contents of the skull were free from disease. (See *Cases recorded by Wardrop, Earle, Lawrence, and Langstaff, in Med. Chir. Trans. Vol. 3 and 8.*)

We shall quit this subject with stating some of the principal differences between two diseases, which have been commonly confounded. A scirrhus tumour is, from its commencement, hard, firm, and incompressible, and is composed of two substances; one hardened and fibrous, the other soft and inorganic. The fibrous matter is the most abundant, consisting of septa, which are paler than the soft substance between them. A scirrhus tumour, situated in a gland, is not capable of being separated from the latter part, so much are the two structures blended. A scirrhus in another situation, sometimes condenses the surrounding cellular substance, so as to form a kind of capsule, and assume a circumscribed appearance. When a scirrhus swelling ulcerates, a thin ichor is discharged, and a good deal of the hard fibrous substance is destroyed by the ulceration; other parts become affected, and the patient dies from the increased ravages of the disease, and its irritation on the constitution. Sometimes, though not always, after a scirrhus has ulcerated, it emits a fungus of a very hard texture. Such excrescence, however, is itself at last destroyed by the ulceration. Cancerous sores, also, frequently put on, for a short time, an appearance in some places of cicatrization. On the other hand, the fungus hæmatodes, while of moderate size, is a soft elastic swelling, with an equal surface, and a deceitful feel of fluctuation. It is, in general, quite circumscribed, being included within a capsule. The substance of the tumour, instead of being for the most

part hard, consists of a soft, pulpy, medullary matter, which readily mixes with water. When ulceration occurs, the tumour is not lessened by this process, as in scirrhus; but a fungus is emitted, and the whole swelling grows with increased rapidity. Cancerous diseases are mostly met with in persons of advanced age, while fungus hæmatodes generally afflicts young subjects. (*Wardrop.*) Many dissections have now proved, that the substance of fungus hæmatodes may contain cellular septa, which include the pulpy, medullary matter.

In cases of external cancer, the viscera are not in general affected at the same time with cancerous disease; but in the majority of examples of fungus hæmatodes, this distemper is found affecting in the same subject a variety of parts. In addition to the outward tumour, we find swellings of a similar nature, perhaps, in the liver, the lungs, the mesenteric glands, or even in the brain. Yet M. Roux will have it, that cancer and fungus hæmatodes are the same disease; or, at least, that the latter is only a species of the former, and that in both cases the same peculiar diathesis prevails. (*Roux, Parallèle de la Chirurgie Angloise avec la Chirurgie Française, p. 216, 217.*)

See *Dissertations on Inflammation, by J. Burns, Vol. 2.* *Hey's Practical Observations in Surgery, ed. 3.* *Freer on Aneurism. Observations on Fungus Hæmatodes, or Soft Cancer, by James Wardrop, 8vo. Edin. 1809.* This last publication is highly deserving of the attention of the surgical practitioner, the disease in different organs being well described, and its character discriminated from that of cancer.

A case of this disease is related in *Vol. 5 of the London Medical Journal.* It was the consequence of an attempt to cure a ganglion by means of a seton, and it proved fatal. A case is also related by Mr. Abernethy, in *Surgical Observations, 1804, p. 99.* See also a *Case of diseased Testicle, accompanied with Disease of the Lungs and Brain, by H. Earle, in Medico-Chirurg. Trans. Vol. 3, p. 59, &c. in which Vol. four other cases are recorded by Mr. Lawrence, p. 71, et seq. and one by Mr. Langstaff, p. 277, which last I remember visiting in company with this gentleman and Mr. Lawrence, a short time before the patient died.* See also *Langstaff's Cases and Observations in the 8th and 9th Vol. of the same work.* *Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Française p. 211, &c.* On Fungus Hæmatodes of the Eye, there are some valuable observations in the last edition of Scarpa's *Treatise on the Diseases of that organ.* See also *Saunders on Diseases of the Eye, and B. Travers's Synopsis of Diseases of the Eye, 8vo. Lond. 1820.*

Respecting medullary sarcoma, which is generally considered as the same affection as fungus hæmatodes, some further observations will be delivered in the article, *Tumours.*

FURUNCULUS. (from *furo*, to rage.)

A boil, so named from the violence of the heat and inflammation attending it.

A boil is a circumscribed, very prominent, hard, deep-red, inflammatory swelling, which is exceedingly painful, and commonly terminates in a slow and imperfect suppuration. The figure of the tumour is generally that of a cone, the base of which is considerably below the surface. Upon the most elevated point of the boil, there is usually a whitish, or livid pustule, which is exquisitely sensible, and immediately beneath this is the seat of the abscess. The matter is mostly slow in forming, is seldom very abundant, and never healthy at first, being always blended with blood. The complaint is seldom attended with fever, except when the tumour is very large, situated on a sensible part, or when several of these swellings occur at the same time in different places. In the last circumstance, they often occasion in children, and even in irritable adults, restlessness, loss of appetite, spasms, &c. They rarely exceed a pigeon's egg in size, and they may originate on any part of the body.

Boils commonly arise from constitutional causes. Young persons, and especially subjects of full plethoric habits, are most subject to them. The disease is also observed to occur with most frequency in the spring. (*Lassus, Pathologie Chir. T. 1, p. 16.*) According to Richerand, the origin of boils depends upon a disordered state of the gastric organs. (*Nosographie Chir. T. 1, p. 124, edit. 2.*)

The suppuration attending a boil is never perfect, and the matter which forms is not only tinged with blood, but surrounded with a sloughy substance, which most generally is discharged before the part affected will suppurate kindly, and the disease end. Richter compares the slough with a kind of bag, or cyst, and the whole boil with an inflamed encysted tumour.

The best plan is mostly to endeavour to make boils suppurate as freely as possible, by applying external emollient remedies. This seems to be the natural course of the disease in its progress to a cure, and, indeed, all endeavours to discuss furunculous tumours commonly fail, or succeed very imperfectly; only removing the inflammation, and leaving behind an indolent hardness, which occasions various inconveniences. according to its situation, every now and then inflames anew, and never entirely disappears, until a free suppuration has been established.

In a very few cases, perhaps, it may be proper to try to discuss boils. For this purpose, besides bleeding, gentle evacuations, and a low diet, which are requisite in this as well as other local inflammations, some prescribe as external applications honey strongly acidulated with sulphuric acid; alcohol; or camphorated oil.

But in the generality of instances, suppuration must be promoted by the use of emollient poultices. The tumour, when allowed to burst, generally does so at its apex. However, as the opening is generally long in forming, and too small to allow the sloughy cellular substance to be discharged, it is always best, as soon as matter is known to exist in the tumour, to make a free opening with a lancet, and immediately afterward to press out as much of the matter and sloughs, as can be prudently done. This having been accomplished, and the rest of the sloughs pressed out, as soon as it is practicable, healthy pus will be secreted, and the part will granulate and heal. Until the suppuration becomes of a healthy kind, and the sloughy substances are entirely discharged, an emollient linseed poultice is the best application; and when granulations begin to fill up the cavity, plain lint, and a simple pledget, are the only dressings necessary.

Where there is reason to suppose the gastric organs to be in a disordered state, an emetic should be given in the early part of the treatment, and afterward small repeated doses of any of the mild purging salts.

When an indolent hardness continues, after the inflammatory, and suppurative state of boils has been cured, the part should be rubbed with a camphorated mercurial ointment.

Besides the above acute boil, authors describe a chronic one, which is said frequently to occur, in subjects who have suffered severely from the small-pox, measles, lues venerea, scrofula, and in constitutions which have been injured by the use of mercury.

The chronic boil is commonly situated upon the extremities, is of the same size as the acute one, has a hard base, is not attended with much pain, nor any considerable discoloration of the skin, until suppuration is far advanced, and the matter is seldom quite formed before three or four weeks. This, like the former, sometimes appears in a considerable number at a time. The discharge is always thinner than good pus, and when the boil is large, and has been long in suppurating, a great deal of sloughy cellular membrane must be cast off, before the sore will heal.

The principal thing requisite in the local treatment of all furunculous, and carbuncular tumours, is to make an early free opening into them, and to press out the matter and sloughs, employing emollient poultices, till all the mortified parts are detached and removed, and afterward simple dressings. (See *Pearson's Principles of Surgery. Richter, Anfangsgrunde der Wundarzn, B. 1. Lassus, Pathologie Chir. T. 1 p. 15 Richerand, Nosographie Chir. T. 1, p. 123, edit. 2.*)

G.

GANGLION, (*γαγγλιον*.) In surgery, a tumour on a tendon, or aponeurosis.

A ganglion is an encysted, circumscribed, moveable swelling, commonly free from pain, causing no alteration in the colour of the skin, and formed upon tendons in different parts of the body, but most frequently upon the back of the hand, and over the wrist. A French gentleman consulted me, who had one upon the upper part of his foot, which created a great sensation of weakness in the motion of the foot, and I have taken notice, that ganglions occur particularly often just below the kneecap, in housemaids, who are in the habit of kneeling a great deal in order to scour rooms. A curious example has been lately recorded, in which a ganglion, situated exactly over the *arteria radialis* and the *arteria superficialis volæ*, was at first supposed to be an aneurism. (See *Edinb. Med. and Surg. Journ. for April, 1821.*)

These tumours, when compressed, seem to possess considerable elasticity. They often occur unpreceded by any accident; frequently they are the consequence of bruises and violent sprains. They seldom attain a considerable size, and ordinarily are not painful, though every now and then there are instances to the contrary. When opened, they are found to be filled with a viscid transparent fluid, resembling white of egg. If they do not disappear of themselves, or are not cured while recent, by surgical means, they, in some cases, become so large, that they cause great inconvenience, by obstructing the motion of the part, and rendering it painful.

Discutient applications sometimes succeed in curing ganglions, and, in this country, friction with the *oleum origani* is a very common method. I have often seen such tumours very much lessened by this plan of treatment, but seldom cured, and no sooner has the friction been discontinued, than the fluid in the cyst has in general accumulated again.

Compression is usually more effectual than discutient liniments. Persons with ganglions, have been recommended to rub them strongly with their thumb, several times a day. After this has been repeated very often, the tumour has sometimes disappeared. But the best method is to make continual pressure on ganglions, by means of a piece of sheet-lead, bound upon the part with a bandage. There is no objection, however, to using once or twice a day, in conjunction with this treatment, frictions with the *oleum origani*, or camphorated mercurial ointment, provided these measures together do not seem likely to make the tumour inflame, an event, which should always be carefully avoided. Ganglions, when irritated too much, have been known to become most malignant fungous diseases.

Setons have been recommended to be in-

roduced through ganglions, with a view of curing them. This method, however, is not an eligible one; for, it is by no means free from danger, as the records of surgery fully prove. Cancerous diseases, and even a malignant fatal fungus, (*Med. Jour. Vol. 5.*) have arisen from the irritation of a seton passed through a ganglion.

Frequently, when a ganglion inflames and ulcerates, the cyst throws out a fungus, which is of a very malignant nature. Hence, the practitioner should avoid making an opening into the swelling, or doing any thing which is likely to occasion sloughing, or ulceration of the disease. Ganglions may be cured by pressure of such force as to rupture the cyst, and some authors have recommended putting the hand affected upon a table, and then striking the ganglion several times with the fist, or a mallet. The cyst of a recent ganglion may also be burst, by compressing it strongly with the thumbs, with or without the intervention of a piece of money; the fluid is effused into the adjacent cellular membrane; and, pressure being now employed, the opposite sides of the cavity become united by the adhesive inflammation, and the recurrence of the disease is prevented. (See *L'Encyclopédie Méthodique, Partie Chir. art. Ganglion*; *Lassus, Pathologie Chir. T. 1, p. 400, &c.*; *Leveillé, Nouvelle Doctrine Chir. T. 3, p. 7.*)

In almost every instance, a ganglion may be cured by pressure and friction, and if not actually cured, the disease may be rendered so bearable by these means, that few patients would choose to have the tumour cut out. Under this plan, the swelling becomes very much diminished, and should it enlarge again, the mode of relief is so simple, and the case so little troublesome, that patients generally content themselves with every now and then wearing a piece of lead on the part.

But when ganglions resist all attempts to disperse or palliate them; when they become extremely inconvenient, either by obstructing the functions of a joint, or causing pain; they should be carefully dissected out, by first making a longitudinal incision in the skin covering them, then separating the cyst on every side from the contiguous parts, and lastly cutting every particle of it off the subjacent tendon or fascia. The greatest care must be taken not to make any opening in the cyst, so as to let out its contents, and make it collapse; a circumstance, which would render the dissection of it much more difficult.

The operation being accomplished, the skin is to be brought together with sticking plaster, and a compress placed over the situation of the tumour, with a view of healing the wound and the cavity by adhesion.

When the ganglion has burst, or is ulcerated, it is best to remove the diseased skin, to-

gether with the cyst, and of course the incision must be oval or circular, as may seem most convenient. The grand object is not to allow any particle of the cyst to remain behind, as it would be very likely to throw out a fungus, and prevent a cure. In Warner's Cases of Surgery, is an account of two considerable ganglions, which this gentleman, in imitation of Celsus and Paulus Aegineta, thought it right to extirpate. These had become adherent to the tendons of the fingers. In the operation, he was obliged to cut the transverse ligament of the wrist, and the patients, who before could not shut their hands, nor close their fingers, perfectly regained the use of these parts. Mr. Gooch relates a case of the same kind, which had been occasioned by a violent bruise, three or four years before. The tumour reached from the wrist to the middle of the hand, and created a great deal of pain. Mr. Gooch extirpated it, and then restored the position of the hand, and free motion of the joint, by the use of emollient applications, and suitable pressure, made with a machine constructed for the purpose. Other cases confirming the safety of cutting out ganglions, are recorded in the *London Medical Journal*, for 1787, p. 154; by Eller, in *Mém. de l'Acad. des Sciences de Berlin*, T. 2, ann. 1746; *Schmucker in Chir. Wahrnehmungen*, 1. B. p. 332; *Girard Lupiologie*.

The ganglions, which occur just below the knee, I have seen cured by a little blister applied over them, and kept open with the savin cerate. Camphorated blisters, indeed, have been proposed as a means of dispersing other ganglions. (*Jaeger, Chir. Cautelen*, 2 B.)

Ball's Surgery*. *Latta's System of Surgery*. *L'Encyclopédie Méthodique*, Partie Chir. art. Ganglion. *Richter, Anfangsgr. der Wundarzn.* B. 1. *Lassus, Pathologie Chir.* T. 1, p. 399; *Dict. des Sciences Méd.* T. 17, p. 311.

GANGRENE. (from *γασσ*, to feed upon.) An incipient mortification, so named from its eating away the flesh.

Authors have generally distinguished mortification into two stages; the first, or incipient one, they name *gangrene*, which is attended with a sudden diminution of pain in the place affected; a livid discolouration of the part, which from being yellowish becomes of a greenish hue; a detachment of the cuticle, under which a turbid fluid is effused; lastly, the swelling, tension, and hardness, of the previous inflammation, subside, and on touching the part, a crepitus is perceptible, owing to the generation of air in the gangrenous parts.

Such is the state, to which the term *gangrene* is applied.

When the part has become quite cold, black, fibrous, incapable of moving, and destitute of all feeling, circulation, and life; this is the second stage of mortification, termed *sphacelus*. Gangrene, however, is frequently

used synonymously with the word mortification. (See *Mortification*.)

GASTROCELE. (from *γαστρ*, the stomach, and *κελη*, a tumour.) A hernia of the stomach.

GASTRORAPHIA, or GASTRORAPHE. (from *γαστρ*, the belly, and *ραφη*, a suture.) A suture of the belly, or some of its contents.

Although the term *gastroraphe*, in strictness of etymology, signifies no more than sewing up any wound of the belly, yet Mr. S. Sharp informs us, that in his time, the word implied, that the wound of the abdomen was complicated with another of the bowels.

The moderns, I think, seem to limit the meaning of the word to the operation of sewing up a wound in the parietes of the abdomen.

What was formerly meant by *gastroraphe* could scarcely ever be practised, because the symptoms laid down for distinguishing when an intestine is wounded, do not with any certainty determine in what particular part it is wounded; which want of information, makes it absurd to open the abdomen in order to get at it. Hence, the operation of stitching the bowels can only take place when they fall out of the abdomen, and when we can see where the wound is situated. And, indeed, even in these circumstances, the employment of sutures is a practice, the propriety of which is questionable, as will be further considered in the article *Wounds*.

The circumstances, making the practice of sewing up a wounded intestine proper, are so rare, that Du Verney, who was the most eminent surgeon in the French army a great many years during the wars, and fashion of duelling, declared, that he had never had a single opportunity of practising *gastroraphe*, according to the former acceptance of that word.

Gastroraphe, or merely sewing up a wound of the parietes of the abdomen, may be done, as Mr. Sharp explains, with the common interrupted suture, (see *Suture*) or with the quilled one, which is better, as follows:

A ligature, capable of splitting into two, has a needle attached to each end of it. The lip of the wound is to be pierced, from within outward, about an inch from its edge. The other needle is to be passed in the same way through the opposite lip. Then the two needles are to be cut off. As many such sutures must be made, as the extent of the wound may require.

The sides of the wound are next to be brought together, and the ligatures tied, not in a bow, in the way of the interrupted suture, because the continual action of the abdominal muscles might make the ligatures cut their way through the parts. On the contrary, it is better to divide each end of the ligatures into two portions, and to tie these over a piece of bougie laid along the line at which the ligatures emerge from the flesh. This is to be done to all the ligatures on one side first. Then the wound being closed, another piece of bougie is to be placed along

the other lip of the wound, and the opposite ligatures tied over it, with sufficient tightness, to keep the sides of the wound in contact. This suture is certainly preferable to the interrupted one, because a great deal of its pressure is made on the two pieces of bougie, and of course it is less likely to cut its way out. Its operation is to be assisted with compresses laid over each side of the wound, and the uniting bandage. Every thing that puts the abdominal muscles into action, drags the suture, irritates the wound, and creates a risk of the threads cutting their way through the part, in which they are introduced; consequently, it must be avoided. In order to prevent, as much as possible, the exertion of the muscles, the bowels should be kept open with clysters. Saline draughts with opium are most likely to stop the vomiting, sometimes attendant on wounds of the abdomen, and producing very injurious effects.

In about a week, the sutures may generally be removed, and sticking plaster alone employed. As to what more relates to these particular cases, we must refer to *Wounds of the Abdomen*.

It is generally allowed, that sutures are violent means, to which we should only resort, when it is impossible to keep the lips of a wound in contact by the observance of a proper posture, and the aid of a methodical bandage. M. Pibrac believes such circumstances exceedingly uncommon, and in his excellent production, in the third volume of the *Memoirs of the Royal Academy of Surgery*, relative to the abuse of sutures, cases are related, which fully prove, that wounds of the belly readily unite by means of a suitable posture and a proper bandage, without having recourse to gastroraphe. These, however, are less decisive and convincing, (if possible to be so) than the relations of the Cæsarean operation, the extensive wound of which has oftentimes been healed by these simple means, after the failure of sutures. It is not only possible to dispense with gastroraphe in the treatment of wounds of the abdomen, it has even been manifested, that this operation has sometimes occasioned very bad symptoms.

Under certain circumstances, however, it may be essentially necessary to practise gastroraphe. For instance, were a large wound to be made across the parietes of the abdomen, a suture might become indispensably requisite to prevent a protrusion of the bowels. Yet, even in this case, the sutures should be as few in number as possible.

A bandage of the eighteen-tailed kind, might prove very useful in a longitudinal wound of the abdomen, and do away all occasion for gastroraphe. (See *Sutures*.)

We shall conclude this article with a fact, perhaps, more curious, than instructive, related by M. Bordier, of Pondicherry, in the *Journal de Medecine*, vol. 26, 538. An Indian soldier, angry with his wife, killed her, and attempted to destroy himself by giving himself a wound with a broad kind of dagger in the abdomen, so as to cause a protrusion

of the bowels. A doctor of the country, being sent for, dissected between the muscles and skin, and introduced a thin piece of lead, which kept up the bowels. The wound soon healed up, the lead having produced no inconvenience. The man was afterward hung, and M. Bordier, when the body was opened, assured himself more particularly of the fact. Indeed, numerous cases prove, that lead may lodge in the living body, without occasioning the inconvenience, which results from the presence of almost any other kind of extraneous body.

See *Le Dran, Opérations de Chirurgie*. *Sharp's Treatise on the Operations of Surgery*. *L'Encyclopedie Méthodique, Partie Chirurgicale*, art. *Gastroraphe*; *Sabatier, Médecine Opératoire*, T. 1.

GASTROTOMIA. (from γαστήρ, the belly, and τέμνω, to cut.) The operation of opening the abdomen and uterus. The Cæsarean operation.

GLAUCOMA (from γλαυκος, bluish green,) is now defined by modern surgeons to be a greenish, or gray opacity of the vitreous humour, attended with the loss, or a considerable impairment of sight. (*Weller on Diseases of the Eye, Trans. by Monleath, Vol. 2, p. 27.*) Professor Beer considers the subjects of glaucoma and the cataracta viridis, or glaucomatosa, together in the same chapter. He observes, that these diseases occur rather frequently, not only as true effects of inflammation of the eye, but sometimes quite unpreceded by this affection. Although glaucoma may continue for a long time as the only disorder, without the crystalline lens being changed in the slightest degree, yet Beer has never seen the case reversed, and the lens become altered as it does in glaucoma first, and the vitreous humour afterward. In what this author describes as gouty ophthalmia, glaucoma is said to come on with the following symptoms. The iris is not observed to expand, but rather to become contracted; the pupil is not equally dilated, but extends more towards the canthi, the iris at length becoming scarcely perceptible towards each angle of the eye, especially the outer one, and the pupil of course assuming something of the appearance which is seen in the eye of a ruminating animal. In a case, however, which I lately saw in the London Eye Infirmary under Mr. Lawrence, it was particularly remarked, that the diameter of the pupil was not greatest in the transverse direction; a circumstance, which Beer's account would lead us to expect as constant. And, it particularly merits notice, that as the iris shrinks towards the margin of the cornea, its pupillary edge is inverted towards the lens, so that its smaller circle completely disappears. In this very dilated state of the pupil, a gray greenish opacity is perceived, seeming to be very deep, and arising from a real loss of transparency in the vitreous humour. At this period, the lens evidently becomes opaque, acquiring a sea-green hue, and the cataracta viridis, or glaucomatosa, now swells and appears to project forwards into

the anterior chamber. The pain then becomes more incessant and violent; the varicose affection of the eyeball seriously increases; and the eyesight, which began hourly to diminish from the moment when the pupil was first observed to be in any degree expanded and opaque, and the iris motionless, is now so entirely destroyed, that not the slightest perception of external light remains, though the patient may vainly congratulate himself on discerning luminous appearances produced within the eye itself, in the form of a fiery, shining circle, especially when the organ is gently pressed upon. An eye in this condition (says Boyer) has really a look, as if it were dead, the cornea being as flaccid, and void of lustre, as in a corpse. Finally, when these symptoms have attained their utmost pitch, an atrophy of the eyeball follows, and the painful sensations about the organ cease. In corpulent individuals, however, they still continue with greater violence. Sooner, or later, the other eye is also either attacked with arthritic iritis, or ophthalmia, or becomes affected with glaucoma, which is ushered in by violent and incessant headache. (*Beer, Lehre von den Augenkrankheiten, B. 1, p. 581, &c. 8vo. Wien. 1813.*) According to this author, glaucoma and the green cataract, are never the consequences of any description of ophthalmia, but what he terms arthritic. (*B. 2. p. 255, Wien. 1817.*) Both these affections, after they are conjoined with a general varicose disease of the eyeball, he sets down as generally incurable. According to Weller, when the vitreous humour first begins to be muddy, the disease may sometimes be checked. (*On Diseases of the Eye. Vol. 2. p. 29.*) The means of relief, depended upon in Germany, are frictions on the eyebrow with tinc. opii croc., or liniment. ammon.; the avoidance of cold; camphorated bags of aromatic herbs applied over the eye, but the effect of which must be rather insignificant; issues; setons; rubbing the antimonial ointment over the spine, or behind the ears, &c. (*Vol. cit. p. 228.*)

Other authors recommend applying blisters and giving internally the extract of cicuta, calomel, and soap. (*Encyclopédie Méthodique, Partie Chir.*) The topical use of aether might be tried; but, from the history of the disease, the chances of cure must evidently be nearly hopeless. (See also *Tr. G. Benedict de Morbis humoris Vitrei, 4to. Lips. 1809.*)

GLAUCOSIS, same as Glaucoma.

GLEET. By the term gleet, we commonly understand a continued running, or discharge after the inflammatory symptoms of a clap for some time have ceased, unattended with pain, scalding in making water, &c. Mr. Hunter remarks, that it differs from a gonorrhœa in being uninfected, and in the discharge consisting of globular bodies, contained in a slimy mucus, instead of serum. He says, that a gleet seems to take its rise from a habit of action, which the parts have contracted. The disease, however, sometimes stops of itself, even after every method has been ineffectually tried. This pro-

bably depends upon accidental changes in the constitution, and not at all upon the nature of the disease itself. Mr. Hunter had a suspicion, that some gleets were connected with scrofula. Certain it is, the sea-bath cures more gleets, than the common cold bath, or any other mode of bathing; and a cure may sometimes, but not always, be accomplished by an injection of diluted sea-water.

Gleets are often attended with a relaxed constitution. They also sometimes arise from other affections of the urethra, besides gonorrhœa. A stricture is almost always accompanied with a gleet; and so sometimes is disease of the prostate gland.

It is remarked by Mr. Hunter, that if a gleet does not arise from any evident cause, and cannot be supposed to be a return of a former gleet, in consequence of a gonorrhœa, either a stricture or diseased prostate gland is to be suspected: an inquiry should be made whether the stream of urine is smaller than common, whether there is any difficulty in voiding it, and whether the calls to make it are frequent. If there should be such symptom, a bougie, rather under the common size, should be introduced; and, if it passes into the bladder with tolerable ease, the disease is probably in the prostate gland, which should next be examined. (See *Urethra, Strictures of; and Prostate Gland.*)

Balsams, turpentine, and the tinctura lyttæ, given internally, are of service, especially in slight cases; and when they are useful, they prove so almost immediately. Hence, if they had neither lessened nor removed the gleet in five or six days, Mr. Hunter never continued them longer. The same observation applies to cubeb, so celebrated of late as a remedy for gonorrhœa and gleet, and the common dose of which is ʒij in any convenient fluid three times a day. As the discharge, when removed, is also apt to recur, such medicines should be continued for some time after the symptoms have disappeared.

When the whole constitution is weak, the cold bath, sea-bath, bark and steel, may be given. The astringent gums, and salt of steel, given as internal astringents, have little power.

With regard to local applications, the astringents, commonly used, are, the decoction of bark, sulphat of zinc, alum, and preparations of lead. The aqua vitriolica cærulea, of the London Dispensatory, diluted with eight times its quantity of water, makes a very good injection.

Irritating applications consist either of injections, or bougies, simple or medicated with irritating medicines. Violent exercise may be considered as having the same effect. Such applications should never be used till the other methods have been fully tried, and found unsuccessful. They at first increase the discharge, and, on this account, are sometimes abandoned too early. Two grains of the oxymuriate of mercury dissolved in eight ounces of water, are a very good irritating injection. In irritable habits, such an

application may do great harm, and therefore, if possible, the capability of the parts to bear its employment, should first be made out.

Bougies sometimes act violently, but Mr. Hunter thought them more efficacious, than injections. A simple unmedicated one is generally sufficient, and must be used a month or six weeks, before the cure can be depended upon. Those medicated with camphor, or turpentine, need not be used so long. The bougie should be under the common size.

Mr. Hunter has known a gleet disappear on the breaking out of two chancres on the glans. Gleet has also been cured by a blister on the under side of the urethra; and, by electricity.

In every plan of cure, rest, or quietness, is generally of great consequence; but after the failure of the usual modes, riding on horseback will sometimes immediately effect a cure.

Regularity and moderation in diet are to be observed.

Intercourse with women often causes a return, or increase of gleet; and, in such cases, it gives suspicion of a fresh infection; but the difference, between this and a fresh infection, is, that here the return is almost immediately after the connexion.

Gleets in women, are cured nearly in the same manner as those of men. Turpentine, however, have no specific effect on the vagina; and the astringent injections used may also be stronger than those intended for male patients.

See *A Treatise on the Venereal Disease*, by John Hunter, Ed. 2. Also *Swediaur's Practical Observations on Venereal Complaints*.

GLOSSOCATOCHUS. (from *γλῶσσα*, the tongue; and *κατεχω*, to depress.) The ancient glossocatochus was a sort of forceps, one of the blades of which served to depress the tongue, while the other was applied under the chin.

GOITRE. See *Bronchocele*.

* **GONORRHŒA.** (from *γονή*, the semen; and *ῥέω*, to flow.) Etymologically, an involuntary discharge of the semen; but always, according to modern surgery, a discharge of a purulent infectious matter, from the urethra in the male, and from the vagina and surfaces of the labia, nymphæ, clitoris, &c. in the female subject.

Dr. Swediaur, after censuring the etymological import, as conveying an erroneous idea, says, if a Greek name is to be retained, he would call it blennorrhagia, from *βλάννα*, mucus, and *ῥέω*, to flow. However, as most of the moderns consider the discharge as pus, not mucus, the etymological import of blennorrhæa is as objectionable as that of gonorrhæa. In English, the disease is commonly called a *clap*, from the old French word *clapises*, which were public shops, kept and inhabited by single prostitutes, and generally confined to a particular quarter of the town, as is even now the case in several of the great towns in Italy. In German, the disorder is named a *tripper*, from dripping; and

in French, a *chaudipisse*, from the heat and scalding in making water. (*Swediaur*.)

We shall first present the reader with some of Mr. Hunter's opinions, concerning the nature of gonorrhæa, its symptoms, and treatment; and, lastly, take notice of the observations of some other writers.

When an irritating matter of any kind is applied to a secreting surface, it increases that secretion, and changes it from its natural state to some other. In the present instance, it is changed from mucus to pus.

Till about the year 1753, it was generally supposed, that the matter from the urethra, in cases of gonorrhæa, arose from ulcers in the passage; but, about that time, it was ascertained, that pus could be secreted without a breach of substance. It was first accidentally proved, by dissection, that pus could be formed in the bag of the pleura, without ulceration; and Mr. Hunter afterward examined the urethra of malefactors and others, who were executed, or died, while known to be affected with gonorrhæa, and demonstrated, that the canal was entirely free from every appearance of ulcer.

The time when a gonorrhæa first appears, after infection, is extremely various. It generally comes on sooner than a chancre. Mr. Hunter had reason to believe, that in some instances, the disease began in a few hours; while in others, six weeks previously elapsed; but he had known it begin at all the intermediate periods. However, it was his opinion, that about six, eight, ten, or twelve days after infection, is the most common period.

The surface of the urethra is subject to inflammation and suppuration, from various other causes besides the venereal poison; and sometimes discharges happen spontaneously, when no immediate cause can be assigned. Such may be called *simple* gonorrhæa, having nothing of the venereal infection in them.

Mr. Hunter knew of cases, in which the urethra sympathized with the cutting of a tooth, and all the symptoms of a gonorrhæa were produced. This happened several times to the same patient. The urethra is known to be sometimes the seat of the gout; and Mr. Hunter was acquainted with instances of its being the seat of rheumatism.

When a secreting surface has once received the inflammatory action, its secretions are increased and visibly altered. Also, when irritation has produced inflammation, and an ulcer in the solid parts, a secretion of matter takes place, the intention of which, in both, seems to be to wash away the irritating matter. But, in inflammations, arising from specific, or morbid poisons, the irritation cannot be thus got rid of; for, although the first irritating matter be washed away, yet, the new matter has the same quality as the original had; and therefore, upon the same principle, it would produce a perpetual source of irritations, even if the venereal inflammation, like many other specific diseases, were not what it really is,

kept up by the specific quality of the inflammation itself. This inflammation seems however, to be only capable of lasting a limited time, the symptoms, peculiar to it, vanishing of themselves by the parts becoming less and less susceptible of irritation; and the subsequent venereal matter can have no power of continuing the original irritation; for otherwise there would be no end to the disease. The time, which the susceptibility of the irritation lasts, must depend upon the difference in the constitution, and not upon any difference in the poison itself.

The venereal disease only ceases spontaneously, when it attacks a secreting surface, and produces a mere secretion of pus, without ulceration. Such were some of the sentiments of the late Mr. Hunter, who was a firm believer in the identity of the poisons of syphilis and gonorrhœa; but this idea and the hypothesis, about the impossibility of any spontaneous cure of venereal sores, are now very generally relinquished.

SYMPTOMS OF GONORRHOEA.

The first symptom is generally an itching at the orifice of the urethra, sometimes extending over the whole glans. A little fullness of the lips of the urethra, the effect of inflammation, is next observable, and soon afterward a running appears.

The itching changes into pain, more particularly at the time of voiding the urine. There is often no pain till sometime after the appearance of the discharge, and other symptoms; and in many gonorrhœas, there is hardly any pain at all, even when the discharge is very considerable. At other times, a great degree of soreness occurs long before any discharge appears. There is generally a particular fullness in the penis, and more especially in the glans. The glans has also a kind of transparency, especially near the beginning of the urethra, where the skin being distended, smooth, and red, resembles a ripe cherry. The mouth of the urethra is, in many instances evidently excoriated. The surface of the glans itself is often in a half excoriated state, consequently very tender; and it secretes a sort of discharge. The canal of the urethra becomes narrower, which is known by the stream of urine being smaller than common. This proceeds from the fullness of the penis in general, and from the lining of the urethra being swollen, and in a spasmodic state. The fear of the patient, while voiding his urine, also disposes the urethra to contract; and the stream of urine is generally much scattered and broken, as soon as it leaves the passage. There is frequently some degree of hemorrhage from the urethra, perhaps from the distention of the vessels, more especially when there is a chordee, or a tendency to one. Small swellings often occur, along the lower surface of the penis, in the course of the urethra. These, Mr. Hunter suspected to be enlarged glands of the passage. They occasionally suppurate, and burst outwardly, but now and then in

the urethra itself. Mr. Hunter has also suspected such tumours to be ducts, or lacunæ of the glands of the urethra distended with mucus, in consequence of the mouth of the duct being closed, in a manner similar to what happens to the duct leading from the lachrymal sac to the nose, and so as to induce inflammation, suppuration, and ulceration. Hardness and swelling may also occur in the situation of Cowper's glands, and end in considerable abscesses in the perineum. The latter tumours break either internally or externally, and sometimes in both ways, so as to produce fistulæ in perinæo.

A soreness is often felt all along the under side of the penis, frequently extending as far as the anus. The pain is particularly great in erections; but the case differs from chordee, the penis remaining straight. In most cases of gonorrhœa, erections are frequent, and even sometimes threaten to bring on mortification: as opium is of great service, Mr. Hunter thought, that there was reason to suppose them of a spasmodic nature.

The natural slimy discharge from the glands of the urethra is first changed, from a fine transparent ropy secretion, to a watery whitish fluid; and the lubricating fluid, which the passage naturally exhales, becomes less transparent: both these secretions becoming gradually thicker, assume more and more the qualities of common pus.

The matter of gonorrhœa often changes its colour and consistence, sometimes from a white to a yellow, and often to a greenish colour. These changes depend on the increase and decrease of the inflammation, and not on the poisonous quality of the matter itself; for any irritation of these parts, equal to that produced in a gonorrhœa, will produce the same appearances.

The discharge is produced from the membrane lining the urethra, and from the lacunæ, but, in general, only for about two or three inches from the external orifice. Mr. Hunter says, seldom further, than an inch and a half, or two inches at most. This he terms the specific extent of the inflammation. Whenever he had an opportunity of examining the urethra affected with gonorrhœa, he always found the lacunæ loaded with matter, and more visible, than in the natural state. Before the time of this celebrated man, it was commonly supposed that the discharge arose from the whole surface of the urethra, and even from Cowper's glands, the prostate, and vesiculæ seminales.

But, if the matter were secreted from all these parts, the pus would collect in the bulb, as the semen does, and thence be emitted in jerks; for, nothing can be in the bulbous part of the urethra, without stimulating it to action, especially, when in a state of irritation and inflammation.

When the inflammation is violent, some of the vessels of the urethra often burst, and a discharge of blood ensues. Sometimes

such blood is only just enough to give the matter a tinge. In other instances, erections cause an extravasation, by stretching the part.

When the inflammation goes more deeply than the membranous lining, and affects the reticular membrane of the urethra, it produces in it an extravasation of coagulable lymph, the consequence of which is a chordee. (See *Chordee*.)

Mr. Hunter suspected, that the disease is communicated or creeps along from the glans to the urethra, or, at least, from the lips of the urethra to its inner surface, as it is impossible, that the infectious matter can, during coition, get as far as the disease extends. He mentions an instance, in which a gentleman, who had not cohabited with any woman for many weeks, to all appearance caught a gonorrhœa from a piece of plaster, which had adhered to his glans penis, in a necessary abroad: the infection is accounted for by supposing that some person, with a clap, had previously been to this place, and had left behind some of the discharge, and that the above gentleman had allowed his penis to remain in contact with the matter, till it had dried.

Many symptoms, depending on the sympathy of other parts with the urethra, sometimes accompany a gonorrhœa. An uneasiness, partaking of soreness and pain, and a kind of weariness, are every where felt about the pelvis. The scrotum, testicles, perinæum, anus, and hips, become disagreeably sensible to the patient, and the testicles often require to be suspended. So irritable, indeed, are they in such cases, that the least accident, or even exercise, which would have no effect of this kind at another time, will make them swell. The glands of the groin are often affected sympathetically, and even swell a little, but they do not suppurate, as they generally do when they inflame from the absorption of matter. Mr. Hunter has seen the irritation of a gonorrhœa so extensive as to affect with real pain the thighs, buttocks, and abdominal muscles. He knew one gentleman, who never had a gonorrhœa without being immediately seized with universal rheumatic pains.

When the disorder, exclusive of the affections from sympathy, is not more violent than has been described, Mr. Hunter termed it a *common, or simple venereal gonorrhœa*; but, if the patient is very susceptible of such irritation, or of any other mode of action, which may accompany the venereal, then the symptoms are in proportion more violent. In such circumstances, we sometimes find the irritation and inflammation exceed the specific distance, and extend through the whole urethra. There is often a considerable degree of pain in the perinæum; and a frequent, though not a constant symptom, is a spasmodic contraction of the acceleratores urinæ, and erectores muscles. In these cases, the inflammation is sometimes considerable, and goes deeply into the cellular membrane, but without producing any

effect except swelling. In other instances, it goes on to suppuration, often becoming one of the causes of fistulæ in perinæo. Thus, Cowper's glands may suppurate, and the irritation often extends even to the bladder itself.

When the bladder is affected, it becomes more susceptible of every kind of irritation. It will not bear the usual distention, and, therefore, the patient cannot retain his water the ordinary time; and, the moment the desire of making water takes place, he is obliged instantly to make it, with violent pain in the bladder, and still more in the glans penis, exactly similar to what happens in a fit of the stone. If the bladder be not allowed to discharge its contents immediately, the pain becomes almost intolerable; and even when the water is evacuated, there remains, for some time, a considerable pain both in the bladder and glans.

Sometimes, though rarely, when the bladder is much affected, the ureters, and even the kidneys, sympathize; and Mr. Hunter had reason for suspecting, that the irritation might be communicated to the peritonæum, by means of the vas deferens.

Mr. Hunter mentions a case, in which, while the inflammatory symptoms of a gonorrhœa were abating, an incontinence of urine came on; but, in time, got spontaneously well.

A very common symptom, attending a gonorrhœa, is a swelling of the testicle. (See *Hernia Humoralis*.)

Another occasional consequence of a gonorrhœa, is a sympathetic swelling of the inguinal glands. (See *Bubo*.)

A hard chord is sometimes observed, leading from the prepuce along the back of the penis, and often directing its course to one of the groins, and affecting the glands. At the part of the prepuce, where the chord takes its rise, there is most commonly a swelling. This sometimes happens when an excoriation and a discharge from the prepuce or glans penis exist.

From the above account, the symptoms of gonorrhœa, in different cases, seem to be subject to infinite variety. The discharge often appears without any pain; and the coming on of the pain is not at any stated time after the appearance of the discharge. There is often no pain at all, although the discharge is in considerable quantity, and of a bad appearance. The pain often goes off, while the discharge continues, and will return again. In some cases, an itching is felt for a considerable time, which is sometimes succeeded by pain; though, in many cases, it continues to the end of the disease. On the other hand, the pain is often troublesome, and considerable, even when there is little or no discharge. The neighbouring parts sympathize, as the glands of the groin, the testicle, the loins, and pubes, the upper parts of the thighs, and the abdominal muscles. Sometimes the disease appears a few hours after the application of the poison; sometimes six weeks elapse first. Lastly, it is often impossible to determine whether

the case is a venereal, or only an accidental discharge, arising from some unknown cause.

GONORRHOEA IN WOMEN.

The disorder is not so easily ascertained in them as in men, because they are subject to a disorder called *fluor albus*, which resembles gonorrhœa. A discharge simply from women, is less a proof of the existence of a gonorrhœa, than even a discharge without pain in men. The kind of matter does not enable us to distinguish a gonorrhœa from a *fluor albus*; for in the latter affection, the discharge often puts on all the appearance of venereal matter. Pain is not necessarily present, and therefore forms no line of distinction. The appearance of the parts often gives us but little information; "for," says Mr. Hunter, "I have frequently examined the parts of those who confessed all the symptoms, such as increase of discharge, pain in making water, soreness in walking, or when the parts were touched, yet I could see no difference between these and sound parts. I know of no other way of judging, in cases where there are no symptoms sensible to the person herself, or where the patient has a mind to deny any uncommon symptoms, but from the circumstances preceding the discharge; such as her having been connected with men supposed to be unsound, or her being able to give the disorder to others; which last circumstance, being derived from the testimony of another person, is not always to be trusted to, for obvious reasons." But, though there may sometimes be great difficulty in forming a judgment of some of these cases, the surgeon may frequently come to a right conclusion by recollecting, as Mr. Dunn has reminded me, that, besides the difference depending on the suddenly severe symptoms of gonorrhœa, *fluor albus* may be known by the great debility; the sinking of the stomach; the weariness of the limbs; the pain of the back always increased by the erect posture; the severe headachs; the painful menstruation, together with the very gradual increase of the disease.

From the manner in which the disease is contracted, it must principally attack the vagina, a part not endowed with much sensation. In many cases, however, it produces a considerable soreness on the inside of the labia, nymphæ, clitoris, carunculæ myrtiformes, and meatus urinarius. In certain cases, these parts are so sore, that they will not bear to be touched; the person can hardly walk; the urine gives pain in its passage through the urethra; and when it comes into contact with the above-mentioned parts.

The bladder sometimes sympathizes, and even the kidneys. The mucous glands, on the inside of the labia, often swell, and sometimes suppurate, forming small abscesses, which open near the orifice of the vagina.

According to Mr. Hunter, the venereal

matter from the vagina sometimes runs down the perinæum to the anus, and produces a gonorrhœa, or chancre, in that situation. The disease in women may probably wear itself out, as in men; but it may exist in the vagina for years, if the testimony of patients can be relied on.

TREATMENT OF GONORRHOEA.

As every form of the venereal disease arises from the same cause, and as we have a specific for some forms, we might expect that this would be a certain cure for every one; and, therefore, that it must be no difficult task to cure the disease, when in the form of inflammation and suppuration in the urethra. Experience teaches us, however, that the gonorrhœa is the most variable in its symptoms, while under a cure; and the most uncertain, with respect to its cure, of any forms of the venereal disease, (if it be a form of this disease at all) many cases terminating in a week, while others continue for months, under the same treatment.

The only curative object is, to destroy the disposition and specific mode of action in the solids of the parts, and as they become changed, the poisonous quality of the matter produced will also be destroyed. This effects the cure of the disease, but does not always remove the consequence.

Gonorrhœa is incapable of being continued beyond a certain time in any constitution; and, when it is violent, or of long duration, it is owing to the part being very susceptible of such irritation, and readily retaining it. As no specific remedy for gonorrhœa is known, it is fortunate that time alone will effect a cure. It is worthy of consideration, however, whether medicine can be of any service. Mr. Hunter is inclined to think it not of the least use, in nine cases out of ten. But even this would be of some consequence, if the cases capable of being benefited could be distinguished.

The means of cure generally adopted are of two kinds, internal remedies and local applications; but, whatever plan is pursued, we are always to attend more to the nature of the constitution, or to any attending disease in the parts themselves, or parts connected with them, than to the gonorrhœa itself.

When the symptoms are violent, but of the common inflammatory kind, known by the extent of the inflammation not exceeding the specific distance, the local treatment may be either irritating or soothing.

In these cases, irritating applications are less dangerous than when irritable inflammation is present, and they may alter the specific action; but, to produce this effect, their irritation must be greater than that of the original injury. The parts will afterward recover of themselves, as from any other common inflammation.

Mr. Hunter believes, however, that in the beginning, the soothing plan is the best. If the inflammation be great, and of the irrita-

ble kind, no violence is to be used, for it would only increase the symptoms; and nothing should be done that can tend to stop the discharge, as it would not put a stop to the inflammation. The constitution is to be altered, if possible, by remedies adapted to each disposition, and reducing the disease to its simple form. If the constitution cannot be altered, nothing is to be done, and the action is to be allowed to wear itself out.

When the inflammation has abated, the cure may be attempted by internal remedies or local applications, which do not operate violently, whereby the irritation might be reproduced. Gentle astringents may be applied.

But if the disease has begun mildly, an irritating injection may be used, in order quickly to get rid of the specific mode of action. This application will increase the symptoms for a time; but when it is left off they will often abate, or wholly disappear; and after such abatement, astringents may be used, the discharge being now the only thing to be removed.

When itching, pain, and other uncommon sensations are felt for some time before the discharge appears, Mr. Hunter diffidently expresses his inclination to recommend the soothing plan instead of the irritating one, in order to bring on the discharge, which is a step towards the resolution of the irritation; and he adds, that to use astringents would be bad practice, as, by retarding the discharge, they would only protract the cure. When there are strictures, or swelled testicles, astringents should not be used; for, while there is a discharge, such complaints are relieved.

Mr. Hunter thus expresses himself in regard to the effect of mercury in gonorrhœa: "I doubt very much of mercury having any specific virtue in this species of the disease; for I find that it is as soon cured without mercury as with it, &c. So little effect, indeed, has this medicine upon a gonorrhœa, that I have known a gonorrhœa take place while the patient was under a course of mercury, sufficient for the cure of a chancre. Men have been also known to contract a gonorrhœa when loaded with mercury for the cure of a lues venerea; the gonorrhœa, nevertheless, has been as difficult of cure as in ordinary cases."

Mr. Hunter does not say much in favour of evacuants, diuretics, and astringents, given internally. He allows, however, that astringents, which act specifically on the parts, as the balsams, conjoined with any other medicine, which may be thought right, may help to lessen the discharge in proportion as the inflammation abates.

Local applications may be either internal to the urethra, external to the penis, or both. Those which are applied to the urethra seem to promise most efficacy, because they come into immediate contact with the diseased parts. They may be either in a solid or fluid form. A fluid is only a very temporary application. The solid ones, or bou-

gies, may remain a long while, but in general irritate immediately, from their solidity alone: and Mr. Hunter says, the less bougies are used, when the parts are in an inflamed state, the better, though he never saw any bad effects from them, when applied with caution.

The fluid applications, or injections, in use, are innumerable; and as gonorrhœa frequently gets well with so many of various kinds, we may infer that such complaints would, in time, get well of themselves. However, there cannot be a doubt, that injections often have an immediate effect on the symptoms, and hence must have power; though the injection, which possesses the greatest power, is unknown. As injections are only temporary applications, they must be used often, especially when found useful, and not of an irritating kind.

Mr. Hunter divides injections into four kinds, the *irritating*, *sedative*, *emollient*, and *astringent*.

Irritating injections, of whatever kind, act in this disease upon the same principle; that is, by producing an irritation of another kind, which ought to be greater than the venereal; by which means the venereal is destroyed and lost, and the disease cured, although the pain and discharge may still be kept up by the injection: effects, however, which will soon go off, when the injection is laid aside. In this way bougies also perform a cure. Most of the irritating injections have an astringent effect, and prove simply astringent when mild.

Irritating injections should never be used when there is already much inflammation; especially in constitutions which are known to be incapable of bearing much irritation; nor should they be used when the inflammation has spread beyond the specific distance; nor when the testicles are tender; nor when, upon the discharge ceasing quickly, these parts have become sore; nor when the perinæum is very susceptible of inflammation, and especially if it formerly should have suppurated; nor when there is a tendency in the bladder to irritation, known by the frequency of making water.

In mild cases, and in constitutions which are not irritable, such injections often succeed, and remove the disease almost immediately. The practice, however, ought to be attempted with caution, and not, perhaps, till milder methods have failed. Two grains of the hydrargyrus muriatus, dissolved in eight ounces of distilled water, form a very good irritating injection; but an injection of only have this strength may be used, when it is not intended to attempt a cure so quickly. If, however, the injection, even in that proportion, gives considerable pain in its application, or occasions a great increase of pain in making water, it should be further diluted.

Sedative injections will always be of service, when the inflammation is considerable, and they are very useful in relieving the pain. Perhaps, the best sedative is opium, as well when given by the mouth, or anus,

as when applied to the part affected, in the form of an injection. But even opium will not act as a sedative in all constitutions, and parts; but on the contrary, often has opposite effects, producing great irritability. Lead may be reckoned a sedative, so far as it abates inflammation; while, at the same time, it may act as a gentle astringent. Fourteen grains of acetate of lead, in $\frac{3}{4}$ viij. of distilled water, make a good sedative astringent injection.

Drinking freely of diluting liquors may, perhaps, have a sedative effect, as it in part removes some of the causes of irritation, by rendering the urine less stimulating to the bladder, when the irritation is there, and to the urethra in its passage through it. Diluting drinks may possibly lessen the susceptibility of irritation. The vegetable mucilages of certain seeds and plants, and the emollient gums, are recommended. Mr. Hunter does not entertain much opinion of their efficacy, though some of his patients told him, that they experienced less uneasiness in making water, when their drink was impregnated with mucilaginous substances.

Emollient injections are the most proper, when the inflammation is very great; and they probably act by first simply washing away the matter, and then leaving a soft application to the part, so as to be singularly serviceable, by lessening the irritating effects of the urine. Indeed, practice proves this; for a solution of gum arabic, milk and water, or sweet oil, will often lessen the pain, and other symptoms, when the more active injections have done nothing, or seemed to do harm.

The irritation at the orifice of the urethra is frequently so great, that the point of the syringe cannot be suffered to enter. In this case no injection should be used till the inflammation has abated; but in the mean while, fomentations may be employed.

Astringent injections act by lessening the discharge. They should only be used towards the latter end of the disease, when it has become mild. But if the disease should begin mildly, they may be used at the very beginning; for by gradually lessening the discharge, without increasing the inflammation, we complete the cure, and prevent a continuance of the discharge called *gleet*. They will have an irritating quality, if used strong, and hence increase the discharge, instead of lessening it. Mr. Hunter's experience did not teach him, that one astringent was much better than another. The astringent gums, as dragon's blood, the balsams, and the turpentine, dissolved in water; the juices of many vegetables, as oak bark, Peruvian bark, tormentil root, and perhaps all the metallic salts, as green, blue, and white vitriols; the salts of mercury, and also alum: probably all act much in the same way; though the mere changing of an injection is often efficacious. The local use of the nitric acid, properly diluted, has been commended by Vigaroux, Toepelmann, and others, as a safe remedy for the stoppage of

gonorrhœa. (See *Pearson on the effects of various Articles in the cure of Lues Venerea*, p. 205, Ed. 2, and *Neuere Erfahr. über zweckm. Behdl. venerisch. Schleimaussflüsse*, &c. Leipz. 1809.)

The external applications are poultices and fomentations, which can only be useful when the prepuce, glans, and orifice of the urethra, are inflamed.

Since Mr. Hunter's time, many surgeons have been in the habit of keeping the penis, in the incipient inflammatory stage of gonorrhœa, covered with linen, continually wet with the liquor plumbi acetatis dilutus; a practice which is certainly both rational and beneficial. Mr. Abernethy, in his *Lectures on Surgery*, speaks in favour of this method. And some surgeons, among whom is my intelligent correspondent, Mr. Dunn, of Scarborough, have seen great relief derived from the use of a suspensor scroti, or double handkerchief, which, combined with rest and the elevation of the penis, the last mentioned practitioner has frequently found, indeed, of more service than any thing else.

When the glands of the urethra are enlarged, mercurial ointment may be rubbed on the part; but this will probably be of most service after the inflammation has subsided.

TREATMENT OF GONORRHOEA IN WOMEN.

This is nearly the same as that of the disease in men, but is more simple. When the disorder is in the vagina, injections are best; and after their use, the external parts should be well washed. It is almost impossible for the patient to throw an injection into the urethra, when it is affected. The same injections are proper as for men; but they may be made doubly strong. When the glands of the vagina suppurate, and form abscesses, these should be opened, and dressed; but the practice of smearing the parts with mercurial ointment, as advised by Mr. Hunter, is now entirely abandoned.

CONSTITUTIONAL TREATMENT OF GONORRHOEA.

In many strong plethoric constitutions, the symptoms are violent, and there is a great tendency to inflammatory fever. In such instances opiate clysters, though at first productive of relief, sometimes occasion in the end fever, and consequently aggravate all the symptoms. In these cases, the balsam of capivi also sometimes increases the inflammatory symptoms. In a constitution of this kind, the treatment consists chiefly in evacuations, the best of which are bleeding, and gentle purging. The patient must live sparingly, and above all, use little exercise.

In a weak and irritable constitution, the symptoms are frequently violent, the inflammation extending beyond the specific distance, running along the urethra, and even affecting the bladder. Here the indication is to strengthen; and according to Mr. Hun-

ter, bark alone has been known to effect a cure. All evacuations are hurtful.

A fever has been known to stop the discharge, relieve the pain in making water, and finally cure the disease. On other occasions, Mr. Hunter has seen all the symptoms of gonorrhœa cease on the accession of a fever, and return when the fever was subdued. In other examples, a gonorrhœa mild at first, has been rendered severe by the coming on of a fever, and upon its subsidence, the gonorrhœa has ceased. Although a fever does not always cure a gonorrhœa, yet, as it may do so, nothing should be done while it lasts. If the local complaint should continue after the fever is gone, it is to be treated according to symptoms.

A gonorrhœa may be considerably affected by the patient's manner of living, and by other diseases attacking the constitution. Most things which hurry or increase the circulation, aggravate the symptoms; such as violent exercise, drinking strong liquors, eating strong indigestible food, some kinds of which act specifically on the urethra, so as to increase the symptoms more than simply heating the body would do; such as pepper, spices, and spirits.

In cases which have begun mildly, in which the inflammation is only slight, or in others in which the violent symptoms have subsided, such medicines as have a tendency to lessen the discharge may be given, together with the local remedies before mentioned. Turpentine is the most efficacious, particularly the balsam of copaiva, and cubeb. (See *Edin. Med. and Surgical Journ.* for January 1818, and for the same month, 1819; also *H. Jeffrey's Pract. Obs. on Cubeb*; 8vo. Lond. 1821.) Of the latter medicine ʒij may be given thrice in the 24 hours; but with respect to these and all other remedies, which act upon the disease through the medium of the urine, if they succeed at all, it is always within a week, or ten days, from the beginning of their use; and therefore, if no amendment takes place in this time, they should not be continued. Cantharides, the salts of lead and copper, and alum, have also been recommended.

Mr. Hunter advises small doses of mercury, in consequence of the possibility of absorption, and with a view of preventing lues venerea.

TREATMENT OF OCCASIONAL SYMPTOMS OF GONORRHOEA.

Bleeding from the Urethra is sometimes relieved by the balsam capivi. Mr. Hunter did not find astringent injections of use.

Painful erections are greatly prevented by taking twenty drops of tinctura opii at bedtime. Cicuta has also some power in this way; and many surgeons, among whom is Mr. Dunn, of Scarborough, have a favourable opinion of camphorated poultices, and of the internal exhibition of camphor; a medicine, which I ought to have mentioned in former editions, as a common means of lessening the pain and inconvenience of

erections in the inflammatory stage of gonorrhœa.

Chordee. See this word.

Bladder affected. Opiate clysters, the warm bath, and bleeding, if the patient is of full habit, are proper. Leeches may be applied to the perinæum. When this affection lasts a considerable time, and is not mitigated by common methods, Mr. Hunter advises trying an opiate plaster on the pubes, or the loins, where the nerves of the bladder originate; or a small blister on the perinæum. In another place he mentions bark, cicuta, sea air, and sea bathing, among the proper means.

Swelled Testicles. See *Hernia Humoralis*.

For a more full account of Gonorrhœa, according to the above doctrines, see a *Treatise on the Venereal Disease*, by John Hunter, from page 29 to 90.

ON THE QUESTION, WHETHER GONORRHOEA IS REALLY A FORM OF THE VENEREAL DISEASE.

The foregoing remarks, and others in Mr. Hunter's work, would lead one to believe that the poison of gonorrhœa and the venereal virus are the same. Here it is my duty impartially to state the arguments, which have been urged for, and against, this important doctrine.

Mr. Hunter assures us, that he has seen all the symptoms of lues venerea originating from gonorrhœa only; that he had even produced venereal chancres by inoculating with the matter of gonorrhœa; and that he afterward repeated these experiments in a manner in which he could not be deceived. (*P.* 293, *et seq.*)

Mr. Hunter's experiments, it is true, have been repeated with a different result; but, as a late writer has remarked, can we wonder at this, when we consider from how many causes gonorrhœa may arise, and how impossible it is to distinguish the venereal from any other? (*Obs. on Morbid Poisons*, by J. Adams, M. D. p. 91, Ed. 2.)

Another argument, adduced by Hunter, in favour of the poisons of gonorrhœa and chancre being the same, is the probability, that the Otaheiteans had the venereal disease propagated to them by European sailors, who were affected with gonorrhœa; for these can hardly be supposed to have had a chancre during a voyage of five months, without the penis being destroyed.

It is impossible, however, to say what time may elapse, between the application of the venereal poison to the penis, and the commencement of the ulceration. Therefore, Bougainville's sailors, alluded to by Mr. Hunter, might have contracted the infection at Rio-de-la-Plata; but actual ulcers on the penis might not have formed till about five months afterward, when the ship arrived at Otaheite.

In attempting to explain, why a gonorrhœa, and a chancre do not equally produce lues venerea, and why the medicine which almost universally cures chancre, has less

effect on gonorrhœa, a modern advocate for Mr. Hunter's doctrine says, that we must take into consideration, that the seat of the two diseases is different; that the same cause may produce different effects upon different parts; that the same poison, when mixed with different fluids, may be more or less violent in its operation; and that there may be greater or less attraction of certain fluids to a part, according to its nature and composition. (*Inquiry into some effects of the Venereal Poison by S. Sawrey, 1802, p. 4.*) Mr. Sawrey very truly remarks, p. 6, that if the gonorrhœal matter has clearly and decidedly produced chancre, or contaminated the system in any one instance, the question is determined. It could in no instance produce these effects, unless it had the power of doing so. This writer brings forward some cases to prove, that the poison of gonorrhœa may produce gonorrhœa, or chancre; but the limits of this work only afford room to observe, that these instances are by no means decisive of the point, because some objections may be urged against them, as indeed, Mr. Sawrey himself allows. That Mr. Hunter's cases are inconclusive, I have particularly endeavoured to explain in the *First Lines of the Practice of Surgery, Vol. 1, Ed. 4*, to which I must refer my readers.

Why does not gonorrhœa commonly produce ulceration in the urethra? Mr. Sawrey tries to solve this question, by saying, that the product of the venereal inflammation, the diseased contents of the small arteries of the urethra, are thrown out of these open-mouthed vessels into this canal, without any breach of their texture, which otherwise would be a necessary consequence.

Why does not gonorrhœa equally contaminate the system as chancre? In gonorrhœa, says Mr. Sawrey, the discharge is very plentiful; it is not, in general, attended with ulceration; the poison is much more diluted, and mixed with a mucous and puriform fluid. It is deposited in the urethra, and its lacunæ, where little or no pressure is applied, and it finds easy egress out of the canal. In chancre there is breach of substance, the poison is not much diluted, &c.

Why does not chancre generally, in the same person, produce gonorrhœa, and gonorrhœa produce chancre? Mr. Sawrey, in answer, expresses his belief, that these incidents are not very unfrequent. He says, he has known persons having a chancre, which continued for months, become affected, after that time, with a clap, without any further exposure. His opinion is, that the matter of the chancre had insinuated itself into the urethra, and produced the disease; though, he confesses, many would explain the circumstance, by supposing that the chancre and gonorrhœa were both communicated at the same time by two different poisons.

Mr. Hunter remarks, that the presence of one disease renders the adjacent parts less susceptible of its influence.

Mr. Sawrey concludes his second chapter with inclining to the idea, that the matter of gonorrhœa is not strictly pus, but of a

more mucous nature than that of a chancre. However, when he mentions chymical attractions, as drawing the poison from mucus to the urethra, and from pus to the dry parts, in order to explain the last of the above questions, every sober reader must feel sorry, that a work, which contains some really sensible observations, should comprehend this most unfortunate one.

Mr. Whately has also written, in support of the opinion, that the matter of gonorrhœa and that of chancre are the same. (*See Whately on Gonorrhœa Virulenta.*)

Another defender of this side of the question is Dr. Swediaur, who endeavours to prove the fallacy of the following positions:—1. *That the poison which produces the clap, does never, like that of chancres, produce any venereal symptoms in the mass or lues itself.* 2. *That the poison of the clap never produces chancres, and that the poison of chancres never produces a clap.* 3. *That mercury never contributes to, nor accelerates the cure of a clap; but that, on the contrary, every blennorrhagia may be certainly cured without mercury, and without any danger of leaving a lues behind.*

His arguments run thus:—the reason why claps do not, like chancres, constantly produce the lues, is, that most of them excite only a superficial inflammation in the membrane of the urethra, without any ulceration. Hence, absorption cannot easily take place, the poison being out of the course of the circulation. But he has seen claps with an ulcer in the urethra, followed by the most unequivocal symptoms of lues itself. He mentions the urethra being defended with a large quantity of mucus, as the thing impeding the common formation of ulcers, which do occasionally occur when the mucus is not secreted as usual, or is washed away. He asserts, that in many cases, where he had occasion to examine both parties, he was convinced that the chancres were communicated by a person affected with a simple gonorrhœa; and, *vice versa*, that a virulent clap had been the consequence of an infection from a person having merely chancres. He says, that if a patient, with a venereal running, does not take care to keep the prepuce and glans perfectly clean, chancres will very often be produced. He owns a great many claps are cured without mercury; yet, repeated experience has shown him, a cure cannot always be thus accomplished. Mild cases, without ulcer or excoriation in the urethra, may certainly be radically cured without a grain of mercury; and though mercury should be given, it would not have the least effect: not because the disease does not proceed from the venereal poison, but because out of the course of the circulation. He contends, that the topical use of mercury in injections, acts usefully even in these cases. But, when a clap is joined with ulceration in the urethra, it is always cured more safely and expeditiously with mercury, and is frequently incurable without it. A lues also follows cases attended with ulcers in the urethra

He allows that all claps are not venereal. (See *Pract. Obs. on Venereal Complaints*, by J. Swediaur.)

One argument urged against the identity of gonorrhœal and chancreous virus, is, that gonorrhœa was not described as a symptom, till nearly half a century after the other symptoms of the venereal disease were known. Fallopius is among the first who observed gonorrhœa, as a symptom of the venereal disease. "If, however," says Dr. Adams, "venereal gonorrhœa was unnoticed till about fifty years after the other forms of the disease were described, what does this prove, but that contagious gonorrhœa was so common, as to be disregarded as a symptom of the new complaint? Can there be a doubt, from the caution given by Moses, that gonorrhœa was considered as contagious in his days? During the classical age, we find inconveniences of the urinary passages were imputed to incontinence; and the police of several states, before the siege of Naples, made laws for preserving the health of such as would content themselves with public stews, instead of disturbing the piece of families.

This is enough to lessen our surprise, that gonorrhœa should be unnoticed for some time after the appearance of the venereal disease. But, so far is it from proving that the two contagions are different, that the fairest inference we can draw is in favour of their identity. For, if by this time the venereal disease began to be so far understood, that secondary symptoms were found the consequence of primary ones in the genitals, it is most probable that the first suspicion of venereal gonorrhœa arose from the occurrence of such secondary appearances, where no other primary symptoms could be traced." (*Adams on Morbid Poisons*, p. 95, Ed. 2.)

In relating the arguments maintained by the best modern writers, to repel the attacks made on the doctrine, that gonorrhœa and chancre arise from the same poison, we have been compelled to disclose the chief grounds on which the assailants venture to entertain a contrary theory.

The sentiments of Mr. B. Bell are quite at variance with those of Hunter, Sawrey, Swediaur, Adams, &c.; but my limits will only allow me just to enumerate a few of his leading arguments.

If the matter of gonorrhœa, and that of chancre, were of the same nature, we must admit, that a person with a chancre only, can communicate to another, not only every symptom of pox, but of gonorrhœa; and that another with gonorrhœa only, can give to all with whom he may have connexion, chancres, with their various consequences. This ought indeed to be a very frequent occurrence; whereas, all allow that it is even in appearance very rare.

On the supposition of the matter of gonorrhœa and lues venerea being the same, the latter ought to be a much more frequent occurrence than the former, from the greater ease with which the matter of infection

must, in every instance, be applied to those parts on which it can produce chancres, than that of the urethra, where instead of chancre or ulceration, it almost always excites gonorrhœa. It is difficult to conceive how the matter by which the disease is communicated, should find access to the urethra; while all the external parts of the penis, particularly the glans, must be easily and universally exposed to it; and yet gonorrhœa is a much more frequent disease than pox. Cases of gonorrhœa are in proportion to those of chancre, according to Mr. B. Bell's experience, as three to one. It is obvious that the very reverse should happen, if the two diseases were produced by the same kind of matter.

I need not adduce other arguments, as the reader must be already acquainted with any worth knowing, from what is said in the previous part of this article.

The grand practical consideration, depending on the possibility of the venereal disease arising from gonorrhœa, is whether mercurials should not be exhibited, in all cases, with a view of preventing such a consequence.

Waiving on my own part, all attempts to decide the point, whether the matter of a chancre, and that of one species of gonorrhœa, are of the same nature, I shall merely content myself with stating, that as far as my observation and inquiries extend, the majority of the best practitioners of the present day consider the exhibition of mercury unnecessary, and consequently improper in all cases of gonorrhœa. This fact almost amounts to a proof, that if venereal symptoms do ever follow a clap, they are so rare, and, I may add, always so imputable to other causes, that the employment of mercury, as a preventive, would, upon the whole, do more injury than benefit to mankind; and this even admitting (what, in my mind, has never been unequivocally proved) that the matter of gonorrhœa is really capable, in a very few instances, of giving rise to the venereal disease.

The reader must weigh the different arguments himself. Some of Mr. B. Bell's reasoning is certainly untenable, as Mr. Sawrey has clearly shown; but the latter, also, is not invulnerable in many points, which he strives to defend.

GORGET. An instrument, used in the operation of lithotomy, for the purpose of cutting the prostate gland and neck of the bladder, so as to enable the operator to introduce the forceps and extract the stone. It is, in fact, a sort of knife, at the end of which is a beak, that fits the groove of the staff, and admits of being pushed along it into the bladder.

Besides cutting gorgets, constructed for the preceding design, there are also blunt ones, intended to be introduced into the wound, when their concavity serves as a guide for the forceps into the bladder.

GRANULATIONS. The little, grain-like, fleshy-bodies, which form on the surfaces of ulcers, and suppurating wounds, and serve both for filling up the cavities, and bringing nearer together and uniting their sides.

We must here consider the operations of nature, in bringing parts as nearly as possible to their original state, whose disposition, action, and structure, have been altered by accident, or disease. Having formed pus, she immediately sets about forming new matter, upon surfaces in which there has been a breach of continuity. This process is called *granulating*, or *incarnation*; and the substance formed is called *granulations*.

Granulations are an accretion of animal matter upon the wounded or exposed surface; they are formed by an exudation of the coagulating lymph from the vessels; into which new substance, both the old vessels very probably extend, and in which new ones are formed. Hence, granulations are extremely vascular; indeed, more so than almost any other animal substance. "That this is the case (says Mr. Hunter) is seen in sores every day. I have often been able to trace the growth and vascularity of this new substance. I have seen upon a sore a white substance exactly similar, in every visible respect, to coagulating lymph. I have not attempted to wipe it off, and the next day of

dressings I have found this very substance vascular; for, by wiping, or touching it with a probe, it has bled freely. I have observed that the same appearance on the surface of a bone that has been laid bare. I once scraped off some of the external surface of a bone of the foot to see if the surface would granulate. I remarked the following day, that the surface of the bone was covered with a whitish substance, having a tinge of blue. When I passed my probe into it, I did not feel the bone bare, but only its resistance. I conceived this substance to be coagulable lymph thrown out from inflammation, and that it would be forced off when suppuration came on; but, on the succeeding day, I found it vascular, and appearing like healthy granulations." The vessels in granulations pass from the original parts to their basis, and thence towards their external surface, in tolerably regular parallel lines. The surface of this new substance has the same disposition to secrete pus, as the parts which produced it. The surfaces of granulations are very convex, the reverse of ulceration, having a great many small points, or eminences, so as to appear rough. The smaller such points are, the more healthy are the granulations. The colour of healthy granulations is a deep florid red. When livid, they are unhealthy, and have only a languid circulation. Healthy granulations, on an exposed or flat surface, rise nearly even with the surface of the surrounding skin, and often a little higher; but when they exceed this, and take on a growing disposition, they are unhealthy, become soft, spongy, and without any disposition to form skin. Healthy granulations are always prone to unite to each other, so as to be the means of uniting parts.

Granulations are not easily formed on the side of an abscess, nearest the surface of the body.

They are not endowed with the same powers as parts originally formed. Hence, they more readily ulcerate and mortify. The curious mode in which granulations contract, when sores are healing, and even for some time after they are healed, we have explained in the article *Cicatrization*. See *A Treatise on the Blood, Inflammation, &c.* by John Hunter, p. 473, et seq. 1794.)

It is a question, whether granulations can ever be formed without suppuration? Mr. Hunter seems inclined to think that they may occasionally be produced without it, and he supports his opinion by the relation of the dissection of a fractured limb, in which he observed a substance resembling granulations. Dr. John Thomson, on the other hand, declares, that he has never seen any thing which he could regard as an example of a granulation, and still less of a granulating surface, where pus was not formed. (See *Lectures on Inflammation*, p. 408.)

The exact process, by which the blood-vessels, nerves, and absorbents of granulations are formed, is still among the secrets of nature. The observations of Mr. Hunter on the subject amount only to conjecture. "The growth of nerves, and their develop-

ment in new formed flesh, or granulations (says Dr. J. Thomson,) is a subject of equal curiosity with the growth of blood-vessels in the same structure. Their existence in granulations is proved by the pain, which is felt on our pinching, rubbing, or wiping the surface of a sore. Even the granulations which arise from the surface of bone, are sensible, though we are not very able to prove the sensibility of the larger branches of nerves, from which the newly formed, and sensible nerves and filaments in the granulation, are immediately derived. All the difficulties which I formerly mentioned to you, as occurring in the explanation, of the manner in which coagulable lymph, or granulations, are penetrated with blood-vessels, present themselves the moment we begin to reflect on the manner in which the same granulations are provided with nerves, and these difficulties are still increased, when we reflect that the same granulations are in the course of a few hours provided, not only with blood-vessels and nerves, but also with a system of absorbents. The existence of absorbents in granulations is proved, not only by the changes of bulk, which we see them daily undergo, becoming gradually, in the healthy state, smaller, firmer, and more compact, but also, by the frequent disappearance, in whole, or in part, of a granulating surface by the process of ulcerative absorption." (See *Thomson's Lectures on Inflammation*, p. 419.) Every young dresser of sores at an hospital, who has been too lavish of the red precipitate ointment, must have learned from experience, that mercury may be absorbed from the surface of ulcers, and bring on an unwished for salivation of the patient.

GUAIAECUM. Many writers of the sixteenth century, contended, that guaiacum was a true specific for the venereal disease; and the celebrated Boerhaave, in the eighteenth, maintained the same opinion. Mr. Pearson mentions, that when he was first entrusted with the care of the Lock Hospital, in 1781, Mr. Bromfield and Mr. Williams were in the habit of reposing great confidence in the efficacy of a decoction of guaiacum wood. This was administered to such patients as had already employed the usual quantity of mercury; but who complained of nocturnal pains, or had gummata, nodes, ozæna, and such other effects of the venereal virus, connected with secondary symptoms, as did not yield to a course of mercurial frictions. The diet consisted of raisins, and hard biscuit; from two to four pints of the decoction were taken every day; the hot bath was used twice a week; and a dose of antimonial wine and laudanum or Dover's powder, was commonly taken every evening. Constant confinement to bed was not deemed necessary; neither was exposure to the vapour of burning spirit, with a view of exciting perspiration, often practised; as only a moist state of the skin was desired. This treatment was sometimes of singular advantage to those whose health had sustained injury from the disease, long confinement, and mercury. The strength increased;

bad ulcers healed; exfoliations were completed; and these anomalous symptoms, which would have been exasperated by mercury, soon yielded to guaiacum.

Besides such cases, in which the good effects of guaiacum caused it to be erroneously regarded as a specific for the lues venerea, the medicine was also formerly given by some, on the first attack of the venereal disease. The disorder being thus benefited, a radical cure was considered to be accomplished; and, though frequent relapses followed, yet, as these partly yielded to the same remedy, its reputation was still kept up. Many diseases, also, which got well, were probably not really venereal cases. Mr. Pearson seems to allow, that in syphilitic affections, it may, indeed, operate like a true antidote, suspending for a time, the progress of certain venereal symptoms, and removing other appearances altogether; but, he observes, that experience has evinced, that the unsubdued virus yet remains active in the constitution.

Mr. Pearson has found guaiacum of little use in pains of the bones, except when it proved sudorific; but that it was then inferior to antimony, or ammonia. When the constitution has been impaired by mercury, and long confinement, a thickened state of the ligaments, or periosteum, or foul ulcers, still remaining, Mr. Pearson says, these effects will often subside, during the exhibition of the decoction. He says, it will often suspend, for a short time, the progress of certain secondary symptoms of the lues venerea; for instance, ulcers of the tonsils, venereal eruptions, and even nodes. Mr. Pearson, however, never knew one instance in which guaiacum eradicated the virus; and he contends, that, its being conjoined with mercury, neither increases the virtue of this mineral, lessens its bad effects, nor diminishes the necessity of giving a certain quantity of it. Mr. Pearson remarks, that he has seen guaiacum produce good effects in many patients having cutaneous diseases, the ozæna, and scrofulous affections of the membranes and ligaments. (See *Pearson on the Effects of Various Articles in the Cure of Lues Venerea*, edit 2. 1807.)

GUMMA, a soft tumour, so named from the resemblance of its contents to gum.

GUNSHOT WOUNDS receive their name from the manner in which they are produced, being generally caused by hard, obtuse, metallic bodies, projected from cannons, muskets, or some other species of fire-arm. With such injuries, it is also usual to comprehend a variety of dreadful accidents arising from the explosion of shells, or the violence with which pieces of stones from ramparts, or splinters of wood on board of ship, are driven about. Gunshot wounds are the most considerable of the contused kind; and what is to be said of them, will apply more or less, to all contused wounds, according to the degree of confusion. They are particularly characterized by, what the French surgeons are fond of calling, a *disorganization* of their surface. The excessive confusion, and

violence, observable in gunshot wounds, depend upon the rapidity, with which the bodies occasioning them, are propelled. The parts touched by the ball, are frequently converted into a blackish slough, the colour of which made our ancestors suppose, that bodies, projected by gunpowder, became heated, and actually burnt the flesh, with which they came into contact. But reason and experience have now proved, that whatever may be the rapidity of a projectile, it never acquires in its passage any perceptible heat. Indeed, a modern writer asserts, that such a degree of heat as would be requisite to make a ball burn parts in its passage, would really melt it. (*Richerand, Nosographie Chir. T. 1, p. 217, edit. 2.*) In general, gunshot wounds do not bleed much, unless large blood-vessels be injured; their circumference is often livid; and the shock that attends their infliction, or the injury done to the nerves, may occasion in the limb, or part, a kind of torpor, sometimes extending itself to the whole system.

However, as Dr. Hennen most truly observes, "the effects of a gunshot wound differ so materially in different men, and the appearances are so various, according to the nature of the part wounded, and the greater or lesser force with which it has been struck, that no invariable train of symptoms can be laid down as its necessary concomitants. If a musket or pistol ball has struck a fleshy part, without injuring any material blood-vessel, we see a hole about the size of or smaller than the bullet itself, with a more or less discoloured lip, forced inwards; and if it has passed through the parts, we find an everted edge, and a more ragged and larger orifice at the point of its exit. The hemorrhage is in this case very slight, and the pain inconsiderable, inasmuch that, in many instances, the wounded man is not aware of his having received any injury. If, however, the ball has torn a large vessel, or nerve, the hemorrhage will generally be profuse, or the pain of the wound severe, and the power of the part lost. Some men will have a limb carried off, or shattered to pieces by a cannon ball, without exhibiting the slightest symptoms of mental or corporeal agitation; nay, even without being conscious of the occurrence; and when they are, they will coolly argue on the probable result of the injury; while a deadly paleness, instant vomiting, profuse perspiration, and universal tremor, will seize another on the receipt of a slight flesh wound. This tremor, which has been so much talked of, and which, to an inexperienced eye, is really terrifying, is soon relieved by a mouthful of wine, or spirits, or by an opiate; but, above all, by the tenderness and sympathizing manner of the surgeon, and his assurance of the patient's safety." (*Principles of Mil. Surgery, p. 33, Ed. 2.*)

On the other hand, it is correctly noticed by Mr. Guthrie, that the continuance of the constitutional alarm, or shock, ought to excite great suspicion of serious injury; and, when wounds have been received in

such situations, or bear such appearances as render it doubtful whether any parts of vital importance have been injured or not, the manner in which the constitutional perturbation lasts may be assumed as evidence of the fact, when other symptoms, more indicative of the injury, are wanting; and, under all such circumstances, a very cautious prognosis should be delivered. (*On Gunshot Wounds, p. 11, Ed. 2.*)

Respecting the general character of gunshot wounds not to bleed much, unless large vessels be injured, it is a fact which necessarily depends upon the degree of contusion usually attending these injuries. But it is also true, as the preceding author has stated, that, although some gunshot wounds bleed but little at first, there is in the greater number of cases more or less of blood; and in wounds of vascular parts, like the face and neck, the quantity lost is often considerable, though the main arterial branches may not be injured. (*Op. cit. p. 5. Ed. 2.*)

In gunshot wounds, another circumstance is observed, which is often remarked in other cases, viz. when a large artery is partially divided, the bleeding is more profuse and dangerous than when the vessel is completely severed, and the hemorrhage, if not repressed by a tourniquet or other means, will often continue until the patient dies. Thus, Mr. Guthrie speaks of three cases, in which life was lost from wounds of the femoral, humeral, and carotid arteries, no effectual means of stopping the hemorrhage having been adopted. (*P. 8.*)

Until Ambroise Paré introduced more correct theories upon the subject of gunshot wounds, ideas the most false, and errors highly prejudicial, prevailed, both in their history and treatment, and particularly respecting what have been falsely named wind contusions. Cannon balls and bullets sometimes produce dreadful degrees of injury, without occasioning any breach of continuity in the integuments. This observation is so strictly true, that the muscles and bones may actually be crushed and broken to atoms, without the skin being at all wounded. Such cases were for a long while imputed to the violent motion, supposed to be communicated to the air by the ball itself. It was imagined, that this elastic fluid, being rapidly displaced by the shock of the projectile, was capable of making such pressure on surrounding bodies as to destroy their texture. But how could this violent pressure originate in the midst of the open and unbounded air? If this theory were true, the effect in question would constantly happen whenever a ball passes near any part of the body. The contrary, however, is so much the case, that pieces of soldiers' and seamen's hats, of their feathers, clothes, and even hair, are shot away in every battle, without any other mischief being done.

In consequence of the manner in which such injuries of the soft parts, and even of the bones, unattended with any breach in the skin, have been supposed to be produ-

ced, they have been erroneously termed *wind-contusions*. In fact, these cases are now universally acknowledged by all the most accurate observers, never to proceed from the cause to which formerly they were always ascribed.

The air does not move with the same rapidity as the ball, but its motion is less in proportion as it is a more subtle matter, and must be too feeble to account for such a violent degree of injury. The air, to which the ball must really communicate the greatest motion, is what is directly before it, and this never bruises the part untouched by the ball itself. It is only the air, situated laterally to the shot, that is imagined to do injury, and it cannot be greatly agitated. The violent consequences of sudden explosions, and the effects produced on the organ of hearing, by strong commotions of the air, prove nothing relative to the point in question. Lastly, experience does not confirm the reality of such wind-contusions; for cannon balls often tear off whole members, without the adjacent parts being in the least injured. (See *Le Vacher, in Memoires de l'Acad. de Chir. T. 4, p. 22*)

An eminent professor, who visited the continent for the purpose of seeing the wounded after the battle of Waterloo, fully coincides with M. Le Vacher and all the moderns upon this subject. "We saw, and were informed of many instances, in which cannon-balls had passed quite close to all the parts of the body, and had removed portions of the clothes and accoutrements, without producing the slightest injury of any kind. In other instances, portions of the body itself were removed by cannon-balls, without the contiguous parts having been much injured. In one case, the point of the nose was carried off by a cannon-ball, without respiration being at all affected; and in another very remarkable case, the external part of the ear was shot away, without even the power of hearing being sensibly impaired. (See *Report of Observations made in the British Military Hospitals in Belgium, &c. by John Thomson, p. 33, Edinb. 1816.*)

I could cite many cases, which I have seen myself, in proof of the truth of Le Vacher's opinions; but the point is now so universally admitted, that I shall merely add one observation that occurred to the notice of many as well as myself. At the bombardment of the French fleet in the basin of Antwerp, early in 1814, a cannon shot shattered the legs of two officers so badly, that the limbs were amputated. These gentlemen were walking at the moment of the accident in the village of Merksam, taking hold of the arm of my friend, assistant surgeon Stobo, of the 37th regiment, who was in the middle. Now the ball, which produced the injury, did not the slightest harm to the latter gentleman, although it must have passed as close as possible to his lower extremities, and most probably between them.

Neither can what have been improperly called *wind-contusions*, be attributed to an

electrical shock on the parts, in consequence of the ball being rendered electrical by friction in the calibre of the gun, and giving off the electricity as it passes by: (*Vide Plenck's Sammlungen, 1 Theil. p. 99.*) for metals never acquire this property from friction.

The mischief imputed to the air is occasioned by the ball itself. Its producing a violent contusion, without tearing the skin, and entering the limb, is to be ascribed to the oblique direction in which it strikes the part, or, in other instances, to the feebleness with which the ball strikes the surface of the body, in consequence of its having lost the greater part of its momentum, and acting principally by its weight; being, in short, what is called a spent ball. Daily observation evinces, that balls, which strike a surface obliquely, do not penetrate, but are reflected; though they may be impelled with the greatest force, and the body struck may be as soft and yielding as water. This alteration in the course of the ball not only happens on the surface of the human body, but also in the substance of a limb which it has entered. Thus, a bone, a tendon, &c. may change the direction of a ball which touches them at all obliquely. Hence, it is manifest how it happens, that the track of a gunshot wound is not always straight, and how balls sometimes run under the integuments nearly all round the body or limb.

The causes of several of the peculiarities attending gunshot wounds, are to be sought among the laws by which moving bodies are governed, and by which the mechanical effect of a ball, propelled against any part of the body, must therefore be determined. The form, the momentum, and the direction of the shot that is received; the position, and the variety of structure, or, in other words, the variety of density and powers of resistance, in the part receiving it, must always be considered, in order to account satisfactorily for the effects which it produces. And though, says Mr. Chevalier, in many cases, a mathematical explication of the course of a ball cannot be given, this arises entirely from the want of data, the laws of matter being fixed and immutable. But, when the data are known, as, for instance, the velocity and direction of the shot, the position of the patient, or of the wounded part at the time of the accident, and the structure of the parts penetrated, a much more probable conjecture of the course of the ball may generally be formed, than if these circumstances had not been regarded.

On the principle of the density and resistance of parts, attempts have been made to explain the reason of the concussion, or shock, which is given, in many instances to the whole system, by gunshot wounds, and which is represented by writers on this subject to be often attended with grave and even alarming effects, extending not only over the injured part, but affecting the system at large. Thus, a shot striking against a tendon, or a bone, in one of the extremities, will produce a greater concussion than

if it struck only against softer parts. A shot, striking a muscle in action, will produce more concussion than if it struck against the same part of the same muscle at rest; and a shot, striking the head, or wounding the liver, lungs, or intestinal canal, will generally bring on instantaneous derangement of the whole system, with which the functions of these parts are so closely connected. (See a *Treatise on Gunshot Wounds*, by T. Chevalier, Part 1, sect. 7.)

Respecting the mechanical effects of the concussion, I am disposed to think with Mr. Guthrie, that they have been rather exaggerated, and that in reality a more accurate explanation of the disorder of the system might be derived from other considerations; "a shot through the lungs (says he) will cause an instantaneous derangement of the whole system, but the resistance afforded by the part, has little to do with it: it is the lesion of the organic functions, intimately connected with life, that is the cause of the derangement. In the same manner, I do not conceive, that the general affection of the system depends alone on the shock received, but on the effect the injury committed has on the nervous system." (*On Gunshot Wounds*, p. 26, Ed. 2.)

A ball, when it strikes a part of the body, may cause four kinds of injury. 1. It may only occasion a contusion, without penetrating the part, on account of its being too much spent, or of the oblique way in which it strikes the surface of the body. 2. It may enter and lodge in the substance of a part; in which case the wound has only one aperture. 3. It may pierce through and through; and then there are two openings, one at the entrance, the other at the exit of the ball. The circumference of the aperture, where the shot entered, is usually depressed; that of the opening, from which it came out, elevated. At the entrance, there is commonly more contusion, than at the exit of the ball. The former opening is generally narrower; the latter wider, and more irregular, especially when the round smooth figure of the ball has been changed by its having struck a bone. 4. A cannon-ball may tear off a whole limb. (*Richter, Anfangsg. der Wundarzn. B. 1.*)

Gunshot wounds differ very much, according to the kind of body projected, its velocity, and the nature and peculiarities of the parts injured. The projected bodies are mostly bullets, sometimes cannon-balls, sometimes pieces of broken shells, and very often, on board of ship, splinters of wood. On account of the contusion, which the parts suffer, from the violent passage of the ball through them, there is most commonly a part of the solids surrounding the wound deadened, which is afterward thrown off in the form of a slough, and which prevents such wounds from healing by the first intention, and makes most of them necessarily suppurate. This does not take place equally in every gunshot wound, nor in every part of the same wound; and the difference commonly arises from the variety in the velocity of the body project-

ed; for, where the ball has passed with little velocity, which is sometimes the case at their entrance, but still more frequent at the part last wounded, the injury may often be healed by the first intention. (*J. Hunter, p. 523.*)

Until I had the pleasure of reading the last edition of a valuable book on gunshot wounds, I did not know, that at the present day, any surgeons entertained the idea, that the whole track of every gunshot wound must unavoidably suppurate, and slough; (*Guthrie on Gunshot Wounds, p. 62, Ed. 2.*) but if this sentiment prevail, it is plain from the preceding statement, that the authority of Mr. Hunter cannot be adduced in its support. At the same time, I believe, that few army surgeons will be inclined to question the correctness of Mr. Hunter's account of the general occurrence of a degree of sloughing, or of the deadened state of a part of the surface of a wound, particularly in the vicinity of the entrance of the ball, or the truth of his observations about the common necessity of the separation of such slough before the parts will heal; and whether the dead part be thrown off in small fragments with the matter, or larger portions, the fact is still correct.

Foreign bodies more frequently lodge in gunshot wounds than any others, and are commonly of three kinds. 1. Pieces of clothing, or other things, which the ball forced before it into the limb. 2. The ball itself. 3. Loose splinters of bone. It is only when the ball strikes the naked flesh, touches no bone, and goes quite through the part, that the wound can be free from extraneous matter. Foreign bodies are the cause of numerous unfavourable symptoms, by irritating sensible parts, and exciting pain, inflammation, convulsions, hemorrhage, long suppurations, &c.; and the more uneven, pointed, and hard they are, the more likely they are to produce these evils. Hence spiculæ of bone are always the most to be dreaded. (*Richter.*)

The great obliquity and length of the fissures produced in the cylindrical bones by musket-balls, are such as are not remarked in any common cases of fracture. When I was with the army in Holland, in the year 1814, I had in my hospital at Oudenbosch, several fatal compound fractures of the thigh, caused by gunshot violence. The fissures in some of these examples were found to extend two-thirds of the length of the bone. This fact is noticed by Mr. Guthrie: "the fractures extend far above and below the immediate part struck by the ball, and as far as depends upon my information from the examination of limbs that were amputated further downwards than upwards; so that from a fracture in the middle of the thigh, I have often seen fissures extend into the condyles, and cause ulceration of the cartilages of the knee joint," &c. (*On Gunshot Wounds, p. 190.*)

When a ball strikes a bone, the concussion produced is another occasion of bad symptoms, to be added to those already

mentioned. When slight, its effects are confined to the injured limb; but sometimes they extend to the neighbouring joints, in which they produce inflammation and abscesses.

It is commonly stated in surgical books, that when a cannon-ball tears off a limb, it produces a violent concussion of the whole body, and a general derangement of all its functions. This, however, is by no means always true. I saw some years ago, in London, a young sailor, whose arm had been completely torn off at the shoulder, by a cannon-ball from one of the forts at Gaudaloupe, in March 1808; he suffered no dreadful concussion of his body, nor were his senses at all impaired. This case was very remarkable, as the scapula was so shattered, that Mr. Cummings, of Antigua, was under the necessity of removing the whole of it. The patient recovered in two months. From the account, which I heard, I do not believe, that the axillary artery bled immediately after the accident. The young man was shown to the gentlemen of St. Bartholomew's Hospital, quite well.

There is one curious effect, which occasionally follows gunshot wounds; but I do not pretend to understand the rationale of it: viz inflammation and suppuration of some internal viscus, especially of the liver. Several such cases are related in the *Mem. de l'Acad. de Chirurgie*, and according to Mr. Guthrie, many patients in the peninsula, who had undergone secondary amputations for gunshot injuries, were destroyed by affections of their lungs, liver, &c. (*On Gunshot Wounds of the Extremities*, p. 74, et seq.)

From the circumstance of the inner surface of gunshot wounds being often more or less deadened, they are late in inflaming. But when a ball has fractured a bone, which fracture has occasioned great injury of the soft parts, independently of that caused immediately by the ball itself, the inflammation will come on as quickly, as in cases of compound fracture; because the deadened part bears no proportion to the laceration or wound in general. (*J. Hunter*, p. 524.)

From the same circumstance of a part being often deadened, gunshot wounds frequently cannot be completely understood in the first instance, for in many cases, it is at first impossible to know what parts are killed, whether bone, tendon, or soft part. Nor can this be ascertained till the slough separates, which often makes the wound much more complicated than was previously imagined. For, very often, some viscus, or a part of some viscus, or a part of some large artery, or even a bone, has been killed by the violence. If a piece of intestine has been killed, the contents of the bowel will begin to come through the wound when the slough separates. If a portion of a large blood-vessel be killed, a profuse, and even fatal hemorrhage may come on, when the slough is detached, although no material quantity of blood may have been previously lost. (See *Hunter*, p. 525.) Thus, several days after the receipt of the wound, and

when all danger from inflammation is over, a bleeding per anum, occasioned by the separation of a slough from some internal vessel, may destroy the patient, as happened in a very interesting case reported by Mr. Guthrie. (*P. 13, Ed. 2.*) A soldier of the 2d battalion of the 44th regiment was shot in the ham at the assault of Bergen-op-zoom in 1814. There was no hemorrhage for ten days; but at the end of this period, the popliteal artery gave way, and I was obliged to take up the femoral artery, by which means the bleeding was effectually stopped, and the man recovered. This fact, and another related by Baron Boyer, (*Annuaire Med. Chir. de Paris*, p. 364, 4to. Paris, 1819,) prove, that a ligature on the femoral artery may sufficiently check the current of blood through the popliteal artery to put a stop to hemorrhage from a wound in it; and though such practice in some other cases of wounded arteries is inefficient, on account of the facility with which the blood passes through the anastomoses into the part of those vessels below the ligature, (See *Arteries*.) its general success, in gunshot wounds of the ham, would be of infinite advantage, not only on account of the difficulties of taking up the popliteal artery itself, (difficulties ably depicted by Scarpa,) but because laying open the inflamed and diseased parts would frequently have a fatal termination. At the same time, I would have surgeons always recollect the important difference between an aneurismal and a wounded artery; for, as in the first case, there is no outlet for the blood, the transmission of this fluid into the part of the vessel below the ligature may keep up a pulsation in the tumour, and retard the cure of the disease, but is attended with no risk of hemorrhage: while the same free passage of the blood into the wounded portion of a large artery, would give rise to dangerous bleeding; and hence the general necessity of applying two ligatures, one immediately above, the other below, the aperture in such a vessel. A single ligature on the brachial artery fails, as I had an opportunity of seeing in Holland in a case of gunshot wound, where either that vessel, or the commencement of the radial, or ulnar, gave way, on the loosening of the sloughs, and as there was considerable swelling, oedema, and inflammation of the limb, threatening gangrene, the surgeon, under whose care the patient was, deemed it right to perform amputation.

I should be sorry, if these observations were to hold out any general encouragement of the wrong and dangerous practice of applying only one ligature above a wound in a large artery, or in any recent case of false diffused aneurism. The remarks, delivered above, were chiefly intended to refer to gunshot wounds of the ham, with injury of the popliteal artery, and hemorrhage first breaking out several days after the receipt of the wound, when all the parts behind the knee are enormously swelled, and in a state of inflammation and suppuration. Here the hope of avoiding any additional violence,

or injury of the diseased parts behind the knee, may be a good reason for taking the chance of stopping the bleeding by a ligature applied to the femoral artery; a reason, however, which would not exist in the case of a recent wound of the popliteal artery with a knife. At the same time, I believe, this means of checking the current of blood will not always suffice, and that occasionally either the dangerous expedient of cutting open the swelling in this diseased state of the ham, and of applying a ligature above and below the aperture in the popliteal artery must unavoidably be encountered, or amputation performed. Why the first plan has answered in some cases, and not in others, may depend upon the size and condition of the wound, or opening in the artery, and in examples of sloughing, upon the degree in which the tube of the vessel may have been closed by the adhesive inflammation. Some wrong conclusions may also have been made respecting the trunk of the vessel being wounded, or opened, while in fact only a branch of it was concerned. As a qualification, therefore, of any inferences, which might be drawn from the partial success of applying one ligature only in cases of large wounded arteries, I annex the following remarks, published some little time ago in an ably conducted periodical work. "It appears to us, that some of the cases, which M. Roux has given, as the most favourable for the operation of Hunter, are the least so; for example, he performs it in the cases where aneurism has formed in consequence of the wound of the artery. In support of this, he gives two cases, where, upon the authority of M. Mirault, of Angers, the ligature of the artery above the wound was sufficient. In one case, the humeral was the artery said to be wounded; in the other, the femoral. We doubt if the femoral were really wounded in this case; for, on referring to the report, we do not find sufficient evidence of that fact; it appears more probable, that a branch only was wounded. We have seen the operation of Hunter performed unsuccessfully in two cases of aneurism, consequent upon a wound of the artery; and we have seen the preparation of a third case, where the same operation was performed and failed; that is to say, the inoculations were so free, that hemorrhage returned by the lower orifice. In the first case, the popliteal artery was ruptured by a spicula of bone. The second was a wound of the femoral artery by an iron spike: and the third was a stab of the femoral artery by a knife. In each of these cases, the hemorrhage returned by the lower part of the artery. There is in the *Bulletins de la Faculté de Médecine*, for 1813, a case by the same Mirault, of an aneurism of the femoral artery, in consequence of a wound some considerable time before. Mirault operated according to the method of Hunter, that is, he tied the artery above the aneurism. The sac burst, two hemorrhages ensued, and the second carried off the patient on the fifteenth day after the operation.

(N.B. Here, however, it is proper to remark, that, if the case had been a true aneurism, and the sac had burst, while a stream of blood was yet passing through it, as always happens for some days after the ligature of the artery, above the tumour, hemorrhage would have occurred just as it did in the present case of false aneurism. The premature bursting of the tumour, in fact, converted the case directly into one, analogous to a wounded artery, the blood having a passage outwards.) It is rather curious that the first case, which occurred to M. Roux, after his return from England, should be one, which forms a strong argument against performing the operation of Hunter for a wounded artery. "The case, here alluded to, was that of a wound of the femoral artery with a knife, a little below the middle of the thigh, where M. Roux immediately cut down to the vessel some way above the injury, and there applied two ligatures, besides a reserve ligature. On the tenth day, hemorrhage came on, when the tightening of the latter ligature having no effect, M. Roux exposed the artery higher up, and applied fresh ligatures immediately below the profunda. This stopped the hemorrhage from the upper end of the vessel, but on the following morning fresh bleeding took place from the lower end of the artery, and it became necessary to lay open the artery below the wound, and also apply ligatures there. No further bleeding took place. (See *Quarterly Journ. of Foreign Medicine*, Vol. 1, p. 14, *Seco. Lond.* 1819.) The tenor of the preceding observations is unquestionably correct, inasmuch as wounded arteries and recent false diffused aneurisms are concerned; but with respect to cases of false circumscribed aneurisms, of some standing, without any external opening in the skin, they are examples, to which the same principles should not always be applied, which are so properly recommended to be observed with regard to the other instances. In these latter, the blood may either escape from the lower end of the vessel out of the external wound, or into the cellular membrane after the ligature is applied above the aperture in the artery; but, no sooner is a false aneurism encysted, than these dangers are prevented.

When the ball moves with little velocity, the mischief is generally less; the bones are not so likely to be fractured; the parts are less deadened, &c. However, when the velocity is just great enough to splinter a bone, which is touched, the splintering is generally more extensive, than if the impetus of the ball had been much greater, in which case, a piece is more likely to be taken out. When the ball moves slowly, it is more likely to be turned by any resistance it may encounter in its passage through parts, and hence the wound is more apt to take a winding course.

When a ball enters a part with great velocity, but is almost spent, before it comes out again, in consequence of the resistance it has met with, there may be a good deal of sloughing about the entrance, and little or

none about the exit, owing to the different degrees of celerity with which the ball traversed the parts. (See *Hunter*.)

Gunshot wounds may have either one, or two apertures, according as the ball has lodged, or passed quite through the part. In some cases, the openings are diametrically opposite each other; in others they are not so, the direction of the ball having been changed by the resistance, which it has met from a bone, cartilage, tendon, &c. Thus a ball has been known to enter just on the inside of the ankle, and come out near the knee, to enter the fore-head and come out at the temple, &c. (*Richerand, Nosographie Chir. T. 1, p. 219, Edit. 2.*) Dr. Hennen mentions an instance, in which a ball entered near the pomum Adami, and after running completely round the neck, was found in the very orifice, at which it had entered. "This circuitous route is a very frequent occurrence, particularly when balls strike the ribs, or abdominal muscles; for they are turned from the direct line by a very slight resistance indeed, although they will at times run along a continued surface, as the length of a bone, along a muscle, or a fascia, to a very extraordinary distance." Dr. Hennen refers to cases, in which the ball traversed almost the whole extent of the body and extremities. "In one instance, which occurred in a soldier, with his arm extended in the act of endeavouring to climb up a scaling ladder, a ball, which entered about the centre of the humerus, passed along the limb, and over the posterior part of the thorax, coursed among the abdominal muscles, dipped deep through the glutæi, and presented on the forepart of the opposite thigh, about midway down. In another case, a ball, which struck the breast of a man standing erect in the ranks, lodged in the scrotum." (*Principles of Military Surgery, p. 34, Ed. 2.*) The opening, where the ball enters, is always smaller than that from which it escapes, and its margin is forced inwards, while the circumference of the other aperture is quite prominent. The contusion and injury, which the parts suffer, are also greatest about the entrance of the ball, owing to the more considerable impetus, with which it moves. The yellowish livid hue, around gunshot wounds, is a sort of ecchymosis, or extravasation of blood. The injured member is often benumbed and stupefied, and, when mortification occurs, it spreads with extraordinary rapidity. When the whole constitution is thrown into this kind of torpor, the most fatal consequences are to be apprehended. "C'est dans cet état, (says Richerand) que mourut le chevau-léger, dont parle Quesnay; l'état d'hébétéude était tel, que cet individu à qui l'on proposa l'amputation de la jambe, répondit que ce n'était pas son affaire." (*Nosographie Chirurg. Tom. 1, p. 221, Edit. 2.*) In cases of gunshot wounds, sudden shiverings, syncope, and nervous symptoms, are not unfrequent. Such occurrences, with other bad effects, made the ancients suspect, that something poisonous was carried into

the wound; an opinion, which is now well known to be erroneous.

When there is only one opening, we may infer, that the wound contains a foreign body. An exception to this observation occurs, however, when a ball, instead of tearing the clothes, or linen, carries a portion of them, in the form of a sac, into the wound, and when such portion of the clothes is withdrawn, the ball falls out, and if this circumstance be not noticed, the presence of a single opening may lead to the idea, that the bullet is lodged in the part. An instance of this kind is cited by *Pare* for the purpose of refuting the former notion, that the ball burnt the parts. A case, in which a piece of a shirt was carried in this manner four inches into the flesh is mentioned by *Mr. Guthrie*. (*P. 20, Ed. 2.*) It is possible also for a ball to be stopped immediately it has entered the body, and then to be ejected by the elasticity of the parts, against which it strikes, as the cartilages of the ribs. (*Guthrie, p. 19, Ed. 2.*) When there are two apertures made by one shot, the ball has escaped; but pieces of the clothes, &c. may still be lodged in the part. Care must be taken, however, not to confound with these cases others, in which the plurality of openings has been made by different balls.

As a modern writer has accurately explained: "It is no uncommon thing for a ball in striking against the sharp edge of a bone, to be split into two pieces, each of which takes a different direction. Sometimes it happens, that one of the pieces remains in the place, which it struck, while the other continues its course through the body. Of a ball, split by the edge of the patella, I have known one half pass through at the moment of the injury, and the other remain in the joint for months, without its presence there being suspected. In the same manner, I have known a ball divided by striking against the spine of the scapula, and one portion of it pass directly through the chest, from the point of impulse, while the other moved along the integuments, till it reached the elbow-joint. But, the most frequent examples of the division of bullets, which we had occasion to see, were those which were produced by balls striking against the spherical surface of the cranium. It sometimes happens, that one portion of the ball enters the cranium, while the other either remains without or passes over its external surface. Not unfrequently, in injuries of the cranium, the balls are lodged between its two tables, in some instances much flattened, and altered in their shape, and, in other instances, without their form being changed." From these facts, it must be evident, that even when a gunshot wound has two orifices, the surgeon cannot be certain, that the bullet has not been divided, and that no portion is lodged, unless the entire ball itself happen to be found. (*See Thomson's Reports of Obs. in Military Hospitals in Belgium. p. 37, &c.*)

As the ends of the torn vessels are contused and compressed, gunshot wounds have

less propensity to bleed at first seriously, than most other wounds, unless vessels of importance happen to be injured. There may even be little hemorrhage at first though a considerable artery be so hurt, that it afterward sloughs and a dangerous, or a fatal bleeding arises. Thus (as I have already mentioned) in one of my own patients, who had received a musket ball through the ham, the popliteal artery gave way about ten days after the injury, and compelled me to take up the femoral artery; and, in the Elizabeth Hospitals at Brussels, among the patients under the care of my friend Mr. Collier and myself, about a week after the battle of Waterloo, the cases of hemorrhage, on the loosening of the sloughs, were tolerably numerous, not at all coinciding with a recent calculation, that the proportion of such examples, requiring the ligature of arteries, is only three or four in 1000. (*Guthrie on Gunshot Wounds*, p. 8, Ed. 2.) In Holland, the truth of Mr. Hunter's observation upon this point appeared to me to be equally confirmed.

It has long been known, that a limb may be torn, or shot off, even near to the trunk of the body, and hardly any hemorrhage arise. We had numerous proofs of this fact after the battle of Waterloo. I had under my care a man of the rifle brigade, whose arm was shattered to pieces as high as the shoulder, yet there was no hemorrhage. I amputated the thigh of a Dutch soldier, whose leg had been completely shot off by a cannon ball; but there was no hemorrhage before the operation. At Merksam, in 1814, I saw a case, in which the greater part of the clavicle, scapula, and many adjacent parts, had been carried away by a cannon-ball; and yet no bleeding of consequence occurred.

Sometimes, after these violent injuries, the large arteries do not bleed in amputation. "We saw a man, (says Dr. Thomson) whose leg had been shot off by a cannon-ball; in amputating his limb above the knee, the arteries of the thigh were not perceived to bleed; nor did any of them afterward require to be tied. A case, similar to this, also presented itself, in which the arm had been shot away close to the shoulder-joint."

Sometimes the contusion, produced by a cannon-ball, or the passage of a bullet in the vicinity of a large artery, seems to cause a laceration of the inner coat of the vessel, and a subsequent obliteration of its cavity by the effusion of coagulable lymph. Facts, in proof of this statement, are recorded by Dr. Thomson. (*See Reports of Observ. in the Military Hospitals in Belgium*, p. 34, 35.)

Angular uneven bodies, such as pieces of iron, cut lead, &c. produce far more dangerous wounds, than round even bodies, like leaden bullets. Wounds occasioned by a small shot, are frequently more perilous, than others produced by larger balls; because their track is so narrow, that it cannot be traced, nor consequently the extraneous body itself extracted. Such a shot often in-

juries a viscus, when there is not the smallest external symptom of the occurrence. Sometimes a great part of the danger, also, arises from the number of the shots which have entered.

TREATMENT OF GUNSHOT WOUNDS.

The first thing in the treatment of a gunshot wound in one of the extremities, is to determine, whether it is most advisable to amputate the limb immediately, or to undertake the cure of the wound. When a bone, especially at a joint, is very much shattered; when the fleshy parts, particularly the great blood-vessels and nerves, are lacerated; when the whole limb has suffered a violent concussion, and is cold and senseless; there is no hope of preserving it. In this case, it is the surgeon's duty to amputate at once, and not to delay till inflammation, fever, and a tendency to mortification come on. But, besides this violent degree of injury, in which the propriety of amputation is obvious, there are several lower degrees, in which it is often a difficult thing to decide whether the operation is necessary or not. Here the surgeon must look not only to the injury, but also to the patient's constitution, and even to external circumstances, such as the possibility or impossibility of procuring good accommodation, rest, attendance, and pure air. But it is impossible to determine the necessity of amputation by general rules. In every individual case, the surgeon must consider maturely the particular circumstances, before he ventures to decide. The grounds against the operation are; the pain which it causes at a period when the whole system is disordered by a terrible injury; the privation of a limb; and frequent examples, in which nature, aided by judicious surgery, repairs the most horrible wounds. The following are the reasons in favour of the operation. By it the patient gets rid of a dreadful contused wound, which threatens the greatest peril, and which is exchanged, as it were, for a simple incised one. The pain of amputation is not of more moment than the pain which the requisite incisions, and the extraction of foreign bodies, would cause in case the operation were abandoned. In cases of gunshot wounds, the loss of the limb cannot be taken into the account; for, the surgeon only undertakes the operation where he designs to save the patient's life by that privation, and anticipates that the part itself cannot be preserved. Even, if he should deprive the patient of a limb, that perhaps, might have been preserved, there is this atonement, that he can furnish him with an artificial leg, which often proves far more serviceable, than the lost limb would have proved, had it been preserved. Should the operation be fixed on, it is to be immediately performed above the wound. (*Richter, Anfangsgr. der Wundarzn. B. 1.*)

When amputation is deemed unnecessary, the surgeon, according to precepts formerly in vogue, is to dilate the wound by one or more incisions. Many of he

missile weapons employed by the ancients, when received into the body, required incisions before they could be extracted; and this was the case, not only with regard to darts and arrows, but also with regard to bits of stone, pieces of iron, and leaden bullets, which were thrown by means of slings. Celsus mentions the necessity of enlarging the orifices, through which these bodies had entered, and may therefore be justly regarded, as the first who recommended the practice of dilatation in the treatment of wounds made by leaden bullets. (*Thomson's Reports of Obs. in the Military Hospitals of Belgium*, p. 39.)

Such a dilatation has been said to have numerous advantages; to facilitate the extraction of foreign bodies; to occasion a topical bleeding, and afford an outlet for the extravasated fluid in the circumference of the wound; to convert the fistulous form of the track of the ball into an open wound; and, lastly, to divide ligamentous aponeuroses, which otherwise might give rise to spasmodic and other untoward symptoms.

More modern experience proves, however, (*Hunter*, p. 529.) that the utility of such incisions has been overrated; that they generally increase the inflammation, which, in these cases, is so much to be apprehended; that wounds which are not dilated, commonly heal more speedily than others which are; and that there are only a few cases, in which incisions are beneficial. In fact, as Dr. Hennen has correctly stated, the knife is now rarely, if ever employed in the first instance by English surgeons, except for the purpose of extracting balls, splinters of bone, and other extraneous bodies, or for facilitating the application of ligatures to bleeding vessels. (See *Principles of Military Surgery*, p. 49, Ed. 2.)

The injuries, arising from the practice of indiscriminate dilatation, (says Dr. Thomson) were very early pointed out by Botallus; and it is singular, how much the opinions of this author, with regard to this point in military surgery, coincide with those of Mr. Hunter. (*Op. cit.* p. 40.)

The cases of gunshot wounds are various. Sometimes the track of the ball lies superficially under the skin, and only has one opening. When it lies in soft parts, and the ball has neither touched a bone, nor a considerable blood-vessel, all incisions are useless, let the wound have one or two apertures. Though dilating the wound has been practised with a view of giving vent to matter, eschars, and foreign bodies, and even its whole track has been laid open, when superficial; yet, experience proves the inutility of such steps. As, when a ball has passed with great force, there is often a real loss of substance in the skin, a portion of which is driven inward before the ball, it follows, that the opening of a gunshot wound must be more capacious than that of a punctured one. By the separation of sloughs, the wound becomes still more dilated, so that not only matter, but foreign bodies, which approach the skin, easily find an exit. Be-

sides incisions commonly close again very soon, and in a few days, the wound falls into the same state, as if no dilatation at all had been made. (*Hunter*, p. 532.)

Ligamentous fibres, and fasciæ, are often situated about the orifice of a gunshot wound, and some surgeons have made it a rule always to divide them completely, lest, when the wound inflames, the tension and confinement of parts should cause violent spasms and nervous symptoms, and afterward impede the discharge of matter and foreign bodies. When they obviously have the first effects, the propriety of dividing them cannot be doubted; but, with a mere expectation of the other evils, I consider the practice injudicious. Here, as Mr. Hunter wisely remarks, the method would be very good, if tension and inflammation were not a consequence of wounds, or, if it could be proved, that the effects of dilating a part, that is already wounded, were different from those of the first wound; but the employment of the knife, being only an extension of the first mischief, must be contradictory to common sense, and common observation. (*On Gunshot Wounds*, p. 534, 4to.)

The extraction of foreign bodies ranks as one of the most urgent motives for the dilatation of the wound, and no doubt it is right to remove, at first, as many of them as possible. Their lodgment irritates the wound, causes violent nervous and inflammatory symptoms, and copious suppuration; circumstances, which the timely extraction of them may prevent. Yet, let it be remembered, that the extraction of foreign bodies is frequently attended with immense irritation, and that, while they lie too firmly fixed in parts, it is often a matter of impossibility. After the sloughs have separated, and the wound has become widened, suppuration frequently does not prevail long before the extraneous substances become loose, spontaneously approach the skin, and easily admit of removal without any dilatation.

Hence, it is generally prudent to extract, at first, only such foreign bodies, as are near the external opening, quite loose, and removeable without much irritation; or such as press on parts of importance, and, thereby excite dangerous symptoms. The surgeon should avoid interfering with those which are deeply and firmly lodged in the wound. He should await suppuration, and the detachment of sloughs, and when the foreign bodies become moveable and apparent, he should extract them, with or without an incision, as circumstances may demand. The examination of the wound ought to be made as much as possible with the finger, which irritates less, and feels more distinctly than a probe. A great variety of instruments have been devised, either for ascertaining the position of balls, and other foreign bodies in gunshot wounds, or for extracting them. But, however numerous and diversified bullet-drawers may be, they all admit of being divided into three kinds. The first are constructed on the principle of a pair of forceps. Others are shaped more or less

like spoons. And a third description are made on the plan of a cork-screw or worm. These last are only designed for cases, in which the ball is fixed in the substance of a bone, and is quite immovable; for, if it were lodged in the soft parts, the pressure requisite for introducing the screw into it, would injure and lacerate the parts at the bottom of the wound. Bullet-drawers, constructed on the plan of forceps, have the inconvenience of not being adapted for seizing the ball, unless their blades are expanded, which always stretches the wound, and creates a great deal of irritation. Forceps have been contrived with blades, which may be introduced separately, and then joined together with a screw. When a ball lies superficially, the fingers, or a small pair of forceps, will extract it most conveniently. And, with respect to bullet-extractors, as Dr. Hennen has justly observed, they are completely superseded by the common forceps, or that of Baron Percy, though unfortunately the aid of instruments is most required in tortuous deep passages, where we can least make use of them. (*Principles of Military Surgery*, p. 76, Ed. 2.)

The event of the treatment above recommended, is various. Extraneous substances remaining in the wound, either loosen gradually, and come into view so as to be easily removeable; or they continue concealed, prevent the cure, and give birth to a fistulous ulcer. In some instances, the wound closes, and the foreign bodies remain in the limb during life, without inconvenience; and in other cases, after a time, they bring on a renewal of inflammation and suppuration. Sometimes a foreign body varies its situation, sinking down, and afterward making its appearance at a different part, where it may excite inflammation and suppuration.

When the ball lodges in the wound, it is usually difficult to trace it, as the parts collapse after its passage, and leave an opening in the skin much smaller than the ball itself. The ball does not regularly take a straight direction through the injured part, but often a very tortuous one, particularly when the ball is nearly spent. In every case, in which it is not easily discoverable, all painful examinations should be abandoned, and the foreign body left in its situation, until its place is better known, and the first inflammation is over.

Sometimes, the ball may be both easily found and extracted. At other times, it lodges on the opposite side of the limb, closely under the skin. According to Mr. Hunter, if the integuments, under which the ball is lodged, should be so contused that they will probably slough, they are to be considered as already dead, and an opening is to be made in them for the extraction of the ball. But, when the ball lies so remotely from the skin that it can only just be felt, and the skin itself is quite uninjured, no counter-opening ought to be made. The wound heals better when the ball is left in, and far less inflammation takes place in the

vicinity of this extraneous body, than about the orifice of the wound. A counter-opening always renders the inflammation at the bottom of the wound, as great as at its orifice. It is better to let the wound heal up, and extract the ball afterward. (See *Hunter*, p. 541.)

To the justness of this advice, Mr. Guthrie does not assent, who assures us, that he has cut out a great number of balls, which were not more than an inch from the surface, and never found any inconvenience ensue. But when the ball lies three or four inches from the surface, and cannot be distinctly felt, he thinks that no incision should at first be made with the view of extracting it. (*On Gunshot Wounds*, p. 94, 95, Ed. 2.)

Sometimes, the ball penetrates the spongy part of a bone, and lodges firmly in it. When it has only entered superficially, it may sometimes be loosened and extracted, by means of an elevator with a thin and somewhat curved extremity, and when it is more firmly fixed, a screw bullet-drawer will sometimes serve for its removal. Should the attempt fail, the employment of a trepan for the removal of the ball is recommended by some writers; while others, fearful of the irritation, difficulty, and effects of such an operation, and recollecting that balls have sometimes remained fixed in bones for many years, without any serious inconvenience, condemn that practice. On the contrary, Mr. Guthrie lays it down as a general rule, subject to a few exceptions, that a ball should never be allowed to remain in a bone; for, says he, "if a ball lodge in the head of a bone, and is not removed, it generally causes caries of the bone, disease of the joint, amputation, or death. If in the shaft of a long bone, necrosis for the most part follows, with months and years of misery. On a flat bone, caries is equally the result, and if it be surrounded by large muscles, sinuses form in various directions, contractions of the limb take place, and the patient drags on for years, careless of life, and ready to submit to any thing to obtain relief." (*On Gunshot Wounds*, p. 91—93, Ed. 2.) In many of these cases, one thing deserves to be recollected, however, that the necrosis, abscesses, and sinuses are less the effect of the lodgment of the ball, than of the violence originally committed on the parts, against which it has struck. Although Baron Larrey only sanctions the attempt to remove balls with a trephine, when they actually produce dangerous effects, (*Mém. de Chir. Mil. T. 4, p. 185*), I am disposed to believe, that whenever the situation of the ball is such, that it can be removed at once from a bone with tolerable certainty, and without too much irritation, the practice is commendable. This branch of the treatment of gunshot wounds appears to me still to require further elucidation, for though experience has been abundant, the right rules and principles of practice are not yet laid down in the best modern works.

As soon as the requisite incisions are made, and foreign bodies extracted, the prime objects in the treatment of gunshot wounds are accomplished, and the rest is, in reality, not different from the surgery of other wounds.

With regard to probing gunshot wounds; when it is evident that the shot has passed out, and no particular object can be fulfilled with the probe, it is often better to dispense with such examination, at least till suppuration has come on. Introducing any instrument is generally productive both of pain and irritation. But when the ball, or any other extraneous substance, has lodged in the wound, and its situation is not immediately evident, it will often be advisable to search for it at once, in order that it may be extracted, if its situation will allow, before inflammation begins. The surgeon, therefore, considering all the circumstances which can assist him in forming a reasonable conjecture of the course of the wound, must give to a probe that curvature or form, which he thinks most likely to pass readily along it, and must then proceed to make the examination. But, when this is very painful, and the course of the wound obscure, it will often be better to desist, and renew the search when suppuration has taken place, in which stage it can be undertaken with more ease, and a greater prospect of success. When gunshot wounds are inflamed, the tenderness and swelling of the parts are peculiarly strong reasons against painful probings, or efforts to extract foreign bodies, as long as this state lasts. (See *Chevalier's Treatise on Gunshot Wounds*, p. 67, 68, Edit. 3.)

There is no fact in the practice of surgery better established, than that the cramming of narrow stabs and gunshot wounds with lint, is particularly hurtful. The only possible reason for doing so in the latter cases must be to keep the orifice of the wound from healing up, and confining extraneous bodies, matter, &c. The apprehension of this happening at first is quite unfounded; for the inside of the mouth of the injured part is often lined with a slough or eschar, which must necessarily be detached before the parts can heal. The first dressings, therefore, should be quite superficial, and of a mild unirritating nature. On the field of battle, indeed, it would be well for many of the wounded, if the surgeon were to content himself with applying simple pledgets, and covering the part with linen wet with cold water. This method would prove much more beneficial, than the hasty and indiscriminate use of adhesive plasters, sutures, and tight bandages, from the bad effects of which thousands of soldiers have lost limbs, or lives, which, under more judicious treatment, might have been saved. Hunter used to employ fomentations, pledgets of simple ointments, and frequently over the latter an emollient poultice. In the suppurative stage of gunshot wounds, poultices are generally allowed to be the best applications.

Possessing these ideas, I cannot altogether approve the following directions, though

they are certainly better than are given in many surgical books. "A small bit of soft lint may be placed lightly between the lips of the wound, in order to keep it from closing. In some instances, it should be introduced a little beyond the lips, in order to conduct off the fluids effused, and to prevent irregular adhesions from forming near the surface during the inflammatory stage; as these would impede the direct exit of the discharge. But the wound is not to be filled with lint, much less crammed with it. A pledget of some simple ointment being then laid on, with tow or cloths to receive the discharge, and these prevented from coming off by a bandage loosely applied, the patient may be put to bed, and so placed, if possible, as to keep the orifice of the wound dependent." (*Chevalier*, p. 125, 126.) The reasons for what I consider objectionable, namely, introducing lint on first dressing the wound, are too frivolous to need comment.

In considering the effects of poultices and cold applications upon gunshot wounds, Mr. Guthrie expresses his decided preference to the use of cold water:—"The inflammation is, in some instances, materially prevented, in many greatly controlled, and, in almost all, very much subdued by it, whilst the suppurative process is not impeded in the generality of cases, in a degree sufficient to interrupt the subsequent one of granulation. In all simple cases of gunshot wounds, that is to say, flesh wounds, in persons of a healthy constitution, a piece of lint, which has been dipped in oil, or on which some ointment has been spread, is the best application at first to prevent irritation, with two slips of adhesive plaster placed across to retain it in its situation. A compress, or some folds of linen, wetted with cold water, are then to be applied over it, and kept constantly wet and cold, even by the use of ice, if it can be obtained, and be found comfortable to the feelings of the patient. A roller is of no use, except to prevent the compress from changing its position during sleep, and is, therefore, at that period useful; but as a surgical application, it is useless, if not positively injurious, because it binds a part, which ought, to a certain extent, to swell, and by pressure causes irritation. Rollers ought not to be applied surgically until after some days have elapsed, and it is inexpedient to employ them in the field of battle, even if they were useful, except where some parts are to be kept in position; because, when they are applied in the first instance, they soon become stiff and bloody, are for the most part cut, and are seldom preserved after the first dressing, so as to become useful at the period, when the surgical application of a roller is indispensable." To this just censure of the wrong employment of rollers, Mr. Guthrie annexes some remarks, in which he enters into a general condemnation of poultices, as applications to gunshot wounds, believing, that in many instances, cold water may be employed with the best effect, during the whole progress of the cure. These remarks are tem-

pered with the following admission:—"Cold water is not, however, an infallible, or even always an advantageous remedy: there are many persons, with whom cold applications do not agree; there are more, with whom they disagree after a certain period; and, in either case, they should not be persisted in. Cold does no good in any stage of inflammation, when the sensation accruing from the first application of it is not agreeable to the feelings of the patient; when, in fact, it does not give relief; for, if it produces a sensation of shivering, or an uncomfortable feeling of any kind, with stiffness of the part, it is doing harm, and a change to the genial sensation of warmth will not only prove more agreeable, but more advantageous. This occurs in general about the period when suppuration has taken place; and cold, in such cases, is preventing the full effect of the action, which warmth encourages. Fomentations are then proper; and, if a poultice be preferred for convenience, by day or by night, an evaporating one of bread will be found sufficient. In the spring of the year, the marshmallow makes an excellent poultice, and so do turnips, gourds, carrots, &c. independently of oatmeal, linseed-meal, Indian-meal, and other farinaceous substances. In all those cases where a poultice is resorted to, as much attention is to be paid to the period of removing, as of applying it. It is used to alleviate pain, stiffness, swelling, the uneasiness arising from cold, and to encourage the commencing, or interrupted action of the vessels towards the formation of matter; and, as soon as the effect intended has been gained, the poultice should be abandoned, and recourse again had to cold water, with compress and bandage." (*P. 62—67. Ed. 2.*) Although I fully coincide with Mr. Guthrie, respecting the general advantage of cold water, the dangers of tight bandages, and the bad effects of continuing poultices too long, I do not join him in many of the sentiments which he has expressed about these last invaluable applications. On the contrary, I appreciate them as the best means, wherever a slough is to be thrown off, or matter is decidedly forming, and as these effects are very frequent in cases of gunshot wounds, my own opinion of the utility of cold applications is limited to the first three or four days after the receipt of the injury. Nor ought cold applications ever to be continued, where the torpor, low temperature, and languid circulation in the limb, indicate a risk of gangrene. Hence, when a principal artery is tied, their employment is always wrong and hazardous. At the same time, I have no hesitation in declaring my firm belief, that fifty times more mischief has been done by tight rollers applied to recent gunshot wounds, than by either poultices, or cold applications.

Formerly, when the track of the ball had two apertures, a seton was sometimes drawn through it, with the view of preventing a premature closure of the wound, and introducing proper applications. The seton was, also, imagined to give free vent to pus, and

to promote the evacuation of foreign bodies. But a gunshot wound is little inclined to close prematurely, and while a seton rather obstructs the exit of pus, it may as easily push foreign bodies more deeply into the limb, as out of it. There are preferable modes of applying the necessary remedies, and, as a seton is an extraneous substance itself, its employment cannot fail to be highly pernicious.

Gunshot wounds generally demand the employment of antiphlogistic means, just as other cases, attended with equal inflammation. When they are in the inflamed state, the application of leeches is highly proper. In these cases, bleeding is recommended, and in such a manner as if it were of more service in them, than wounds in general. But the necessity for the practice is really not greater than in other wounds, which have done the same degree of mischief, and from which the same quantity of inflammation and other consequences are expected. Bleeding is certainly proper here, just as it is in all considerable wounds attended with a strong full habit, and great chance of extensive inflammation, and much symptomatic fever. In every instance, however, the practitioner must take particular care not to be too bold in the practice of bleeding: for when the patient is reduced below a certain degree, his strength is inadequate to support the large and long-continued suppurations which often cannot be avoided. (*See Hunter, p. 563, 564.*)

As the orifices of the vessels torn by the ball are compressed, and, as it were, obliterated, sometimes no hemorrhage of importance is remarked at first. But, as I have already stated, after some days, and frequently at a very late period, when the sloughs separate, copious hemorrhages may occur, which are the more dangerous as they come on unexpectedly, and often when the suppuration has already induced great debility. The surgeon himself may occasion the bleeding, by removing the dressings carelessly. Hence, in every case, where, from the situation of the wound, there is reason to apprehend injury of some considerable vessel, the patient must be constantly and attentively watched, and every thing necessary for the immediate stoppage of hemorrhage provided.

Another kind of hemorrhage, still more dangerous than the former, particularly occurs in such gunshot wounds as have long been in a state of copious suppuration. The blood does not issue from one individual vessel, but from the whole surface of the wound, as from a sponge, and is so thin as to resemble blood and water. This hemorrhage is very dangerous, because it is particularly apt to exhaust the patient, who is already debilitated, and its causes are difficult of removal. The case demands the exhibition of bark, and diluted sulphuric acid; the decoction of bark, with a proportion of muriatic acid, being applied to the wound. (*Richter.*)

Gunshot wounds, in crowded military hospitals, especially when they are established in unhealthy, low situations, and due atten-

tion is not paid to ventilation, cleanliness, and fumigations with nitric acid gas, are often attacked with hospital gangrene, a very serious and dangerous complication, of which I shall speak under the head of *Hospital Gangrene*.

The plan of removing the first dressings too soon is as injurious in gunshot wounds as other cases, by creating a premature disturbance of the parts. This observation is particularly true, where dry lint has been used, and it is adherent to the wound. Unless the occurrence of bleeding, severe pain, or other unfavourable symptoms, were to render a different line of conduct necessary, I think such dressings should rarely be removed before the end of the fourth day. And, if cold water has not been continually applied over the lint, so as to keep it moist, or if such lint has not been spread with some mild salve, or dipped in oil, I deem it a good rule to apply an emollient poultice over it the evening preceding the morning on which the dressings are to be first changed. By this means, they will be loosened, and admit of being taken away without pain or irritation. With the same view, plenty of warm water should be squeezed from a sponge, and allowed to fall upon the dressings. Pledgets of oil, or ointment, should generally be taken off earlier than dry lint, for they are less adherent, and in warm weather, soon become rancid and irritating.

For the first days, the matter seldom assumes a healthy appearance; but as soon as the sloughs separate, it then becomes of a proper quality, and the wound is to be treated as a simple abscess.

Sometimes the healing process does not commence, though suppuration has prevailed a considerable time. On the contrary, notwithstanding the exhibition of tonics, and a generous diet, the suppuration ceases to proceed favourably, and the wound becomes unhealthy, and the matter thin. The bones show no disposition to unite, and the patient, reduced by hectic symptoms, is rapidly approaching dissolution. In this state, life may sometimes be preserved by amputation: the *anceps*, but *unicum remedium*. We ought never to be deterred from undertaking the operation by the fever and weakness, which frequently soon disappear when the local cause is removed.

OF AMPUTATION IN CASES OF GUNSHOT WOUNDS.

The 2d edition of this dictionary, published in 1813, contained all the valuable observations of Baron Larrey, in favour of *immediate* amputation in every instance in which the operation is considered indispensable. Since then, the public have been favoured with several good practical books, in which the propriety and necessity of early or immediate amputation in such cases are urgently inculcated, and the truth of the doctrine is illustrated by additional facts. It is to be observed, however, that for nearly two hundred years past, there have always

been some advocates for this judicious practice. "Du Chesne (says Dr. J. Thomson) is the first writer on military surgery, in whose works I have found the recommendation to amputate in the severer injuries of the extremities; and it is worthy of remark, that he directs the operation to be performed before inflammation and other constitutional symptoms shall have supervened." (See *Traité de la Cure générale et particulière des Arbusades*. Par Jos. Du Chesne; Paris, 1625, p. 143; and *Thomson's Report*, &c. p. 160.) Wiseman not only recommended and practised immediate amputation; but the same thing was not unfrequently done by the military surgeons of his time. (*Chirurgical Treatises*, by R. Wiseman, 3d Edit. London, 1696, p. 410.) The celebrated Le Dran, in his excellent little manual of military surgery, declared himself an advocate for *immediate* amputation in all cases, in which that operation from the first appears to be indispensable. Le Dran has at the same time stated briefly, but most distinctly, the comparative advantages of that practice, with those which may be expected by delay. (See *Traité ou Réflexions tirées de la Pratique sur les Plaies d'Armes à feu*. Par H. F. Le Dran; à Paris, 1737.) Ranby, who was serjeant surgeon to King George II. entertained similar opinions to those of Le Dran, with regard to the utility of immediate amputation. In order to give immediate relief to the wounded, and to facilitate the performance of the necessary operations, Ranby proposed, that the surgeons, during battle, should be collected into small bodies, and stationed in the rear of the army. (See the *Method of treating Gunshot Wounds*. By John Ranby. Edit. 3, p. 29. London, 1781.)

After the battle of Fontenoy, in the year 1756, the Royal Academy of Surgery in France offered a prize for the best dissertation on the gunshot injuries requiring immediate amputation, and on other cases of the same nature, where the operation, though deemed inevitable, might be delayed. *L'amputation étant absolument nécessaire dans les playes compliquées de fracas des os, et principalement celles qui sont faites par armes à feu, déterminer les cas où il faut faire l'opération sur le champ, et ceux où il convient de la différer, et en donner les raisons.*" The prize was adjudged to the dissertation of M. Faure, the main object of whose paper was to recommend delaying the operation. The side of the question espoused by M. Faure has found some modern advocates of distinguished talents and celebrity. Suffice it to mention the names of Hunter, Baron Percy, and Lombard. It is, however, only justice to M. Faure to state in this place, that, though he regarded immediate amputation as full of danger, he admitted, that there were several kinds of injuries of the extremities, in which it was indispensably and immediately required. "The enumeration (says Dr. Thomson) which this author has given of these injuries, is more full and distinct than any which had been published before his time; and, what may appear singular, it does not

differ, in any essential respect, from the enumeration given by later writers, who, in combating his opinions, have represented him as an enemy to amputation in almost all injuries of the extremities." (See *Report of Observations made in the Military Hospitals in Belgium*, p. 169.)

In 1792, Baron Percy, who was a few years ago at the head of the medical department of the French army, published a book, in which he gives a preference to delaying amputation at first, even in cases where it is certain that the operation cannot ultimately be dispensed with. (See *Manuel de Chirurgien d'Armée*.) Even as late as 1804, Lombard, Professor in the Military Academy of Strasburg, defended the doctrines of M. Faure. (See *Clinique Chirurgicale des Plaies faites par armes à feu*.)

Although, in France, the academy of surgery thought proper to decree the prize to M. Faure, whose doctrine thus received the highest approbation, yet, in that country, very opposite tenets were set up by some men of distinguished talents and extensive military practice. Thus Le Dran, consulting surgeon to the French army, in his work on gunshot wounds, published in 1737, expressly states, "That when the amputation of a limb is indispensably necessary in the case of a gunshot wound, it ought to be done without delay." (*Aphorism 9*.) De La Martinière in particular also wrote some excellent arguments in reply to Bilguer; arguments which, I think, would do honour to the most accomplished surgeon of the age in which we live. (See *Mémoire sur le Traitement des plaies d'armes à feu*, in *Mém. de l'Acad. de Chirurgie*, T. 11, p. 1, Edit. in 12mo.) M. Boucher, of Lisle, was an advocate for the same side of the question. (See *Obs. sur des plaies, d'armes à feu, &c.* in *Mém. de l'Acad. de Chirurgie*, Tom. 5, p. 279, &c. Edit. in 12mo.) Schmucker, who was many years surgeon-general to the Prussian armies, published in 1776, an essay on amputation, in which he particularly mentions, that, during his stay at Paris in 1738, the surgeons of the Hôtel Dieu had been in the habit of performing immediate amputation in severe injuries of the extremities. He also declares himself an advocate for operating immediately, in all cases in which amputation from the first appears to be necessary, and insists, in a particular manner, on the increased danger which he had seen arise from the operation during the second period. He gives (as Dr. J. Thomson has observed) a minute and circumstantial enumeration of those injuries, both of the upper and lower extremities, in which he conceived amputation to be necessary, and in many of which he had actually performed it with great success. Schmucker appears to Dr. Thomson to have given a better account than any preceding military surgeon of the injuries of the thigh; and from the results of his experience, he was led to believe, that though compound fractures of the lower part of the thigh-bone might, in favourable circumstances, be cured without amputation, yet that this operation is peculiarly

necessary in all cases, in which the fracture is situated in, or above, the middle of that bone. (J. L. Schmucker, *Vermischte Chirurgische Schriften*, B. 1. Berlin, 1785.) With the foregoing high authority we have to join one of not less celebrity, namely, that of Baron Larrey, who has proved most convincingly, that when amputation is to be done in cases of gunshot wounds, nothing is so pernicious as delay. (See *Mémoires de Chirurgie Militaire*, Tom. 2, p. 451, &c.)

It becomes me here to state, also, that the principles inculcated by Baron Larrey, are, in point of fact, the same as those which were so strenuously insisted upon by Mr. Pott, whose principal remarks on the necessity of amputation in certain cases, are detailed in another part of this publication. (See *Amputation*.) Mr. Pott, indeed, was not an army surgeon, and what he says was not particularly designed to apply to military practice; but he has represented, as well as any body can do, the propriety of immediate amputation for injuries which leave no doubt that such operation cannot be dispensed with.

Mr. John Bell, among the moderns, appears to me likewise to have much merit for the able manner in which he defended the propriety of early amputation, long before the sentiments of later writers were ever heard of. He distinctly states, that "amputation should, in those cases where the limb is plainly and irrecoverably disordered, be performed upon the spot." (See *Discourses on the Nature, &c. of Wounds*, p. 488, Edit. 3.) In short, notwithstanding all the modern pretensions to novelty upon this interesting topic, we must acknowledge, with Dr. Thomson, that the evidence in favour of the advantages of immediate amputation, has always preponderated over that for delay. (See *Report of Obs. made in the Military Hospitals in Belgium*, p. 225.)

The strongest body of evidence upon this matter, is undoubtedly adduced by Baron Larrey, whose situation at the head of the medical department of the French armies afforded him most numerous opportunities of judging from actual experience. "Upon this subject, (says he,) now that twenty years of continual war have carried our art to the highest pitch of perfection, there can only be one opinion. It is after having incessantly directed the medical service all this time, in quality of head surgeon and inspector-general of the armies, that I proceed to discuss the different opinions delivered in the academy, and to settle definitively this great question, which I regard as the most important in military surgery.

"If we are to be told, that the amputation of a limb is a cruel operation, dangerous in its consequences, and always grievous for the patient, who is thereby mutilated; that, consequently, there is more honour in saving a limb than in cutting it off with dexterity and success; these arguments may be refuted by answering, that amputation is an operation of necessity, which offers a chance of preservation to the unfortunate, whose death

appears certain under any other treatment; and that if any doubt should exist of amputation being absolutely indispensable to the patient's safety, the operation is to be deferred till nature has declared herself, and given a positive indication for it. We are also justified in adding, that this chance of preservation is at the present day much greater, than at the epoch of the academy of surgery. We learn from M. Faure, that, of about three hundred amputations performed after the battle of Fontenoy, only thirty were followed by success, whilst, on the contrary, says Baron Larrey, we have saved more than three-fourths of the patients on whom amputation has been done, and some of whom also had two limbs removed. This improvement is ascribed by Larrey, 1st, To our now knowing better how to take advantage of the indication and favourable time for amputating. 2. To the better method of dressing. 3. To the mode of operating being more simple, less painful, and more expeditious, than that formerly in vogue."

To the preceding authorities against delaying amputation, in cases of gunshot wounds requiring such operation, I have to add Mr. Guthrie, deputy inspector of military hospitals, whose opportunities of observation, during the late war in Spain, were particularly extensive. In his work, he has detailed the opinions of many eminent foreign and British surgeons, respecting the propriety, or impropriety, of the doctrine of immediate amputation; and he has introduced some good criticisms, particularly on Bilguer's statement of the success which was experienced in the Prussian hospitals, from not performing the operation. Mr. Guthrie, however, does not recommend amputation to be done immediately, if the patient be particularly depressed by the shock of the injury directly after its receipt; a piece of advice, which I believe has in reality been at all times followed, not only in respect to amputations in cases of gunshot wounds, but all other severe local injuries. "I believe it to be (says Mr. Guthrie) a stretch of fancy in those surgeons who conceive, that if the knife followed the shot in all cases, the patient would have the best chance of success. No one will deny, that if the shot performed a regular amputation, it would not be better than to have it to do afterward; but if they mean to say the operation should in general be performed immediately after the injury, I can only oppose to them the facts above stated, and the general result of my experience, which is decidedly in favour of allowing the first moments of agitation to pass over before any thing be done; a period extending from that to one, six, or eight hours, according to the difference of constitution, and the different injuries that have been sustained. But from one to three hours will in most cases be found sufficient." (*On Gunshot Wounds*, p. 226, Edit. 2, Lond. 1820.) In the first edition of this gentleman's book, some little want of precision rather concealed his exact meaning, with respect to the period of time which should generally be allowed to transpire between the receipt of the injury and the per-

formance of amputation; but after all the disposition to controversy upon this point, it appears there is little to fight about, as there is rather a misunderstanding, than a difference of opinion. All acknowledge the advantage of doing the operation immediately, when the patient is not faint and depressed by the shock of the accident; all admit the prudence of deferring the use of the knife in other cases until the constitution has revived sufficiently to be capable of bearing the removal of the limb. (See *A. C. Hutchinson, Pract. Obs. in Surgery*, 8vo. Lond. 1816; and his further *Observations on the proper period for amputating in Gunshot Wounds*, 1817. *Quarrier, in Med. Chir. Trans.* Vol. 8; and *Dewar, in Med. Chir. Journ.* April, 1819.)

As far as my experience goes, when the necessity of amputation is undoubted, all delay is improper beyond the short period, during which the faintness immediately arising from the injury usually lasts. In the campaign in Holland, 1814, the most successful amputations were those done in the field hospitals directly after the arrival of the patients, or rather, as Dr. Hennen has expressed it, with as little delay as possible. "While hundreds are waiting for the decision of the surgeon, he will never be at a loss to select individuals, who can safely and advantageously bear to be operated upon, as quickly as himself, or assistants, can offer their aid; but he will betray a miserable want of science indeed, if, in this crowd of sufferers, he indiscriminately amputates the weak, the terrified, the sinking, and the determined. While he is giving his aid to a few of the latter class, encouragement and a cordial will soon make a change in the state of the weakly, or the terrified; and a longer period, and more active measures, will render even the sinking proper objects for operation." (*On Military Surgery*, p. 45, Ed. 2.) It appears from some returns, collected by Mr. Guthrie, that in the peninsula, the comparative loss in secondary or delayed operations, and in primary, or immediate amputations, was as follows:—

	Secondary.	Primary.
Upper extremities . . .	12 to . . .	1
Lower extremities . . .	3 to . . .	1

The great success attending amputation on the field of battle was also convincingly proved after the battle of Toulouse. Here of 47 immediate amputations, 38 were cured, while of the 51 delayed operations, on that occasion, 21 had fatal terminations. (*P. 42—44, Ed. 1.*) After the attack on New Orleans, out of 45 primary amputations, 38 patients recovered, while only 2 of 7 secondary amputations terminated in the preservation of the patients. (*Op. cit. p. 294, Ed. 2.*)

OF IMMEDIATE AMPUTATION.

When a limb, that has received a gunshot wound, cannot be saved, amputation should be immediately practised. The first four and twenty hours, Baron Larrey observes, are the only time that nature remains tranquil,

(I should say, she does not remain quiet so long,) and we must hasten to take advantage of this period, in order to administer the necessary remedy.

In the army, a variety of circumstances make the urgency for amputation still greater. 1. The inconvenience attending the transport of the wounded from the field of battle to the military hospitals, in carriages badly suspended, the jolting of which would produce such disorder in the wound, and in the whole body, that most patients would die in the journey, especially if it were long, and the weather either extremely hot or cold.

2. The danger of a long continuance in the hospitals; a danger, which amputation materially diminishes, by changing a gunshot injury into a wound, that may be speedily healed, and reducing the causes of fever, and the hospital gangrene.

3. The cases, in which there is a necessity for abandoning the wounded. In this circumstance, it is of importance to have amputated, for after the operation, the patients may remain some days without being dressed, and the dressings are afterward more easy. Besides, it might often happen, that these unfortunate objects would not meet with surgeons of sufficient skill to do the operation; a circumstance, says Larrey, that we have seen happen among certain nations, whose caravans, for the medical service of the army (*ambulances*), are not constructed like those in use with the French.

OF CASES, IN WHICH AMPUTATION SHOULD BE DONE IMMEDIATELY.

First case. A limb carried away by a cannon-ball, or the explosion of a howitzer, or bomb, requires amputation without any loss of time: the least delay puts the patient's life in danger.

In this case, the necessity of the practice is inculcated by M. Faure himself, as well as by Schmucker, Richter, Larrey, Dr. Thomson, and every modern writer upon gunshot wounds.

When a cannon-ball has torn off a limb, amputation of the stump should be performed, in order to procure the patient an even, smooth incision, instead of an irregular, jagged, and highly dangerous wound. As the limb has commonly suffered a violent concussion, is almost bereft of sense, and power of motion, and the bone frequently has a fissure extending some way upward, the amputation is sometimes recommended to be done, if possible, above the nearest joint. Were the operation not done, this kind of injury would require large and free incisions, for the extraction of foreign bodies, the shortening of projecting muscles and tendons, and the discharge of abscesses; and as these incisions are likely to occasion at least as much irritation as amputation itself, without being productive of equal good, the avoidance even of pain cannot be urged as a reason against the practice. The occasional healing of such wounds only proves, that it is

not altogether impossible, in certain instances, to effect a cure without amputation. The surgeon can the more readily make up his mind to amputate, as in this case, the operation does not occasion the loss of a limb. As for the place of the incision, no one would be justified in amputating above the knee, when the limb is injured at the foot or ankle.

The skin has been violently stretched and lacerated; the muscles have been ruptured and irregularly torn away; the tendons and aponeuroses lacerated; the nerves and vessels divided and forcibly dragged; lastly, the bones broken and smashed to a greater or lesser extent. These first effects are followed by a general, or partial commotion; by a kind of torpor in the injured part, and a good way above the wound; by a painful trembling in the remains of the member, an event that is singularly afflicting to the patient; and by a local swelling preceding the erethismus, which quickly shows itself. The hemorrhage, says Baron Larrey, an accident much more to be apprehended than has been supposed, often comes on a few moments after the injury, and if prompt succour were not afforded, would put a period to the patient's existence. "I can even declare, that had it not been for the activity of the train of flying surgical carriages, (*ambulances volantes*) by means of which the wounded have always been dressed upon the field of battle, many soldiers would have perished from this accident alone."

If the operation is not speedily done, pain commences, fever occurs, and the functions of the system become disordered; the irritation then increases, and convulsive motions take place. If the patient should not be a victim to these first symptoms, gangrene of the stump follows, the fatal consequences of which it is extremely difficult to prevent.

After this short exposition, it is easy to see, that in this case, amputation ought to be practised immediately, and to delay the operation, and merely apply simple dressings, would be affording time for the preceding accidents to arise.

At Strasburgh, during the bombardment of the fort of Kell, in 1792, three volunteers, says Baron Larrey, had limbs shot off by the explosion of shells: one, an arm; another, a fore-arm; and the third, a leg. They were conveyed to the hospital for the wounded in that town, which was superintended by M. Boy. Several days were suffered to elapse before the amputation was performed; not one of the patients escaped.

At Mentz, after the retreat from Frankfurt, several of the wounded, who had had limbs shot off, did not have amputation done till some time afterward, and not one of them recovered.

At Nice, after the taking of Saorgio, two amputations were practised at the Hospital, No. 2; one of the fore-arm, the other of the arm, nine or ten days after the receipt of the injuries: both the patients died.

At Perpignan, Baron Larrey visited two soldiers, on whom amputation had been done, seven or eight days after the receipt

of gunshot injuries in the action of the 14th of July, 1794. One had had a leg shot off, and the other his right arm. Notwithstanding Larrey's utmost care, he could not save their lives: one died of tetanus; the other of gangrene.

In the month of August, 1805, two cannoniers of the guards, in discharging the artillery, had each a hand shot away, and all the forepart of their bodies burnt. These were the two men whose office it was to charge the gun. At the moment when they had just rammed down the wadding on the cartridge, a spark, that had been left unextinguished, from the neglect to keep the touch-hole closed, set fire to the powder: the ramrod was violently repelled by the explosion, together with every thing that was situated in front of the charge. The right hand of one of the cannoniers was completely torn off, between the two phalanges of the carpus, and thrown more than two hundred paces. The counter shock even threw the man down into the ditch of the square of the Hôtel des Invalides. The left hand of the other cannonier was torn away, together with the fore-arm of the elbow-joint, and also forced to a considerable distance. The tendons and muscles sustained vast injury, and the worst symptoms would have occurred if amputation had not been instantly performed. In one case, amputation was done at the wrist; and in the other at the lower third of the arm. The two operations were followed by complete success, although the burns upon the face and chest, in both the patients, were serious and extensive.

Second case. When a body, propelled by gunpowder, strikes a limb in such a manner as to smash the bones, violently contuse, lacerate, and deeply tear away the soft parts, amputation ought to be immediately performed. If this measure be neglected, all the injured parts will soon be seized with gangrene: and besides, as Larrey has explained, the accidents which the gravity of the first case produces, will also here be excited. It is only doing justice to the memory of M. Faure to state, that this second case was one which he also particularly instanced as demanding the immediate performance of amputation. (See *Prix de l'Acad. Royale de Chirurgie*, T. 8, p. 23, Edit. 12mo.)

Third case. If a similar body were to carry away a great mass of the soft parts, and the principal vessels of a limb, (of the thigh, for instance,) without fracturing the bone, the patient would be in a state demanding immediate amputation; for, independently of the accidents which would originate from a considerable loss of substance, the limb must inevitably mortify. Mr. Guthrie also says, "a cannon-shot destroying the artery and vein, on the inside (of the thigh) without injuring the bone, requires amputation." (P. 185.) When, however, the femoral artery, or vein, is injured by a musket-ball, or small canister-shot, this gentleman recommends tying the vessel above and below the wound in it, if the nature of the case be evinced by hemorrhage. But he believes,

that when both vein and artery are injured, amputation is necessary. (P. 186.) With respect to bleeding from the femoral vein, as it may easily be stopped by moderate pressure, the propriety of using any ligature at all is questionable.

"An injury of the femoral artery, (observes Mr. Guthrie) requiring an operation, accompanied with fracture of the bone of the most simple kind, is a proper case for immediate amputation; for, although many patients would recover from either accident alone, none would, I believe, surmount the two united, and the higher the accident is in the thigh, the more imperious is the necessity for amputation." (*Guthrie on Gunshot Wounds*, p. 187.)

Fourth case. A grape-shot strikes the thick part of a member, breaks the bone, divides and tears the muscles, and destroys the large nerves, without, however, touching the main artery. According to Larrey, this is a fourth case, requiring immediate amputation.

Mr. Guthrie seems to coincide on this point with Larrey: "If a cannon-shot strike the back part of the thigh, and carry away the muscular part behind, and with it the great sciatic nerve, amputation is necessary, even if the bone be untouched, &c. In this case, I would not perform the operation by the circular incision, but would preserve a flap from the forepart, or sides, as I could get it, to cover the bone, which should be short." (*Guthrie on Gunshot Wounds of the Extremities*, p. 184.)

Fifth case. If a spent cannon-shot, or one that has been reflected, should strike a member obliquely, without producing a solution of continuity in the skin, as often happens, the parts which resist its action, such as the bones, muscles, tendons, aponeuroses, and vessels, may be ruptured and lacerated. The extent of the internal disorder is to be examined; and if the bones should feel, through the soft parts, as if they were smashed, and if there should be reason to suspect, from the swelling and a sort of fluctuation, that the vessels are lacerated, amputation ought to be immediately practised. We learn from Larrey, that this is also the advice of Baron Percy. Sometimes, however, the vessels and bones have escaped injury, and the muscles are almost the only parts disordered. In this circumstance, we are enjoined to follow the counsel of De La Martinière, who recommended making an incision through the skin. By this means, a quantity of thick blackish blood will be discharged, and the practitioner must await events. According to Larrey, such incision is equally necessary in the preceding case, before amputation, in order to ascertain the extent of the mischief which the parts have sustained.

It is to such injury, done to internal organs, that we must ascribe the death of many individuals, which was for a long while attributed to the commotion produced in the air. (See *Ravaton, Traité des Plaies d'Armes, à Feu*.)

Although, says Larrey, this opinion has been sanctioned by surgeons of high repute, we may easily convince ourselves of its falsity, if we carefully consider, 1st, the direction and course of solid hard bodies, and their relation to the air, through which they have to pass; 2dly, the internal disorder, observable in the dead bodies of persons, whose death is imputed to the mere impression of the air, agitated by the ball; 3dly, the properties of the elastic substances, such as the integuments, cellular substance, &c. struck by the shot.

It is universally agreed among philosophers, that a solid body, moving in a fluid, only acts upon a column of this fluid, the base of which column is nearly equal to the surface which the solid body presents. (See *Le Vacher sur quelques particularités concernant les playes faites par armes à feu*, in *Mém. de l'Acad. de Chirurgie*, T. 11, p. 34, Ed. 12mo.)

Thus a cannon-ball, in traversing a space equal to its diameter, can only displace a portion of air, in the relation of 3 to 2, compared with the size of the shot. This fluid, in consequence of its divisibility and homogeneity with the ambient air, is dispersed in all directions, and confounded with the total mass of the atmosphere. The effects of this aeriform substance amount to nothing, and not a doubt can be entertained, that if there is the slightest solution of continuity of any part of the body, it must depend upon the direct action of the ball itself.

If, besides, the quickness of the motion of a ball be considered, which quickness is known to diminish in an inverse ratio to the squares of the distance, it will be seen, that the space through which the shot has passed, before striking the object against which it was directed, will already have materially lessened the celerity of the projectile, while the motion of the column of air must be totally lost.

The different movements which the ball describes in its course, and the elasticity of the skin, enable us to explain how internal injuries are produced, without any external solution of continuity, and often even without ecchymosis. The motion, communicated to the ball by the power which projects it, is, for a given space, rectilinear. If, at this instance, it strikes against the body, it carries the part away to an extent proportioned to the mass with which it touches the part. But the ball, after having traversed a certain distance, undergoes, in consequence of the resistance of the air, and the attraction of gravity, a change of motion, and now turns on its own axis, in the diagonal direction.

If the shot should strike any rounded part of the body, towards the end of its course, it will run round a great portion of the circumference of the part, by the effect of its curvilinear movement. It is also in this manner, observes Larrey, that the wheel of a carriage acts in passing obliquely over the thigh, or leg, of an individual stretched upon

the ground. In this case, the results are the same as those of which we have been speaking. The most elastic parts yield to the impulse of the contusing body; while such as offer resistance, as, for instance, the bones, tendons, muscles, and aponeuroses, are fractured, ruptured, and lacerated. For the same reason it sometimes happens, that the viscera are similarly injured.

At first sight, all the parts appear to be entire; but a careful examination will not let us remain long in doubt about the internal mischief. In this case, an ecchymosis cannot manifest itself outwardly, because the vessels of the skin, which communicate with the internal parts, are ruptured, because the extravasation of blood naturally takes place in the deep excavations occasioned by the rupture of the muscles and other parts, and because this fluid cannot make its way through the texture of the skin. Such extravasations can only be detected by the touch.

The foregoing reasoning is supported by experience. How often, says Larrey, have we not seen the ball carry away pieces of helmets, hats, cartridge-boxes, knapsacks, or other parts of the soldier's dress, without doing any other injury? The same ball, perhaps, takes off his arm, often at a time when it is closely applied to the body of his comrade, and yet the latter does not receive the slightest harm. The shot may pass betwixt the thighs, and these members hardly exhibit an ecchymosis at the points, which are gently grazed; the only example in which ecchymosis does occur. In other instances, the ball severs the arm from the trunk, and the functions of the thoracic viscera are not at all injured.

Baron Larrey then relates the following case, which is analogous to one which I saw near Antwerp, and have already mentioned in the foregoing columns. M. Méget, a captain, marching in the front of a square of men, in the heat of the battle of Alzey, 30th March, 1793, had his right leg almost entirely carried away by a large cannon-shot, without the contiguous limb of his lieutenant, who was as close as possible to him, receiving the least injury. The violent general commotion excited, and the extreme severity of the weather, made this officer's condition imminently perilous. The progress of the symptoms, however, was checked by amputation, which was instantly performed. M. Méget was then capable of being conveyed to the hospital at Landau, fifteen leagues from the field of battle, where he got quite well.

Larrey declines relating numerous other analogous amputations, which he has been called upon to practise under the same circumstances. M. Buffy, a captain of the artillery of the army of the Rhine, was struck by a howitzer, his left arm being injured, and his head so nearly grazed, that the corner of his hat, which was placed forwards over his face, was shot away as far as the crown. This officer, the skin of whose nose was even torn off, was not deprived of his

senses, and he was actually courageous enough to continue for some minutes commanding his company. At length he was conveyed to Larrey's ambulance, who amputated his arm: in about a month, the patient was well.

Larrey expresses his belief, that what have been erroneously termed *wind contusions*, if attended with the mischief above specified, require immediate amputation. The least delay makes the patient's preservation extremely doubtful. The internal injury of the member may be ascertained by the touch, by the loss of motion, by the little sensibility retained by the parts, which have been struck; and lastly, by practising an incision, as already recommended.

In order to confirm the principle which he endeavours to establish, in opposition to many writers, Larrey indulges himself with the following digression.

At the siege of Roses, two cannoniers, having nearly similar wounds, were brought from the trenches to the ambulance, which Baron Larrey had posted at the village of Palau. They had been struck by a large shot, which, towards the termination of its course, had grazed posteriorly both shoulders. In one, Larrey perceived a slight ecchymosis over all the back part of the trunk, without any apparent solution of continuity. Respiration hardly went on, and the man spit up a large quantity of frothy vermilion blood. The pulse was small and intermitting, and the extremities were cold. He died an hour after the accident, as Larrey had prognosticated. This gentleman opened the body in the presence of M. Dubois, inspector of the military hospitals of the army of the eastern Pyrenees. The skin was entire; the muscles, aponeuroses, nerves, and vessels of the shoulders were ruptured and lacerated, the scapulae broken in pieces, the spinous processes of the corresponding dorsal vertebræ, and the posterior extremity of the adjacent ribs fractured. The spinal marrow had suffered injury; the neighbouring part of the lungs was lacerated, and a considerable extravasation had taken place in each cavity of the chest.

The second cannonier died of similar symptoms, three quarters of an hour after his arrival at the hospital. On opening the body, the same sort of mischief was discovered as in the preceding example.

In the German campaigns of the French armies, Larrey met with several similar cases, and accurate examination has invariably convinced him of the direct action of a spherical body, propelled by means of gunpowder.

Sixth case. According to Baron Larrey, when the articular heads are much broken, especially those which form the joints of the foot, or knee, and the ligaments, which strengthen these articulations, are broken and lacerated by the fire of a howitzer or a grapeshot, or other kind of ball, immediate amputation is indispensable. The same indication would occur, were the ball lodged

in the thickness of the articular head of a bone, or were it so engaged in the joint, as not to admit of being extracted by simple and ordinary means. (See also Guthrie on *Gunshot Wounds*, p. 197.)

Fractures extending into the joints, and accompanied with great laceration of the ligaments, were cases of gunshot injuries pointed out by M. Faure, as indispensably requiring immediate amputation. (See *Prix de l'Acad. de Chir.* T. 8.) Thus we see, that this author was not so averse to early amputation as several modern writers have represented.

It is only in this manner that the patients can be rescued from the dreadful pain, the spasmodic affections, the violent convulsions, the acute fever, the considerable tension, and the general inflammation of the limb, which, Larrey observes, are the invariable consequences of bad fractures of the large joints. But, adds this author, if the voice of experience be not listened to, and amputation be deferred, the parts become disorganized, and the patient's life is put into imminent peril.

It is evident, says he, that, in this case, if we wish to prevent the patient from dying of the subsequent symptoms, amputation should be performed before twelve, or at most twenty-four hours, have elapsed: even M. Faure himself professed this opinion in regard to certain descriptions of injury. (*Mém. de Chir. Militaire*, T. 2.)

With respect to wounds of the knee, the sentiments of Mr. Guthrie nearly coincide with those of Larrey. "I most solemnly protest (says Mr. G.) I do not remember a case do well, in which I knew the articulating end of the femur, or tibia, to be fractured by a ball that passed through the joint, although I have tried great numbers, even to the last battle of Toulouse. I know that persons, wounded in this way, have lived; for, a recovery it cannot be called, where the limb is useless, bent backward, and a constant source of irritation and distress, after several months of acute suffering, to obtain even this partial security from impending death; but, if one case of recovery should take place in fifty, is it any sort of equivalent for the sacrifice of the other forty-nine? Or is the preserving of a limb of this kind an equivalent for the loss of one man?" (*On Gunshot Wounds*, p. 196.)

In the attack of the village of Merksam near Antwerp early in 1814, a soldier of the 95th regiment was brought to our field hospital, having received a musket-ball through the knee-joint. The staff surgeons on duty, and Mr. Curtis, surgeon of the 1st guards, were preparing to amputate the limb, when a surgeon, attached to the 95th, urgently recommended deferring the operation. Superficial dressings were applied, and the patient sent to the rear. He lived several months after the accident, at times affording hopes of a perfect recovery; but, in the end, he fell a victim to hectic symptoms.

Indeed, such is the general unfortunate

result of these cases, that, Dr. Hennen lays it down as a law of military surgery, that no lacerated joint, particularly the knee, ankle, or elbow, should ever leave the field unamputated, where the patient is not obviously sinking. (*On Military Surgery*, p. 41, Ed. 2.)

According to Mr. Guthrie, fractures of the patella, without injury of the other bones, admit of delay, provided the bone is not much splintered.

Seventh case. Larrey observes, that if a large biscayen, a small cannon-shot or a piece of a bomb-shell, in passing through the substance of a member, should have extensively denuded the bone, without breaking it, amputation is equally indicated, although the soft parts may not appear to have particularly suffered. Indeed, the violent concussion, produced by the accident, has shaken and disorganized all the parts; the medullary substance is injured, the vessels are lacerated, the nerves immoderately stretched, and thrown into a state of stupor; the muscles are deprived of their tone; and the circulation and sensibility in the limb are obstructed. Before we decide, however, Baron Larrey cautions us to observe attentively the symptoms, which characterize this kind of disorder. The case can be supposed to happen only in the leg, where the bone is very superficial, and merely covered at its anterior part with the skin.

The following are described as the symptoms: the limb is insensible, the foot cold as ice, the bone partly exposed, and on careful examination, it will be found that the integuments, and even the periosteum, are extensively detached from it. The commotion extends to a considerable distance; the functions of the body are disordered; and all the secretions experience a more or less palpable disturbance. The intellectual faculties are suspended, and the circulation is retarded. The pulse is small and concentrated; the countenance pale; and the eyes have a dull moist appearance. The patient feels such anxiety, that he cannot long remain in one posture, and requests, that his leg may be quickly taken off, as it incommodates him severely, and he experiences very acute pain in the knee. When all these characteristic symptoms are conjoined, says Larrey, we should not hesitate to amputate immediately: for, otherwise, the leg will be attacked with sphacelus, and the patient certainly perish.

Larrey adduces several interesting cases in support of the preceding observations.

Eighth case. When a large gynglimoid articulation, such as the elbow, or especially the knee, has been extensively opened with a cutting instrument, and blood is extravasated in the joint, Larrey deems immediate amputation necessary. In these cases, the synovial membranes, the ligaments and aponeurosis inflame, the part swells, and erethismus rapidly takes place; and acute pains, abscesses, deep sinuses, caries, febrile symptoms, and death, are the speedy consequences. Larrey has seen numerous sub-

jects die of such injuries, on account of the operation having been postponed through a hope of saving the limb. In his *Memoires de Chirurgie Militaire*, Tom. 2, some of these are detailed.

Although a wound may penetrate a joint, yet, if it be small and unattended with extravasation of blood, M. Larrey informs us, it will generally heal, provided too much compression be not employed. This gentleman believes in the common doctrine of the pernicious effect of the air on the cavities of the body; yet, in this place, a doubt seems to affect him: speaking of the less danger of small wounds of joints, he says; "*à quoi tient cette différence, puisque l'air pénètre dans l'articulation dans l'un comme dans l'autre cas?*"

When two limbs have been at the same time so injured, as to require amputation, we should not be afraid of amputating them both immediately, without any interval. We have, says Larrey, several times performed this double amputation, with almost as much success, as of the amputation of a single member. He has recorded an excellent case in confirmation of this statement. (*Mém. de Chir. Militaire*, T. 2, p. 478.)

When a limb is differently injured at the same time in two places, and one of the wounds requires amputation, (suppose a wound of the leg with a splintered fracture of the bone, and a second of the thigh, done with a ball, but without any fracture of the os femoris, or other bad accident) Larrey recommends us, first to dress the simple wound of the thigh, and amputate the leg immediately afterward, if the knee be free from injury. When it is necessary to amputate above this joint, the less important wound need not be dressed, till after the operation, provided it can be comprehended in the section of the member, or be so near the place of the incision as to alter the indication. When the wound, demanding amputation, is the upper one, the operation of course is to be done above it, without paying any regard to the injury situated lower down.

Ninth case. To the foregoing species of gunshot wounds, pointed out by Baron Larrey as urgently requiring immediate amputation, my own experience, and the observations of Dr. Thomson, justify me in adding compound fractures of the thigh from gunshot violence. I am particularly glad, that the latter gentleman has devoted a proper degree of attention to these cases, for, the opportunities which I had of judging when abroad, incline me to believe, that military surgeons are hardly yet sufficiently impressed with the propriety of immediate amputation in gunshot fractures of the thigh. There were brought into my hospital at Oudenbosch in 1814, about eight of such cases, all in the worst state for an operation, because several days had elapsed after the receipt of the injuries. All these patients died, excepting one, whose fracture was not far above the condyles, and I do not know, that he ever regained a very useful limb. An-

other had indeed been rescued by amputation from the dangers of the injury; but was unfortunately lost by secondary hemorrhage about three days after the operation. The bleeding was almost instantly suppressed; yet, such was the weakness of the patient, that the irritation of securing the vessel, and the loss of blood together destroyed at once every hope of recovery. Were I to judge, then, from my own personal observations in the army, and from some other cases, which I saw under my colleagues, I should without hesitation recommend immediate amputation in all cases of compound fractures of the thigh, caused by grape-shot, musket balls, &c. If there are any exceptions to this advice, they are such as are specified in the article *Amputation*.

"Gunshot fractures of the thigh (says Dr. J. Thomson) have been universally allowed to be attended with a high degree of danger; indeed, till of late years, very few instances have been recorded of recovery from these injuries. Ravaton acknowledges, that, in his long and extensive experience, he had never seen an example of recovery from a gunshot fracture of the thigh; and Bilguer, in his calculations, with regard to those, who recover from gunshot fractures, sets aside those of the thigh-bone, as being of a nature altogether hopeless. In the present improved state of military surgery, instances not unfrequently occur of recovery from this fracture: but, of these, the number will be found, I believe, to be exceedingly small, in comparison with those who die, particularly when the fracture has had its seat above the middle of the bone," &c.

According to the observation of Percy, scarcely two of ten recover of those, who have suffered gunshot fractures of the thigh-bone. Mr. Guthrie, who seems to have paid greater attention to this subject, than any preceding author, says, that "upon a review of the many cases, which I have seen, I do not believe, that more than one-sixth recovered, so as to have useful limbs; two-thirds of the whole died either with or without amputation; and the limbs of the remaining sixth, were not only nearly useless, but a cause of much uneasiness to them for the remainder of their lives." (See *Guthrie on Gunshot Wounds*, p. 19.)

"In fractures by musket bullets of the lower part of the thigh-bone (says Dr. Thomson) recovery not unfrequently takes place; and both Schmucker and Mr. Guthrie conceive, that they are injuries in which amputation may be delayed with safety. It would be very agreeable, that this opinion should be confirmed by future experience; but, it appears to me, that before it can be received as a maxim in military surgery, much more extensive and accurate observation, than we yet possess, will be required with regard to the proportion of those who recover without amputation, or after secondary operations, and of those who recover after primary amputation. Of those who had suffered this injury, we saw, comparatively, but a small number recover-

ing in Belgium, and they had been attended with severe local and constitutional symptoms." See *Report of Observations made in the Military Hospitals in Belgium*, p. 247, *et seq.*

In the article *Amputation*, I have described the manner in which balls produce fissures of several inches in length in the thigh-bone. This state of the bone, observes Dr. Thomson, must be very unfavourable to recovery, and his conclusion is, that, in general, even in fractures of the lower part of the thigh-bone a greater number of lives will be preserved, in military practice, by immediate amputation, than by attempting the cure without that operation. "When the bone appears on a careful examination, to be broken without being much splintered, and when the patient can be removed easily to a place of rest and safety, it may be right to attempt to preserve the limb; but if the bone be much splintered, or if the conveyance is to be long, or uncertain, it will, in most instances, I am convinced, be a much safer practice, even in fractures of this part of the thigh-bone, to amputate without delay.

"Musket bullets, in passing through the femur, near to the knee-joint, produce fissures of the condyles, which generally communicate with the joint. These cases, like those in which the bullets have passed directly through the joint, require immediate amputation.

"The writings of military surgeons contain but few histories of cases, in which the thigh bone had been fractured above its middle by the passage of musket bullets. These are cases, I believe, which have generally had a fatal termination; and the danger, attendant upon the amputation, which they require, seems long to have deterred surgeons from attempting to ascertain what advantages might be derived from the employment of that operation. Schmucker recommends, and states, that he had practised with success, immediate amputation in those cases, in which a sufficient space was left below the groin for the application of the tourniquet. It is curious to remark, in the history of amputation, how long surgeons were in discovering the ease and safety, with which the femoral artery may be compressed by the fingers, or pads, in its passage over the brim of the pelvis. Boy, from the immediate danger, protracted suffering, and ultimate want of success, which he had observed to follow this kind of injury, urges strenuously the propriety of immediate amputation: Mr. Guthrie's opinion, with regard to the dangerous nature of these injuries, and the advantages to be derived in them from immediate amputation, coincides in every respect with those of Schmucker and Boy. He observes, that, those whose thigh bone has been fractured in its upper part by a musket bullet, generally die with great suffering, before the end of the sixth, or eighth week; and that few even of those escape, in whom that bone has been fractured in its middle part. Of the few, whom

we saw, who had survived gunshot fractures in the upper part of the thigh-bone in Belgium, scarcely any one could be said to be in a favourable condition. In all, the limbs were much contracted, distorted, and swollen, and abscesses had formed round and in the neighbourhood of the fractured extremities of the bones. In some instances, these abscesses had extended down the thigh; but, more frequently, they passed upwards, and occupied the region of the hip-joint and buttocks. In several instances, in which incisions had been made for the evacuation of matter, the fractured and exfoliating extremities of the bones sometimes comminuted, and sometimes forming the whole cylinder, could be felt bare, rough, and extensively separated from the soft parts, which surrounded them. In other instances, these extremities were partially enclosed in depositions of new bone, which, from the quantity thrown out, seemed to be present in a morbid degree. It was obvious, that, in all of these cases, several months would be required for the reunion of the fractured extremities; that, in some, much pain and misery were still to be endured from the processes of suppuration, ulceration, exfoliation, and ejection of dead bone; that in some cases, the patients were incurring great danger from hectic fever, and from diarrhoea; that the ultimate recovery in most of them was doubtful, and that of those in whom this might take place, there was but little probability, that any would be able to use their limbs! The sight of these cases (says Dr. Thomson) made a deep impression upon my mind, and has tended to increase my conviction, that this is, of all others, the class of injuries, in which immediate amputation is most indispensably required." (See *Report of Observations made in the Military Hospitals in Belgium*, p. 254—258.)

Dr. Thomson adds, that what has been said of the danger of fractures, produced by musket bullets, in the upper part of the femur, is true in a still greater degree of those which have their seat in the neck or head of that bone. In such instances, Dr. Thomson joins the generality of modern army surgeons in strongly recommending amputation at the hip-joint; a subject, of which I have already spoken. (See *Amputation*.)

OF GUNSHOT WOUNDS, IN WHICH AMPUTATION MAY BE DEFERRED.

If, says Baron Larrey, it be possible to specify the cases, in which amputation ought to be immediately performed, it is impossible to determine *a priori* those, which will require the operation subsequently. One gunshot wound, for example, will be cured by ordinary treatment, while another, that is at first less severe, will afterward render amputation indispensable, whether this be owing to the patient's bad constitution, or the febrile complaints, which are induced. However this may be, the safe rule for fulfilling the indication, that presents itself, is

to amputate consecutively only in circumstances, in which every endeavour to save the limb is manifestly in vain. Upon this point, Larrey's doctrine differs from that of Faure.

The latter practitioner admits cases, which he terms cases of the *second kind*, in which he delays amputation, not with any hope of saving the limb, but in order to let the first symptoms subside. The operation, done between the fifteenth and twentieth day, appears to him less dangerous, than when performed immediately after the receipt of the injury. At the above period, according to M. Faure, the commotion, occasioned by the gunshot injury, is dispelled; the patient can reconcile himself to amputation, the mere mention of which fills the pusillanimous with terror in a greater or lesser degree; the debility of the individual is no objection; and it is laid down as an axiom "that the consequences of every amputation, done in the first instance, are in general extremely dangerous." In support of this theory, M. Faure adduces ten cases of gunshot injuries, in which, after the battle of Fontenoy, the operation was delayed, in order that it might afterward be performed with more success: a plan, which, according to the author, proved completely successful. (See *Prix de l'Acad. de Chirurgie*, Tom. 8, Edit. in 12mo.)

This division of the cases for amputation in two classes, not consistent with nature, Larrey conceives, has been the cause of a great deal of harm. Very often the partisans of M. Faure have not dared to resort in the first instance to amputation, the dangers of which they exaggerate; while on other occasions, they amputate consecutively without any success.

Larrey, after arguing that the effects of commotion, instead of increasing, gradually diminish and disappear after the operation, ventures into some hypothesis about the proximate cause of the ill effects of commotion, which, as being wild and unsatisfactory, I shall not here repeat.

Baron Larrey will not even admit, that the patient's alarm ought to be a reason for postponing the operation; because the patient, just after the accident, will be much less afraid of the risk, which he has to encounter, than at the expiration of the first four and twenty hours, when he has had time to reflect upon the consequences of the injury, or of amputation; a remark made by the illustrious Paré.

"Experience, agreeing with my theory, (says Baron Larrey) has proved both to the army and navy surgeons, that the bad symptoms which soon follow such gunshot injuries, as must occasion the loss of a limb, are much more to be dreaded, than those of immediate amputation. Out of a vast number of the wounded, who suffered amputation in the course of the first four and twenty hours after the memorable battle of the first of June, 1794, a very few lost their lives. This fact has been attested by several of our

colleagues, and especially by M. Fercoc, surgeon of the ship *le Jemmappe*.

The following is said to be an extract from one of his letters.

"After the naval engagement on the first of June, 1794, a great number of amputations were done immediately after the receipt of the injuries. Sixty of the patients, whose limbs had been thus cut off, were taken to the naval hospital at Brest, and put under the care of M. Duret. With the exception of two, who died of tetanus, all the rest were cured; and there was one, who had both his arms amputated. The surgeon of the *Téméraire*, which ship was captured by the English, was desirous, in compliance with the advice of their medical men, to defer the operation, which many of the wounded stood in need of, till his arrival in port; but, he had the mortification to see them all die during the passage, &c."

Larrey next acquaints us, that, when he was sent to the army of Italy, in 1796, he had also the pain of seeing, in the hospitals, great numbers of the wounded fall victims to the confidence, which many of the surgeons of that army placed in the principles of M. Faure. General Bonaparte saw that the *ambulance volante* was the only thing, that, in the event of fresh hostilities, could prevent such accidents; and, in consequence of his orders, Larrey formed the three divisions d'*ambulance* which are described in his *Mémoires de Chirurgie Militaire*.

Since this period it has always been customary in the French armies, on the day of battle, to make every preparation for performing amputation as speedily as possible. The mere sight of these *ambulances*, (always attached to the advanced guard,) says M. Larrey, encourages the soldiers, and inspires them with the greatest courage. On this occasion, the following anecdote is cited from Ambroise Paré.

This famous surgeon having been urgently sent for by the Duke de Guise besieged in Metz, to attend the wounded of his army, who were in want of assistance, Ambroise Paré was shown to the frightened soldiers at the breach. Upon this, they immediately filled the air with shouts of the most lively joy, and cried out: "*Nous ne pouvons plus mourir, s'il arrive que nous soyons blessés, puisque Paré est parmi nous.*" Their courage revived, and their confidence in this skilful surgeon, contributed to the preservation of a place, before which a formidable army was destroyed.

Larrey desires us to interrogate the invalids, who have lost one or two of their limbs, and nearly all will tell us, that they suffered amputation a few minutes after the accident, or in the first four and twenty hours.

"If Faure now retains any partisans," says Larrey, "I recommend them to repair to the field of battle, the day after an action; they would then soon be convinced, that, without the prompt performance of amputation, great number of soldiers must inevitably

lose their lives. In Egypt, this truth was particularly manifested."

The following communication upon this point was made to Baron Larrey by M. Masclet, a French surgeon on duty at Alexandria.

"In the naval hospital of this port, I have seen eleven soldiers, or sailors, who were wounded in the naval action off Aboukir, and who had suffered amputation in the first four and twenty hours. In five of these cases, the operation had been done on the arm; in two, on the thigh; and in three others on the leg. All these men are recovering. In the army hospital, there have been only three thigh amputations, which we performed seven or eight days after the battle, and these three patients died a few days after the operation, although the operation was done methodically, and no grave symptoms prevailed at the time of its performance. You see, sir, experience has, in this instance, quite confirmed your principles."

In 1780, during the American war, we are informed by Larrey, that the surgeons of the French army performed a great number of amputations, according to the opinion then generally adopted in France, that the operation should not be undertaken till after the subsidence of the first symptoms. Almost all the patients, thus treated, died after the operation. On the contrary, the Americans, who had the boldness to amputate immediately (or in the first twenty-four hours) upon many of their wounded countrymen, lost only a very few. Yet, M. Dubor, at that time surgeon to the Artois dragoons, and from whom Larrey has collected this fact, relates, that the situation of the hospital for the French wounded was, on many accounts, the most advantageous. (*Dubor These Inaugurale soutenue 16 Sept. 1803, à l'Ecole de Strasburg.*)

Admitting that, by a concurrence of fortunate circumstances, which are not always to be calculated upon, some patients escape the danger of the first symptoms, as Larrey remarks, this proves nothing in favour of doing the operation afterward: it must be seen what nature will do towards the event of the case.

If, at the end of twenty, or thirty days, the prognosis is as bad as it was previously, amputation cannot be avoided. Thus all the sufferings, which the patient has endured, have been undergone for nothing, and the operation will now be attended with considerable risk, inasmuch as the patient may lie in a dangerously weakened state.

If nature revives at all, no doubt the success of the operation becomes more probable; but, in this case, the surgeon, instead of having recourse to amputation, should redouble his efforts to preserve the limb.

CASES DEMANDING AMPUTATION CONSECUTIVELY.

Upon this subject Larrey gives us the annexed information.

First case. A spreading Mortification. If the disorder be owing to an internal and general cause, it would then be rashness in the surgeon to amputate before nature had put limits to the disease. Larrey describes this kind of gangrene, as being distinguished from that, which is named *traumatic*, by the symptoms which precede and accompany it. These symptoms are similar to those which are observed in nervous ataxia, or adynamia. Here the operation ought to be deferred, and endeavours made to combat the general causes with regimen and internal medicines.

But, when the gangrene is *traumatic*, Larrey advises the limb to be immediately cut off above the disorganized part. Several facts, in support of this doctrine, are related by this experienced surgeon in his *Mémoire sur la Gangrene Traumatique*. (See *Mortification*.)

In that part of the dictionary will be found several additional observations, in favour of the practice adopted and recommended by Larrey, which is so opposite to that inculcated by Sharp, Pott, and the generality of writers.

In the article *Amputation*, I have noticed a particular case of gangrene, which has been pointed out by Mr. Guthrie, as demanding the early performance of amputation, and a deviation from the old rule of waiting till the mortification has ceased to spread. (See *Guthrie on Gunshot Wounds of the Extremities*, p. 63, &c.)

Second case. Convulsions of the wounded Limb. It is one of Larrey's doctrines, (though of a very questionable description,) that amputation of the member, performed immediately the first symptoms of tetanus manifest themselves, interrupts all communication between the source of the disorder, and the rest of the body. He states, that the operation unloads the vessels, and thus puts a stop to the tension of the nerves, and to the convulsions of the muscles. These first effects, he says, are followed by a general collapse, which promotes the excretions, sleep, and the equilibrium of every part of the system. He argues, that the whole of the momentary pain caused by the operation, cannot increase the existing irritation: besides the sufferings of tetanus render those of amputation more bearable, and lessen their intensity, especially when the principal nerves of the limb are strongly compressed. Some observations will be made on this proposal in the article *Tetanus*.

Third case. Bad State of the discharge. It often happens, that in gunshot wounds, complicated with fractures, notwithstanding the most skilful treatment, the discharge becomes of a bad quality; the fragments of bone lie surrounded with the matter, and have not the least tendency to unite; the patient is attacked with hectic fever, and a colliquative diarrhoea. Under these circumstances, life may sometimes be preserved by amputation.

Fourth case. Bad State of the Stump. In hospitals, as Baron Larrey observes, the cure

of amputations is sometimes prevented by a fever of a bad character. The stump swells, the integuments become at first retracted, and then reverted and diseased a good way upward. The wound changes into a fungous ulcer, the cicatrization of which is hindered by the deep disorder of the bone, and the ulceration of the soft parts. The extremity of the bone projects. In order to remedy this last evil, it has been proposed to saw off the projecting part of the bone, and with this, even to amputate all the flesh beyond the level of the skin. Larrey condemns such practice, as unnecessary and dangerous, and he recommends giving nature time to effect the exfoliation of the diseased projecting part of the bone, and heal the wound. (See *Mémoires de Chir. Militaire*, T. 2.)

GUNSHOT WOUNDS OF THE ABDOMEN.

These cases may be divided into two kinds; one only penetrates the parietes of the belly, without hurting the contained parts; the other does mischief also to the viscera. The event of these kinds of wounds is very different. In the first, little danger is to be expected, if properly treated; but, in the second, the success will be extremely uncertain, for in many instances, nothing can be done for the patient, and on other occasions, a good deal of art may be employed with advantage.

It is observed by Mr. Hunter, that such wounds of the abdomen, as do not injure parts like the stomach, intestines, bladder, ureters, gall-bladder, large blood-vessels, &c. all which contain particular fluids, will generally end well. But he adds, that there will be a great difference, when the ball has passed with immense velocity, as a slough will be produced; whereas, when the ball has moved with less impetus, there will not be so much sloughing, and the parts will, in some degree heal by the first intention. Even when the ball occasions a slough, the wound frequently terminates well, the adhesive inflammation taking place on the peritoneum, all round the wound, so as to exclude the general cavity of the abdomen from taking part in the inflammation. Such is often the favourable event, when the ball, besides entering the abdomen, has wounded parts like the omentum, mesentery, &c. and gone quite through the body. (*Hunter on Inflammation; Gunshot Wounds*, &c. p. 543.)

In gunshot wounds of the belly, an extravasation is apt to take place on the sloughs becoming loose, about eight, ten, twelve, or fourteen days after the accident; but, says Mr. Hunter, although this new symptom is in general very disagreeable, most of the danger is usually over, before it can appear.

In the article *Wounds*, I have detailed at large the general principles, which should be observed in the treatment of wounds of the belly; consequently, it would be superfluous here to go over the whole of this extensive subject again. As a modern writer observes, "In their treatment, the violence

of symptoms is to be combated more by general means, than by any of the mechanical aids of surgery. The search for extraneous bodies, unless superficially situated, is altogether out of the question, except they can be felt by the probe, as in Ravaton's case, (*Chir. d'Armée*, p. 241,) or in other cases of lodgment in the bladder, where they may become the object of secondary operations. Enlargement, or contraction of the original wound, as the case may require, for returning the protruded intestine, securing the intestine itself, and promoting the adhesion of the parts, are all that the surgeon has to do in the way of operation; and even in this, the less he interferes the better. Nature makes wonderful exertions to relieve every injury inflicted upon her, and they are often surprisingly successful, if not injudiciously interfered with. In a penetrating wound of the abdomen, whether by gunshot, or by a cutting instrument, if no protrusion of intestine take place, (and this it must be observed, in musket or pistol wounds rarely occurs,) the lancet, with its powerful concomitants, abstinence and rest, particularly in the supine posture, are our chief dependence. Great pain and tension, which usually accompany these wounds, must be relieved by leeches to the abdomen, (if they can be procured) by topical application of fomentations, and the warm bath; and, if any internal medicine is given as a purgative, it must, for obvious reasons, be of the mildest nature. The removal of the ingesta, as a source of irritation, is best effected, by frequently-repeated oleaginous clysters: (see *Hennen's Principles of Military Surgery*, p. 401. Ed. 2.) and with respect to dressings, as the same author has observed, concerning cases, in which a ball has passed directly through the abdomen, the mildest applications should be employed, and no plugging with tents, nor introduction of medicated dressings thought of. (P. 406.) In this publication may be found cases, in which musket balls were passed by stool; (p. 404,) in which an artificial anus was formed; (p. 407, &c.) or the kidneys, liver, (p. 430—432,) diaphragm, (p. 437,) and other viscera, injured.

The following case exhibiting the possibility of recovery, though the small intestine be completely severed with a ball, is interesting, particularly as cases of this kind have been regarded as positively fatal. The success was also obtained, notwithstanding the treatment appears to have been rather too officious, especially in regard to four incisions made in the end of the bowel, when one would have removed the constriction spoken of.

At the assault of Cairo, 1799, M. N. was shot in the abdomen with a ball, which divided the muscular parietes of this cavity, on the right side, and a portion of the ileum. Larrey being upon the field of battle, gave him the first assistance. The two ends of the intestine protruded in a separated and inflated state. The upper end was everted, in such a way that its contracted edge, like the prepuce in a case of paraphymosis, strangula-

ted the intestinal tube. The course of the feces was thus obstructed, and the contents of the bowel accumulated above the constriction.

Although the patient's recovery was nearly hopeless, both from the nature of the wound, and from the debility and cholera morbus, which had already seized him in the short period that he remained without succour in one of the entrenchments, Larrey was desirous of trying what could be done for so singular a case. He first made four small cuts, through the constricted part of intestine, with a pair of curved scissors, and put the bowel into its ordinary state. He passed a ligature through the piece of the mesentery, corresponding to the two extremities of the bowel. These he reduced as far as the margin of the opening which he had taken care to dilate, and the dressings having been applied, he awaited events. The first days were attended with alarming symptoms, which, however, afterward subsided. Those which depended upon the loss of the alimentary matter, successively abated; and, after two months, the ends of the ileum were opposite to each other, and disposed to become connected together. Larrey seconded the efforts of nature, and dressed the patient with a tampon, or sort of tent, that was occasionally employed for two months. The patient was then discharged from the hospital quite cured.

In several instances, says Larrey, the sigmoid flexure of the colon was injured, and yet the wounds were cured without any fecal fistulæ. At the siege of Acre, three examples occurred; and at that of Cairo, two. Larrey dilated the entrance and exit of the ball. Clysters, made of the decoction of linseed, and emollient beverages were frequently exhibited; and the patients were kept on a low diet, and in the most quiet state.

Sword wounds, and those made with the bayonet, or lance, may injure some part of the bladder, or even pass through both sides of this organ. In the latter case, the injury is usually fatal, as the urine escapes from the inner wound into the abdomen, and immediately excites mortal inflammation. Baron Larrey dressed on the field of battle several soldiers, whose bladders were thus completely transfixed, and who all perished of inflammation and gangrene, within the first forty-eight hours. However, he observes, that if the weapon enter the bladder at that part of its fundus, which is not covered by the peritoneum, the case is curable, unless complicated with too much internal hemorrhage.

The surest criterion of these cases is the escape of the urine from the external wound; and its discharge may either be momentary, occasional, or continual; differences to be accounted for by the situation of the wound, and the changes which happen in the bladder. When the bladder is full, and its upper part is pierced, the urine will issue only just at the moment of the accident, and, as soon as it is discharged, the edges of the wound will come together, and permanently close, espe-

cially if the urine can pass freely through the natural channel. But when this favourable condition is absent, the bladder becomes enormously distended again, the wound is opened anew, and the urine discharged once more from the external opening. The same things might happen, if one were to withdraw too soon the elastic gum catheter, which has been introduced; and by introducing the instrument again, the urine might be diverted from the wound, and its natural course re-established. Lastly, Larrey observes, that when the wound is situated at one of the lowest points of the bladder, the discharge of urine may be incessant, and be of more or less duration.

When the track of these punctured wounds is extensive, and not direct, abscesses form at different points where the urine passes. These abscesses, Larrey directs to be immediately opened, and their recurrence prevented by the introduction of an elastic gum catheter through the urethra; one of the chief means of relief in all wounds of the bladder. Together with this treatment, he recommends the warm bath, the application of camphorated oily liniments to the belly, antispasmodic cooling medicines, frequent clysters, and sometimes cupping in the vicinity of the wound, or bleeding. (See *Mém. de Chir. Mil. T. 4, p. 286, 287.*) On the last means of relief, it would have been better if Larrey had laid more stress; for, next to the catheter, they are unquestionably the most essential.

Baron Larrey informs us, that the gunshot wounds of the bladder, which occurred in Egypt, had for the most part a favourable termination. The most remarkable case was that of F. Chaumette, a light horseman, who was wounded at the battle of Tabor. The ball passed across the hypogastrium, about one finger breadth above the pubes, to the point of the left buttock, which corresponds to the ischiatic notch. The direction of the wound and the issue of feces and urine from the two orifices left no doubt, that the bladder and rectum were injured. M. Milioz, who directed the surgical affairs of the division of the army under Kleber, diligently pursued the same kind of treatment which he had seen Larrey adopt at the siege of Acre. During the suppurative stage, the patient was affected with fever; and, after the sloughs were detached, the discharge was very copious. A catheter, that was passed into the bladder, prevented an extravasation of the urine, and at the same time, promoted the union of the wound of that viscus. This was healed the first, and the patient, upon his return to Cairo, was quite cured.

Larrey has recorded several other interesting cases of wounds, either of the bladder alone, or of it and the rectum together, to which I must content myself with referring. (See *Mém. de Chir. Militaire, T. 2, p. 160—165. T. 3, p. 340, &c. T. 4, p. 296, &c.*)

A ball may go through both sides of the bladder, and then either perforate the neigh-

bouring parts, and escape externally, or bury itself deeply in the flesh. When it has gone quite through the bladder, and afterward passed out of the body again, urine, blended with blood, immediately issues from one or both apertures, according to their situation. The flow of urine through the urethra is either lessened, or completely suppressed; but through this passage, the patient generally voids more or less blood. Acute and incessant pain is felt in the course of the wound, together with a frequent painful desire to make water, nausea, sometimes actual vomiting, and extreme anxiety, and restlessness. Either in its passage inwards, or its course outwards, the ball may have injured, or perforated the rectum, in which case, the urine passes into this bowel, and mixing with the feces, is discharged from the anus.

When a part of the bladder, towards the cavity of the abdomen, is injured, as for instance, its posterior surface which is covered by the peritoneum, the urine is generally extravasated within the belly, and inflammation of the preceding membrane is the immediate consequence. This inflammation spreads with rapidity, and attacks all the viscera, producing vast distention of the abdomen, fever, coma, and other bad symptoms, soon terminating in gangrene and death. (Larrey, *Mém. de Chir. Mil. T. 4, p. 292, 93.*)

During the first four and twenty hours, very little urine escapes from gunshot wounds of the bladder, in consequence of the swelling, which almost instantly affects the lips of the wound. When the bladder is full, this fluid is discharged only at the moment of the accident, and mostly only from the wound, by which the ball has made its exit. An extravasation is prevented by the thick slough, which fills all the track of the injury, and it is not till the deadened parts become loose, that any effusion can happen. Hence, it is of the highest importance to introduce an elastic gum catheter into the urethra, where it should be kept, and the instrument should be large enough to fill exactly this canal; for, according to Baron Larrey's observations, if at the period, when the sloughs are detached, the urine has not a ready passage outward, it passes through the wound, and is extravasated the more readily, inasmuch as the separation of the sloughs has occasionally many openings, by which the fluid may insinuate itself into the cellular membrane. Hence, gangrenous mischief and death.

On two points, my own experience would not lead me to join in the sentiments of Larrey: first, in opposition to his statement, I am sure, there is risk of extravasation of urine earlier than the period which he specifies, having known this accident commence as it were within a few hours after the receipt of the wound; and therefore, I should not depend upon the sloughs being always at first a complete barrier to extravasation of urine, (indeed, their formation throughout the whole track of a gunshot wound is by

no means a regular occurrence,) but invariably pass a catheter as soon as possible, for the more certain prevention of this dangerous consequence. Secondly, the period of the separation of sloughs may, indeed, often be contemporary with the first appearance, or symptoms of extravasation, particularly in cases where the employment of the catheter is for some time deferred, as in Baron Larrey's practice, because then a partial extravasation of the urine, soon after the injury, and previous to the introduction of the catheter, will cause rapid sloughing, and actually prevent the adhesive inflammation from closing up the cavities of the cellular membrane in time to prevent a fatal extension of that irritating fluid among the surrounding parts. Were it not for the partial early effusion of urine, no doubt the adhesive inflammation would, in these cases, soon have the same effect, in obviating the danger of urinary extravasation, which it has after lithotomy, or paracentesis of the bladder. (See *Bladder*.)

It is the practice of Baron Larrey to dilate the wounds, in order to facilitate the escape of the urine, which might otherwise lodge in the track of the ball; and perhaps, here the method may frequently be right, though I should conceive its propriety must usually depend upon whether the urine has a tendency to continue to flow out through the wounds, or not, and upon the presence of obstruction, or not. And in confirmation of this opinion, I may cite Dr. Hennen's declaration, that in these cases, he has very rarely found it necessary to enlarge the wound, when the catheter and proper dressings have been employed. (*On Military Surgery*, p. 421, Ed. 2.) And as soon as possible, a large elastic gum catheter should be introduced, and left in the urethra, taking care to withdraw it, and pass in a clean one every two or three days, so that no incrustations may occur. Sometimes, however, the passage of a catheter is very difficult, as is the case, when there are splinters of bone in the urethra, or the parts about the neck of the bladder are inflamed. (*Mém. de Chir. Militaire*, T. 4, p. 294.) Emollient clysters, and acidulated demulcent drinks are to be prescribed, and the patient is to be kept upon a very low regimen, and in the most quiet state. The dressings are to be light and simple, and cleanliness observed. (*Op. cit.* T. 2, p. 165—170.) Instead of camphorated embrocations to the abdomen, another means commended by Larrey, it appears to me, that this author's directions would have been more complete and judicious, had he advised in these cases bleeding, both topical and general.

From the injury of arterial ramifications, or varicose vessels, blood is sometimes extravasated within the wounded bladder, and causes deep-seated irritation. According to Baron Larrey, the case is indicated by the symptoms of retention of urine, and those of inflammation, with a small pulse, pallor of the countenance, and dryness of the wounds. (T. 4, p. 295.) A more decided

criterion, I should think, would be the partial escape of urine mixed with blood, a symptom, which could deceive only where the urethra itself had been injured. Larrey states that blood, extravasated in the bladder, rarely coagulates, because blended with urine, and hence, he advises its discharge to be facilitated by means of a catheter, and tepid, emollient, anodyne injections. (T. 4, p. 295.)

Sometimes balls carry before them into the bladder, fragments of bone, small coins, pieces of buttons, &c. or bits of bullets break off, and lodge in that viscus. When these extraneous bodies are not above a certain size, they are frequently voided through the urethra, (see *Cases in Dr. Hennen's Work*, p. 419, 422, 424, &c. Ed. 2.) and their evacuation may be materially facilitated by the introduction of an elastic gum catheter, the size of which is to be increased gradually, until the largest can be passed, when the foreign substances will readily enter the tube, or pass out through the dilated urethra. In this way, Baron Larrey has saved gravel patients from a vast deal of suffering. (*Mém. de Chir. Mil.* T. 4, p. 302.) When the ball is too large to be taken out in this manner, the lateral operation is to be performed, and it ought to be done before the bladder falls into an ulcerated, or gangrenous state from the pressure and irritation of the foreign body. However, as wounds of this organ frequently give rise to dangerous inflammation, Larrey recommends this operation, (and not that above the pubes, as is stated by mistake in Dr. Hennen's valuable book, p. 428, Ed. 2.) to be done either before its attack, or not till after its subsidence. (*Vol. cit.* p. 309.) In fact, almost all the operations of this kind on record have been done some considerable time after the receipt of the wound, and to this practice my own judgment would lead me to give a general preference. In one case, however Larrey operated on the fourth day after the receipt of the wound, and with success.

After the battle of Waterloo, I was not a little surprised to find in the St. Elizabeth hospital at Brussels, a considerable number of cases, in which either the intestines, the stomach, the omentum, or the bladder, protruded. I think we had in the division under Mr. Collier and myself, not less than three protrusions of the bladder. An order, which I received to join the army in the field on the 27th of June, deprived me of the opportunity of witnessing the progress and termination of these interesting cases. However, many had ended fatally before my departure from Brussels.

GUNSHOT WOUNDS OF THE THORAX.

Wounds of the lungs, abstracted from other mischief, are now well known not to be always fatal. Balls have been found in the substance of the lungs after having lodged there twenty years, during all which time the patients were healthy, and free from symptoms indicative of the case.

(*Percy, Manuel, &c. p. 25.*) Mr. Hunter had some reason to believe, that wounds of the lungs, made with balls, were generally less dangerous than such as were made with sharp-pointed instruments; for he had seen several patients recover after they had been shot through the lungs, while other persons died of very small wounds of those organs, done with swords and bayonets. Perhaps, one cause of this fact may be owing to the circumstance of gunshot wounds generally bleeding less than other wounds, so that there is not so much danger of blood being effused in the cavity of the chest, or the cells of the lungs. The indisposition of the orifice of a gunshot wound to heal up too soon, is also another circumstance that must lessen the hazard, as whatever matter happens to be extravasated has thereby an opportunity of escaping.

But from what has been stated, it must not be inferred, that gunshot wounds of the lungs are not accompanied with a serious degree of danger. Frequently the patient expires instantly, being suffocated in consequence of profuse hemorrhage from those organs; for though it be true, that gunshot wounds generally do not bleed much, when the injured vessels are under a certain size, yet the contrary is the case, when the wounded vessels are like those situated towards the root of the lungs. Gunshot wounds of the chest also often prove fatal by the inflammation that is excited within this cavity.

Appearances sometimes create a belief, that a ball has passed completely through the chest and lungs, when the fact is otherwise. "Thus (as Dr. Hennen observes,) I have traced a ball by dissection, passing into the cavity of the thorax, making the circuit of the lungs, penetrating nearly opposite to the point of entrance, and giving the appearance of the man having been shot fairly across, while bloody sputa seemed to prove the fact, and in reality, rendered the same measures, to a certain extent, as necessary as if the case had been what was suspected. The bloody sputa, however, were only secondary, and neither so active and alarming as those which pour out at once from the lungs when wounded." (*Military Surgery, p. 368, Ed. 2.*) A second cause of deception is the frequent long course of a ball, round the chest under the skin and muscles, previously to its exit, whereby an appearance is presented, as if the patient had been shot through the thorax. And another source of deception, as to the actual penetration of balls, is "where they strike against a handkerchief, linen, cloth, &c. and are drawn out unperceived in their folds, a peculiarity which has not escaped M. Larrey, who gives an interesting notice on it in the *Bulletins de la Faculté de Méd. Paris, 1815, No. 2.* I have also given an instance in the preceding pages." (*Hennen loco cit.*) In these cases, the absence of bloody expectoration directly after the injury, the undisturbed state of respiration, and the greater freedom from oppression, anxiety, syncope,

and other bad symptoms, than in cases where the lungs are hurt, form grounds for a correct opinion on the true nature of the accident.

It cannot be supposed, that adhesions always take place round the opening of a gunshot wound in the chest, because the lungs must sometimes collapse, and become considerably distant from the pleura, especially when the communication established between the atmospheric air and the cavity of the thorax is very free and direct. However, as adhesions are extremely common between the outer surface of the lungs, and the inner surface of the pleura costalis, they must, in many instances, exist before the receipt of a wound, and of course, prevent the usual collapse of the lungs.

As the general symptoms and treatment of wounds of the chest, are detailed in the article *Wounds*, I shall not here detain the reader long upon this subject. When a patient has been shot in the chest, the most important indication is to prevent and subdue inflammation of the lungs and pleura. In few other cases can repeated and large bleedings be so advantageously practised. Here there will not be so much danger of an extravasation of blood as in stabs, and even if an effusion of that fluid were to happen within the cavity of the pleura, the opening would generally be sufficient for its escape, and it would not be so frequently found necessary to dilate the wound, or make a new opening, as when the injury has been inflicted with a sharp-pointed weapon.

In this last kind of case, when attended in the beginning with bleeding, Baron Larrey particularly insists upon the advantage of immediately bringing the edges of the wound together with adhesive plaster, instead of leaving it open, as advised by the generality of writers; and he endeavours to prove, that this immediate closure of the wound has great effect in stopping the hemorrhage from the pulmonary vessels. Supposing an extravasation of blood in the chest were to follow, he argues that it would be better to let it out afterward by a suitable incision, than to suffer the patient to perish of hemorrhage at once, by not closing the wound. (*Mem. de Chir. Mil. T. 4, p. 151, &c.*) Dr. Hennen is in favour of the same practice. (*On Military Surgery, p. 373, Ed. 2.*) In a penetrating gunshot wound of the chest, after taking away from thirty to forty ounces of blood, the surgeon should extract all extraneous substances, and splinters of bone within reach, and even dilate the external wound for this purpose, if necessary. Light unirritating dressings are then to be applied. The patient may now be (comparatively speaking) easy, until the spitting of blood, and danger of suffocation, from inward hemorrhage, come on again, when the lancet must be again employed; "and if by this management, repeated as often as circumstances demand, the patient survives the first twelve hours, hopes may begin to be entertained of his recovering from the immediate effects of hemorrhage," and, until this danger is over,

as Dr. Hennen truly observes, the lancet is the only thing which can save life. Afterward, when the paroxysms of pain, the sense of suffocation, and the return of hemorrhage have become more moderate, digitalis may be prescribed with the most beneficial effect; and if the cough be very troublesome, no medicine is more useful than the spermaceti mixture with opium. With this treatment must be combined the exhibition of saline purgatives, mild laxative clysters, and a strictly low diet, the patient being allowed only slops. (See *Hennen's Military Surgery*, p. 373. Ed. 2.)

When matter forms in the thorax, in consequence of gunshot wounds, the opening will generally suffice for its escape; but should the collection of pus be confined, and occasion dangerous symptoms, the external wound must either be enlarged, or a new incision practised, according as circumstances may indicate. The mode of making an opening into the chest is considered in the article *Paracentesis*.

When a ball lodges, without falling into the chest, it may lie either in the substance of the parietes of this cavity between the muscles, or in one of the intercostal spaces, and continue there a very long time without causing much inconvenience, or making its way outward. But when it is lodged in the thoracic cavity itself, it descends by its weight, and sometimes excites considerable irritation, suppuration, sinuses, and hectic symptoms: in this case, if its situation can be ascertained, Baron Larrey recommends an attempt to extract it. In an early stage of the case, he says, that the intercostal space will often be wide enough to let the ball pass through it; but that, at a later period, this space becomes too narrow, and it will be necessary to cut away a portion of the upper edge of the rib with a lenticular knife, which is to be preferred to a trephine, or saw. This advice is supported by some very interesting cases. (See *Mem. de Chir. Mil.* T. 4, p. 253.) Frequently the ball fractures the rib, and with the aid of dilatation, sufficient room for its extraction may be made; but the possibility and propriety of removing it through the original opening will, of course, depend upon the situation of the foreign body, and the urgency of the symptoms. A case is recorded, in which a ball, weighing three ounces and a half, was thus removed. (*Med. and Surg. Journ.* Vol. 3, p. 353.)

GUTTA SERENA. A term said to have been first applied by Actuarius to amaurosis, or the species of blindness arising from a morbid state of the retina, or optic nerve. (See *Amaurosis*.)

In the present place, I mean first briefly to advert to a case, which the late Mr. Ware has described as combined with a particular kind of ophthalmia, that occasions excruciating pain, and requires peculiar treatment. One example of this kind was greatly relieved by a puncture, made through the tunica sclerótica into the ball of the eye with a grooved needle, somewhat larger than a common sized couching needle, nearly in the part where this instrument is introduced in the operation of depressing the cataract. Through the groove of the instrument, a watery fluid immediately issued, which was not unlike that which Mr. Ware several times found, after death, effused between the choroid coat and retina, in cases of gutta serena. After the pain of the operation had ceased, the patient became quite easy, and the inflammation soon subsided. Mr. Ware afterward performed a similar operation in a considerable number of resembling instances, and in several of them the proceeding was attended with almost immediate good effect. (See *Ware on the operation of largely puncturing the capsule of the crystalline humour, &c. and on the Gutta Serena, accompanied with pain and inflammation, 1812.*)

Under the head of gutta serena, I promised to notice Beer's opinions concerning amaurotic remedies, which, whether employed upon rational or upon empirical principles, he divides into two classes, viz. *general*, or *internal* means; and *local*, or *external*. Sometimes only the first are requisite; more rarely only the second; but frequently both together.

Amongst the internal remedies are eme-

tics, which may be useful in two ways, either as real evacuates, or as nauseating means. It is the opinion of Professor Beer, that for the purpose of exciting actual vomiting, they should be exhibited only when the stomach is foul, and no considerable plethora exists; and he deems them improper whenever a great determination of blood to the head and eyes prevails, or any increased velocity of the circulation. Should the surgeon find it necessary to employ emetic medicines, simply as alteratives, he must consider well whether the digestive organs will bear their great and long-continued operation. (*Lehre von den Augenkr. B. 2, p. 463.*) Notwithstanding the favourable accounts given by Schmucker, Richter, and Scarpa, of the good effects of emetics in many cases of amaurosis abroad, this treatment has had but little success in England. Mr. Travers even declares that he does not recollect an instance of decided benefit from the emetic practice, although he has often fairly tried it. "The cases of gastric disorder, to which it is especially applicable, are most benefited by a long-continued course of the blue pill, with gentle saline purgatives and tonic bitters." (*Synopsis of the Diseases of the Eye, p. 304.*)

When the bowels are loaded, and there is frequent determination of blood to the head and eyes, and an accelerated circulation, and particularly if, after these effects, the sight is always manifestly worse, brisk purgatives may be prescribed. When, however, constipation has prevailed for a long time, drastic purgatives should not be exhibited before one or two loose motions have been procured with laxative clysters. Gentle aperients are more particularly indicated when the patient does not have a stool daily, and the evacuation is never made with ease, nor without considerable straining; when he often passes two or three days without any evacuation at all, circumstances sure to be followed by repeated determination of blood to the head and eyes, and other ill consequences, which, according to Beer, have a very prejudicial effect on amaurosis.

Beer is of opinion, that diaphoretics should be employed with great caution, because they are apt to bring on violent determinations of blood, and an accelerated state of the circulation; and they can only be employed with judgment, and a hope of benefit, when there are good grounds for believing that a previous stoppage of the cutaneous functions has had a real share in producing, or keeping up, the blindness. They are still more strongly indicated, when the cessation of those functions is, in some measure, evinced by the dry state of the integuments, wandering pains between the skin and muscles, and considerable melioration of the eyesight after the breaking out of any accidental perspiration. (*B. 2, p. 465.*)

Professor Beer thinks, that in amaurosis medicines for promoting the menstrual discharge are too often employed on empirical principles, to the serious detriment of the

patient, the cessation of this discharge being mostly regarded as the cause of the amaurosis, while, in reality, it is very seldom really so, both affections being dependent upon one and the same cause. Hence much circumspection, and the closest investigation, are necessary to trace the connexion between these morbid effects, and to ascertain when such medicines can be given without risk.

Still greater mischief results from the treatment of amaurotic children with anthelmintics; nay, Beer assures us, that he has seen numerous amaurotic boys and girls thus wrongly treated, who had not the slightest symptom of worms. However, when amaurosis is unattended with any leading indications, anthelmintics may be tried, for they are less injurious to the eyes than many other medicines, though, as they consist of drastic purgative means, they must soon occasion great debility.

According to Beer, when there is good ground for suspecting any thing syphilitic about the patient, mercurials may be given with great prospect of benefit. Also, when no suspicion of this kind can be entertained, but amaurosis is accompanied with infarction of the abdominal viscera, especially a manifest chronic disease of the liver, or serious chronic swellings and indurations of the glands, a periodical headach, of no determinate character in other respects, and aggravation of the blindness after every such attack, mercurial preparations, as Beer can assert from manifold observation, are productive of the best effects upon the disease of the eyes. Yet, says he, under these circumstances, mercury should never be exhibited where the individuals are of a debilitated scorbutic diathesis, or subject to bleedings, and more particularly where there is the least mark of a dissolution of the vitreous humour. (*Lehre von den Augenkr. B. 2, p. 466.*) Upon the whole, from what I am able to learn of the practice in London, mercury is more extensively and successfully used, as a remedy for amaurosis, than any other medicine in the whole pharmacopœia. "When the amaurosis is recent and sudden, (says Mr. Travers) and either the signs of an obscure inflammation are present, or only the amplitude and inactivity of the pupil correspond to the patient's history—mercury should be introduced with all convenient rapidity into the system, I mean so as to ruffle it in the least possible degree. No advantage is obtained by salivation; on the contrary, I think it hurtful: when mercury is beneficial, its efficacy is perceived as soon as the mouth is sore." (*Synopsis of the Diseases of the Eye, p. 305.*)

Anti-nervous medicines have, at all times, ranked very high, on empirical principles, as means for the cure of amaurosis; but, how often is this disease not simply a nervous affection? Beer divides the medicines of this sort, employed in cases of amaurosis, into three classes, namely, *antiparalytic, antispasmodic, and tonic.* To the first class be-

long *arnica, naphtha, camphor, millepedes, sulphur auratum antimonii, liquor ammoniæ lavendulatus, pulsatilla, black hellebore, and phosphorus.* These medicines can be safely given to amaurotic patients, when an evident general nervous debility, and morbid irritability prevail, without any other particular appearances of disease, and especially when, at the same time, there are genuine paralytic appearances in the eye itself, or in the parts immediately surrounding it, or not very far from it. Among the *antispasmodic* remedies, particularly when used on empirical principles, Beer has found the most efficacious to be *valerian, liquor ammoniæ carbonatis, assafœtida, opium, hyosciamus, castoreum, musk, flores zinci, and extract of chamomile.* Tonic nervous remedies, says Beer, are to be used with more caution; for bitter medicines, when injudiciously prescribed for nervous debilitated individuals, rather promote the formation of amaurosis. When *calamus aromaticus* is in question, care must be taken that there be no tendency to pectoral complaints, which this medicine is too apt to bring on in weak subjects, in which event the sight is always very much impaired by it. In costive habits, bark is likewise apt to render the blindness worse. And according to the same experienced oculist, it is necessary to be very circumspect with steel medicines, empirically prescribed, as they frequently occasion determinations of blood to the head and eyes, and quicken the circulation, whereby every remnant of vision may be abolished. Steel medicines do the greatest and quickest injury to amaurotic eyes, when combined with narcotics. Above all things, it is generally prudent, in cases of amaurosis, carefully to abstain from all the stronger and long-operating nervous medicines, whenever plethora, determinations of blood, and tendency to inflammation exist. (*Lehre von den Augenkr. B. 2, p. 467.*) In this country, I do not believe that antinervous and antispasmodic medicines have obtained credit for their efficacy in this disease. Thus, Mr. Travers states, that he has never known any real benefit derived from camphor, assafœtida, valerian, &c. though he has seen much good derived from tonics, the mineral acids, bark, steel, and arsenic, after a due regulation of the digestive functions. (*Synopsis, &c. p. 304.*) In *arnica montana, aconite, euphrasia, and stimulants* in general, he has no confidence.

Local, or external medicines, for amaurosis, are divided by Beer into two classes, namely, into those which are applied to parts more or less distant from the eyes, and having some sympathetic connexion with these organs; and into others, which are usually put upon the eye itself.

In the first class bleeding has obtained high repute, either by venesection in the common way, the application of leeches to the pudenda, the arms, behind the ears, or upon the temple; cupping the back, or by opening the temporal artery or jugular vein. Bleeding is indicated when manifest ple-

thora, a determination of blood to the head and eyes, or an accelerated circulation, is combined with a considerable decrease of vision; when the menses are nearly or quite suppressed in plethoric subjects; a manifest determination of blood to the parts of generation prevails; or the same thing occurs in hemorrhoidal patients. (*Beer, Lehre, &c. p. 469.*)

According to Mr. Travers, all the cases of direct debility, and proper paralysis of the optic nerve, are aggravated by loss of blood. (*Synopsis, &c. p. 303.*)

Professor Beer gives his testimony also, in favour of the efficacy of such applications as produce a counter-irritation, not merely as rubefacients, but as means occasioning an evacuation of lymph; such are blisters, sinapisms, laid on the back or calves of the legs, vesication by means of the bark of mezezon, issues, and setons. These means are proper when the blindness is attended with continual, but wandering pains in the aponeurotic covering of the head, or in the vicinity of the eye, with a whizzing noise and irritating pain in the ear, or with the suppression of a purulent discharge from the meatus auditorius. In such cases, however, there must be no particular plethora, still less any determination of blood to the head and eyes. Here should also be mentioned friction with antimonial ointment, which is especially indicated where there is reason to believe, that the amaurosis has been preceded, and partly produced, by a long interruption of the cutaneous secretion.

Formerly, according to Beer, clysters were too commonly employed in cases of amaurosis; for whenever the cause of the disease was not understood, it was usual to refer it to a morbid state of the abdominal viscera. At present, clysters in amaurotic cases are employed quite empirically, as stimulants to the intestinal canal, and evacuates, when the loaded state of the bowels and obstinate constipation require them, and when the scantiness and difficulty of the evacuations keep up a constant determination of blood to the head and eyes, and when perhaps for other reasons, common purgative medicines cannot be employed. Beer says that aperient clysters are attended with the most decided good effects in that amaurotic-weakness of sight, which sometimes occurs towards the end of pregnancy, and is combined with obstinate constipation, continual headach, evident determination of blood to the head and eyes, and such an inflammatory diathesis as cannot be mistaken. On the other hand, the employment of clysters as anodyne remedies, not as evacuates, is principally useful in hypochondriacal and hysterical amaurotic patients, when they are troubled with much general cramp, and spasms in the abdomen. (*Vol. cit. p. 470.*)

According to the statements of the same writer, baths, whether warm or cold, adapted for the whole body, or in the form of a slipper-bath, a pediluvium, or effusion, have hitherto not proved very efficacious empiri-

cal remedies for amaurosis, and this, whether they consist of simple water, or aromatic decoctions, or of waters impregnated with sulphur or iron. The reason why baths in general are less frequently employed as empirical remedies in cases of amaurosis, and why they are still more rarely successful, may be, because in the very cases of amaurosis, in which baths of various kinds are clearly indicated, the greatest attention must be paid to the patient's constitution, to the state of the skin especially, and to the temperature of the fluid employed; for, in a healthy subject, too warm a bath may, under certain circumstances, (as for instance when there is plethora,) of itself occasion a serious aromatic amblyopia; and therefore, under similar circumstances, must be likely to increase any present amaurotic weakness of sight into complete blindness. In general warm whole, or slipper, baths must be employed as empirical remedies in amaurosis only when the regular action of the skin is disturbed, without febrile symptoms, when the affection of the eyes has been preceded by the sudden stoppage of a profuse perspiration; or some cutaneous effluence is coexistent with the amaurosis. On the contrary, pediluvia with salt, mustard, &c. are chiefly proper when amaurosis is accompanied with a determination of blood to the head and eyes, or any local inflammations, after which the eyesight is always found to be worse. In cases of amaurosis affusion can be seldom used empirically, and only under those circumstances where modern experience has proved the shower bath to be allowable. Cold bathing generally agrees badly with an amaurotic patient, and when his skin is extremely sensible, when wandering pains are felt between the integuments and muscles, or there is a tendency to erysipelatous inflammation, the power of vision evidently declines after every trial of the plan. But, according to Beer, mineral waters, impregnated with iron, in the form either of a bath for one half, or for the whole of the body, generally produce, under these circumstances, the most favourable effects upon the skin, and through the medium of it, upon the diseased eye. The case, however, is to be excepted where flying rheumatic, and perhaps gouty pains constantly tease the patient, unaccompanied with fever, and where bathing of the whole body in sulphurous mineral water should be preferred. (*Lehre von den Augenkr. B. 2, p. 471, 472.*)

If we are to believe Beer, the empirical employment of applications, which have the effect of increasing the secretion of mucus, is very seldom proper, such as irritating gargles, the smoking of tobacco, and sternutatory powders; for these means can only be adopted with any prospect of benefit when amaurosis is accompanied with plethora, a sense of spasm and weight about the frontal sinuses, an incessant obtuse heaviness at the bridge of the nose, and unusual dryness of the nostril, in an individual, who has frequently suffered catarrhal complaints, but

some time previously to the origin of the amaurotic symptoms has continued nearly, or quite free from colds; and when the patient has no tendency to plethora, determination of blood to the head and eyes, and acceleration of the circulation. (*Vol. cit. p. 473.*)

The application of sternutative powders to the nostrils is, perhaps, to be regarded as a mode of treatment, established on empirical principles, unless we can place confidence in the statement of Schmucker, Richter, and Beer, that an unusual dryness of the mucous membrane of the nose, following tedious and severe catarrhs, may have the effect of inducing amaurosis. The snuff employed by Schmucker, is thus composed: *R. Mercur. viv. 3j. Sacchar. alb. 3ij, Lill. Alb. Rad. Valerian. aa 3j. Misce.*

The late Mr. Ware imputed considerable efficacy to electricity and a mercurial snuff in cases of gutta serena. The snuff was compounded of ten grains of turbith mineral (*hydrargyrus sulphuratus*) well mixed, with about a dram of the pulvis sternutatorius, glycirrhiza, or common sugar. A small pinch of this snuff, taken up the nose, is found to stimulate it very considerably—sometimes exciting sneezing, but, in general, producing a very large discharge of mucus. (See *Chir. Obs. relative to the Eye, Vol. 1.*)

Among the remedies, which, in cases of amaurosis, are intended to be applied directly to the eye, and its surrounding parts, local bleeding merits the first rank. The extraction of blood, by means of leeches, is the only mode in which the practice can here be executed. The method, however, is only proper when manifest turgescence of the vessels of the conjunctiva and sclerotica is combined with a feeling of constant pressure about the eye, a sense of fulness and tension in the ball, and evident plethora, without any local inflammations or increase in the velocity of the circulation.

Experience proves also, says Beer, that the empirical application of rubefacients, or drawing plasters, to the temples, or eyebrows, is fraught with not less efficacy, when all sensibility in the retina appears to be extinguished, without any defect in the texture of the eye, any varicose dilatation of its blood-vessels, or any particular determination of blood to it. Applications, producing an evacuation of lymph, including both blisters and antimonial ointment, may be alternately employed upon the eyelids and temples, when there are grounds for believing, that the functions of the skin have already been long suspended by porrigo, or the stoppage of perspiration on the forehead. (*Beer, Lehre von der Augenkr. B. 2, p. 474.*)

As in the rational plan of treatment, the rubbing of fluid, pungent, or irritating medicines upon the eyebrows, in certain kinds of amaurotic blindness, is often attended with considerable efficacy; so, in Beer's opinion, it should not be neglected in cases where the surgeon is compelled to have re-

course to empirical methods of cure; for instance, where it is observable, that generally in the evening, or the shade, the eyesight immediately grows weaker; that, on the patient's first awaking in the morning, it is weaker than in the middle of the day; and what particularly merits notice, while the case is unattended with any sensations of imaginary flashes of light; a very feeble, or entirely abolished motion of the iris; not the least vestige of any defect in the structure of the eye; and no symptoms of determination of blood to the head and eyes, or of a general tendency to inflammation. Beer recommends pungent applications to be first tried; such as the spiritus aromaticus, balsamus vitæ Hoffmanni, or Cologne water. These may be followed by aqueous substances, naphtha, &c. then by narcotics, like the tincture of opium, and lastly, by irritating remedies, like the tinctura lyttæ. Fluid applications, which are applied in the form of vapour to the eye, demand greater circumspection, like naphtha, the liquor ammoniæ, &c. These may be best applied by putting a small quantity of them into the hand, over which the eye must be held in such a manner that none of the fluid will come into contact with it. But as soon as the eye begins to be irritated by the vapour, the tears to run, or actual pain is felt, the hand is to be removed, lest too much irritation be produced. (*Beer, Vol. cit. p. 475.*)

Not only in the empirical, but also in every scientific mode of treating amaurosis, says this author, such remedies, as are intended to produce a shock upon the nerves and vessels, require the utmost caution, because, of all the various classes of remedies, they are the most powerful; and consequently, if misapplied, are likely to convert an amaurotic weakness of sight into complete blindness. This mournful event is most rapidly produced, when applications of this description are employed in plethoric subjects, affected with partial determinations of blood and local inflammations, a varicose state of the blood-vessels of the eye, defects in the transparent media of that organ, or frequent headach. To this class of remedies belong especially the shower bath, electricity, galvanism, &c. On the empirical plan they can only be used with safety or advantage, when decided marks of paralysis, either in the amaurotic eye or its appendages, are present. (*Lehre von den Augenkr. B. 2, p. 477.*)

Mr. Ware has observed, that the pupil has been generally dilated in the cases benefited by electricity. He notices, however, that there are many instances, in which a contraction of the pupil is the only change which takes place in the appearance of the eye. In this sort of case, the impairment of sight is usually preceded by severe pain, and the original cause may be an internal ophthalmia of long continuance. The crystalline is sometimes visibly opaque. Here electricity has been found useful; but Mr. Ware states, that in these instances, the sublimate

has proved superiorly and more certainly efficacious, and, consequently, he prefers it to all external applications whatever. He recommends one-fourth of a grain, as a quantity proper for a common dose, and says, that it agrees best with the stomach when first dissolved, as Van Swieten directs, in half an ounce of brandy, and taken in a basin of sago or gruel. For young patients the dose must be diminished in proportion to their youth. The medicine is to be continued as uninterruptedly as the constitution will allow, for a month, six weeks, or even longer.

Electricity is said to have proved more strikingly useful, in cases of amaurosis, originating from lightning, than when the disease has arisen from any other cause. Mr. Ware relates a most interesting instance of the success of electricity, in a case which came on very suddenly, after great pain in the teeth, and a swelling of the face, had gone off. The disorder came on more suddenly; the temporary blindness was more entire; the eyelids were more affected, and the cure more speedy, than in the instances related by Mr. Hey, in the 5th Vol. of the *Med. Obs. and Inq.* (*Chir. Observ. relative to the Eye, by J. Ware, Vol. 1.*) However, the amaurosis produced by lightning may also be sometimes cured in other ways. Mr. Wardrop mentions that he has only seen one case of this kind, and the sight was restored by the repeated application of small blisters over the frontal nerve. (*Essays on the Morbid Anatomy of the Human Eye, Vol. 2, p. 173.*)

With the exception of one case related by Valsalva, Scarpa was unacquainted with any instance of amaurosis, arising from a wound of the eyebrow, that was relieved, and he has, therefore, set down this species as incurable. The opinion, however, is not perhaps correct, for the first case related by Mr. Hey arose from this cause, and was cured by giving every night the following dose: *R. Calomel. pp Camphor. aa iij. Conserv. Cynosb. q. s. probe misceant et f. Bolus*, in conjunction with electricity. The lady, however, had been previously bled twice, had taken some nervous medicines, and had had a blister between the shoulders. The patient was first set upon a stool with glass

feet, and had sparks drawn from the eyes, and parts surrounding the orbits, especially, where the superciliary, and infra-orbitary branches of the fifth pair of nerves spread themselves. After this operation had been continued half an hour, she was made to receive, for an equal time, slight shocks through the affected parts. In a few days sight began to return, and in less than three months it was quite restored:—In another case, one grain of calomel, and two of camphor, given every night, and the employment of electricity, effected a cure. The disease had come on gradually, without any previous accident, or pains in the head. The patient a boy nine years old.

There are several other very interesting cases of amaurosis related by Mr. Hey, all of which make electricity appear an efficacious remedy, though it is true, as Scarpa observes, that in most of these instances, internal medicines were also given, and bleeding occasionally practised. Mr. Hey attributes the benefit chiefly to the electricity, because, in two of his cases, no medicines were used, yet the progress of the amendment seemed to be as speedy in them, as in the rest, and in two instances, a degree of sight was obtained by the first application of electricity. At present, I think electricity and galvanism, as means of benefiting amaurosis, are now less valued in England than on the continent: Mr. Travers states, that he has had recourse to them in many cases, some of which were of a very favourable description, but he never saw any good produced by them. (*Synopsis of the Diseases of the Eye, p. 303.*)

How far, however, the statements of Beer, Ware, &c. about the efficacy of local applications can be trusted, is yet a question; for they disagree with reports made by other writers. Thus, with the exception of cupping, issues, setons, and particularly blisters, Mr. Travers declares, that his experience leads him to attach no value to the various forms of external remedies. (*Synopsis, &c. p. 30, 8vo. Lond. 1820.*)

In Dr. Vetch's *Practical Treatise on Diseases of the Eye*, 8vo. Lond. 1820, a work published since the article *Amaurosis* in this Dictionary was printed, the reader will find a chapter on this disease worthy of his attention. (See p. 133, &c.)

H.

HÆMATOCELE, (from *αιμα*, blood, and *κελη*, a tumour. This is a swelling of the scrotum, or spermatic cord, proceeding from, or caused by, blood.

According to Mr. Pott, when the tunica vaginalis has been long, or much distended, "it becomes thick and tough; and the vessels (especially those of its inner surface) are sometimes so large as to be very visible, and even varicose. If one of these lies in the way of the instrument, wherewith the palliative cure is performed, it is sometimes wounded; in which case the first part of the

serum which is discharged, is pretty deeply tinged with blood.

"Upon the collapsion of the membranes, and of the empty bag, this kind of hemorrhage generally ceases, and nothing more comes of it. But it sometimes happens, either from the toughness of the tunic, or from the varicose state of the vessel, that the wound (especially if made by a lancet) does not immediately unite; but continues to discharge blood into the cavity of the said tunic, thereby producing a new tumour, and a fresh necessity of operation."

This is what Mr. Pott calls the first species of hæmatocele, which evidently proceeds from a wound of a vessel of the vaginal tunic.

"Upon the sudden discharge of the fluid, from the bag of an over-stretched hydrocele, and thereby removing all counter-pressure against the sides of the vessels, some of which are become varicous, one of them will, sometimes without having been wounded, burst; (hence, the last running of the water from a hydrocele is often bloody.) If the quantity of blood, shed from the vessel so burst be small, it is soon absorbed again; and creating no trouble, the thing is not known. But if the quantity be considerable, it, like the preceding, occasions a new tumour, and calls for a repetition of the operation." This, Mr. Pott calls the second species: "which, like the first, belongs entirely to the vaginal coat, and has no concern either with the testicle, or with the spermatic vessels. In both, the bag which was full of water, becomes in a short space of time distended with blood; which blood, if not carried off by absorption, must be discharged by opening the containing cyst: but in neither of these can castration (though said to be the only remedy) be ever necessary: the mere division of the sacculus, and the application of dry lint to its inside, will, in general, if not always, restrain the hemorrhage, and answer every purpose, for which so severe a remedy has been prescribed." With respect to filling the cavity of the tunica vaginalis with lint, I believe few good surgeons of the present day would consider the measure at all necessary or proper. I have seen three or four cases of hæmatocele of the above kind laid open, but never knew the surgeon compelled by the bleeding to cram the tunica vaginalis with lint to the great irritation and injury of the testicle itself. On the contrary, after taking out the blood, letting the parts collapse, and applying the cold *lotio plumbi acetatis*, for a few hours to the scrotum, by means of linen wet with the application, they substituted for the lotion an emollient poultice, and had recourse to fomentations, saline purgatives, leeches, and even venesection, according to circumstances.

The next example, pretended by Pott and Richter, to be a form of hæmatocele, is not admitted by Richerand, Jourdan, (See *Dict. des Sciences Méd. T. 20, p. 126.*) and other modern surgeons.

"If," says Mr. Pott, "blood be extravasated within the tunica albuginea, or proper coat of the testicle, in consequence of a great relaxation, and (as it were) dissolution of part of the vascular compages of that gland, and the quantity be considerable, it will afford or produce a fluctuation, to the hand of an examiner, very like to that of an hydrocele of the tunica vaginalis; allowing something for the different density of the different fluids, and the greater depth of the former from the surface.

"If this be mistaken for a simple hydrocele, and an opening be made, the discharge

will be blood, not fluid, or very thin; not like to blood circulating through its proper vessels; but dark and dusky in colour, and nearly of the consistence of thin chocolate (like to what is most frequently found in the imperforate vagina.) The quantity discharged will be much smaller than was expected from the size of the tumour; which size will not be considerably diminished. When this small quantity of blood has been so drawn off, the testicle will, upon examination, be found to be much larger than it ought to be; as well as much more loose and flabby; instead of that roundness and resistance arising from an healthy state of the gland, within its firm strong coat, it is soft, and capable of being compressed almost flat, and that generally without any of that pain and uneasiness, which always attend the compression of a sound testicle. If the bleeding ceases upon the withdrawing the cannula (supposing a trocar to have been used) and the puncture closes, a fresh accumulation of the same kind of fluid is soon made, and the same degree of tumefaction is produced, as before the operation: if the orifice does not close, the hemorrhage continues, and very soon becomes alarming.

In the two first species, "the blood comes from the tunica vaginalis, the testis itself being safe and unconcerned; and the remedy is found, by opening the cavity of the said tunic; but in this the hemorrhage comes from the substance of the testicle: from the convolutions of the spermatic artery, within the tunica albuginea: the division of the vaginal coat can here do no good; and an incision made into the albuginea can only increase the mischief: the testicle is spoiled or rendered useless, by that kind of alteration made in it, previous to the extravasation; and castration is the only cure which a patient in such circumstances can depend upon."

I confess, that no good reason appears for arranging cases of the preceding kind with hæmatocele; for, what are they but diseased testicles? which have been punctured, either on account of their seeming to contain a fluid, or really having within them cysts filled with a chocolate coloured or other fluid, as I have seen in hundreds of instances of sarcocele, and, whatever blood is discharged, was not extravasated in the substance of the testes previously to the puncture, but issues as a necessary consequence of that proceeding. However, of the propriety of the practice advised by Mr. Pott, no doubt can be entertained.

"The last species of this disease, noticed by Mr. Pott, arises from a bursting of a branch of the spermatic vein, between the groin and scrotum, in what is generally known by the name of the spermatic process. This, which is generally produced by great or sudden exertions of strength, feats of agility, &c. may happen to persons in the best health, whose blood and juices are in the best order, and whose genital parts are free from blemish or disease.

"The effusion, or extravasation, is made

into the cellular membrane, which invests and envelopes the spermatic vessels, and has something the appearance of a true hernia. When the case is clear, and the extravasated blood does not give way to discutient applications, the only remedy is to lay the tumour fairly open, through its whole length. If the vessel or breach be small, the hemorrhage may be restrained by mere compression with dry lint, or by the use of styptics; but if it be large, and these means do not succeed, the ligature must be made use of."

I cannot conceive, that, in any case of a mere rupture of one of the spermatic veins, it can ever be justifiable to tie the whole spermatic chord, and then perform castration, though Mr. Pott advises this plan in case the bleeding branch cannot be tied singly. Discutient applications, and an occasional purge, will almost always disperse the swelling; and if not, opening it, taking out the blood, applying cold, or, if necessary, filling the cavity with lint, and using compression, would be, according to my humble judgment the most judicious treatment.

A case, precisely of the latter kind, is not very common, yet Mr. Pott has not omitted it, as one of the forms of hæmatocele; but, why he has not taken notice of the most frequent of all the varieties of this disease, I am at a loss to conjecture; I mean the extravasation of blood in the loose cellular membrane of the scrotum from blows on the part, and sometimes from lithotomy, castration, &c. quite unconnected with any rupture of the spermatic veins. These are the cases which are mostly met with in practice. I have seen them followed by suppuration; but, in general, the effused blood is gradually absorbed, with the aid of discutient applications, leeches, fomentations, poultices, and saline purges. A surgeon should generally be reluctant to lay open the tumour, as, in many instances, sloughing and very severe symptoms have been the result.

Celsus and Paulus Aegineta are the best of the old writers on hæmatocele. For modern information, consult Pott's Chir. Works, Vol. 2. B. Bell on Hydrocele. Flajani, Collezione d' Osservazioni, &c. T. 2; Richter, Anfangsgr. der Wundarzn. B. 6; Richerand, Nosographie Chir. T. 4; Oslander, in Arnetmann's Magazin für die Wundarzn. 1 B. p. 355,—the patient died after an opening had been made in the swelling. Follet, in Journ. de Méd. continué, Vol. 13, p. 422,—a case from contusion, cured by an incision. Harris in Mem. of Lond. Med. Society, Vol. 5.

HARELIP. (*Labia Leporina*.) A fissure, or perpendicular division of one or both lips. The term has arisen from the fancied resemblance of the part to the upper lip of a hare. Occasionally the fissure is more or less oblique. In general, it is directly below the septum of the nose; but sometimes it corresponds to one of the nostrils. The two portions of the lip are generally movable, and not adherent to the alveolar

process; in less common cases they are closely attached to the forepart of the jaw.

Children are frequently born with this kind of malformation, which is called a *natural* harelip, while that which is produced by a wound is named *accidental*. Sometimes the portions of the lip, which ought to be united, have a considerable interspace between them; while in other instances, they are not much apart. The cleft is occasionally double, a little lobe, or small portion of the lip, being situated between the two fissures.

The fissure commonly affects only the lip itself, and usually the upper one. In many cases, however, it extends along the bones and soft parts forming the palate, even as far as the uvula; and sometimes those bones are entirely wanting.

A harelip, in its least degree, occasions considerable deformity; and when more marked, it frequently hinders infants from sucking, and makes it indispensable to nourish them by other means. When the lower lip alone is affected, which is rare as a malformation, the child can neither retain its saliva, nor learn to speak, except with the greatest impediment. The constant escape of the saliva, besides being an annoyance, is found to be detrimental to the health; for its loss impairs the digestive functions, the patient becomes emaciated, and even death would sometimes ensue, if the incessant discharge of so necessary a fluid in the animal economy were not prevented. Thus, a lady, who was in this state, consulted Tronchin, who immediately saw the cause of her indisposition, and recommended the fissure in the lip to be united; the operation was done, and the dyspeptic symptoms then ceased. And, when the fissure pervades the palate, the patient not only articulates very imperfectly, but cannot masticate, nor swallow, except with great difficulty, on account of the food readily getting up into the nose.

An early removal of the deformity must obviously be very desirable; but, as it cannot be accomplished without an operation, attended with some degree of pain, Dionis, Garengot, and others, advise waiting till the child is four or five years old, on the supposition, that, at an earlier age, the child's agitations and cries would render the operation impracticable, or derange all the proceedings taken to ensure its success. It is plain, however, that such reasons are not of great weight. A child four or five years old, and, very often, even one eight or ten years of age, is more difficult to manage, than an infant only a few months old. Every child of the above age has a thousand times more dread of the pain, than of the deformity, or of the inconveniences of the complaint, to which he is habituated; while an infant of tender years fears nothing, and only feels the pain of the moment.

A more rational objection is the liability of infants to convulsions after operations, and this has induced many excellent surgeons of the present day to advise postpo-

uing the cure of the harelip, till the child is about two years old. Perhaps, however, this apprehension does not vindicate quite so much delay.

Mr. Sharp observes, "there are many lips, where the loss of substance is so great, that the edges of the fissure cannot be brought together, or, at best, where they can but just touch; in which case, it need not be advised to forbear the attempt; it is likewise forbid in young children, and with reason, if they suck; but otherwise it may be undertaken with great safety, and even with more probability of success, than in others that are older." (*Operations in Surgery*, chap. 34.)

Le Dran performed the operation on children of all ages, even on those at the breast. B. Bell did it with success on an infant only three months old. Mays advises it to be undertaken as soon as the child is six months old. Roonhuysen operated on children ten weeks after their birth, and all his contemporaries have praised his singular dexterity and success. As an essential step to the success of the operation, the latter surgeon recommended hindering the children from sleeping a certain length of time before it was undertaken, in order that they might fall asleep immediately afterward; and with the same view, opiates have been prescribed.

Putting out of consideration the partial success, which has attended the use of blistering plaster for making the edges of the fissure raw and capable of union, all practitioners entertain the same sentiment, with regard to the object of this operation, which consists in reducing the preternatural solution of continuity to the state of a simple wound, by cutting off the edges of the separated parts throughout their length, and then keeping these parts in contact until they have completely grown together. But although such principles have been generally admitted, there was formerly some difference of opinion, with respect to the best method to be followed in practice; some operators having preferred sutures for keeping the edges of the wound in contact; while others disapproved of them, believing that a perfect cure might always be accomplished by means of adhesive plaster and an uniting bandage, so as to save the patient from all the pain and annoyance of sutures.

M. Louis thought, that the use of sutures, in the operation for the harelip, proceeded from a false idea respecting the nature of the disease; for the fissure in the lip being wrongly imputed to loss of substance, it was deemed impossible to keep the parts in contact, except by a suture.

"The separation of the edges of the fissure in the lip," says M. Louis, "is only the effect of the retraction of the muscles, and is always proportioned to the extent of the cleft. Persons with harelips, are capable of bringing the edges of the fissure together by muscular action, by puckering up their mouths. On the other hand, the separation is considerably increased when they laugh,

and the breach appears excessively large, after superficially paring off its edges on both sides. The interspace in the harelip must not, therefore, be mistaken for a loss of substance. This truth is confirmed by the effects of sticking plaster, which has sometimes been applied to the harelip, as a preparatory measure before the operation, and which materially lessens the separation of the parts.

"According to the confession of all who have written in favour of the twisted suture, it seems advisable only on the false idea, that the harelip is the effect of a greater or lesser loss of substance: and they say, positively, that we must not have recourse to it when there is only a simple division to be united. The twisted suture must then be proscribed from the operation for the natural harelip, since it is proved, that this malformation is unattended with loss of substance. At the same time, a loss of substance is but too real, after the extirpation of scirrhous and cancerous tumours, to which the lips are very subject. Yet, even in these cases, the extensibility of the lips allows an attempt to be made to reunite the double incision, by which the tumour has been removed, and it succeeds without the smallest deformity, when care is taken to direct each incision obliquely, so that both of them form, where they meet, an acute angle, in the base of which the tumour is comprised. Here the means of union ought to be the more efficacious, because the difficulty of keeping the edges of the wound approximated is greater. M. Pibrac in his memoir on the abuse of sutures, when speaking of the harelip, has already explained that they are badly conceived means, and more hurtful in proportion as there is a greater loss of substance, because the greater the interspace is between the two parts, the more fear is there of their efforts on the needles or pins left in the wound. Hence, care has always been taken to make the dressings aid the operation of the suture. After this consideration, judiciously made by the partisans of this plan, there was only one more step to be taken, according to M. Pibrac, in order to evince the necessity of proscribing it. The cap, or copper head-piece, described by Verduc and Nuck, for compressing the cheeks; the clasps of Heister; and strips of adhesive plasters; are all only inventions for the support of the parts, and keeping them from being disunited. When the suture failed, it was by these means, that the original deformity was corrected, together with that produced by the laceration, which would not have occurred without the suture. As then the dressings, when methodically applied, are capable of effectually rectifying the mischief of the suture, M. Louis inquires, why should they be considered only as a resource in a mere accidental case? Why should they not be made the chief and primary means of reuniting the lip, even when there is a loss of substance?

"Nothing can be opposed to the proofs adduced upon this point. They are even

from the practice of those, who have employed sutures without success. Such persons have themselves furnished the proofs of the bandage being capable of repairing the mischief resulting from the twisted suture."

M. Louis, with a view of perfecting our notions on this matter, lays it down as a fact, that the retraction of the muscles being the cause of the separation of the edges of the fissure, it is not to these edges we are to apply the force which is to unite them; but that it should be applied further to the very parts, whose action (the cause of the separation) is to be impeded, and whose contraction is thus to be prevented. A great many means for supporting the wound, only irritate the muscles and excite them to action, and it is this action which we should endeavour to overcome. The means for promoting union can only be methodical, when directly employed to prevent such action, by an immediate application on the point where it is to be resisted. The facility with which the parts may be brought forward, so as to bring the two commissures of the lips into contact, by the mere pressure of the hands, shows what may be expected from a very simple apparatus, which will execute the same office without any effort, in a firm and permanent manner, and which will render sutures unnecessary, the inconveniences of which are too well known.

M. Louis, after having explained the reasons of the theory, on which he founded his method, relates several cases, taken either from his own practice, or that of others, to illustrate its advantages. He details the history of twenty cases, in which his plan perfectly succeeded, both in accidental harelips, with considerable loss of substance, and in natural ones. In most of these instances, however, it was thought proper to assist the bandage with one stitch at the extremity of the fissure, close to the vermilion border of the lip, for the purpose of keeping the parts securely on a level.

Notwithstanding the operation, as performed with the twisted suture, is opposed by an authority of such weight as that of M. Louis, still it is the method most commonly practised. No modern surgeons doubt, that a harelip may be cured by means of adhesive plaster, and uniting bandages, quite as perfectly as with a suture; and all readily allow, that the first of these methods, as being more simple and less painful, would be preferable to the latter one, if it were equally sure of succeeding. But it is considered far more uncertain in its effect. To accomplish a complete cure, the parts to be united must be maintained in perfect contact, until they have contracted the necessary adhesion; and how can we always depend upon a bandage for keeping them from being displaced? What other means, besides a suture, affords in this respect such perfect security?

I shall first describe the operation, as usually done by surgeons of the present day

with the twisted suture. The first thing is to examine, whether there is any adhesion of the lip to the gum; and if there be, to divide it with a knife. Some authors (*Sharp*) recommend the frænulum, which attaches the lip to the gum, always to be divided: but when the harelip is at some distance from this part, it will not be in the way of the operation, and need not be cut. On the other hand, when the frænulum is situated in the centre of the division, it is clear, that in operating we must necessarily include it in the incision, and it should therefore be divided beforehand, taking care not to encroach too much upon the gum, lest the alveolar process be laid bare; nor too much upon the lip, because making it thinner would be unfavourable to its union.

When one of the incisor teeth, opposite the fissure, projects forward, it must be drawn, lest it distend and irritate the parts, after they have been brought into contact.

Sometimes, but particularly in cases in which there is a cleft in the bony part of the palate, a portion of the os maxillare superius forms such a projection, just in the situation of the fissure in the lip, that it would render the union very difficult, if not impracticable. In this circumstance, the common plan has been to cut off the projecting angles of bone with a strong pair of bone-nippers. The part was then healed, and the operation for the harelip performed. Instead of cutting off the projection of bone, which is always a painful measure, Desault used to employ simple compression, by which means the prominence was usually reduced in a few weeks, and the opportunity afforded of operating for the cure of the harelip. (*Œuvres Chir. par Bichat, T. 2, p. 207.*) Of course, the actual necessity for using bone-nippers, or even of having recourse to compression of the bony projection, will depend upon circumstances; for if the prominence of bone be sharp and irregular, no surgeon, I conceive, would hesitate about the removal of such inequalities, in preference to the trial of pressure. Mr. Dunn, of Scarborough, has expressed to me his doubts whether cutting off the projections of the alveolar process be ever necessary, as the pressure of the entire lip gradually diminishes the deformity. "I had (says he) two very unseemly cases, with an immense division of the palate, together with a projection of the alveolar process, which, with the incisor teeth, resembled the talons of a bird. A tubercular appendage of skin hung upon the base of the nose. By drawing the teeth, in the first place, very delicately, I avoided fracturing the bony projection. I then cut off one edge of the nasal appendage, and of the lip of the same side, and attached them together with two needles. The wound was sufficiently united in a week or ten days to allow the same operation on the other side. In less than three weeks, the boy was sent home quite well to the astonishment of the neighbourhood, where his frightful appearance made him an object of disgust and ridi-

cule. I succeeded in the other case, even without the extraction of the teeth. Both the patients can now articulate labial sounds, retain their saliva, and are gradually losing the inconvenience of the passage of the mucus from the nose into the mouth, as the fissure is more contracted, and the projection by no means so disagreeable." These facts should lessen the haste, with which certain operators proceed to cut off every projection of the alveolar process; for a moderate prominence of bone without any sharp, irritating edges, or angles, will not hinder the success of the operation; and even the propriety of removing teeth must entirely depend upon their being likely, by their direction, to irritate the lip, and disturb the union of the fissure.

In the operation, the grand object is to make as smooth and even a cut as possible, in order that it may more certainly unite by the first intention, and of such a shape, that the cicatrix may form only one narrow line. The edges of the fissure should, therefore, never be cut off with scissors, which constantly bruise the fibres which they divide, and a sharp knife is always to be preferred. The best plan is, either to place any flat instrument, such as a piece of horn, wood, or pasteboard, underneath one portion of the lip, and then holding the part stretched and supported on it, to cut away the whole of the callous edge: or else to hold the part with a pair of forceps, the under blade of which is much broader than the upper one: the first serves to support the lip; the other contributes also to this effect, and at the same time, serves as a sort of ruler in guiding the knife in an accurately straight line. When the forceps are preferred, the surgeon must of course leave on the side of the upper blade, just as much of the edge of the fissure as is to be removed, so that it can be cut off with one sweep of the knife. This is to be done on each side of the cleft, observing the rule, to make the new wound in straight lines, because the sides of it can never be made to correspond without this caution. For instance, if the harelip had this shape, the incision of the edges must be continued in straight lines, till they meet in the manner here represented. In short, the two incisions are to be perfectly straight, and are to meet at an angle above, in order that the whole track of the wound may be brought together and united by the first intention.

Two silver pins, made with steel points, are next to be introduced through the edge of the wound, so as to keep them accurately in contact, the lowest pin being introduced first, near the inferior termination of the wound, and the upper pin afterward about a quarter of an inch higher up. A piece of thread is then to be repeatedly wound round the ends of the pins, from one side of the division to the other, first transversely, then obliquely, from the right or left end of one pin above, to the opposite end of the lower

one, &c. Thus the thread is made to cross as many points of the wound as possible, which greatly contributes to maintaining its edges in even apposition. Any portion of the wound above the pins, not closed by the preceding means, may now have its edges brought together with a strip of adhesive plaster. Lastly, the ends of the pins are to be supported by small dossils of lint, placed between them and the flesh; a minute, but essential circumstance, which, as my friend, Mr. Dunn, of Scarborough, reminds me, I forgot to mention in the last edition of this work. It is obvious, that a great deal of exactness is requisite in introducing the pins, in order that the edges of the incision may afterward be precisely applied to each other. For this purpose, some surgeons previously place the sides of the wound in the best position, and mark with a pen the points at which the pins should enter, and come out again; a method which, as far as my observations extend, merits imitation. The pins ought never to extend more deeply than about two-thirds through the substance of the lip, and it would be a great improvement always to have them of a flat, instead of a round shape, and a little curved, as this is the course which they naturally ought to take when introduced. The steel points should also admit of being easily taken off, when the pins have been applied, and, perhaps, having them to screw off and on is the best mode, as removing them in this way is not so likely to be attended with any sudden jerk, which might be injurious to the wound, as if they were made to pull off. In general, the pins may be safely removed in about four days, when the support of sticking plaster will be quite sufficient.

After the operation, the surgeon should never omit the use of compresses and a bandage for keeping forward the cheeks.

The process just described, is what is well known by the name of the *twisted suture*, which is applicable to other surgical cases, in which the grand object is to heal some fistula or opening, by the first intention. Mr. Sharp says, it is of great service in fistulæ of the urethra, remaining after the operation for the stone, in which case the callous edges may be cut off, and the lips of the wound held together by the above method.

What has hitherto been stated, refers to the most simple form of the harelip, viz. to that which presents only one fissure. When there are two clefts, the cure is accomplished on the same principle; but it is rather more difficult of execution; so that the old surgeons, until the time of Heister, almost all regarded the operation for the double harelip as impracticable, though they described it, with the direction to operate on each fissure, just as if it were single: M. de la Faye even operated in this way with success. (*Mémoires de l'Acad. de Chirurgie, Tom. 4. 4to.*) M. Louis was of opinion, that all difficulties would be obviated by doing the operation at two different times, and awaiting the perfect cure of one of the fissures, before that of the other was undertaken. Heis-

ter had similar ideas; but he never put the scheme in practice, nor did he even positively advise it.

After all, however, experience proves that it is not essential to perform two operations for the cure of the double harelip: Desault found, that when the edges of two fissures were pared off, and care taken to let one of the pins pass across the central piece of the lip, the practice answered extremely well. (See *Œuvres Chir. par Bichat*, T. 2, p. 201.)

In cutting off the edges of the fissure, the incision must be carried to the upper part of the lip; and even when the fissure does not reach wholly up the lip, the same thing should be done, for in this manner the sides of the wound will admit of being applied together more uniformly, and the cicatrix will have a better appearance. We should also not be too sparing of the edges which are to be cut off. Practitioners, says M. Louis, persuaded that the harelip was a division with loss of substance, have invariably advised the removal of the *callous edges*. But in the natural harelip there is no callosity; the margins of the fissure are composed, like those of the lip itself, of a pulpy, fresh-coloured, vermillion flesh, covered with an exceedingly delicate cuticle. The whole of the part having this appearance, must be taken away, together with a little of the true skin. At the lower part of the fissure, towards the nearest commissure, a rounded red substance is commonly situated, which it is absolutely necessary to include in the incision. Were this neglected, the union below would be unequal, and, through an injudicious economy, a degree of deformity would remain. The grand object, however, is to make the two incisions diverge at an acute angle, so that the edges may be put into reciprocal contact their whole length, without the least inequality.

M. Louis used to operate as follows: the patient being seated in a good light, his head is to be supported on an assistant's breast, who, with the fingers of both hands, pushes the cheeks forward, in order to bring the edges of the fissure near to each other. These are to be laid on a piece of pasteboard, which is to be put between the jaw and lip, and be an inch and a half long, from twelve to fifteen lines broad, and at most one line thick. The upper end should be rounded, by flattening the corners. In order to facilitate the incision, the lip is to be stretched over the pasteboard, the operator holding one portion over the right with the thumb and index finger of the left hand, while the assistant does the same thing on the left side. These being thus disposed, the edges of the harelip are to be cut off with two sweeps of the bistoury, in two oblique lines, forming an acute angle above the fissure.

For the removal of the edges of the harelip, scissors have sometimes been preferred to a knife, but, notwithstanding Desault's partiality to them, as most convenient, (See *Œuvres Chir. par Bichat*, T. 2, p. 179,) they are now very generally disused. The pinching and bruising which result from the action

of the blades, are circumstances which cannot be favourable to the union of the wound; and though they may not commonly be serious enough to prevent union by the first intention, they might occasionally tend, with any other untoward occurrence, to hinder this desirable event. Let not practitioners here be led by Mr. B. Bell's statement, that in one instance he cut off one side of the fissure with a knife, and the other with scissors; that the latter cut produced least pain, and that on this side there was no more swelling nor inflammation than on the opposite one.

The pins should be introduced at least two-thirds of the way through the substance of the lip, lest a furrow should remain on the inside of the part, which might prove troublesome, by allowing pieces of food to lodge in it. There is, however, a stronger reason for attending to this circumstance, viz. the hemorrhage which may take place when it is neglected. As soon as the edges of the wound have been brought together by means of the suture, and the pins are properly placed, the bleeding almost always ceases; but when the pins have not been introduced deeply enough, and the posterior surfaces of the incisions are not applied to each other, the blood may continue to run into the mouth, and give the surgeon an immense deal of trouble. In the memoir written by Louis, there is a case in which the patient died in consequence of such an accident. Persons who had undergone the operation, were always advised to swallow their spittle, even though mixed with blood, in order to avoid disturbing the wound, by getting rid of it otherwise. In the case alluded to, the patient, who had been operated upon for a cancerous affection of the lip, swallowed the blood as he had been directed to do, and he bled so profusely that he died. On the examination of the body, the stomach and small intestines were found full of blood. "This deplorable case," says the illustrious author who relates it, "deserves to be recorded for public instruction, for the purpose of keeping alive the attention of surgeons on all occasions, where, in consequence of any operation whatsoever, there is reason to apprehend bleeding in the cavity of the mouth. Platner is the only writer who, as far as I know, foresaw this kind of danger. The bleeding from the edges of the wound stops of itself, (says he,) as soon as they have been brought into contact, and stitched together; but care must be taken that the patient does not swallow the blood, which might make him vomit, or else suffocate him. Hence, his head should be elevated, that the blood may escape externally, a precaution more particularly necessary in young children."

Having described the mode of operating for the harelip as approved of by the generality of practitioners, and detailed every thing which seemed material, I have now only to explain the method adopted by M. Louis. His sentiments respecting several particular points of the operation, have been already stated; and an account of the means

which he employed in lieu of the twisted suture, for uniting the edges of the wound, is all that remains to be noticed.

Several bandages for supporting the two portions of the divided lip, and lessening the pressure which they make against the pins, have been mentioned by authors. Franco and Quesnay, in particular, describe two kinds. These means were not only employed as auxiliary, but even sometimes as curative ones, when it was impossible to use needles. To such bandages, too complicated and too uncertain in their effect, M. Louis prefers a simple linen roller, one inch wide, three ells long, and rolled up into two unequal heads. He begins by applying the body of this bandage to the middle of the forehead; he unrolls the two heads, from before backward, above the ears, between the upper part of the cartilage and the cranium, in order to let them cross on the nape of the neck, and then pass forward again. The assistant, who supports the head, and pushes forward the cheeks, must lift up the ends of his fingers, in the place of which, on each side, a thick compress is to be put. This being covered, and pushed from behind forward, by the roller, will constantly perform the office of the assistant's fingers, who is to continue to support the apparatus until it is all completely applied. The longest of the two heads of the roller being slit in two places near the lip, presents two parallel openings; the remnant of the shortest one is divided into two parts, as far as its ends. The two little narrow bands in which it terminates, must then pass through the openings of the former, and cross upon the middle of the lip. The ends of the roller being carried from before backward, are then to be made to cross again on the nape of the neck, where the shortest is to end. The remainder of the long one is to be employed in making turns round the head. This bandage may be still more securely fixed by means of a piece of tape, which is to pass the forehead, over the sagittal suture, and be pinned at each end to the circumvolutions of the roller; while a second piece of tape is to cross the first one at the top of the head, and also to be attached, at its extremities, to the uniting bandage, and the compresses placed under the zygomatic arches, for the purpose of pushing forward the cheeks.

This bandage is extremely simple, and would promise great advantages if the twisted suture were unknown to practitioners. I think this last means will always be the favourite of the practical surgeon, because the desired effect can be produced by it with much less trouble than must be taken with the bandage, in order to render the operation of the latter sufficiently certain. Besides, as I have noticed, M. Louis himself mostly made one stitch near the red part of the lip, so that he cannot be said to have trusted altogether to the bandage.

However, as an auxiliary to the twisted suture, and a means of preventing the parts from being drawn to each side of the face so forcibly as to create a risk of the pins

cutting their way out by ulceration, a thick compress applied to each cheek, and pressed forward with a bandage, is still very usefully employed.

What has been said concerning the operation for the harelip, is equally applicable, not only to the treatment of cancer of the lip, but also to that of accidental cuts, or lacerations of this part, from any cause whatsoever. We shall only remark, that in a recent wound, all the surgeon has to do, is to apply the twisted suture and adhesive plaster without delay.

When there is a fissure in the bones forming the roof of the mouth, it usually diminishes, and gradually closes, after the harelip is cured. But this does not always happen, and when the parts remain so considerably separated, as to obstruct speech and deglutition, or cause any other inconvenience, a plate of gold or silver, exactly adapted to the arch of the palate, and steadied by means of a piece of sponge, fixed to its convex side, and introduced into the cleft, may sometimes be usefully employed. When the sponge is of suitable size, and very dry, before being used, the moisture of the adjacent parts will make it swell, and in many cases, be sufficient to keep it in its situation, so as greatly to facilitate speaking and swallowing. Sometimes, however, the fissure is so shaped, that the sponge cannot be fixed in it: this principally happens when the opening widens very much, towards the front of the jaw. In such cases, it has been proposed to fix a plate of gold, by means of springs, covered with the same metal. Platina, which is cheaper, might be used for the same purpose. The subject, however, of artificial palates is one, on which much mechanical ingenuity may yet be usefully exerted, and it can hardly be expected, that I should here do more, than give references to works, in which the reader may find information upon it. (See *Fauchard, Le Chirurgien Dentiste*, 2 Tom. 12mo. Paris, 1728; *Camper, Vermischte Schriften*, No. 13; *Loder's Journ.* 2 B. p. 25. p. 185, &c. *Von Seveling über eine merkwürdige Kunstliche Ersetzung mehrerer, sowohl zur Sprache, als zum Schlucken nothwendiger zerstörter, Werkzeuge*; 8vo. * HEAD, INJURIES OF. Mr. Pott remarks, that though the scalp be called the common tegument of the head, yet from the variety of parts of which it is composed, from their structure, connexions, and uses, injuries done to it by external violence, become of much more consequence, than the same kind of ills can prove, when inflicted on the common teguments of the rest of the body.

Passing over incised wounds, which have no particularity, Mr. Pott proceeds immediately to lacerated and punctured wounds. "The former may be reduced to two kinds, viz. those in which the scalp, though torn, or unequally divided, still keeps its natural situation, and is not stript nor separated from the cranium, to any considerable distance beyond the breadth of the wound; and those in which it is considerably detached from the parts it ought to cover. The first of these, if simple, and not combined with the symptoms, or appearances of any other mischief, do not require any particular or different treatment, from what the same kind of wounds require on all other parts;" but with respect to those in which the scalp is separated and detached from the parts it ought to cover, Mr. Pott makes no scruple of declaring it as his opinion, that its preservation ought always to be attempted, unless it be so torn as to be absolutely spoiled, or there are manifest present symptoms of other mischief. In former days, the excision of the lacerated and detached scalp was the general practice; but Mr. Pott had so often made the experiment of endeavouring to preserve the torn piece, and so often succeeded, that he recommended it as a thing

always to be attempted, even though a part of the cranium were perfectly bare.

Here I may remark, that all practitioners now invariably avoid cutting away the scalp, even in the circumstances in which such practice was allowed by Pott. By spoiled, this eminent writer must mean so injured as necessarily to slough afterward. However, as no harm results from taking the chance of its not sloughing, which never can be with certainty foretold; and as the excision of the part is painful, and productive of no benefit, even if sloughing must follow, such operation is, in every point of view, hurtful and wrong. With respect to other mischief, as a reason, the examination of the cranium, and even the application of the trephine, never require any of the scalp to be cut away. See *Trephine*.

Let the surgeon, therefore, free the torn piece from all dirt, or foreign bodies, and restore it as quickly, and as perfectly as he can, to its natural situation.

Notwithstanding Mr. Pott assents to the employment of sutures, for uniting certain lacerated wounds of the scalp, the best practitioners of the present day generally employ only sticking-plaster. Sometimes, the loosened scalp will unite with the parts from which it is torn and separated, and there will be no other sore, than what arises from the impracticability of bringing the lips of the wound into smooth and immediate contact, the scar of which sore must be small in proportion. Sometimes such perfect reunion is not to be obtained; in which case, matter will be formed and collected in those places where the parts do not coalesce: but this does not necessarily make any difference, either in the general intention, or in the event; this matter may easily be discharged, by one or two small openings made with a lancet; the head will still preserve its natural covering; and the cure will be very little retarded by a few small abscesses.

In some cases (as Pott proceeds to describe,) the whole separated piece will unite perfectly, and give little or no trouble, especially in young and healthy persons. In some, the union will take place in some parts and not in others; and consequently, matter will be formed, and require to be discharged, perhaps at several different points; and in some particular cases, circumstances, and habits, there will be no union at all, the torn cellular membrane, or the naked aponeurosis, will inflame and become sloughy, a considerable quantity of matter will be collected, and perhaps the cranium will be denuded. But even in this state of things, which does not very often happen, where care has been taken, and is almost the worst which can happen, in the case of mere simple laceration and detachment, if the surgeon will not be too soon, nor too much alarmed, nor in a hurry to cut, he will often find the cure much more feasible than he may at first imagine: let him take care to keep the inflammation under by proper means, let him have patience till

the matter is fairly and fully formed, and the sloughs perfectly separated, and when this is accomplished, let him make a proper number of dependent openings for the discharge of them, and let him by bandage, and other proper management, keep the parts in constant contact with each other, and he will often find, that although he was foiled in his first intention of procuring immediate union, yet he will frequently succeed in this his second; he will still save the scalp, shorten the cure, and prevent the great deformity arising (particularly to women) not only from the scar, but from the total loss of hair.

This union may often be procured, even though the cranium should have been perfectly denuded by the accident; and it is true, not only though it should have been stripped of its pericranium at first, (See *Abernethy on the Injuries of the Head, Case 6.*) but even if that pericranium should have become sloughy and cast off, as Mr. Pott has often seen.

"Exfoliation from a cranium laid bare by external violence, and to which no other injury has been done, than merely stripping it of its covering, is a circumstance (says Pott) which would not so often happen, if it was not taken for granted that it must be, and the bone treated according to such expectation. The soft open texture of the bones of children and young people, will frequently furnish an incarnation, which will cover their surface, and render exfoliation quite unnecessary; and even in those of mature age, and in whom the bones are still harder, exfoliation is full as often the effect of art as the intention of nature, and produced by a method of dressing, calculated to accomplish such end, under a supposition of its being necessary. Sometimes, indeed, it happens that a small scale will necessarily separate, and the sore cannot be perfectly healed till such separation has been made; but this kind of exfoliation will be very small and thin, in proportion to that produced by art, that is, that produced by dressing the surface of the bare bone with spirituous tinctures, &c.

"Small wounds, that is, such as are made by instruments, or bodies which pierce, or puncture, rather than cut, are in general more apt to become inflamed, and to give trouble, than those which are larger, and in this part particularly, are sometimes attended with so high inflammation, and with such symptoms as alarm both patient and surgeon.

"If the wound affects the cellular membrane only, and has not reached the aponeurosis or pericranium, the inflammation and tumour affect the whole head and face, the skin of which wears a yellowish cast, and is sometimes thick set with small blisters, containing the same coloured serum; it receives the impression of the fingers, and becomes pale for a moment, but returns immediately to its inflamed colour; it is not very painful to the touch, and the eyelids and ears are always comprehended in the tumefaction, the

former of which are sometimes so distended as to be closed; a feverish heat and thirst generally accompany it; the patient is restless, has a quick pulse, and most commonly a nausea, and inclination to vomit.

"This accident generally happens to persons of bilious habit, and is indeed an inflammation of the erysipelatous kind; it is somewhat alarming to look at, but is not often attended with danger. The wound does indeed neither look well, nor yield a kindly discharge, while the fever continues, but still it has nothing threatening in its appearance, none of that look which bespeaks internal mischief; the scalp continues to adhere firmly to the skull, and the patient does not complain of that tensive pain, nor is he afflicted with that fatiguing restlessness which generally attends mischief underneath the cranium.

"Phlebotomy, lenient purges, and the use of the common febrifuge medicines, particularly those of the neutral kind, generally remove it in a short time. When the inflammation is gone off, it leaves on the skin a yellowish tint, and a dry scurf, which continue until perspiration carries them away, and upon the disappearance of the disease, the wound immediately recovers a healthy aspect, and soon heals without any farther trouble.

"Wounds and contusions of the head, which affect the brain and its membranes, are also subject to an erysipelatous kind of swelling and inflammation; but it is very different, both in its character and consequences from the preceding.

"In this, (which is one of the effects of inflammation of the meninges,) the febrile symptoms are much higher, the pulse harder and more frequent, the anxiety and restlessness extremely fatiguing, the pain in the head intense; and as this kind of appearance is, in these circumstances, most frequently the immediate precursor of matter forming between the skull and dura mater, it is generally attended with irregular shiverings, which are not followed by a critical sweat, nor afford any relief to the patient. To which it may be added, that in the former case, the erysipelas generally appears within the first three or four days; whereas in the latter, it seldom comes on till several days after the accident, when the symptomatic fever is got to some height. In the simple erysipelas, although the wound be crude and undigested, yet it has no other mark of mischief; the pericranium adheres firmly to the skull, and upon the cessation of the fever, all appearances become immediately favourable. In that which accompanies injury done to the parts underneath, the wound not only has a spongy, glassy, unhealthy aspect, but the pericranium in its neighbourhood separates spontaneously from the bone, and quits all cohesion with it. In short, one is an accident, proceeding from a bilious habit, and not indicating any mischief beyond itself; the other is a symptom, or a part of a disease, which is occasioned by injury done to the membranes of the brain: one portends little

or no ill to the patient, and almost always ends well; the other implies great hazard, and most commonly ends fatally. It is therefore hardly necessary to say, that it behooves every practitioner to be careful in distinguishing them from each other.

"If the wound be a small one, and has passed through the cellular membrane to the aponeurosis, and pericranium, it is sometimes attended with very disagreeable, and even very alarming symptoms, but which arise from a different cause, and are very distinguishable from what has been yet mentioned.

"In this, the inflamed scalp does not rise into that degree of tumefaction, as in the erysipelas, neither does it pit, or retain the impression of the fingers of an examiner, it is of a deep red colour, unmixed with the yellow tint of the erysipelas; it appears tense, and is extremely painful to the touch; as it is not an affection of the cellular membrane, and as the ears and the eyelids are not covered by the parts in which the wound is inflicted, they are seldom, if ever, comprehended in the tumour, though they may partake of the general inflammation of the skin; it is generally attended with acute pain in the head, and such a degree of fever as prevents sleep, and sometimes brings on a delirium.

"A patient, in these circumstances, will admit more free evacuations by phlebotomy, than one labouring under an erysipelas; the use of warm fomentation is required in both, in order to keep the skin clean and perspirable, but an emollient cataplasm, which is generally forbid in the former, may in this latter case be used to great advantage.

"When the symptoms are not very pressing, nor the habit very inflammable, this method will prove sufficient; but it sometimes happens, that the scalp is so tense, the pain so great, and the symptomatic fever so high, that by waiting for the slow effect of such means, the patient runs a risk from the continuance of the fever, or else the injured aponeurosis and pericranium becoming sloughy, produce an abscess, and render the case both tedious and troublesome. A division of the wounded part by a simple incision down to the bone, about half an inch or an inch in length, will most commonly remove all the bad symptoms, and if it be done in time, will render every thing else unnecessary." (*Pott.*) With respect to the good effects of such an incision, Desault considers them greatly exaggerated by authors; and while he admits, that they are useful, when the inflammation extends under the aponeurosis, he is not inclined to sanction it as a right proceeding in every other instance. (*See Œuvres Chir. par Bichat, T. 2, p. 8.*)

Thus, Mr. Pott was of opinion, that the differences of the symptoms in the foregoing cases depended upon, whether the wound only affected the skin and cellular membrane, or reached more deeply to the aponeurosis and pericranium; a doctrine which has been justly regarded as questionable. With respect to the observation, that in a puncture of the aponeurosis, the swelling is confined within the limits of this fascia, and

does not extend to the ears and eyelids, it is a sentiment which Desault thought arose rather from anatomical considerations, than the observation of nature. The doctrine indeed, must appear doubtful, when it is recollected: 1st, That the aponeurosis and pericranium are parts of scarcely any sensibility. 2dly, That the opinion had its origin at a period when these parts were imagined to be highly sensible. 3dly, That in other parts of the body, a wound in which a fascia, or the periosteum is concerned, is rarely attended with the above described severe symptoms. 4thly, That here the wounds often affect only the skin and cellular membrane, and yet these symptoms occur, even with a phlegmonous character. 5thly, On the contrary, in other instances in which the aponeurosis and pericranium are undoubtedly wounded, no bad symptoms at all take place. 6thly, These symptoms may almost always be removed by the exhibition of tartarized antimony. (*Œuvres Chir. de Desault, T. 2, p. 8.*) In the case, often named inflammation of the fascia after bleeding, it is not the fascia itself, which is the real and chief seat of the pain, inflammation, &c. but the subjacent cellular membrane and muscles. The theory of Desault is, that the erysipelatous affections of the scalp, so frequent after injuries of the head, are connected with disorder of the functions of the liver, produced by such accidents. Yet it is difficult to understand, why a mere puncture of the scalp should cause this disorder of the liver, more commonly than the same kind of wound of any other superficial part of the body.

The injuries to which the scalp is liable from contusion, or appearances produced in it by such general cause, may be divided into those, in which the mischief is confined merely to the scalp; and those in which other parts are interested.

The former, which only come under our present consideration, are not indeed of importance, considered abstractedly. The tumour is either very readily dissipated, or the extravasated blood causing it, is easily got rid of by a small opening. J. L. Petit first, and afterward Pott, particularly noticed this case, on account of an accidental circumstance, which sometimes attends it, and renders it liable to be very much mistaken.

"When the scalp receives a very smart blow, it often happens that a quantity of extravasated blood immediately forms a tumour, easily distinguishable from all others, and generally very easily cured. But it also sometimes happens, that this kind of tumour produces to the fingers of an unadvised or inattentive examiner, a sensation, so like to that of a fracture, with depression of the cranium, as may be easily mistaken." Now, if upon such supposition, a surgeon immediately makes an incision into the tumid scalp, he may give his patient a great deal of unnecessary pain, and for that reason run some risk of his own character.

"The touch is, in this case, so liable to deception, that recourse should always be

had to other circumstances and symptoms, before an opinion be given.

"If a person, with such tumour occasioned by a blow, and attended with such appearances and feel, has any complaint, which seems to be the effect of pressure made on the brain and nerves, or of any mischief done to the parts within the cranium, the division or removal of the scalp, in order to inquire into the state of the skull, is right and necessary; but if there are no such general symptoms, and the patient is in every respect perfectly well, the mere feel of something like a fracture will not authorize or vindicate such operation, since it will often be found, that such sensation is a deception, and that when the extravasated fluid is removed, or dissipated, the cranium is perfectly sound and uninjured."—(Pott.)

With the exception of instances, in which the dura mater suppurates from a blow on the head, and the symptoms are such as to require the trephine, or other examples, in which an abscess forms under the scalp, or a large quantity of blood is effused in the same situation, none of the cases which have here been considered, can justify making incisions in the scalp: and the utility of the practice in what was supposed by Pott to be an inflammation of the aponeurosis, is at least questionable, as far as it is done under the idea of merely obviating tension, without there being any matter to be discharged. Incisions expressly for the purpose of exposing the bone are only right, as a preparatory step to trephining, when the necessity for this operation is indicated by decided and urgent symptoms of pressure on the brain. Now, such pressure, in any of the examples above treated of, can only arise from suppuration under the skull, a subject, which I shall leave, as having been already fully discussed.

Dr. Hennen, in his truly practical work, has very properly advised surgeons not to be content with clipping away a little of the hair around the injury, but always to have the head shaved to a proper extent. This proceeding, which is perfectly harmless in itself, is more generally right, than the custom of cutting the scalp, which has been too frequently employed without any rational aim. The free removal of the hair directly after the accident, often brings into view marks indicative of other parts of the head having been struck, besides that which is at first noticed, and thus the practitioner will have a more correct notion of the serious nature of the accident, than he might otherwise have conceived, and be more strict in his mode of treatment. Nay, fractures and depression of the skull, sometimes not denoted by any disturbance of the functions of the brain, and liable to escape observation, while concealed under the hair, are frequently detected after its removal, and the surgeon, being now aware of the extent and situation of the mischief, must of course be better qualified to conduct the treatment. In short, as Dr. Hennen has observed; "Independent of the more accurate view, (thus procured,) we facilitate the application of leeches, if they

may be found necessary, and of a most excellent adjuvant on all occasions, viz. cold applications."

It affords me particular pleasure to be able to number so good a surgeon as Dr. Hennen, among the advocates of Schmucker's plan of having the head well shaved and covered with cloths, wet with a very cold lotion; a practice which the latter eminent surgeon always adopted, whether a sabre cut, or gunshot injury of this part, had the appearance of being serious, or not. "As soon as the patient was brought to the hospital with a wound of the head, whether the injury looked important or not, (says Schmucker) I directed the hair to be immediately removed, and after the necessary dilatation, applied dressings. Sixteen ounces of blood were next taken away, and the evacuation, in less quantity, repeated according to circumstances, three or four times, within the space of twenty-four hours. The pulse now generally became softer, and the determination of blood to the head lessened. Over the dressings, and the whole of the head, thick cloths, dipped in the cold mixture, hereafter specified, were laid, and renewed every hour. These cloths were kept in their place with the bandage called the grand couvre-chef. (See *Bandage*.) As internal medicines, the nitrate of potassa, neutral salts, and emollient and stimulating clysters, and gentle aperients, were given. These means were employed, both in slight injuries, and in those where the bones were depressed, and fissures and fractures were accompanied with violent convulsive twitchings, coma, paralysis, and other bad symptoms; and even in cases where the use of the trephine was indispensable, the practice was continued until the cure was complete." Schmucker assures us, that under such treatment, fewer patients with wounds of the head were lost, than used previously to happen, especially of those whose injuries at first had the appearance of being but slight. (See *Chir. Wahrnehmungen*, 1 B. p. 154.)

Schmucker was led to try this practice by the great benefit which he had seen afforded by the application of cold water to the head in cases of mania, attended with great determination of blood to the brain. And, in order to increase the efficacy of the water, he added to every five gallons of it two quarts of vinegar, sixteen ounces of nitre, and eight of the muriate of ammonia. This mixture was then preserved for use in a cold place. (*Vol. cit.* p. 153.) Or in order to avail ourselves of the full frigorific effects of this mixture, it should be prepared, as Dr. Hennen observes, in small quantities, and used immediately before its temperature has risen; or, "snow or pounded ice, or ice-water, applied to the parts in a half filled bladder, or cloths simply dipped in cold water, will often answer every purpose." (*On Military Surgery*, p. 279, Edit. 2.) Dr. Hennen mentions one important fact, in recommendation of cold applications, antimonials, and saline purgatives, preceded by the common blue pill, and assisted with quiet,

and abstinence, viz. by such means, "those troublesome puffy enlargements and erysipelalous affections of the scalp, which so often succeed to bruises," are prevented, and, where the evacuant plan is duly observed, the "extensive and formidable erysipelalous affections, so common formerly, are rare and mild at present in military hospitals."

2. Effects of Contusion on the Dura Mater and Parts within the Skull.

It is observed by Mr. Pott, that by blows, falls, and other shocks, some of the larger of those vessels which carry on the communication between the dura mater and the skull are broken, and a quantity of blood is shed upon the surface of that membrane. This is one species of bloody extravasation, and indeed the only one which can be formed between the skull and dura mater. If the broken vessels be few, and the quantity of blood which is shed be small, the symptoms are generally slight, and by proper treatment disappear. If they are large, or numerous, or the quantity of extravasated fluid considerable, the symptoms are generally urgent in proportion; but whether they be slight, or considerable, whether immediately alarming or not, they are always and uniformly such as indicate pressure made on the brain and nerves, viz. stupidity, drowsiness, diminution or loss of sense, speech, and voluntary motion.

According to Mr. Pott, it also often happens, from the same kind of violence, that some of the small vessels, which carry on the circulation between the pericranium, skull, and dura mater, are so damaged, as not to be able properly to execute that office, although there are none so broken as to cause an actual effusion of blood.

"Smart and severe strokes on the middle part of the bones, at a distance from the sutures, are most frequently followed by this kind of mischief; the coats of the small vessels, which sustain the injury, inflame and become sloughy, and in consequence of such alteration in them, the pericranium separates from the outside of that part of the bone, which received the blow, and the dura mater from the inside, the latter of which membranes, soon after such inflammation, becomes sloughy also, and furnishes matter, which matter being collected between the said membrane and the cranium, and having no natural outlet, whereby to escape, or be discharged, brings on a train of very terrible symptoms, and is a very frequent cause of destruction. The effect of this kind of violence is frequently confined to the vessels connecting the dura mater to the cranium, in which case, the matter is external to the said membrane; but it sometimes happens, that by the force either of the stroke or of the concussion, the vessels which pass between, and connect the two meninges, are injured in the same manner; in which case, the matter formed in consequence of such violence is found on the surface of the brain, or between the pia and

dura mater, as well as on the surface of the latter; or, perhaps, in all these three situations at the same time.

"The difference of this kind of disease, from either an extravasation of blood, or a commotion of the medullary parts of the brain, is great and obvious. All the complaints produced by extravasation, are such as proceed from pressure made on the brain and nerves, and obstruction to the circulation of the blood through the former; stupidity, loss of sense and voluntary motion, laborious and obstructed pulse and respiration, &c. and (which is of importance to remark,) *if the effusion be at all considerable, these symptoms appear immediately, or very soon after the accident.*

"The symptoms attending an inflamed or sloughy state of the membranes, in consequence of external violence, are very different; they are all of the febrile kind, and never, at first, imply any unnatural pressure; such are, pain in the head, restlessness, want of sleep, frequent and hard pulse, hot and dry skin, flushed countenance, inflamed eyes; nausea, vomiting, rigour; and toward the end, convulsion and delirium. And *none of these appear at first, that is, immediately after the accident; seldom until some days are passed.*

"One set or class of symptoms is produced by an extravasated fluid, making such pressure on the brain and origin of the nerves, so as to impair or abolish voluntary motion and the senses; the other is caused by the inflamed or putrid state of the membranes covering the brain, and seldom affects the organs of sense, until the latter end of the disease, that is, until a considerable quantity of matter is formed, which matter must press like any other fluid.

"If there be neither fissure nor fracture of the skull nor extravasation, nor commotion underneath it, and the scalp be neither considerably bruised, nor wounded, the mischief is seldom discovered or attended to for some few days. The first attack is generally by pain in the part which received the blow. This pain, though beginning in that point, is soon extended all over the head, and is attended with a languor, or dejection of strength and spirits, which are soon followed by a nausea, and inclination to vomit, a vertigo or giddiness, a quick and hard pulse, and an incapacity of sleeping, at least quietly. A day or two after this attack, if no means preventive of inflammation are used, the part stricken generally swells, and becomes puffy and tender, but not painful; neither does the tumour rise to any considerable height, or spread to any great extent: if this tumid part of the scalp be now divided, the pericranium will be found of a darkish hue, and either quite detached, or very easily separable from the skull, between which will be found a small quantity of a dark-coloured ichor.

"If the disorder has made such progress, that the pericranium is quite separated and detached from the skull, the latter will even now be found to be somewhat altered in co-

lour from a sound healthy bone. Of this alteration it is not very easy to convey an idea by words, but it is a very visible one, and what some very able writers have noticed.

"From this time the symptoms generally advance more hastily and more apparently; the fever increases, the skin becomes hotter, the pulse quicker and harder, the sleep more disturbed, the anxiety and restlessness more fatiguing; and to these are generally added irregular rigours, which are not followed by any critical sweat, and which, instead of relieving the patient, add considerably to his sufferings. If the scalp has not been divided or removed, until the symptoms are thus far advanced, the alteration of the colour of the bone will be found to be more remarkable; it will be found to be whiter and more dry than a healthy one; or, as Fallopius has very justly observed, it will be found to be more like a dead bone: the sanies, or fluid, between it and the pericranium, will also, in this state, be found to be more in quantity, and the said membrane will have a more livid diseased aspect.

"In this state of matters, if the dura mater be denuded, it will be found to be detached from the inside of the cranium, to have lost its bright silver hue, and to be, as it were, smeared over with a kind of mucus, or with matter, but not with blood. Every hour after this period, all the symptoms are exasperated, and advance with hasty strides: the headach and thirst become more intense, the strength decreases, the rigours are more frequent, and at last convulsive motions, attended in some with delirium, in others with paralysis, or comatose stupidity, finish the tragedy.

"If the scalp has not been divided till this point of time, and it be done now, a very offensive discoloured kind of fluid will be found lying on the bare cranium, whose appearance will be still more unlike to the healthy natural one; if the bone be now perforated, matter will be found between it and the dura mater, generally in considerable quantity, but different in different cases and circumstances. Sometimes it will be in great abundance, and diffused over a large part of the membrane; and sometimes the quantity will be less, and consequently the space which it occupies smaller. Sometimes it lies only on the exterior surface of the dura mater; and sometimes it is between it and the pia mater, or also even on the surface of the brain, or within the substance of it, &c.

"As the inflammation and separation of the dura mater is not an immediate consequence of the violence, so neither are the symptoms immediate, seldom until some days have passed; the fever at first is slight, but increases gradually; as the membrane becomes more and more diseased, all the febrile symptoms are heightened; the formation of matter occasions rigours, frequent and irregular, until such a quantity is collected, as brings on delirium, spasm, and death."

Hitherto Mr. Pott has been describing this disease as unaccompanied with any other, not even with any external mark of injury,

except perhaps a trifling bruise of the scalp; "Let us now, (says this eminent surgeon) suppose the scalp to be wounded at the time of the accident, by whatever gave the contusion; or let us suppose, that the immediate symptoms having been alarming, a wound had been made, in order to examine the skull.

"In this case, the wound will for some little time have the same appearance as a mere simple wound of this part, unattended with other mischief, would have; it will, like that, at first discharge a thin sanies, or gleet, and then begin to suppurate; it will digest, begin to incarn, and look perfectly well; but, after a few days, all these favourable appearances will vanish; the sore will lose its florid complexion, and granulated surface; will become pale, glassy, and flabby; instead of good matter, it will discharge only a thin discoloured sanies; the lint with which it is dressed, instead of coming off easily (as in a kindly suppurating sore) will stick to all parts of it; and the pericranium instead of adhering firmly to the bone, will separate from it, all round, to some distance from the edges.

"This alteration in the face and circumstances of the sore, is produced merely by the diseased state of the parts underneath the skull; which is a circumstance of great importance, in support of the doctrine advanced; and is demonstrably proved, by observing that this diseased aspect of the sore, and this spontaneous separation of the pericranium, are always confined to that part which covers the altered or injured portion of the dura mater, and do not at all affect the rest of the scalp; nay, if it has by accident been wounded in any other part, or a portion has been removed from any part where no injury has been done to the dura mater, no such separation will happen, the detachment above will always correspond to that below, and be found nowhere else.

"The first appearance of alteration in the wound immediately succeeds the febrile attack; and as the febrile symptoms increase, the sore becomes worse and worse, that is, degenerates more and more from a healthy, kindly aspect.

"Through the whole time, from the first attack of the fever, to the last and fatal period, an attentive observer will remark the gradual alteration of the colour of the bone, if it be bare. At first it will be found to be whiter, and more dry, than the natural one; and as the symptoms increase, and either matter is collected, or the dura mater becomes sloughy, the bone inclines more and more to a kind of purulent hue, or whitish yellow; and it may also be worth while in this place to remark, that if the blow was on or very near to a suture, and the subject young, the said suture will often separate in such a manner as to let through it a loose painful, ill-natured fungus; at which time also, it is no uncommon thing for the patient's head and face to be attacked with an erysipelas.

"In those cases, in which the scalp is very

little injured by the bruise, and in which there is no wound, nor any immediate alarming symptoms or appearances, the patient feels little or no inconvenience, and seldom makes any complaint, until some few days are past. At the end of this uncertain time, he is generally attacked by the symptoms already recited; these are not pressing at first, but they soon increase to such a degree, as to baffle all our art: from whence it will appear, that when this is the case, the patient frequently suffers from what seems at first to indicate his safety, and prevents such attempts being made, and such care from being taken of them, as might prove preventive of mischief.

"But if the integuments are so injured as to excite or claim our early regard, very useful information may from thence be collected; for whether the scalp be considerably bruised, or whether it be found necessary to divide it for the discharge of extravasated blood, or on account of worse appearances, or more urgent symptoms, the state of the pericranium may be thereby sooner and more certainly known: if in the place of such bruise, the pericranium be found spontaneously detached from the skull, having a quantity of discoloured sanies between them under the tumid part, in the manner already mentioned, it may be regarded as a pretty certain indication, either that the dura mater is beginning to separate in the same manner, or that if some preventive means be not immediately used, it will soon suffer; that is, it will inflame, separate from the skull, and give room for a collection of matter between them. And with regard to the wound itself, whether it was made at the time of the accident, or afterward artificially, it is the same thing; if the alteration of its appearance be as related, if the edges of it spontaneously quit their adhesion to the bone, and the febrile symptoms are at the same time making their attack, these circumstances will serve to convey the same information, and to prove the same thing.

"The particular effect of contusion is frequently found to attend on fissures, and undepressed fractures of the cranium, as well as on extravasations of fluid, in cases where the bone is entire; and on the other hand, all these do often happen without the concurrence of this individual mischief. All this is matter of accident; but let the other circumstances be what they may, the spontaneous separation of the altered pericranium, in consequence of a severe blow, is almost always followed by suppuration between the cranium and dura mater; a circumstance extremely well worth attending to in fissures and undepressed fractures of the skull, because it is from this circumstance principally, that the bad symptoms, and the hazard, in such cases arise.

"It is no very uncommon thing for a smart blow on the head to produce some immediate bad symptoms, which after a short space of time disappear, and leave the patient perfectly well. A slight pain in the

head, a little acceleration of pulse, a vertigo and sickness, sometimes immediately follow such accident, but do not continue many hours, especially if any evacuation has been used. These are not improbably owing to a slight commotion of the brain, which having suffered no material injury thereby, soon cease. But if, after an interval of some time, the same symptoms are renewed; if the patient, having been well, becomes again feverish, and restless, and that without any new cause; if he complains of being languid and uneasy, sleeps disturbedly, loses his appetite, has a hot skin, a hard quick pulse, and a flushed, heated countenance; and neither irregularity of diet, nor accidental cold, have been productive of these; mischief is most certainly impending, and that most probably under the skull.

"If the symptoms of pressure, such as stupidity, loss of sense, voluntary motion, &c. appear some few days after the head has suffered injury from external mischief, they do most probably imply an effusion of a fluid somewhere: this effusion may be in the substance of the brain, in its ventricles, between its membranes, or on the surface of the dura mater; and which of these is the real situation of such extravasation, is a matter of great uncertainty, none of them being attended with any peculiar mark or sign that can be depended upon, as pointing it out precisely; but the inflammation of the dura mater, and the formation of matter between it and the skull, in consequence of contusion, is generally indicated and preceded by one which Mr. Pott has hardly ever known to fail; *a puffy, circumscribed, indolent tumour of the scalp, and a spontaneous separation of the pericranium from the skull under such tumour.*

"These appearances, therefore, following a smart blow on the head, and attended with languor, pain, restlessness, watching, quick pulse, headach, and slight irregular shiverings, do almost infallibly indicate an inflamed dura mater, and pus, either forming or formed between it and the cranium."

By detachment of the pericranium, is not meant every separation of it from the bone which it should cover. It may be, and often is, cut, torn, or scraped off, without any such consequence; but these separations are violent, whereas that which Mr. Pott means is spontaneous, and is produced by the destruction of those vessels by which it was connected with the skull, and by which the communication between it and the internal parts was carried on; and therefore it is to be observed, that it is not the mere removal of that membrane which causes the bad symptoms, but it is the inflammation of the dura mater; of which inflammation, this spontaneous secession of the pericranium is an almost certain indication.

Sometimes the scalp is so wounded at the time of the accident, or so torn away, as to leave the bone perfectly bare; and yet the violence has not been such as to produce the evil just now spoken of. In this case, if the pericranium be only turned back, along with

the detached portion of scalp, there may be probability of its reunion; and it should therefore be immediately made clean and replaced for the purpose of such experiment; which, if it succeeds, will save time, and prevent considerable deformity. Should the attempt fail, it can only be in consequence of the detached part sloughing. Hence, removing it with a knife, though allowed by Pott, is now never practised. Frequently when the scalp does not adhere at once, it becomes attached to the cranium afterward by a granulating process. When the detached piece sloughs, the worst that can happen, is an exfoliation from the bare skull.

Sometimes the force which detaches or removes the scalp, also occasions the mischief in question; but the integuments being wounded or removed, we cannot have the criterion of the tumour of the scalp for the direction of our judgment. Our whole attention must be directed to the wound and general symptoms. The edges of the former will digest as well, and look as kindly for a few days, as if no mischief was done underneath. But after some little space of time, when the patient begins to be restless and hot, and to complain of pain in the head, these edges will lose their vermilion hue, and become pale and flabby. Instead of matter, they will discharge a thin gleet, and the pericranium will loosen from the skull, to some distance from the said edges. Immediately after this, all the general symptoms are increased and exasperated; and as the inflammation of the membrane is heightened or extended, they become daily worse and worse, until a quantity of matter is formed and collected, and brings on that fatal period, which, though uncertain as to date, very seldom fails to arrive.

"The method of attempting the relief of this kind of injury consists in two points, viz. *to endeavour to prevent the inflammation of the dura mater*; or, that being neglected, or found impracticable, *to give discharge to the fluid collected within the cranium in consequence of such inflammation*.

"Of all the remedies in the power of art for inflammations of membranous parts, there is none equal to phlebotomy. To this truth many diseases bear testimony; pleurisies, ophthalmies, strangulated hernias, &c. and if any thing can particularly contribute to the prevention of the ills likely to follow severe contusions of the head, it is this kind of evacuation; but then it must be made use of in such a manner as to become truly a preventive; that is, it must be made use of immediately and freely."

Mr. Pott admits that it will in general be found very difficult to persuade a person, who has had what may be called only a knock on the pate, to submit to such discipline, especially if he finds himself tolerably well: yet in many instances, the timely use, or the neglect of this single remedy, makes all the difference between safety and fatality.

"It may be said that as the force of the blow, the height of the fall, the weight of the instrument, &c. can never precisely, or

certainly determine the effect, nor inform us whether mischief is done under the bone or not, a large quantity of blood may be drawn off unnecessarily, in order to prevent an imaginary evil. This is in some degree true; and if the advice just given was universally followed, many people would be largely bled without necessity; but then, on the other hand, many a very valuable life would be preserved, which, for want of this kind of assistance, is lost. *Nihil interest, præsidium an satis tutum sit, quod unicuique*, is an incontestable maxim in medicine; and if it be allowed to use such means as may be in themselves hazardous, surely it cannot be wrong to employ one which is not so; at least, if it be considered in a general sense, whatever it may accidentally prove to some few particular individuals."

Acceleration or hardness of pulse, restlessness, anxiety, and any degree of fever, after a smart blow on the head, are always to be suspected and attended to. Immediate, plentiful, and repeated evacuations by bleeding, have, in many instances, removed these, in persons, to whom, Mr. Pott firmly believes, very terrible mischief would have happened, had not such precaution been used. In this, as well as some other parts of practice, we neither have, nor can have any other method of judging, than by comparing together cases apparently similar. Mr. Pott has more than once or twice seen that increased velocity and hardness of pulse, and that oppressive languor, which most frequently precede mischief under the bone, removed by free and repeated bloodletting; and has often, much too often, seen cases end fatally, whose beginnings were full as slight, but in which such evacuation had been either neglected, or not complied with. This judicious writer "would by no means be thought to infer from hence, that early bleeding will always prove a certain preservative; and that they only die, to whom it has not been applied: this, like all other human means, is fallible; and, perhaps, there are more cases out of its reach, than within it: but, where preventive means can take place, this is certainly the best, and the most frequently successful."

"The second intention, viz. *the discharge of matter collected under the cranium*, can be answered only by the perforation of it."

"When, from the symptoms and appearances already described, there is just reason for supposing matter to be formed under the skull, the operation of perforation cannot be performed too soon; it seldom happens that it is done soon enough."

In short, whenever the dura mater, after the head has received external violence, separates, or is detached spontaneously from the bone underneath it, and such separation is attended with the collection of a small quantity of thin, brown ichor, an alteration of colour in the separated pericranium, unnatural dryness of the bone, chilliness, horripilation, languor, and some degree of fever, Mr. Pott considers the operation indispensably necessary to save the patient's life.

"When the skull has been once perforated, and the dura mater thereby laid bare, the state of the matter must principally determine the surgeon's future conduct. In some cases, one opening will prove sufficient for all necessary purposes; in others, several may be necessary."

Notwithstanding the operation of perforation be absolutely and unavoidably necessary, as Mr. Pott remarks, "the repetition of bloodletting or cooling laxative medicines, the use of antiphlogistic remedies, and a most strict observance of a low diet and regimen, are indispensably requisite after such operation as before; the perforation sets the membrane free from pressure, and gives vent to collected matter, but nothing more; the inflamed state of the parts under the skull, and all the necessary consequences of such inflammation, call for all our attention, full as much afterward as before; and although the patient must have perished without the use of the trephine, yet, the merely having used it, will not preserve him, without every other caution and care. (Pott.)

I think it not improper to recommend again the practice of applying cold wet cloths to the head for the prevention and relief of inflammation of the dura mater; a plan to which, as already explained, Schmucker ascribed a good deal of the success with which he treated injuries of the head. It is favourably mentioned by Dr. Hennen, and has received the recommendation of another modern writer, whose opinion must have great weight: "in the inflammation, which succeeds slowly to injuries of the head, a species of inflammation not more insidious in its approach, than dangerous in its consequences, cold is by far the most efficacious remedy that has yet been discovered." (See *Thomson's Lectures on Inflammation*, p. 181.)

Both tables of the skull sometimes exfoliate in consequence of external violence. The dead bone must be removed, as soon as loose; and, if necessary, the scalp divided for the purpose.

3. *Fissures and Fractures of the Cranium, without depression.*

Fractures of the cranium are divisible into "those, in which the broken parts keep their proper level, or equality of surface, with the rest of the skull, and those in which they do not; or, in other words, fractures without depression, and fractures with.

"These two distinctions are all which are really necessary to be made, and will be found to comprehend every violent division of the parts of the skull (not made by a cutting instrument) from the finest capillary fissure, up to the most complicated fracture."

No truth in surgery is now better understood, and established, than that the bad symptoms very frequently accompanying a broken skull, are not produced by the breach made in the bone; nor indicate such breach to have been made. "They proceed, (as Mr. Pott correctly observes,) from an affec-

tion of the brain, or from injury done to some of the parts within the cranium, independent of any ill which the bones composing it may have sustained. They are occasioned by violence offered to the contents of the head in general; are quite independent of the mere breach made in the bone; and either do or do not accompany fracture, as such fracture may happen to be, or not to be complicated with such other ills.

"They are frequently produced by extravasations of blood, or serum, upon, or between the membranes of the brain; or by shocks, or concussions of its substance, in cases where the skull is perfectly entire and unhurt. On the other hand, the bones of the skull are sometimes cracked, broken, nay, even depressed, and the patient suffers none of these symptoms. In short, as the breach made in the bone is not, nor can be the cause of such complaints, they ought not to be attributed to it; and that for reasons, which are by no means merely speculative. For the practitioner who supposes, that such symptoms do necessarily and certainly imply, that the cranium is fractured, must regulate his conduct by such supposition, and remove the scalp, very often without either necessity or benefit; that is, without discovering what he looks for; and, on the other hand, if he does find the skull to be broken, believing all these complaints to be caused by, and deducible from the fracture, he will most probably pay his whole attention to that supposed cause, and may think, that when he has done what the rules of his art prescribe for such case, he has done all that is in his power:—an opinion not unfrequently embraced; and which has been the destruction of many a patient. For, as on one hand, the loss of sense, speech, and voluntary motion, as well as the hemorrhage from the nose, ears, &c. are sometimes totally removed by, or at least disappear, during the use of free and frequent evacuation, without any operation on the scalp or skull: so, on the other, as these symptoms and appearances are not produced by the solution of continuity of the bone, they cannot be remedied by such chirurgic treatment as the mere fracture may require.

"If any one doubts the truth of this doctrine, (continues Mr. Pott,) I would desire him to consider the nature, as well as most generally successful method of treating these symptoms; and at the same time, to reflect seriously on the operation of the trepan, as practised in simple, undepressed fractures of the skull.

"The sickness, giddiness, vomiting, and loss of sense and motion, can only be the consequence of an affection of the brain, as the common sensorium. They may be produced by its having been violently shaken, by a derangement of its medullary structure, or by unnatural pressure made by a fluid extravasated on its surface, or within its ventricles; but never can be caused by the mere division of the bone, (considered abstractedly;) which division, in a simple

fracture, can neither press on, nor derange the structure of the parts within the cranium.

"If the solution of continuity in the bone be either produced by such a degree of violence, as hath caused a considerable disturbance in the medullary parts of the brain, or has disturbed any of the functions of the nerves going off from it; or has occasioned a breach of any vessel or vessels, whether sanguine or lymphatic, and that hath been followed by an extravasation, or lodgment of fluid; the symptoms necessarily consequent upon such derangement, or such pressure, will follow: but they do not follow, because the bone is broken, their causes are superadded to the fracture, and although produced by the same external violence, are yet perfectly and absolutely independent of it: so much so, that they are frequently found where no fracture is.

"The operation of the trepan is frequently performed in the case of simple fractures, and that very judiciously and properly; but is not performed, because the bone is broken or cracked: a mere fracture, or fissure of the skull, can never require perforation, or that the dura mater under it be laid bare; the reason for doing this, springs from other causes than the fracture, and those really independent of it; they spring from the nature of the mischief which the parts within the cranium have sustained, and not from the accidental division of the bone. From these arise the threatening symptoms; from these all the hazard; and from these, the necessity, and vindication of performing the operation of the trepan.

"If a simple fracture of the cranium was unattended in present with any of the before-mentioned symptoms, and there was no reason for apprehending any other evil in future, that is, if the solution of continuity in the bone was the whole disease, it could not possibly indicate any other curative intention, but the general one in all fractures, viz. the union of the divided parts." (*Pott.*)

I could relate numerous examples to the point, if it were any longer necessary, in the present state of surgical knowledge, to cite facts, in proof of the important truth, that the mere undepressed fissure, or fracture of the skull itself, cannot be the source of the immediate bad symptoms, but that, in these cases, the whole of the sudden peril arises from the manner in which the brain and its membranes have been hurt by the same violence, which caused the injury of the bone. Professor Thomson had opportunities of witnessing in the Netherlands several instances, which can leave no doubt upon the subject. "In some of the wounds, (says he) in which the head had been struck obliquely by the sabre, portions of the cranium had been removed, without the brain appearing to have sustained much injury. In one case of this kind, where a considerable portion of the upper part of the occipital bone, along with the dura mater, had been removed, a tendency to protrusion of the brain took place during an attack of inflam-

mation; a slight degree of stupor with loss of memory occurred; but on the inflammatory state having been subdued, the brain sunk to its former level, the stupor went off, and the memory returned:"—and in another remarkable sabre cut, more than an inch in breadth of the left lobe of the cerebellum was exposed, and was seen pulsating for a period of eight weeks, yet the injury was unaccompanied with any particular constitutional symptoms. (*See Observations made in the Military Hospitals of Belgium, p. 50, 51.*)

In many cases of simple undepressed fractures of the cranium, it is true, that trephining is necessary: but the reasons for the operation, in these instances, are, first, the immediate relief of present symptoms arising from the pressure of extravasated fluid; and, secondly, the discharge of matter, formed between the skull and dura mater, in consequence of inflammation. The operation of trephining was also recommended by Pott, as a preventive of ill consequences; a practice, however, which is now never adopted by the most eminent surgeons; and many writers of the highest reputation, especially Desault, Dease, Mr. John Bell, and Mr. Abernethy, urgently and properly remonstrate against the method.

The latter remarks: "In the accounts which we have of the former practice in France, it is related, that surgeons made numerous perforations along the whole track of a fracture of the cranium; and, as far as I am able to judge, without any clear design. Mr. Pott also advises such an operation, with a view to prevent the inflammation and suppuration of the dura mater, which he so much apprehended. But many cases have occurred of late, where, even in fractures with depression, the patients have done well without an operation."

Mr. Abernethy next relates several cases of fracture of the cranium with depression, which terminated favourably, although no operation was performed. This judicious surgeon thinks that these cases, as well as a great many others on record, prove that at all events a slight degree of pressure may not derange the functions of the brain, for a limited time after its application, and in this circumstance probably never; for all those patients, whom he had an opportunity of knowing, for any length of time after the accident, continued as well as if nothing of the kind had happened to them. In Mr. Hill's cases in surgery, two instances of this sort are related, and Mr. Hill knew both the patients for many years afterward; yet no inconvenience arose. Indeed, it is not easy to conceive, that the pressure, which caused no ill effects at a time, when the contents of the cranium filled its cavity completely, should afterward prove injurious, when they have adapted themselves to its altered size and shape. Severe illness, it is true, often intervenes between the receipt of the injury, and the time of its recovery; and many surgeons might be inclined to attribute this to pressure; but it equally occurs when the depressed portion

is elevated. If a surgeon, prepossessed with the opinion, that elevation of the bone is necessary in every instance of depressed cranium, should have acted upon this opinion in several of the cases which Mr. Abernethy has related, and afterward have employed proper evacuations, his patients would probably have had no bad symptoms, and he would naturally have attributed their well-doing to the mode of treatment which he had pursued: yet these cases did equally well without an operation. (See *Abernethy's Surgical Works*, Vol. 2, p. 4, &c. 8vo. Lond. 1811.)

Depressed fractures of the skull not being our immediate consideration, we need not expatiate upon them; but it seemed right to make the preceding remarks, in order to show how unnecessary it must be to trephine a patient, merely because there is a fracture in the cranium, and with a view of preventing bad consequences. Even when the fracture is depressed, it is not necessary, unless there are evident signs, that the degree of pressure, thus produced on the brain, is the cause of existing bad symptoms.

The inflammation and suppuration of the parts, beneath the skull, which Mr. Pott wished so much to prevent by trephining early, do not arise from the occurrence of a breach in the cranium, but are the consequences of the same violence, which was the occasion of the fracture. Hence, it is obvious, that removing a portion of the bone cannot in the least prevent the inflammation and suppuration, which must result from the external violence which was first applied to the head; but on the contrary, such a removal being an additional violence, must have a tendency to increase the inevitable inflammatory mischief.

From what has been said, it is not to be inferred, however, that trephining is never proper, when there is a simple undepressed fracture of the skull. Such injury may be joined with an extravasation of blood on the dura mater; or it may be followed by the formation of matter between this membrane and the cranium; in both which circumstances, the operation is essential to the preservation of the patient, immediately, but not before the symptoms indicative of the existence of dangerous pressure on the brain, begin to show themselves. (See *Trephine*.)

A fracture of the skull, unattended with urgent symptoms, and not brought into the surgeon's view by any accidental wound of the integuments, often remains for ever undiscovered; and as no benefit could arise from laying it bare by an incision, such practice should never be adopted. The surgeon ought only to be officious in this way, when he can accomplish by it some better object, than the mere gratification of his own curiosity. And as we shall find from the perusal of this article, and the one entitled, *Trephine*, that in these cases, the removal of pressure off the surface of the brain is the only possible reason for ever perforating the cranium with this instrument; and as dividing the scalp is only a useful mea-

sure, when it is preparatory to such operation; neither the one nor the other should ever be practised, unless there exist unequivocal symptoms, that there is a dangerous degree of pressure operating on the brain, and caused either by matter, extravasated blood, or a depressed portion of the skull. If any exceptions can be made to this observation, they are cases, in which it is advisable to remove loose splinters and fragments of bone, or balls plainly felt under the scalp.

The true mode of preventing the bad effects frequently following, but not arising from simple fractures of the skull, is not to trephine, but to put in practice all kinds of antiphlogistic means. For this purpose, let the patient be repeatedly and copiously bled, both from the arm and temporal arteries; let him be properly purged; give him antimonials; keep him on the lowest diet; let him remain in the most quiet situation possible; and if, notwithstanding such steps, the symptoms of inflammation of the brain continue to increase, let a large blister be applied to the scalp. These are the cases, also, in which the topical application of cold water to the shaved and naked head, by means of cloths kept constantly wet, is an eligible, though in this country, a much neglected practice. Numerous instances, however, in favour of the method are recorded by the experienced Schmucker, (see his *Chirurgische Wahrnehmungen*, B. 1, Berlin, 1774.) and the trials which I have seen made of it, give me a high opinion of its superior efficacy. When, in spite of all these measures, matter forms under the cranium, attended with symptoms of pressure, a puffy tumour of the injured part of the scalp, or those changes of the wound, if there is one, which Mr. Pott has so excellently described, and we have already related; not a moment should be lost in delaying to perforate the bone with the trephine, and giving vent to the matter beneath.

4. *Fractures of the Cranium with Depression.*

In simple fractures of the skull, or those in which the parts of the broken bone are not depressed from their situation, Mr. Pott remarks, that "The surgical intention and requisite treatment are the same in each, viz. to procure a discharge for any fluid which may be extravasated in present, (provided the pressure of such extravasation produces urgent symptoms, a condition which should here be added,) and to guard against the formation, or confinement of matter." The prevention of suppuration will, as we have already remarked, be best accomplished, not by perforating the cranium, as Mr. Pott advised, but by copious bleeding, evacuations, cold washes to the head, blisters, and a rigorous antiphlogistic regimen. However, the confinement of matter, producing symptoms of pressure on the brain, certainly indicates the immediate use of the trephine.

"But, says this author, in fractures attended with depression, there are other intentions. In these the depressed parts are to be elevated, and such as are so separated as to

be incapable of reunion, or of being brought to lie properly, and without pressing on the brain, are to be totally removed. These circumstances are peculiar to a depressed fracture; but although they are peculiar, they must not be considered as sole, but as additional to those which have been mentioned at large under the head of simple fracture: commotion, extravasation, inflammation, suppuration, and every ill which can attend on, or be found in the latter, are to be met with in the former, and will require the same method of treatment." That loose splintered pieces of the cranium, when quite detached, and already in view, in consequence of the scalp being wounded, ought to be taken away, no one will be inclined to question. That they ought also to be exposed by an incision, even when the scalp is unwounded, and then taken away, whenever they cause symptoms of irritation, or pressure, I believe, will be universally allowed. But the reader will already understand, from what has been said in the preceding section, that several excellent surgeons do not coincide with Pott, in believing that every depressed fracture of the skull necessarily demands the application of the trephine.

"There certainly are (says Mr. Abernethy) degrees of this injury, which it would be highly imprudent to treat in this manner. Whenever the patient retains his senses perfectly, I should think it improper to trephine him, unless symptoms arose that indicated the necessity of it." (P. 21.)

It is extraordinary and unaccountable, but it is not less true, that no calculation of the bad effects can be made by the degree in which a part of the skull is depressed. This is a fact which has been long known. It has also been particularly adverted to by an eminent modern writer. "Various instances also presented themselves, in which, though a considerable degree of compression must have been occasioned, sometimes by the depression of both tables, and at other times by the depression of the inner table only of the skull, yet neither stupor, paralysis, nor loss of memory were produced. In one of these cases, the middle of the right parietal bone was fractured, and considerably depressed by a ball, which was extracted on the twentieth day. In this case, neither stupor nor paralysis appeared. In another, a musket-ball had struck the right parietal bone, fractured it, and was flattened and lodged between the tables of the skull. The inner table was much depressed, yet no bad symptoms supervened." (See *Thomson's Observations made in the Military Hospitals in Belgium*, p. 59, 60.) The same author also saw a singular case, in which a ball, entering behind the right temple, and passing backwards and downwards, had fractured the bones in its passage, and lodged in the surface of the brain, over the tentorium, from which place it was extracted on the seventeenth day after the injury. No bad symptom had manifested itself previously to the operation, and the man recovered under the strictest antiphlog-

istic regimen, with little or no constitutional derangement. Dr. Hennen has recorded two cases, fully proving the correctness of Mr. Abernethy's opinion about the impropriety of using the trephine in cases of depression, unattended with urgent symptoms: in one of these instances, the upper and posterior angle of the parietal, which had been struck by a musket-ball, was depressed exactly *an inch and a quarter from the surface of the scalp, yet no bad symptoms followed*, and with the aid of bleeding and other antiphlogistic remedies, the soldier recovered perfectly in a few weeks. "In a similar case, where the man survived thirteen years, with no other inconvenience than occasional determination of blood to the head on hard drinking, *a funnel-like depression to the depth of an inch and a half was formed in the vertex.*" (See *Hennen's Military Surgery*, p. 287. Ed. 2.)

If then the violence of the symptoms is not always in proportion to the compression, but is sometimes considerable when the pressure is slight, every surgeon cannot be too fully impressed with the following truth, that *existing symptoms of dangerous pressure on the brain, which symptoms will be presently related, can alone form a true reason for perforating the cranium.* The mode of operating, in order to elevate depressed portions of the skull, is explained in the article, *Trephine*.

In military surgery, particular cases present themselves, which scarcely admit of being comprehended within the tenor of any general rules and principles. Thus, it sometimes happens, that a ball breaks the os frontis, and the whole or a part of it lodges in the frontal sinus, with or without fracture of the inner boundary of this cavity. In cases of this description, Baron Larrey recommends exposing the course of the fracture by a free incision, and the use of the trephine for the removal of the extraneous body. When the inner side of the sinus was found broken and depressed, he next perforated that part of the cavity with a small conical trephine, took away such pieces of bone as required removal, and let out any extravasated blood. Sometimes, however, the front of the sinus is so splintered, that the fragments, when taken away with the forceps, leave the cavity sufficiently opened, not only for the extraction of the ball, but for the application of the trephine to the inside of the sinus, as we find exemplified in one of the two cases of this nature, which Larrey met with in the Egyptian campaign. (*Mém. de Chir. Militaire*, T. 2, p. 138.) After the battle of Witepsk, in 1812, he was called to two Russian soldiers, whose cases were remarkable; one of them had been struck above the right eyebrow with a grape-shot, which, after breaking and penetrating the frontal bone, entered the cavity of the cranium, so as to lodge upon the anterior right lobe of the brain, and the orbital process and internal crista of the os frontis. Notwithstanding the large size of the ball, little of it could be seen externally, and the aperture through

which it had passed, was not more than three or four lines broad : every attempt to extract it, therefore, was vain. The patient experienced a painful sense of oppression and weight in the head, and whenever he inclined it backward, was seized with syncope. He kept himself constantly in a sitting posture, with his head on his knees. Larrey adds, that every symptom of compression of the brain also prevailed, though this account is rather difficult to comprehend, considering that the patient could sit up, and choose his posture. As for any description given by himself, of his sufferings, that is another circumstance on which I should not be inclined to dwell, supposing, that probably the Baron was not able to converse in the Russian language, and that the inferences, respecting the man's feelings, were made in some other way. But whatever might be the real state of the symptoms, (and in a case of this kind a correct account of them would have been interesting,) the ball was plainly ascertained, by means of a probe, to be of iron, and of much larger diameter than the opening, through which it had entered ; and, that for the purpose of extracting it, the application of the trepan was urgently necessary. The fracture was fairly brought into view by suitable incisions, three perforations were made with a small trephine at its upper part, and after the removal of the angles of the bone between these perforations, the ball, which weighed seven French ounces, was readily extracted with the aid of a strong pair of forceps, and an elevator. A considerable quantity of coagulated blood was also removed, under which the brain was found with a depression of three or four lines deep. As soon as some splinters of the bone had been taken away, the part was dressed with a bit of fine linen dipped in warm wine, sweetened with sugar, over which were placed charpie, several compresses, and a bandage. With respect to the application of warm wine, and other stimulants, to the surface of the brain, in wounds exposing or interesting that organ, it seems to be an invariable practice with Larrey, as well as Schmucker, and the older surgeons. On what principle the custom is still kept up ? and whether it is truly right and useful ? are questions which may be rationally put. In whatever way experience may hereafter decide these matters, suffice it to add, that the patient was relieved by the treatment, and fell into a quiet sleep for two hours ; but in the evening he became feverish, and the wound acutely painful. A considerable quantity of blood was taken from the vena saphena, (and why bleeding was not practised at first, seems extraordinary.) The dressings, which according to my ideas, were highly objectionable, were removed, and a large emollient poultice applied. Cooling beverages, containing a small quantity of tartarized antimony, and antispasmodic anodyne medicines, were prescribed. The following day, the patient's state appeared satisfactory, without the slightest disturbance of the senses, and in due time, he perfectly recovered.

The other soldier had been wounded in the left temple, with a lead ball, five days before Larrey saw him. One half of the ball had gone into the cranium, through a very narrow breach ; the other had burrowed under the temporal muscle, and lodged near the mastoid process. The right side of the body was paralytic, the senses were annihilated, and the man was in a state of incessant agitation. After dilating the wound in the temple, and exposing the fracture, Larrey discovered the track of the piece of lead, which had gone towards the mastoid process, and which he immediately extracted by a counter-opening. At the lower part of the temporal wound, he applied a trepan very near the spot where the other portion of the ball was lodged. This, with some fragments of the bone, and extravasated blood, was easily extracted. The patient, however, was not saved ; a circumstance ascribed by Larrey, to the operation having been done too late.

In another case, one of the Imperial Guards, wounded at the battle of Moskowa, died with symptoms of compression, and, after death, a quarter of a bullet, and a fragment of bone, were found under the skull, attended with an ulcerated (or wounded) state of the adjacent portion of the brain. Larrey very properly expresses his opinion, that this soldier would have had a chance of being saved, had the trepan been used. (*See Mém. de Chir. Mil. T. 4, p. 183, &c.*) The practice of trephining for the removal of balls, situated near a fracture of the skull, within this bony cavity, or lodged among the fragments, or between the two tables, forced asunder, (see *Engel's Case in Vermischte Chir. Schriften von J. L. Schmucker. B. 1, p. 242,*) is not peculiar to Larrey, for it has been done by many other surgeons, (see *Schmucker's Wahrnehmungen, B. 1, p. 298* ; but, I do not know, that he has been anticipated in his bold practice of making a counter-opening in the skull, when the ball is lodged at such distance from the fracture, that it cannot be extracted through any perforation made in the vicinity of the original injury ; for, it is a principle, which he ventures to lay down, that *when a ball has entered the cranium, without quitting the root of this cavity, the case is one requiring the application of the trepan. Mém. de Chir. Mil. T. 4, p. 180.*) In the 2d vol. of this work, (p. 139,) the reader will find the account of a soldier, who was struck on the middle of the forehead with a ball, which penetrated the os frontis, and then passed obliquely backwards, between the skull and the dura mater, in the course of the longitudinal sinus, as far as the lambdoidal suture, where it stopped. Larrey traced the situation of the ball, by the introduction of an elastic gum catheter into the opening and measuring the distance between the fracture and the place, where he felt the ball, he cut down upon that part of the skull, beneath which he concluded that the ball was lodged. The bone was then perforated with a large trepan ; a good deal of pus was discharged ; the ball was extracted, and the patient recovered.

One thing here merits the attention of surgeons: Larrey tells us, that a good deal of pus issued as soon as an opening was made in the skull; there must then have been suppuration under the bone, and inflammation and detachment of the dura mater; circumstances always indicated, according to Pott, by a corresponding separation of the pericranium, and a puffy tumour of the scalp. Did these symptoms take place in the foregoing case, so as to be of any assistance to Larrey, in judging of the place where the ball was lodged? And, has the mention of them been omitted only by accident? or, are we to infer, that suppuration may happen between the cranium and dura mater, without any detachment of the pericranium and puffy tumour of the scalp; a thing, which Bichat asserts, is proved by daily experience in the Hôtel-Dieu, at Paris? (See *Œuvres Chir. de Desault*, T. 2, p. 29.) Larrey, in his 3d vol. p. 82, gives us another case, in which a ball pierced the left parietal bone, and lodged near the lambdoidal suture. Its situation was detected with the aid of an elastic gum catheter, and partly in consequence of there being a slight ecchymosis over the part. Here a crucial incision was made through the scalp, and a small fissure discovered. As the symptoms of compression increased, the trepan was applied, so as to include the fissure. A half of the ball flattened was found directly under the perforation, and a good deal of blood was voided from the two openings in the cranium. For a fortnight, the case went on favourably, but the patient was then attacked with what Larrey terms hospital fever, but which, in all probability, was inflammation and suppuration of the membranes of the brain, and died.

The records of surgery furnish numerous instances, in which the patients lived a considerable time with balls lodged in the cavity of the cranium. Thus, one is related by Paroisse, where the patient soon recovered his senses after the injury, and at the end of six months, felt no inconvenience, except a difficulty of opening the mouth (*Opusculs de Chir. Obs. 1, Svo. Paris, 1806.*) Ramdohr has published another case, where a soldier was shot through the frontal sinus, and the ball was found after death in the medullary substance of the left hemisphere of the brain, half an inch above the ventricle: yet, this patient lived four months after the injury, and soon recovered his senses after its occurrence. For a considerable part of this time, he was also free from any bad symptoms. At last, he was affected with a kind of stupor, and an inability to open his left eye, and fell into a lethargic, and convulsed state. (*Schmucker Vermischte Chir. Schriften*, B. 1, p. 277) A French soldier, at the battle of Waterloo, was wounded with a musket-ball, which entered at the anterior portion of the squamous suture, lodged in the substance of the brain, and on the fifth day, after an enlargement of the wound, and the removal of several fragments of bone,

was extracted from the posterior lobe of the right hemisphere of the brain, where it was found resting on the tentorium. Yet, during the several previous days, the man, with the exception of a slight headach, and partial deafness of the right ear, seemed to enjoy perfect health. The case ended well. (See *Hennen's Mil. Surg.* p. 289. Ed. 2.) Still more remarkable instances of the duration of life, and even of the absence of very serious symptoms, after great and serious wounds of the brain, and the lodgment of balls, might here be cited; but, it will suffice to refer to the instructive Essay of M. Quesnay, on the subject, in vol. 1, of the *Mém. de l'Acad. de Chir.* 4to. and to the account of twenty-two French soldiers, whose vertices, with more or less of the brain, were cut off by sabre strokes. All these men ultimately died; but, at first, had not a single bad symptom, and performed a journey of thirty leagues after being wounded, and one half of this distance on foot. (See *Paroisse Opusculs de Chir.* p. 41, &c.)

5. Extravasation under the Cranium, Symptoms of Pressure on the Brain, &c.

Mr. Pott remarks, "the shock, which the head sometimes receives by falls from on high, or by strokes from ponderous bodies, does not unfrequently cause a breach in some of the vessels, either of the brain, or its meninges; and thereby, occasions extravasation of the fluid, which should circulate through them. This extravasation may be the only complaint produced by the accident; or it may be joined with, or added to, a fracture of the skull. But this is not all, for it may be produced not only when the cranium is unhurt by the blow, but even when no violence of any kind has been offered to, or received by the head."

The effused blood may lie between the cranium and dura mater, between the latter membrane and the pia mater; or in the substance, or cavities of the brain. The first species of extravasation, which is observed to be always more or less circumscribed, may occur at any part of the skull, but when situated at its base, is generally fatal. In the second, the blood is widely scattered about between the dura mater and arachnoides, and on this account, unless its quantity be very considerable, it does not cause any great degree of pressure. In the third example, if the blood be situated in the convolutions, it is also widely diffused, but if it be within the substance, or ventricles, of the brain, it is circumscribed (*Œuvres Chir. de Desault par Bichat*, T. 2, p. 23.) Sometimes, in cases of great violence, as Mr. Pott has justly observed, the blood is found at the same time in all these different parts.

When the blood is extravasated beneath the skull, the violence, which produces the rupture of the vessel, usually stuns the patient, from which state, provided the quantity and pressure of the blood, and the force of the concussion be not too great, he gradually recovers, and regains his senses. If the first extravasation be trivial, the patient, after re-

gaining his senses, may only feel a little drowsiness, and go to bed. The bleeding from the ruptured vessel continuing, and the pressure on the brain increasing, he becomes more and more insensible, and begins to breathe in a slow, interrupted, stertorous manner. In cases of compression whether from blood or a depressed portion of the skull, there is a general insensibility; the eyes are half open, the pupils dilated, and motionless, even before the vivid light of a candle; the retina is insensible; the limbs relaxed; the breathing stertorous; the pulse slow, and, according to Mr. Abernethy, less subject to intermission, than in cases of concussion. The absence of stertor, however, as this gentleman admits, must not be relied upon, as a proof of there being no compression; for, Morgagni relates dissections of apoplectic persons, in whom the effusion was considerable, yet no stertor occurred.

In a case of wound of the posterior part of the skull, with depression, seen by Dr. J. Thomson, the pulse at one time sunk as low as 36 strokes in a minute. This eminent professor, however, is at variance with Mr. Abernethy upon one point, by stating, that irregularity of the pulse is a very frequent attendant upon compressed brain. (*Report of Observations, &c. p. 54, 55.*) Sometimes convulsions arose from the pressure of portions of the skull, driven in upon the brain. This is a very dangerous symptom; but Dr. Thomson saw it cease in a few examples, after the depressed piece of bone had been elevated, and the antiphlogistic regimen adopted. (*P. 60.*) Convulsions, I am disposed to regard with Bichat, rather as a symptom of injury of the brain, than of compression. (*Œuvres Chir. Desault, T. 2, p. 27.*)

Indeed, the difficulty of the diagnosis of many cases may be well conceived by what Dr. Hennen remarked, in his practice, viz. that, in some instances, the pupils were contracted, in others dilated, where the injury was nearly of a similar nature and degree; while, sometimes, in the same patient, one pupil was dilated, and the other much contracted. He saw, also, paralysis occur on one side, and convulsions on the other, when the blow had been on the forehead and the same when it had been on the occiput. (*Op. cit. p. 300, 301.*)

The patient is hardly ever sick, when the pressure on the brain and the general insensibility, are considerable; for the very action of vomiting betrays sensibility in the stomach and œsophagus. These symptoms are not peculiar to pressure from blood, but arise also from that of many depressed fractures of the skull, and of suppuration under this part. They are all attributable to the unnatural pressure made on the brain and nerves, and have too often been mistaken, as indications of an injury, which, considered abstractedly, can never cause them; we allude to a simple undepressed fracture of the cranium, which may be accompanied with them, but cannot cause them. They differ in degree, according to the quantity, kind,

and situation of the pressing fluid. The hemorrhage from the nose and ears, which often follows violence applied to the head, leads to no particular or useful inference: we cannot even calculate, by this sign, that the force has exceeded a certain degree; for, such bleedings take place, in some persons, from much slighter causes than in others.

Paralysis is a symptom, which generally attends hurtful pressure on the brain. The particular circumstance, however, which determine its degree, extent, and situation, are not well understood. "In some instances of paralysis from sabre-wounds, as well as in those made by gunshot, (says Dr. J. Thomson) paralysis was confined to the upper, and in others to the lower extremity. *In every instance, in which it distinctly appeared that the injury existed on one side of the head, the paralysis uniformly manifested itself upon the other*; but, we were unable to perceive any other fixed relation, between the part of the brain, which had been injured, and the part of the body affected with palsy. A wound of the right parietal bone by a musket-ball was followed by palsy of the left arm and leg. In another case, a wound, penetrating the upper part of the right parietal bone, was accompanied with a slight paralytic affection of the left side of the mouth, and complete palsy of the left leg. In a third case, a sabre-wound of the same bone, followed by extensive exfoliations, gave rise to a complete palsy of the left side." (*Observations made in the Military Hospitals in Belgium, p. 52, 53.*)

With respect to paralysis, it is unquestionably one of the common symptoms of pressure on the brain; but, according to Bichat, it may also be caused by concussion; and we know, that it may arise in cases of inflammation and suppuration, within the skull. The above statement respecting the paralysis being always on the side of the body opposite that on which the brain is compressed, agrees with what is generally remarked by other surgical writers. (See *Larrey's Mém. de Chir. Mil. T. 4, p. 180; Hennen's Principles, p. 301, Ed. 2, &c.*) Yet, at the Hôtel Dieu, at Paris, says Bichat, extravasation has very often been found both on the side affected with paralysis, and the opposite one; or else the blood was generally diffused, while the paralysis was local. (*Œuvres Chir. de Desault, T. 2, p. 27.*)

The preceding class of symptoms only informs us, that the brain is suffering compression, and leaves us quite in the dark respecting several other very important circumstances. "We not only have no certain infallible rule, whereby to distinguish what the pressing fluid is, or where it is situated, but we are, in many instances, absolutely incapable of knowing, whether the symptoms be occasioned by any fluid at all; for, a fragment of bone broken off from the internal table of the cranium, and making an equal degree of pressure, will produce exactly

the same complaints." (Pott.) In detailing the symptoms of pressure from blood, I took particular notice of the patient being at first generally stunned by the blow; of his gradually regaining his senses, and of his afterward relapsing into a state of insensibility again. The interval of sense, which thus occurs, was pointed out by Petit as a circumstance of the greatest consequence in elucidation of the nature of the case.

"A concussion, and an extravasation (as Mr. Pott observes,) are very distinct causes of mischief, though not always very distinguishable.

"M. Le Dran, and others of the modern French writers, have made a very sensible and just distinction between that kind and degree of loss of sense which arises from a mere commotion of the brain, and that which is caused by a mere extravasation, in those instances, in which the time of the attack, or appearance of such symptoms, are different, or distinct. The loss of sense, which immediately follows the violence, say they, is most probably owing to a commotion; but that which comes on after an interval of time has past, is most probably caused by extravasation.

"This distinction is certainly just and good, as far as it will go. That degree of abolition or diminution of sense, which immediately attends or follows the blow or fall, and goes off again without the assistance of art, is in all probability occasioned by the sudden shake, or temporary derangement of the contents of the head; and the same kind of symptoms recurring again some time after they had ceased, or not coming on until some time has passed from the receipt of the violence, do most probably proceed from the breach of a vessel within or upon the brain. But unluckily, we have it not very often in our power to make this exact distinction. An extravasation is often made so immediately, and so largely, at the instant of the accident, that all sense and motion are instantaneously lost, and never again return. And it also sometimes happens, that although an extravasation may possibly not have been made at the moment of the accident, and the first complaints may have been owing to commotion merely, yet a quantity of fluid having been shed from its proper vessels very soon after the accident, and producing its proper symptoms, before those caused by the commotion have had time to go off, the similarity of the effects of each of these different causes is such, as to deprive us of all power of distinguishing between the one and the other, or of determining with any tolerable precision, to which of them such symptoms as remain are really owing."

As Bichat remarks, a man meets with a fall; a slight concussion of the brain is the consequence, and the patient is instantly stunned. The effects of concussion gradually subside, but an extravasation takes place, and the loss of the senses continues, though from a different cause. Here, according to the principles of Petit, the case

would be set down as concussion; yet, things are quite the contrary, the extravasation now keeping up the symptom, which was only temporarily produced by concussion. In many instances also the effects of concussion and extravasation exist together, and then how is a surgeon to judge of the nature of the case? (See *Œuvres Chir. de Desault*, T. 2, p. 25.)

"When an extravasation of any kind is made, either upon or within the brain, if it be in such quantity, or so situated, as to disorder the economy of the animal, it always produces such disorder, by making an unnatural pressure on the parts where it lies. The nature and degree of the symptoms, hereby produced, are various and different in different persons, according to the kind, quantity, and situation of the pressing fluid. Sometimes it is mere fluid blood, sometimes blood in a state of coagulation, sometimes it is a clear lymph, and at others blood and water are found mixed together; each of these is found either simple or mixed in different situations, that is, between the skull and dura mater, between the dura and pia mater, or in the natural cavities of the brain, called its ventricles, and sometimes, in cases of great violence, they are found at the same time in all these different parts. Sometimes a considerable quantity is shed instantly, at the time of the accident; and sometimes the breach by which the effusion is made is so circumstanced, both as to nature and situation, that it is at first very small, and increases by faster or slower degrees. In the former, the symptoms are generally immediate and urgent, and the extravasation is of the bloody kind; in the latter, they are frequently slight at first, appear after some little interval of time, increase gradually till they become urgent or fatal, and are in such case generally occasioned by extravasated lymph. So that although the immediate appearance of bad symptoms does most certainly imply mischief of some kind or other, yet, on the other hand, no man ought to suppose his patient free from hazard, either because such symptoms do not show themselves at first, or because they appear to be but slight: those which come on late, or appearing slight at first, increase gradually, being full as much to be dreaded as to consequence, as the more immediately alarming ones; with this material difference between them, that the one may be the consequence of a mere concussion of the brain, and may by means of quietude and evacuation go quite off; whereas, the other being most frequently owing to an extravasation of lymph, (though sometimes of blood also) within the substance of the brain, are very seldom removed by art." (Pott.)

The case of extravasation between the cranium and dura mater, is almost the only one which admits of relief from trephining. Mr. Abernethy informs us, that in the cases which he has seen of blood extravasated, between the dura and pia mater, on a division of the former membrane being made

for its discharge, only the serous part of it could be evacuated: for the coagulum was spread over the hemisphere of the brain, and had descended as low as possible towards its inferior part, so that very little relief was obtained by the operation. (*Surgical Works, Vol. 2, p. 46.*) This statement, we see, is confirmed by that of Bichat.

Fractures of the cranium, which take place across the lower and front angle of the parietal bone, and the rest of the tract of the trunk, and large branches of the spinous artery of the dura mater, are cases very apt to be attended with a copious extravasation. This vessel, and others more deeply seated, however, may be ruptured, pour out a considerable quantity of blood, and induce urgent symptoms of pressure on the brain, not only without the co-existence of a fracture, but even of any external mark of violence on the scalp.

The effused blood is frequently situated below the part on which the violence has operated, and hence, when such part is pointed out by a wound, or discoloration of the scalp, or a fracture, and the symptoms of pressure are considerable, I should have no hesitation about immediately trephining, in the situation of the external injury. I have seen many cases, in which such practice was justified by the result, and even when no extravasation exists, this plan will sometimes detect a depression of the inner table of the skull, and be the means of saving life, as happened in one very remarkable case, which I trephined at Brussels, after the battle of Waterloo. At the same time, it would be wrong to hold out the expectation, that, by acting on this principle, the surgeon will always find blood immediately under the part of the cranium which he perforates. With respect to a fracture also, as a guide to the place for the application of the trephine in cases of extravasation, Desault regards it as very fallacious, dissections proving that numerous fractures of the skull are unattended with any effusion of blood immediately under them; and his experience taught him, that the most frequent cases were those, in which there was either extravasation without fracture, or a fracture with blood effused in a part of the head remote from the injury of the bone. (*Œuvres Chir. T. 2, p. 130.*) Even when blood is seen issuing from the fissure, he regards it as no proof of the dura mater being detached, as such blood may proceed from the vessels of the diploe. (*P. 31.*) But what is to be done, when dangerous symptoms of pressure prevail, without any external mark to denote what part of the head has received the blow, or whether any at all? for, a general concussion of the head may produce an effusion of blood within the cranium. Under these circumstances, Mr. Pott was against the operation, and says that "the only chance of relief is from phlebotomy, and an open belly; by which we hope so to lessen the quantity of the circulating fluids as to assist nature in the dissipation or absorption of what has been extravasated.

This is an effect which, although not highly improbable in itself, yet is not to be expected from a slight or trifling application of the means proposed. The use of them must be proportioned to the hazard of the case. Blood must be drawn off freely and repeatedly, and from different veins; the belly must be kept constantly open, the body quiet, and the strictest regularity of general regimen must be rigidly observed. By these means, very alarming symptoms have now and then been removed, and people in seemingly very hazardous circumstances, have been recovered." Desault also promulgated the same advice, and blamed the doctrine formerly in vogue, that it was better to apply the trephine many times uselessly, than to let a single extravasation remain undetected; for Desault was convinced, that the trephine, when used on this principle, was a source of greater mischief, than the effused blood itself. (*Œuvres Chir. T. 2, p. 34.*)

But should the mode of judging, whether blood lies immediately under the skull, suggested by Mr. Abernethy, prove invariably correct, the question, whether the trephine should be applied, or not, may in future be more easily determined. Even when the injured scalp shows where the violence has operated, the criterion, about to be noticed, may inform us whether we should perforate the bone or not; for though the extravasation is sometimes found immediately under the external mark, yet it often is not so; but is in a part distant from that mark, to which situation we have nothing to lead us, and to which, indeed, if we knew it, we could not reach. Mr. Abernethy has observed, "that unless one of the large arteries of the dura mater be wounded, the quantity of blood poured out will probably be inconsiderable; and the slight compression of the brain, which this occasions, may not be attended with any peculiar symptoms, or perhaps it may occasion some stupor, or excite an irritation, disposing the subjacent parts to become inflamed. It is indeed highly probable, that in many cases, which have done well without an operation, such an extravasation has existed. But if there be so much blood on the dura mater as materially to derange the functions of the brain, the bone, to a certain extent, will no longer receive blood from within, and by the operation performed for its exposure, the pericranium must have been separated from its outside. I believe, that a bone so circumstanced, will not be found to bleed; and, I am at least certain, it cannot with the same freedom and celerity, as it does when the dura mater remains connected with it internally. (See *Abernethy's Surgical Works, Vol. 2, p. 47.*) In some cases related by this gentleman, there was no hemorrhage; twice he was able, by attending to this circumstance, to tell how far the detachment of the dura mater extended; and often, when symptoms seemed to demand a perforation of the skull, he has seen the operation contra-indicated by the hemorrhage

from the bone, and as the event showed, with accuracy. Mr. Abernethy admits, however, that in aged persons, and in those in whom the circulation has been rendered languid by the accident, the mode of distinction, which he has pointed out, will be less conclusive.

Pott remarks, that "if the extravasation be of blood, and that blood be in a fluid state, small in quantity, and lying between the skull and dura mater, immediately under or near to the place perforated, it may happily be all discharged by such perforation, and the patient's life may thereby be saved; of which many instances are producible. But if the event does not prove so fortunate, if the extravasation be so large or so situated that the operation proves insufficient, yet the symptoms having been urgent, general evacuation having been used ineffectually, and a wound or bruise of the scalp having pointed out the part which most probably received the blow: although the removal of that part of the scalp (a simple incision ought to have been said) should not detect any injury done to the bone, yet the symptoms still subsisting, I cannot help thinking, that perforation of the cranium is in these circumstances so fully warranted, that the omission of it may truly be called a neglect of having done that which might have proved serviceable, and *rebus sic stantibus*, can do no harm. It is very true, that no man can beforehand tell whether such operation will prove beneficial or not, because he cannot know the precise nature, degree, or situation of the mischief; but this uncertainty, properly considered, is so far from being a dissuasive from the attempt, that it is really a strong incitement to make it; it being fully as impossible to know, that the extravasated fluid does *not* lie between the skull and dura mater, and that under the part stricken, as that it *does*; and if the latter should be the case, and the operation be not performed, one, and most probably the only means of relief, will have been omitted."

When there is no interval of sense, between the blow, and the coming on of perilous symptoms, it is frequently impossible to determine, whether the mischief be owing to the largeness and suddenness of the extravasation, to the violence of the shock which the brain has received, or to both these causes at once, which unfortunately, is too often the case. In this latter complication, indeed, trephining will frequently be of no avail, even though it serve for the entire removal of all pressure off the brain; for the patient cannot recover from the violence of the concussion, and never regains his senses. This is no reason, however, why the chance of the operation doing good should not be taken, when there are evident symptoms of pressure. Let us, in these darkened cases, call to mind the sentiments of Pott, who says: "No man, who is at all acquainted with this subject, will ever venture to pronounce or promise success from the use of the trephine, even in the most

apparently slight cases; he knows that honestly he cannot; it is enough that it has often been successful where and when every other means have failed. The true and just consideration is this: does the operation of perforating the cranium in such case add at all to that degree of hazard which the patient is in before it is performed? or can he in many instances do well without it? If it does add to the patient's hazard, that is certainly a very good reason for laying it aside, or for using it very cautiously; but if it does not, and the only objection made to it is, that it frequently fails of being successful, surely it cannot be right to disuse that, which has often been, not only salutary, but the *causa sine qua non* of preservation, merely because it is also often unsuccessful, that is, because it is not infallible."

Giving vent to the confined blood "may produce a cure, or it may prove only a temporary relief, according to the different circumstances of different cases. The disappearance, and even the alleviation of the most pressing symptoms, is undoubtedly a favourable circumstance, but is not to be depended upon as absolutely portending a good event. Either a bloody, or limpid extravasation may be formed, or forming between the meninges, or upon or within the brain, and may prove as certainly pernicious in future, as the more external effusion would have done had it not been discharged; or the dura mater may have been so damaged by the violence of the blow as to inflame and suppurate, and thereby destroy the patient.

"If the disease lies between the dura and pia mater, mere perforation of the skull can do nothing; and therefore, if the symptoms are pressing, there is no remedy but division of the outer of these membranes. The division of the dura mater is an operation, which I have several times seen done by others, and have often done myself; I have seen it, and found it now and then successful; and from those instances of success, am satisfied of the propriety, and necessity of its being sometimes done." He next states, however, his sentiment, that wounding the dura mater is itself attended with dangerous consequences. Mr. Abernethy's opinion of such operation has already been given.

"Upon the removal of a piece of bone by means of the trephine; if the operation has been performed over the part where the disease is situated, and the extravasation be of the fluid kind, and between the cranium and dura mater; such fluid, whether it be blood, water, or both, is immediately seen, and is partly discharged by such opening; if, on the other hand, the extravasation be of blood in a coagulated or grumous state, it is either loose, or in some degree adherent to the dura mater; if the former of these be the case, it is either totally or partially discharged at the time of, or soon after the operation, according to the quantity or extent of the mischief; if the latter, the perforation discovers, but does not immediately

discharge it." Mr. Pott then lays it down as a rule, that a large extravasation must necessarily require a more free removal of bone than a small one; and a grumous or coagulated extravasation, a still more free use of the instrument.

All cases of pressure on the brain are attended with hazard of inflammation of this organ, and its membranes. The danger must be averted, as much as possible, by applying cold washes to the head, and employing free and repeated bleeding, leeches, antimonials, saline purgatives, and other antiphlogistic means.

CONCUSSION, OR COMMOTION OF THE BRAIN.

It is observed by Mr. Pott, that "very alarming symptoms, followed sometimes by the most fatal consequences, are found to attend great violence offered to the head; and upon the strictest examination, both of the living and the dead, neither fissure, fracture, nor extravasation of any kind can be discovered. The same symptoms, and the same event are met with, when the head has received no injury at all *ab externo*, but has only been violently shaken; nay, when only the body, or general frame, has seemed to have sustained the whole violence." And he afterward remarks, that "the symptoms attending a concussion are generally in proportion to the degree of violence which the brain itself has sustained, and which indeed, is cognizable only by the symptoms. If the concussion be very great, all sense and power of motion are immediately abolished, and death follows soon; but between this degree, and that slight confusion (or stunning as it is called,) which attends most violences done to the head, there are many stages." I am of opinion, that Mr. Abernethy has particularly excelled other writers, in his description of the symptoms of concussion, which he thinks may be divided into three stages.

"The *first* is, that state of insensibility and derangement of the bodily powers, which immediately succeeds the accident. While it lasts, the patient scarcely feels any injury that may be inflicted on him. His breathing is difficult, but in general without stertor; his pulse intermitting, and his extremities cold. But such a state cannot last long; it goes off gradually, and is succeeded by another, which I consider as the *second* stage of concussion. In this, the pulse and respiration become better, and though not regularly performed, are sufficient to maintain life, and to diffuse warmth over the extreme parts of the body. The feeling of the patient is now so far restored, that he is sensible if his skin be pinched; but he lies stupid and inattentive to slight external impressions. As the effects of concussion diminish, he becomes capable of replying to questions put to him in a loud tone of voice, especially when they refer to his chief suffering at the time, as pain in the head, &c.; otherwise, he answers incoherently, and as if his attention was occupied by something else.

As long as the stupor remains, the inflammation of the brain seems to be moderate; but as the former abates, the latter seldom fails to increase; and this constitutes the *third* stage, which is the most important of the series of effects proceeding from concussion.

"These several stages vary considerably in their degree and duration; but more or less of each will be found to take place in every instance where the brain has been violently shaken. Whether they bear any certain proportion to each other or not, I do not know. Indeed, this will depend upon such a variety of circumstances in the constitution, the injury, and the after-treatment, that it must be difficult to determine.

"With regard to the treatment of concussion, it would appear, that in the first stage very little can be done; and perhaps, what little is done, had better be omitted, as the brain and nerves are probably insensible to any stimulants that can be employed. From a loose, and I think, fallacious analogy between the insensibility in fainting, and that which occurs in concussion, the more powerful stimulants, such as wine, brandy, and volatile alkali, are commonly had recourse to, as soon as the patient can be got to swallow. The same reasoning which led to the employment of these remedies in the *first* stage, in order to recall sensibility, has given a kind of sanction to their repetition in the *second*, with a view to continue and increase it.

"But here the practice becomes more pernicious and less defensible. The circumstance of the brain having so far recovered its powers, as to carry on the animal functions in a degree sufficient to maintain life, is surely a strong argument that it will continue to do so, without the aid of means which probably tend to exhaust parts already weakened, by the violent action they induce.

"And it seems probable, that these stimulating liquors will aggravate that inflammation which must sooner or later ensue." (*Essay on Injuries of the Head*, p. 59.)

The following passage, extracted from a writer, who has already been of material assistance to us on this subject, cannot be too deeply impressed on the memory of every surgical practitioner.

"To distinguish between an extravasation and a commotion, by the symptoms only, is frequently a very difficult matter, sometimes an impossible one. The similarity of the effects in some cases, and the very small space of time which may intervene between the going off of the one, and accession of the other, render this a very nice exercise of the judgment. The first stunning or deprivation of sense, whether total or partial, may be from either, and no man can tell from which; but when these first symptoms have been removed, or have spontaneously disappeared; if such patient is again oppressed with drowsiness, or stupidity, or total or partial loss of sense, it then becomes most probable, that the first complaints were

from commotion, and that the latter are from extravasation; and the greater the distance of time between the two, the greater is the probability not only that an extravasation is the cause, but that the extravasation is of the limpid kind, made gradatim, and within the brain.

"Whoever seriously reflects on the nature of these two causes of evil within the cranium, and considers them as liable to frequent combination in the same subject, and at the same time considers, that in many instances no degree of information can be obtained from the only person capable of giving it (the patient,) will immediately be sensible how very difficult a part a practitioner has to act in many of these cases, and how very unjust it must be to call that ignorance, which is only a just diffidence arising from the obscurity of the subject, and the impossibility of attaining materials to form a clear judgment.

"When there is no reason to apprehend any other injury, and commotion seems to be the sole disease, plentiful evacuation by phlebotomy and lenient cathartics, a dark room, the most perfect quietude and a very low regimen, are the only means in our power; and are sometimes successful." (Pott.)

With these means should also be associated the constant application to the head of cloths dipped in very cold water, or Schmucker's frigorific lotion; and where the symptoms increase, or prove obstinate, blisters. Leeches are also frequently of great service.

I cannot conclude this article without adverting to the great propensity to relapse, after patients have long appeared out of every danger from wounds of the head, the bad symptoms sometimes coming on again, and proving fatal, many years after the original injury, as is exemplified in a case related in a work of high character. (See Schmucker's *Vermischte Schriften*, B. 1, p. 247.)

HEMERALOPIA. According to M. Dujardin, this term is derived from *hēmerā*, the day, *ἀλσος*, blind, and *ὤψ*, the eye, and its right signification is therefore inferred to be *diurna cæcitas*, or day-blindness. (See *Journal de Med.* T. 19, p. 348.) In the same sense, Dr. Hillary (*Obs. on the Diseases of Barbadoes*, p. 298, Edit. 2.) and Dr. Heberden (*Med. Trans.* Vol. 1, Art. 5.) have employed the term.

Hemeralopia then, which is of very rare occurrence, stands in opposition to the *nyctalopia* of the ancients, or night-blindness. Numerous modern writers, however, have used these terms in the contrary sense; considering the hemeralopia, as denoting sight during the day, and blindness in the night; and nyctalopia, as expressing night-seeing, owl-sight, as the French call it, and blindness during the day-time.

Hemeralopia, in the meaning of day-blindness, is a very uncommon affection. Dr. Hillary never met with but two examples. He mentions a report, however, that there are a people in Siam, in the East Indies, and also in Africa, who are subject to the disease of being blind in the day, and seeing well by night. (*Mod. Univ. Hist.* Vol. 7.)

According to Sauvages, hemeralopia, (in

this nomenclature called *amblyopia crepuscularis*,) was in some degree epidemic in the neighbourhood of Montpellier, in the villages, in damp situations adjoining rivers, and it particularly affected the soldiers, who slept in the open damp air. They were cured, he says, by blistering, together with emetics and cathartics, and other evacuations. (*Nosol. Method. Class 6, Gen. 3, Spec. 1.*)

See some ingenious observations on the subject in *Dr. Rees's Cyclopædia, Art. Hemeralopia*, and by Mr. Bampffield in *Med. Chir. Trans. Vol. 5, p. 34, &c.*

Scarpa, with the generality of modern writers, has considered hemeralopia as an affection, in which the patient sees very well in the day, but not in the nighttime.

The abolition of eyesight by night (observes Mr. Bampffield,) has occurred in all ages, and is a common disease of seamen in the East and West Indies, Mediterranean, and in all hot and tropical countries and latitudes, and affects more or less the natives likewise of those regions of the globe. It also occurs frequently among soldiers in the East and West Indies; but he has been informed, that it is by no means so prevalent among them as sailors. It is not an uncommon complaint of the Lascars, employed in the East-India Company's ships, trading between India and Europe. It has very rarely indeed affected the officers of his Majesty's, or of the East-India Company's ships. Celsus has remarked, that women and virgins, whose menstrual returns are regular, are exempt from this disease (*lib. 6, cap. 6.*) and it may be observed, that the inhabitants of cold latitudes are less subject to hemeralopia in their own climate, than the natives of tropical countries are in their's; but more so, when they visit the tropics. (*Med. Chir. Trans. Vol. 5, p. 38.*)

"*Hemeralopia*, or *nocturnal blindness* (says Scarpa,) is properly nothing but a kind of imperfect periodical amaurosis, most commonly sympathetic with the stomach. Its paroxysms come on towards the evening, and disappear in the morning. The disease is endemic in some countries, and epidemic, at certain seasons of the year, in others.

"At sunset, objects appear to persons affected with the complaint, as if covered with an ash-coloured veil, which gradually changes into a dense cloud, which intervenes between the eyes, and surrounding objects. Patients with hemeralopia have the pupil, both in the day and night-time, more dilated, and less moveable, than it usually is in healthy eyes. The majority of them, however, have the pupil more or less moveable in the daytime, and always expanded and motionless at night. When brought into a room faintly lighted by a candle, where all the by-standers can see tolerably well, they cannot discern at all, or in a very feeble manner, scarcely any one object; or they only find themselves able to distinguish light from darkness; and at moonlight their sight is still worse. At daybreak they recover their sight, which continues perfect

all the rest of the day, till sunset." (*Cap. 19, p. 322, Edit. 8vo.*)

According to Mr. Bampffield, the disease always affects both eyes at the same time. "In general, (says this gentleman) the nocturnal blindness is at first partial, the patient is enabled to see objects a short time after sunset, and perhaps will be able to see a little by clear moonlight. At this period of the complaint, he is capable of seeing distinctly by bright candlelight. The nocturnal sight, however, becomes daily more impaired and imperfect, and, after a few days, the patient is unable to discriminate the largest objects after sunset, or by moonlight, &c. and finally, after a longer lapse of time, he cannot perceive any object distinctly by the brightest candlelight. If the patient is permitted to remain in this state of disease, the sight will become weak by daylight, the rays of the sun will be too powerful to be endured, whether they are direct, or reflected; lippitude is sometimes induced; myopism, or shortness of sight, succeeds; and, in progress of time, vision becomes so impaired and imperfect, that apprehensions of a total loss of sight are entertained; and this dreadful consequence has been known to ensue, where the complaint has been totally neglected, or left to nature, or where ineffectual remedies have been employed. (*Bontius, p. 73.*)

"It has been remarked by some, that the patients are capable of seeing distinctly, at all periods of the complaint, with the aid of a strong artificial light; but, in *bad* cases of hemeralopia, in my practice, the patients positively denied the existence of the sense of distinct sight by very clear candlelight. (*Bampffield in Medico-Chir. Trans. Vol. 5, p. 39, 40.*)

The duration of the disease, when left to itself, is generally from two weeks to three, or six months. Experience has not proved, that the disposition to the complaint depends upon any particular colour of the iris, as several writers have conjectured; nor upon the largeness of the eyes, as alleged by Hippocrates. (*Lib. 6, sec. 7.*)

In idiopathic cases, the health does not in general suffer, and except in the worst stage, the eye is not altered in appearance. But in cases of long duration, the pupil, according to Mr. Bampffield, "is often contracted, and the eyes and actions of the patient evince marks of painful irritation, if the eyes are exposed to a vivid light; or if he looks upward. But, if they meet the direct rays of the sun, which in the tropics are always powerful, or a strong glaring reflection of them, pain and temporary blindness are induced, from which the patient recovers, by closing his eyelids for a time to exclude the rays of light, and retiring to the shade. The pupil of the eye is considerably dilated, both by day and night, in the proportion of about one case in twelve, and at night the pupil is often dilated, and does not perform its expansions and contractions, when exposed to the moon, or artificial light. The cases, at-

tended with dilated pupil, were generally those of long duration, &c.

"Europeans, who have been once affected with hemeralopia, in tropical climates, are particularly liable to a recurrence of this disease, as long as they remain in them." (*Bampf. op. cit. p. 42, 43*)

The remote causes of idiopathic hemeralopia are not well ascertained. Bontius imputes the complaint to eating hot rice. (*P. 72, 73.*) Sleeping with the face exposed to the brilliancy of daylight, the vivid reflection of the sun's rays from the sandy shores of hot countries, and bright moonlight, have been enumerated as causes. Dr. Pye thinks the disorder intermittent. (*Med. Obs. and Inquiries, Vol. 1, art. 13.*) But, as Mr. Bampf. properly observes, though the complaint is certainly periodical, there is nothing in its character tending to prove, that it is influenced by the same causes as intermittent fever. The latter gentleman conjectures, "that too much light suddenly transmitted to the retina, or for a long period acting on it, may afterward render it unsuceptible of being stimulated to action, by the weaker or smaller quantities of light, transmitted to it by night." (*P. 44*) Among other objections to this explanation, however, it might be remarked, that the patients do not always see, though the light be good; and Mr. Bampf. his own "patients positively denied the existence of distinct sight by very clear candlelight." Besides, if the disease were entirely caused by the sudden, or long operation of vivid light, one would conclude, that all persons subjected to that cause, ought to have the effect produced, which is far from being the case.

When the tongue is white, and the patient has headach and bilious complaints, M. Lassus thinks the cause of the disease is in the stomach and primæ viæ. The same author likewise states, that hemeralopia attacks debilitated persons, subject to catarrhal affections, residing in damp situations, and living on indigestible food. From the combination of such causes, (says he) the disorder was epidemic in the vicinity of Montpellier, (*Sauvage, Nosolog. Method. T. 2, p. 732*) at Belle-Isle sur Mer, (*Recueil d'Observ. de Médecine des Hôpitaux militaires. par Richard, T. 2, p. 573*;) and hence it is endemic in watery situations, where the nights are cold and damp. They who expose themselves to this humidity, (says M. Lassus,) or who navigate along the eastern coasts of Africa, who traverse the Mozambic canal, or sail along the coasts of Malabar and Coromandel, are sometimes attacked by it. (*See Pathologic Chirurgicale, Tom. 2, p. 542, 543.*) Hemeralopia sometimes occurs as a symptom of the scurvy. This fact was noticed by Mr. Telford, in Sir G. Blane's Treatise on Diseases of Seamen, and it is likewise confirmed by Mr. Bampf., who remarks, that hemeralopia should be referred to the same causes as scurvy, "when the subject of it has for a long period subsisted on a salted diet at sea, &c. and if any other scorbutic symptom be present, such as spongy gums,

ecchymoses, saline smell of the secretions, ulcers with liver-like fungus, &c. (*Medico-Chir. Trans. Vol. 5, p. 45.*)

This disease (according to Scarpa) may commonly be completely cured, and oftentimes in a very short time, by treating it on the same plan by which the imperfect amaurosis is remedied; (see *Amaurosis*;) viz. by employing emetics, the resolvent powders, and pills, and a blister on the nape of the neck; and topically, the vapours of the caustic volatile alkali: lastly, by prescribing, towards the end of the treatment, bark conjoined with valerian. In cases in which the disease has been preceded by plethora, and suppressed perspiration, bleeding and sudorifics are also indicated. (*Cap. 19, p. 322—333.*)

Scarpa supports this statement by the relation of three cases, in which he cured the disease by such treatment. These patients were all unhealthy, and evidently labouring under disorder of the gastric organs.

One hundred cases, however, of idiopathic and two hundred of symptomatic hemeralopia, occurred in the practice of Mr. Bampf., in different parts of the globe, but chiefly in the East Indies. All these cases perfectly recovered: and hence, we may infer, that under proper treatment, a favourable prognosis may always be given.

Scarpa notices, that the ancients have strongly recommended, for the cure of this disease, the fumigations of a sheep's liver fried. These were directed against the eyes through a funnel; and the liver thus prepared, was also directed to be eaten. Even in Italy, according to Scarpa, this remedy in general obtains confidence, not only with the vulgar, but also with surgeons. Some writers add, that it is productive of wonderful success among the Chinese, who are said to be very liable to this complaint. Scarpa says he has no observation of his own to offer in support of this account; but the plan was tried without success in a boy, whom Scarpa cured by emetic and aperient medicines, and the ammoniacal vapours.

Celsus has stated that persons who have been for some time affected with amaurosis, have regained their sight on being attacked by a diarrhœa. This seems to Scarpa to be corroborated by the case related by Doctor Pye. (*Med. Obs. and Inq. Vol. 1.*) A man, forty years of age, says he, had been affected for two months with periodical amaurosis, which, for a certain time, had occurred regularly every evening, but afterward came on irregularly, at different intervals, with considerable dilatation of the pupil, and such obscuration of sight on the approach of night, that even the light of a candle could not be discerned. The man was seized with a diarrhœa. Doctor Pye ordered him to take, for eight successive days, a potion with the kali præparatum; then he prescribed an electuary, composed of bark, nutmeg, and syrup of orange peel. The two latter ingredients were added to the bark, on account of the continuance of the diarrhœa.

The second day after the electuary had been taken, the diarrhoea increased, and the patient vomited copiously; after which he suddenly recovered his sight, so as to see equally well by day and by night. As the diarrhoea continued, the electuary was omitted, after having been taken two days. A violent fever succeeded the diarrhoea, and it was remarked, that during the highest stage of the former, the patient became rather deaf, but without losing his sight in the night or daytime. Dr. Pye does not mention what steps were taken to moderate the fever, which proved fatal to the patient. At all events, adds Scarpa, it is a fact, that this spontaneous laxness of the bowels entirely freed the man from an imperfect periodical amaurosis. Scarpa entertains no doubt, that by looking attentively into the numerous collections of medical observations, one might find in them a great many facts similar to the preceding one, showing the influence of what he terms morbid gastric stimuli over the organ of sight, and consequently, the great utility of a spontaneous looseness of the bowels in the cure of the imperfect amaurosis.

But, says Scarpa, even if such examples of the incomplete amaurosis being dissipated in consequence of spontaneous vomiting, or copious evacuations from the bowels, produced entirely by nature, were rare and noticed by few, we now have so many observations, evincing the successful cure of this disease by means of such evacuations, artificially produced by emetics, and purgative medicines, that no doubt whatever can be entertained concerning the accuracy of the second part of Celsus's admonition relative to the present view of the imperfect amaurosis: *et recenti re, et interposito tempore, medicamentis quoque moliri dejectiones, quæ omnem noxiam materiam per inferiora depellant*. Of this Scarpa remarks, we undoubtedly have numerous satisfactory proofs, in the accurate observations related by Schmucker and Richter; but our confidence, says Scarpa, in the above method of curing the imperfect and periodical amaurosis must increase, when we take notice that the most respectable practitioners of past times have, in the majority of cases, cured this disease only by means of emetics, and opening medicines, though, in their writings, they may have imputed the success of the treatment to other causes, or the efficacy of other remedies, which were also prescribed.

Scarpa, after several valuable remarks on amaurosis in general, refers to the *Mercur de France*, for February, 1756, where there is an account of the cures performed by Fournier on several subjects affected with hemeralopia. The first were three soldiers, to whom an emetic was administered after bleeding them. The next day, as they also complained of a heaviness in their heads, and nausea, the bleeding and emetic were repeated. This expedient removed all the above symptoms, and these three soldiers were no longer unable to see in the night-

time. Fournier met with equal success in treating eight other soldiers upon the same plan, who were affected with the same disease, and belonged to the same garrison.

Night-blindness is sometimes congenital, and therefore constitutional, and altogether beyond the reach of any curative measure. It is said sometimes to be hereditary, and the writer of the article *Nyctalopia*, in Dr. Rees's *Cyclopædia*, was acquainted with an instance in which it occurred to two children of the same family. A case of congenital nyctalopia, which had continued many years without change, and independently of any disease, is related by Dr. Parham. (See *Med. Obs. and Inquiries*, Vol. I. p. 122, note.)

Scarpa notices that Pellier (*Recueil de Mem. et Obs. sur l'Œil*. Obs. 132.) cured captain Micetti of an hemeralopia by repeated doses of tartar-emetic, a seton in the nape of the neck, and cooling aperient beverages. Pellier also assures us, that he has several times cured the recent imperfect amaurosis, by means of small doses of tartar-emetic, and topical aromatic fumigations. (*Observ.* 136—138.)

The method of treatment which Mr. Bampffield adopted, is certainly quite simple. "A succession of blisters to the temples, (says he) of the size of a crown or half-crown piece, applied tolerably close to the external canthus of the eye, has succeeded in every case of idiopathic hemeralopia, which I have seen, &c. The first application of blisters commonly enables the patient to see dimly by candlelight, or perceive objects without the power of discriminating what they are. In some slight cases, that admitted of easy cure, the first application has succeeded perfectly. The second application of blisters commonly enables the patient to see by candlelight distinctly, perhaps by bright moonlight, and even half an hour after sunset, or the sight is restored for short periods during the night, and is again abolished. The second application very often effects a perfect recovery. The third, fourth, or fifth applications, in succession, generally produce a complete recovery, where the first or second have failed; but some rare instances of very obstinate hemeralopia have required even ten successive blisters to each temple; or instead of using them in succession, a perpetual vesicatory has been formed on each temple, and maintained, until a cure has been accomplished, an event which has generally followed in a fortnight." (*Bampffield in Medico-Chir. Trans.* Vol. 5, p. 47, 48.) In some cases, shades over the eyes were worn during the treatment, and a certain time after the cure. The patients were also often directed to bathe their eyes with cold water two or three times a day.

Mr. Bampffield also knew of instances in which electricity was successfully employed as a topical stimulus to the eye. He also informs us, that a spontaneous cure sometimes followed the eruption of boils on the

head or face, or the formation of abscesses on these parts, or in the ears.

Although the blisters will generally effect a cure, there were particular cases in which Mr. Bampffield administered cathartics, such as calomel and the neutral salts. In these examples the patient had bilious complaints, indicated by a yellow state of the tongue and skin, headach, and pain about the præcordia; or symptoms of indigestion, white tongue, loss of appetite, pain and flatulence of the stomach, &c.

In the scorbutic hemeralopia, the application of blisters is to be deferred until the state of the constitution is amended, by giving lemon and lime-juice, and fresh animal and vegetable food; because the hemeralopia often gradually ceases as the scurvy is cured; and before this last event, the blister might produce a scorbutic ulcer. Mr. Bampffield estimates, that about one-third of the cases of scorbutic hemeralopia resist the efficacy of the antiscorbutic regimen and medicines; and consequently, must ultimately be treated as idiopathic cases.

The frequent recurrence of this disease, during the patient's continuance in a tropical or hot climate, naturally suggests the propriety of recommending him to return to his native climate, by which change the tendency to a relapse is in general completely removed. (*Bampffield, in Medico-Chir. Trans. Vol. 5, p. 53.*)

HEMIOPIA. (from ἡμιος, half, and ὤψ, the eye. A certain disorder of the eye, in which the patient cannot see the whole of any object which he is looking at, but only

a part of it. Sometimes he sees the middle, but not the circumference, sometimes the circumference, but not the centre; while on other occasions, it is only the upper, or lower half, which is discerned. Sometimes objects are seen thus imperfectly, whether distant or near; sometimes, only when they are near, and not at a great distance.

The causes of hemiopia are divided by Richter into four kinds.

To the first belong opacities of the cornea and crystalline lens, especially such as destroy the transparency of only a certain portion of these parts.

The cure of this species of hemiopia depends upon the removal of the partial opacity from which it originates. (*See Cataract and Cornea, Opacities of.*)

Under certain circumstances, persons, whose upper eyelid cannot be properly raised, are affected with hemiopia. They can only discern the lower half of an object, which is near and of large size, unless they go farther from it, draw their heads backward, or turn their eyes downward. The pupil, in particular instances, becomes drawn away from the middle of the iris. This may also be a cause of hemiopia: it is a case that does not admit of a cure. The affection may likewise proceed from a separation of the iris from the margin of the cornea by external violence, or other causes. Here the cure is equally impracticable.

The foregoing species of hemiopia are merely effects of other diseases. The fourth and last kind is the most important, being generally regarded as an independent disorder. Sometimes it appears rather to be the effect of a sudden and transient irritation, producing a morbid sensibility in the optic nerve.

The causes of this sort of case, if we can credit Richter, are mostly seated in the abdominal viscera. When the affection is more durable, forming what has been termed *amaurosis dimidiata*, the same treatment is indicated as in *Amaurosis*, in which indeed, it often terminates. (*Richter Anfangsgr. der Wundarzn. B. 3, Kap. 17.*)

HEMORRHAGE. (from αἷμα, blood, and ῥεῖν, to break out.) *Bleeding.*

This is doubtless one of the most important subjects in Surgery. The fear of hemorrhage retarded the improvement of our profession for ages: the ancients, ignorant how to stop bleeding, were afraid to cut out the most trivial tumour, or they did so with terror. They generally performed slowly and imperfectly, by means of burning irons, or ligatures, the same operations which the moderns execute quickly and safely with a knife. If the old surgeons ventured to amputate a limb, they only did so after it had mortified, by dividing the dead parts, and so great was their apprehension of hemorrhage, that they only dared to cut parts which could no longer bleed. (*John Bell's Principles of Surgery, Vol. 1, p. 142.*) But not only as a consequence of surgery, is hemorrhage to be feared; it is also one of the most alarming accidents, which surgery is called upon to

relieve. "Un sentiment naturel attache à l'idée de perdre son sang; un terreur machinale, dont l'enfant, qui commence à parler, et l'homme le plus décidé, sont également susceptibles. On ne peut point dire, que cette peur soit chimérique. Si l'on comptoit ceux, qui perdent la vie dans une bataille, on verroit, que les trois quarts ont péri par quelque hemorrhagie; et dans les grandes opérations de chirurgie cet accident est presque tous les jours le plus formidable." (Morand. Mem. de l'Acad. Royale de Chirurgie, Vol. 5. 8vo.

As the blood circulates in the arteries with much greater impetus and rapidity, than in the veins, it necessarily follows, that their wounds are generally attended with much more hemorrhage, than those of the latter vessels, and that such hemorrhage is more difficult to suppress. However, as the blood also flows through veins of great magnitude with great velocity, bleedings from them are frequently highly dangerous, and sometimes unavoidably fatal. When an artery is wounded, the blood is of a bright scarlet colour, and gushes from the vessel *per saltum*, in a very rapid manner. The blood issues from a vein in an even unbroken stream, and is of a dark purple red colour. It is of great practical use to remember these distinguishing differences between arterial and venous hemorrhage, because, though in both cases the oozing of blood may be equal in quantity, yet in the latter instance, the surgeon is often justified in bringing the sides of a wound together, without taking farther means to suppress the bleeding, while it would not be proper to adopt the same conduct, were there an equal discharge of arterial blood.

Dr. Jones has favoured the world with a matchless work, on the present subject; and as one grand object of this Dictionary is to present a careful account of the principal modern improvements in surgical science, I shall first endeavour to make the reader acquainted with the more accurate doctrines first promulgated by this gentleman relative to the subject of hemorrhage. Afterward, the surgical means to be practised in different cases, will be considered.

The sides of the arteries are divisible into three coats. The *internal one* is extremely thin and smooth. It is elastic and firm, (considering its delicate structure) in the longitudinal direction, but so weak in the circular as to be very easily torn by the slightest force applied in that direction. Its diseases show, that it is vascular, and it is also probably sensible.

The *middle coat* is the thickest, and is composed of muscular fibres, all arranged in a circular manner; they differ, however, from common muscular fibres in being more elastic, by which they alone keep a dead artery open, and of a cylindrical form. As this middle coat has no longitudinal fibres, the circular fibres are held together by a slender connexion, which yields readily to any force applied in the circumference of the artery.

The *external coat* is remarkable for its whiteness, density, and great elasticity. When an artery is surrounded with a tight

ligature, its middle and internal coats are as completely divided by it, as they could be by a knife, while the external coat remains entire.

Besides these proper coats, all the arteries, in their natural situations, are connected by means of fine cellular substance, with surrounding membranous sheaths. If an artery be divided, the divided parts, owing to their elasticity, recede from each other, and the length of the cellular substances, connecting the artery with the sheath, admits of its retracting a certain way within the sheath.

Another important fact is: that when an artery is divided, its truncated extremities contract in a greater or less degree, and the contraction is generally, if not always, permanent.

Arteries are furnished with arteries, veins, absorbents, and nerves; a structure, which makes them susceptible of every change to which living parts are subjected in common; enables them to inflame when injured, and to pour out coagulating lymph, by which the injury is repaired, or the tube permanently closed. (See Jones on Hemorrhage.)

Petit the surgeon, in 1731, first endeavoured to explain the means which nature employs for the suppression of hemorrhage. He thought, that bleeding from a divided artery is stopped by the formation of a coagulum of blood, which is situated partly within, and partly without the vessel. The clot, he says, afterward adheres to the inside of the artery, to its orifice, and to the surrounding parts; and he adds, that when hemorrhage is stopped by a ligature, a coagulum is formed above the ligature, which only differs in shape from the one which takes place when no ligature is employed. His opinion leads him to recommend compression for the support of the coagulum.

In 1736, Morand published additional interesting remarks. He allowed, that a coagulum had some effect in stopping hemorrhage; but contended, that a corrugation, or plaiting of the circular fibres of the artery which diminish its canal, and a shortening and consequent thickening of its longitudinal ones, which nearly rendered it impervious, had some share in the process. He thought that the cavity of an artery might be obliterated by the puckering, or corrugation, when circular pressure, like that of a ligature, is made.

Morand erred chiefly in his mode of explanation, and in his belief in the existence of longitudinal fibres, which no modern anatomists admit; for the contraction and retraction of divided arteries, are indisputable facts, and, as Dr. Jones remarks, this does not affect the truth of his general conclusion, that the change produced on a divided artery, contributes with the coagulum to stop the flow of blood.

Mr. S. Sharp (2d Edit. of *Operations of Surgery*. 1739,) supported the same doctrine. "The blood-vessels, immediately upon their division, bleed freely and continue bleeding, till they are either stopped by art, or at length contracting and withdrawing themselves into the wound, their extremities are shut up by coagulated blood."

agula, and is somewhat intermingled with them, or adheres to them, and is firmly united all round to the internal coat of the vessel. Dr. Jones further states, that the permanent suppression of hemorrhage chiefly depends on this coagulum of lymph; but that the end of the artery is also secured by a gradual contraction which it undergoes, and by an effusion of lymph between its tunics, and into the surrounding cellular substance; whereby these parts become thickened, and so incorporated with each other, that one cannot be discerned from the other. Should the wound in the integuments not heal by the first intention, the coagulating lymph, soon effused, attaches the artery firmly to the subjacent and lateral parts, gives it a new covering, and entirely excludes it from the outward wound.

The same circumstances are also remarkable in the portion of the vessel, most remote from the heart. Its orifice, however, is usually more contracted, and its external coagulum smaller than the one which attaches itself to the other cut end of the artery. (*Jones on Hemorrhage, p. 56.*)

The impervious extremity of the artery, no longer allowing blood to circulate through it, the portion which lies between it and the first lateral branch gradually contracts, till its cavity is completely obliterated, and its tunics assume a ligamentous appearance. In a few days the external coagulum, which in the first instance stopped the hemorrhage, is absorbed, and the coagulating lymph, effused around it, and by which the parts were thickened, is gradually removed, so that they resume again their cellular texture.

At a still later period, the ligamentous portion is reduced to a filamentous state, so that the artery is, as it were, completely annihilated from its cut end to the first lateral branch; but long before this final change is accomplished, the inosculating branches have become considerably enlarged, so as to establish a free communication between the disunited parts of the main artery.

When an artery has been divided at some distance from a lateral branch, three coagula are formed: one of blood externally, which shuts up its mouth; one of lymph, just within the extremity of its canal; and one of blood within its cavity, and contiguous to that of lymph. But, when the artery has been divided near a lateral branch, no internal coagulum of blood is formed. (*Jones, p. 63.*)

The external coagulum is always formed when the divided artery is left to nature; not so, however, if art interferes, for under the application of the ligature it can never form. If agaric, lycoperdon, or sponge, be used, its formation is doubtful, depending entirely upon the degree of pressure that is used; but the internal coagulum of blood will be equally formed, whether the treatment be left to art, or nature, if no collateral branch is near the truncated extremity of the artery; and lastly, effused lymph, which, when in sufficient quantity, forms a distinct coagulum, just at the mouth of the artery,

will be always found, if the hemorrhage is permanently suppressed. (*Jones, p. 74.*)

MEANS WHICH NATURE EMPLOYS FOR SUPPRESSING THE HEMORRHAGE FROM PUNCTURED, OR PARTIALLY DIVIDED ARTERIES.

The suppression of hemorrhage by the natural means is sometimes more easily accomplished, when an artery is completely divided, than when merely punctured, or partially divided. Completely dividing a wounded artery was one means practised by the ancients for the stoppage of hemorrhage: the moderns frequently do the same thing, when bleeding from the temporal artery proves troublesome.

Dr. Jones has related many experiments, highly worthy of perusal, and which were undertaken to investigate the present part of the subject of hemorrhage. This gentleman, however, owns, that in regard to the temporary means, by which the bleeding from a punctured artery is stopped, he has but little to add to what Petit has explained, in his third publication on hemorrhage. (*Mem. de l'Acad. des sciences; 1735.*) The blood is effused into the cellular substance, between the artery and its sheath, for some distance, both above and below the wounded part; and when the parts are examined, a short time after the hemorrhage has completely stopped, we find a stratum of coagulated blood between the artery and its sheath, extending from a few inches below the wounded part to two, or three inches above it, and somewhat thicker, or more prominent over the wounded part, than elsewhere.

Hence, rather than say the hemorrhage is stopped by a coagulum, it is more correct to say that it is stopped by a thick lamina of coagulated blood, which, though somewhat thicker at the wounded part, is perfectly continuous with the coagulated blood lying between the artery and its sheath. (*Jones, p. 113.*)

When an artery is punctured, the hemorrhage immediately following, by filling up the space between the artery and its sheath, with blood, and consequently distending the sheath, alters the relative situation of the puncture in the sheath to that in the artery, so that they are not exactly opposite to each other; and by this means a layer of blood is confined by the sheath over the puncture in the artery, and by coagulating there, prevents any further effusion of blood.

But this coagulated blood, like the external coagulum of a divided artery, affords only a temporary barrier to the hemorrhage: its permanent suppression is effected by a process of reparation, or of obliteration.

Dr. Jones's experiments prove, that an artery, if wounded only to a moderate extent, is capable of reuniting and healing so completely, that after a certain time the cicatrization cannot be discovered, either on its internal, or external surface; and that even oblique and transverse wounds (which gape most) when they do not open the artery to

Pouteau (*Mélanges de Chirurgie*, 1760,) denied that a coagulum is always found after an artery is divided: and when it is, he thought it only a feeble and subsidiary means towards the suppression of hemorrhage. He contended, that the retraction of the artery had not been demonstrated, and could not be more effectual than a coagulum. His theory was, that the swelling of the cellular membrane, at the circumference of the cut extremity of the artery, forms the principal impediment to the flow of blood; and that a ligature is useful in promoting a more immediate and extensive induration of the cellular substance.

Gooch, White, Aikin, and Kirkland, all oppose Petit's doctrine of coagulum. The first, blends some of Pouteau's theory with his own, by observing that "when a small artery is totally divided, its retraction may bring it under the surrounding parts, and with the natural contraction of the diameter of its mouth, assisted by the compressive power of those parts, increased by their growing tumid, the efflux of blood may be stopped."

White was convinced, from what Gooch had suggested, and Kirkland confirmed, that the arteries, by their natural contraction, coalesce, as far as their first ramification.

Dr. Jones admits, that an artery contracts after it has been divided, and his experiments authorize him to say, that the contraction of an artery is an important means, but certainly not the only, nor even the chief means by which hemorrhage is stopped. When the artery is above a certain size, the impetuous flow of blood through the wound of the artery would resist the contraction of the vessel in such a degree, that the consequences would be fatal in almost every instance, were it not for the formation of a coagulum. (*Jones*.)

Mr. J. Bell thinks, that when hemorrhage stops of its own accord, it is neither from the retraction of an artery, nor the constriction of its fibres, nor the formation of clots, but by the cellular substance, which surrounds the artery, being injected with blood.

We must refer the reader to Dr. Jones's work for a complete exposure of the inconsistencies and absurdities in Mr. Bell's account of his own theory. (See P. 25. &c.)

Dr. Jones concludes his criticisms on Mr. Bell with observing, that if this gentleman really means to confine his doctrine of the natural means of suppressing hemorrhage to the injection of the cellular substance round the artery, with blood, he dwells improperly on one of the attendant circumstances to the exclusion of the retraction, and contraction of an artery, and the formation of a distinct clot, all primary parts of the process.

The blood, besides filling the cellular substance round the artery, also fills the cellular substance at the mouth of the artery in a particular manner; for the divided vessel, by its retraction within its cellular sheath, leaves a space of a determinate form, which, when all the circumstances necessary for the suppression of hemorrhage operate, is gradually filled up by a distinct clot. (*Jones*.)

MEANS OF NATURE IN STOPPING BLEEDING FROM DIVIDED ARTERIES.

Dr. Jones has given a faithful and accurate detail of a series of experiments on animals, which demonstrate "that the blood, the action, and even the structure of the arteries, their sheath, and the cellular substance, connecting them with it," are concerned in stopping bleeding from a divided artery of moderate size, in the following manner: "An impetuous flow of blood a sudden and forcible retraction of the artery within its sheath, and a slight contraction of its extremity, are the immediate, and almost simultaneous effects of its division. The natural impulse, however, with which the blood is driven on, in some measure counteracts the retraction, and resists the contraction of the artery. The blood is effused into the cellular substance, between the artery and its sheath, and passing through that canal of the sheath, which had been formed by the retraction of the artery, flows freely externally, or is extravasated into the surrounding cellular membrane, in proportion to the open, or confined state of the wound. The retracting artery leaves the internal surface of the sheath uneven, by lacerating, or stretching the cellular fibres, that connected them. These fibres entangle the blood as it flows, and thus the foundation is laid for the formation of a coagulum at the mouth of the artery, and which appears to be completed by the blood, as it passes through this canal of the sheath, gradually adhering and coagulating around its internal surface, till it completely fills it up from the circumference to the centre." (*Jones* p. 53.)

The effusion of blood into the surrounding cellular membrane, and between the artery and its sheath; but in particular, the diminished force of the circulation from loss of blood, and the speedy coagulation of this fluid under these circumstances, most essentially contribute, says Dr. Jones, to the desirable effect.

It appears then, that a coagulum, which Dr. Jones calls the *external* one, situated at the mouth of the artery, and within its sheath, forms the first complete obstacle to the continuance of bleeding, and though it seems externally like a continuation of the artery, yet, on slitting open this vessel, its termination can be plainly observed, with the coagulum shutting up its mouth, and contained in its sheath.

No collateral branch being very near the impervious mouth of the artery, the blood just within it is at rest, and usually forms a slender conical coagulum, which neither fills up the canal of the artery, nor adheres to its sides, except by a small portion of the circumference of its base, near the extremity of the vessel. This coagulum is distinct from the former, and what Dr. Jones calls the *internal* one.

The cut end of the artery next inflames, and the vasa vasorum pour out lymph, which fills up the extremity of the artery, is situated between the internal and external co-

a greater extent than one-fourth of its circumference, are also filled up and healed by an effusion of coagulating lymph from their inflamed lips, so as to occasion but little, or no obstruction to the canal of the artery. The utmost magnitude of a wound, which will still allow the continuity of the canal to be preserved is difficult to be learnt; for when the wound is large, but yet capable of being united, such a quantity of coagulating lymph is poured out, that the canal of the vessel, at the wounded part, is more or less filled up by it. And when the wound is still larger, the vessel soon becomes either torn, or ulcerated completely across, by which its complete division is accomplished.

Beclard made a series of experiments upon dogs, whose arteries are said not to differ much from those of man, though *the impulse of the heart is not so strong, and the blood is more coagulable*; two circumstances which should be duly considered, in applying any of the inferences drawn from such experiments to the human subject. "In his first experiment, he pricked the femoral artery with a needle; the blood flowed; but soon stopped. On removing the coagulum it again flowed, but in a small stream; it gradually ceased to bleed, and finally stopped, though the coagulum was again scraped off. On examination of the artery no trace of the cicatrix was found. Several similar experiments had the same result. In experiment 4, he denuded the femoral artery, and made a longitudinal cut in it, from two to three lines. The lips of the wound were seen in contact during the diastole of the ventricle, and to be separated by a jet of blood during the systole. The blood was stopped by a coagulum; this was removed twice, and each time the blood flowed in a diminished stream, but the animal died. In experiment 6, he made the same incision, but did not detach the sheath from the artery, and the wound was left to nature. The hemorrhage was not great; there was an infiltration of blood into the sheath the size of an almond, which at the end of some days began to diminish, and disappeared in two or three weeks. On the limb being examined fifteen days afterward, a little white ridge was found adhering firmly to the artery, and to the sheath, and completely closing the wound. In the interior, there was a depressed longitudinal cicatrix of the breadth of the fifth of a line. *The canal was regular and pervious through its whole extent.*

"In experiments 7, 8, 9, he made transverse incisions of 1-4, 1-2, and 3-4 of the circumference of the femoral artery, *separated from its sheath*: all the animals died. In experiment 10, he made a transverse incision through 1-4 of the circumference, *without disturbing the sheath*. The bleeding was stopped by a coagulum, but on the animal moving, it again flowed, and the dog died. But in the next experiment of the same kind, the blood was stopped by a coagulum, and the artery was closed by nearly the same process as in the 6th experiment. So complete was the cure, at the end of six weeks, that the

external part of the artery did not show any mark of a wound, and the cicatrix was scarcely observable on the interior surface. In his 12th experiment he cut one-half of the circumference; the animal died; and so did it in several similar experiments. In experiment 13, he cut 3-4 of the circumference; after the animal was much reduced, the bleeding ceased, and the artery was closed in the same manner that it is when the section is complete.

"From these experiments, he concludes wounds of the arteries of dogs are cured by nature, when they are only occasioned by a puncture, or a longitudinal incision, whether the artery be denuded or not; but when arising from transverse incisions, they are always mortal if the artery be laid bare. If the artery retain its sheath, and the wound be 1-4, or 3-4 of the circumference, it may be cured by the efforts of nature; but it is always fatal, if 1-2 of it be cut through." (See *Quarterly Journ. of Foreign Medicine and Surgery*, Vol. 1, p. 26.) The inferences respecting the curability of a wound, extending through 3-4 of the circumference, and the incurability of one that affects only 1-2 of the circumference of the vessel, I should presume, must require further examination, notwithstanding an accidental faintness produced by the sudden loss of blood in the first instance may have been the means of saving one or two of the animals on which Beclard made his experiments.

This author thinks it probable, that a puncture, or longitudinal incision, in the artery of a man, may be cured by nature; but that a transverse wound never cicatrizes properly, but the clot becomes displaced, or, if a cicatrix be formed, it will be distended and torn.

One fact, made out by the same gentleman, is, that when an artery is deprived of its sheath for an extent greater, than its distance of retraction, the hemorrhage is mortal. I have not yet had time to look over the original paper; but it appears to me, that it would be desirable to know precisely to what sized arteries the author is referring, when he is making some of the above inferences. The size and condition of each animal, the subject of experiment, should also be particularly specified; as experiments made on the femoral artery of a lady's lap-dog would surely not have the same results, as those performed on the same artery of a large terrier, setter, or Newfoundland dog.

According to Dr. Jones, the lymph, which fills up the wound of an artery, is poured out very freely, both from the vessel and the surrounding parts, and it accumulates around the artery, particularly over the wound, where it forms a more distinct tumour. The exposed surrounding parts at the same time inflame, and pour out coagulating lymph, with which the whole surface of the wound becomes covered, and which completely excludes the artery from the external wound. This lymph granulates,

and the wound is filled up and healed in the usual manner. (See *Jones on Hemorrhage*, p. 113, &c.)

SURGICAL MEANS OF SUPPRESSING HEMORRHAGE.

It must be plain to every one, who understands the course of the circulation, that pressure, made on that portion of a wounded artery, which adjoins the wound towards the heart, must check the effusion of blood. The current of blood in the veins, running in the opposite direction, requires the pressure to be applied to that side of the wound, which is most remote from the heart. However, on account of the freedom and facility with which the blood is transmitted through the anastomoses, from the portion of the artery above the point of pressure into the lower continuation of the artery, such pressure will often only check, and not effectually stop the bleeding, unless the part of the vessel directly below the wound be also compressed, or secured. As pressure is the most rational means of impeding hemorrhage, so it is the most effectual; and almost all the plans, employed for this purpose, are only modifications of it. The tourniquet, the ligature, the application of a roller, and compresses, even agaric itself, only become useful in the suppression of hemorrhage, on the principle of pressure: the cautery, caustics, and styptics, however, have a different mode of operation.

In order to prevent a wounded person from dying of hemorrhage, Celsus advises the wound to be filled with dry lint, over which was laid a sponge dipped in cold water, and pressed on the part with the hand. If, notwithstanding these means, the hemorrhage should continue, he recommends repeatedly applying fresh lint, wet with vinegar; but, he is against the use of corroding escharotic applications, on account of the inflammation which they produce; or only sanctions the employment of the mildest ones. When the hemorrhage resists these methods, he advises two ligatures to be applied to the wounded part of the vessel, and then dividing the portion situated between them:—*"Quod si illa quoque profluvio vincuntur, venæ, quæ sanguinem fundunt, apprehendendæ, circaque id, quod ictum est, duobus locis deligandæ, intercidendæque sunt, ut et in se ipsæ coeant, et nihilominus ora præclusa habeant."* Lib. 5. cap. 26. When the ligature was impracticable, the wound bled dangerously, and there were no large nerves, nor muscles at the bleeding part, Celsus proposed the actual cautery.

Galen also mentions tying the vessels for the purpose of stopping hemorrhage; and there are some traces of the same information in other authors, who lived before him, as Archigenes, and Rufus. Probably, however, the ligature was little used at these early periods, as may be inferred from the multitude of astringents, caustics, and other applications, which were advised for stopping bleeding, and in which less confidence

would have been put, had the use of the ligature been familiarly known. No one can doubt, that if the old surgeons had had many opportunities of seeing the advantages of the ligature, they would soon have used it after amputations; but, so far were they from adopting such practice, that, Albucasis, a long while afterward, refused to amputate at the wrist, lest he should see his patient bleed to death.

Paré is considered as the first who regularly employed the ligature after amputation. His method having been attacked, he modestly defends it in the part of his works, intitled, *Apologie*, where he takes great care to impute the origin of it to the ancients, and cites many of them, who have made mention of it. However, he thinks its utility in amputations of such high consequence, that he ascribes to inspiration of the Deity his first adoption of this practice.

The method, in which the ancients placed most confidence, for stopping hemorrhage after the amputation of a limb, was the cauterization of the cut vessel, and surrounding flesh. The parts, thus affected by the heat, formed an eschar, of greater, or less thickness, which blocked up the opening of the vessel, and hindered the blood from escaping. The separation of the eschar, however, which frequently took place too soon, occasioned a return of the hemorrhage, and rendered it the more dangerous, as its suppression was now more difficult than before the cautery was applied. Sometimes, the instrument being too much heated, immediately brought away with it the eschar. At the present time, the cautery is never employed, as a means of suppressing hemorrhage, or, at most, only in a few very unusual cases, in which neither compression, nor the ligature can be made use of. In Great Britain, the cautery may be said to be entirely exploded; but, in France, the best hospital surgeons now and then employ it to stop bleedings from the antrum, and the mouth.

The old surgeons also very commonly applied to bleeding parts pledgets, dipped in boiling turpentine, a practice, that has long been most justly abandoned.

ASTRINGENTS, STYPTICS, &c.

Le Dran, in his treatise on the operations of surgery, says, that a button of vitriol, or alum, applied and properly confined on the extremity of the vessel, is sufficient to stop the hemorrhage in amputations. Heister recommends the application of vitriol, in preference to the ligature, in the amputation of the fore-arm. Great praises have also been conferred on agaric, and sponge, for their styptic properties. Solutions of iron, and all the mineral acids in various forms, have been recommended to the public, as remedies of the same kind, and possessing great efficacy. The ancients, centuries ago, left no application of this nature untried, and the pretended discoveries of new and more effectual styptics in latter times, may

almost all be met with in their writings. This fact merits particular notice, because the little success attending their practice, especially when bleeding from a considerable artery was to be suppressed, clearly proves what little reliance ought to be placed on means of this description. (*Encyclopédie Méthodique; Partie Chir.*) The most which styptics can do, is to stop hemorrhages from small arteries; but they ought never to be trusted when large vessels are concerned.

There is no doubt, that cold air has a styptic property; by which expression, I mean, that it promotes the contraction of the vessels; for no styptics can contribute to make the blood coagulate, though such an erroneous idea is not uncommon. We frequently tie, on the surface of a wound, every artery that betrays the least disposition to bleed, as long as the wound continues exposed to the air. We bring the opposite sides of this wound into contact, and put the patient to bed. Not an hour elapses, before the renewal of hemorrhage necessitates us to remove the dressings. The wound is again exposed to the air, and again the bleeding ceases. This often happens in the scrotum, after the removal of a testicle, and on the chest, after the removal of a breast. The proper conduct, in such cases, is not to open the wound unnecessarily, but to apply wet linen to the part so as to produce such an evaporation from its surface, as shall create a sufficient degree of cold to stop the bleeding. As all styptics are more or less irritating, no judicious practitioners apply them to recent wounds. However, for the suppression of hemorrhage from diseased surfaces, where the vessels seem to have lost their natural disposition to contract, these applications are sometimes indicated.

COMPRESSION.

We have already remarked, that all the best means of checking hemorrhage, operate on the principle of pressure; the actual and potential cautery, and some styptics excepted; the two first of which act by forming a slough, which stops up the mouths of the vessels; while the latter operate by promoting their contraction. Let us next consider the various modifications of pressure.

In a dissertation on the manner of stopping hemorrhage, printed in the *Mem. de l'Acad. de Sciences*, année 1731, Petit endeavoured to prove, that different articles praised as infallible specifics, would seldom or never have succeeded without compression. Even when caustics were employed, it was usual to bind compresses tightly on the part, so as to resist the impulse of the blood in the artery, and the premature separation of the eschar. Had this precaution not been taken, Petit believes, hemorrhage would almost invariably have followed, and indeed, notwithstanding the pains taken to avert it by suitable compression, it did but too frequently take place on the detach-

ment of the eschar. Petit has noticed, that the end of a finger gently compressing the mouth of a vessel, is a sufficient means of stopping hemorrhage from it, and that nothing else would be necessary, if the finger and stump could always be kept in this posture. Hence, he endeavoured to obviate these difficulties by inventing a machine which securely and incessantly executed the office of the finger. The instrument was a double tourniquet, which, when applied, compressed at once, both the extremity of the divided artery and its trunk above the wound. The compression on the end of the vessel was permanent; that on the trunk was made only at the time of dressing the wound, or when it was necessary to relax the other. An engraving and particular description of the instrument are to be found in Petit's memoir.

Surgeons formerly filled the cavities of wounds with lint, or charpie, and then made pressure on the bleeding vessels, by applying compresses and a tight roller, over the part. The practitioners of the present day are too well acquainted with the advantages of not allowing any extraneous substance to intervene between the opposite surfaces of a recent wound, to persist in the above plan. They know, that the sides of the wound may be brought into contact, and that compression may yet be adopted, so as both to restrain particular hemorrhages, and rather promote than retard, the union of the wound.

When the blood does not issue from any particular vessel, but from numerous small ones, compression is preferable to the ligature. In the employment of the latter, it would be necessary to tie the whole surface of the wound. The sides of the wound are to be brought accurately together, and compresses are then to be placed over the part, and a roller to be applied with sufficient tightness to make effectual pressure, but not so forcibly as to produce any chance of the circulation in the limb being completely stopped.

If, in bleedings from large arteries, compression can ever be prudently tried, it is when these vessels lie immediately over a bone. Bleedings from the radial and temporal arteries are generally cited as cases of this kind, though from the many instances of failure, which I have seen happen where the first of these vessels is concerned, I should be reluctant either to advise, or make such an attempt. Compression is sometimes tried, when the brachial artery is wounded in phlebotomy. Here it is occasionally tried, in preference to the ligature, because the latter cannot be employed without an operation to expose the artery.

When there is a small wound in a large artery, the following plan may be tried: a tourniquet is to be applied, so as to command the flow of blood into the vessel. The edges of the external wound are next to be brought into contact. Then a compress, shaped like a blunt cone, and which is best formed of a series of compresses, gradually

increasing in size, is to be placed with its apex exactly on the situation of the wound in the artery. This *graduated compress*, as it is termed, is then to be bound on the part with a roller.

In this manner I once healed a wound of the superficial palmar arch, in a young lady in Great Pultney-street. The outward wound was very small, and though the hemorrhage was profuse, I conceived, that it might be permanently stopped, if compression could be so made as to keep the external wound incessantly and firmly covered for the space of a day or two. At first I tried a compress of lint, bound on the part with a roller; but this proving ineffectual, I took some pieces of money, from the size of a farthing to that of a half crown, and, wrapping them up in linen, put the smallest one accurately over the wound, so as completely to cover it. Then the others were arranged, and all of them were firmly confined with a roller, and the arm kept as quiet as possible in a sling. They were taken off after three days, and no hemorrhage ensued.

It is to be observed, that the palmar fascia, in this instance, would prevent the compression from operating on the vessel; but the case shows that this artery, when wounded, is capable of healing, if the blood be completely prevented from getting out of the external wound by the proper application of compression. Were the outer wound too large to admit of this plan, it would probably be the safest practice to cut down, at once, to the ulnar artery, and put a ligature round it, though as this would only certainly stop the bleeding from one end of the vessel in the hand, pressure on the wound would yet be necessary. I have never seen a surgeon succeed in taking up the artery in the hand.

Besides compressing the wounded part of the artery, some surgeons also apply a longitudinal compress over the track of the vessel above the wound, with a view of weakening the flow of blood into it. Whatever good effect it may have in this way is more than counterbalanced by the difficulty which it must create to the circulation in the arm. If the graduated compress be properly arranged, an effusion of blood cannot possibly happen, and pressure along the course of the artery must at all events be unnecessary. After relaxing the tourniquet, if no blood escape from the artery, the surgeon (supposing it to be the brachial artery wounded) should feel the pulse at the wrist, in order to ascertain that the compression employed is not so powerful as entirely to impede the circulation in the fore-arm and hand. The arm is to be kept quietly in a sling, and in forty-eight hours, if no bleeding take place, there will be great reason to expect that the case will do well. In another work I have given an engraving and description of an instrument, invented by Plenck, for making pressure on the wounded brachial artery, at the bend of the arm, without pressing upon the whole circumfe-

rence of the limb, and consequently without stopping the circulation. No one, however, would prefer compression when large arteries are injured, except in the kind of cases to which we have just now adverted, or in those in which the wounded vessel can be firmly compressed against a subjacent bone. Sometimes the compresses slip off, or the bandages become slack, and a fatal hemorrhage may arise; and a still greater risk is that of mortification from the constricted state of the limb. When the method is tried, the tourniquet should always be left loosely round the limb, ready to be tightened in an instant. Sometimes the external wound heals, while the opening in the artery remains unclosed, and a false aneurism is the consequence.

TOURNIQUET.

When hemorrhage takes place from a large artery in one of the limbs, where the vessel can be conveniently compressed above the wound in it, a tourniquet, judiciously applied, never fails in putting an immediate stop to the bleeding.

Before the invention of this instrument, which did not take place till the latter part of the 17th century, surgery was really a very defective art. No important operation could be undertaken on the extremities, without placing the patient in the most imminent peril; and many wounds were mortal, which with the aid of this simple contrivance, would not have been attended with the least danger.

The first invention of this instrument has been claimed by different surgeons, and even different nations. But whoever was the inventor, it was first presented to the public in a form exceedingly simple; so much so, indeed, that it seems extraordinary that its invention did not happen sooner. A small pad being placed on the principal artery of a limb a band was applied over it, so as to encircle the limb twice. Then a stick was introduced between the two circles of the band, which was twisted: thus the pad was made to compress powerfully enough completely to stop the flow of blood into the lower part of the vessel.

Although, in the *Armamentarium Chirurgicum* of Scultetus, there is a plate of a machine, invented by this author for compressing the radial artery by means of a screw, J. L. Petit is universally allowed to be the first who brought the tourniquet to perfection, by combining the circular band with a screw, so that the greatest pressure may operate on the principal artery.

The advantages of the modern tourniquet are, that its pressure can be regulated with the utmost exactness; that it operates chiefly on the point where the pad is placed, and where the main artery lies; that it does not require the aid of an assistant to keep it tense; that it completely commands the flow of blood into a limb; that it can be relaxed or tightened in a moment; and that,

when there is reason to fear a sudden renewal of hemorrhage, it can be left slackly round the limb, and, in case of need, tightened in an instant. Its utility, however, is confined to the limbs, and as the pressure necessary to stop the flow of blood through the principal artery, completely prevents the return of blood through the veins, its application cannot be made very long without inducing mortification. It is only of use also in putting a sudden stop to profuse hemorrhages for a time, that is, until the surgeon has put in practice some means, the effect of which is more permanent.

LIGATURE.

The ancients were quite unacquainted with the use of the tourniquet, and though some of their writers have made mention of the ligature, they do not seem to have known how to make proper use of it, nor to have possessed any other certain means of suppressing hemorrhage from wounds. In modern times it is easily comprehensible, that when any great operation was undertaken, while surgery was so imperfect, there was more likelihood of the patient's life being shortened than lengthened by what was attempted. Under these circumstances, it is not surprising, that the old practitioners should have taken immense pains to invent a great many topical astringents. But, now that the ligature is known to be a means which is safer and less painful than former methods, no longer search need be made for specifics against hemorrhage.

It may, indeed, be set down as a rule in surgery, that whenever large arteries are wounded, no styptic application should ever be employed, but immediate recourse had to the ligature, as being, when properly applied, the most simple and safe of all methods.

In order to qualify the reader to judge of the best mode of applying ligatures to arteries, I shall first explain to him their effect on these vessels, as related by Dr. Jones.

This gentleman learned from Dr. J. Thomson, of Edinburgh, that, in every instance in which a ligature is applied around an artery, without including the surrounding parts, the internal coat of the vessel is torn through by it, and that this fact had been originally noticed by Desault. Dr. Thomson showed to Dr. Jones, on a portion of artery taken from the human subject, that the internal and middle coats are divided by the ligature. (*Jones, p. 126.*)

This led Dr. Jones to make some experiments on the arteries of dogs and horses, tending to the conclusion, that when several ligatures are applied round an artery with sufficient tightness to cut through its internal and middle coats, although the cords be immediately afterward removed, the vessel will always become impervious at the part which was tied, as far as the first collateral branches above and below the obstructed part. Dr. Jones thinks it reasonable to expect, that the obstruction produced in the

arteries of dogs and horses, in the manner he has related, "might be effected by the same treatment in the arteries of the human subject; and, if it should prove successful, it might be employed in some of the most important cases in surgery. The success of the late important improvements which have been introduced in the operation for aneurism, may perhaps appear to most surgeons to have rendered that operation sufficiently simple and safe; but if it be possible to produce obstruction in the canal of an artery of the human subject, in the above-mentioned manner, may it not be advantageously employed in the cure of aneurism; inasmuch as nothing need be done to prevent the immediate union of the external wound?" Dr. Jones next questions, whether this mode of obstructing the passage of blood through the arteries may not also be advantageously practised in cases of bronchocele? (*P. 136.*)

Subsequent experimenters, as a late writer observes, have not, however, been equally successful with Dr. Jones in obtaining the obliteration of the cavity of the vessel after this operation. Mr. Hodgson tried the experiment in two instances upon the carotid arteries of dogs; and in neither of them was the cavity of the vessel obliterated. The same experiment has been repeated by several surgeons upon the arteries of dogs and horses; but, in no example, as far as Mr. Hodgson knows, has the complete obliteration of the cavity of the vessel been accomplished. "It appears, however, that an effusion of lymph is an invariable consequence of the operation: the want of union is therefore owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion. (See *Observations on the Application of the Ligature to Arteries, &c.* by B. Travers, Vol. 1, *Med. Chir. Trans.*) The presence of the ligature, in the common mode of its application, effects this object; and for the success of Dr. Jones's experiment, it appeared only necessary, that the opposite sides of the wounded vessel should be retained in contact, until their adhesion is sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure as shall retain the opposite sides of an artery in contact at the bottom of a recent wound, are too great to permit its employment. It occurred to Mr. Travers, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to ensure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger produced by the residence of a ligature upon an artery arises from the irritation which, as a foreign body, it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application

of a ligature ; whilst it is an ascertained fact, that lymph is in a favourable state for organization in less than six hours, in a wound, the sides of which are preserved in contact. (*Jones, chap. 4, exp. 1.*) If it be sufficient, therefore, to ensure their adhesion, that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may in a great degree be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained that if a ligature be kept six, two, or even one hour upon the carotid artery of a horse, and then removed, the adhesion was sufficiently advanced to effect the permanent obliteration of the canal. It appeared probable, that the same result would be obtained upon the healthy artery of a human subject." (*Hodgson on the Diseases of Arteries, &c. p. 228, et seq.*) Mr. A. C. Hutchison, in the year 1800, tied the brachial arteries of two dogs, and removed the ligatures immediately after their application. In both instances, the complete obliteration of the canal of the artery was the consequence of the operation. (*See Practical Observations in Surgery, p. 103.*) He has also tried this method, as modified by Mr. Travers, in an operation which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery. The ligatures were tied with loops, or slip-knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumour was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed without the slightest disturbance of the vessel. In less than half a minute afterward, the artery became distended with blood, and the pulsations in the tumour were as strong as they were before the operation. Mr. Hutchison then applied two fresh ligatures ; hemorrhage afterward came on ; amputation was performed, and the patient died. (*See Practical Observations in Surgery, p. 102, &c.*) Now as, Mr. Hutchison chose to apply other ligatures, on finding that the pulsation returned, the above case only proves, that the artery is not obliterated in about six hours, and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph, and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hemorrhage which occurred, I think it might have been expected, considering the disturbance and irritation which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas, only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures which

were employed ; an essential piece of information in forming a judgment of the merits of the preceding method. The application removal, and reapplication of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones, and have in more instances than that recorded by Mr. Hutchison, brought on ulceration of the artery and hemorrhage.

From Dr. Jones's experiments, it appears, that the first effects of a ligature upon an artery are, a complete division of its internal and middle coats, an apposition of its wounded surfaces, and an obstruction to the circulation of the blood through its canal. There must be a small quantity of stagnant blood, just within the extremity of the artery ; but this does not, in every instance, immediately form a coagulum, capable of filling up the canal of the artery. In most cases, only a slender coagulum is formed at first, which gradually becomes larger by successive coagulations of the blood ; and hence, the coagulum is always at first of a tapering form, with its base at the extremity of the artery. But, as Dr. Jones remarks, the formation of this coagulum is not material ; for soon after the ligature has been applied, the end of the artery inflames, and the wounded internal surface of its canal being kept in close contact by the ligature, adheres, and converts this portion of the artery into an impervious, and, at first, slightly conical sac. It is to the effused lymph that the base of the coagulum adheres, when found to be adherent. Lymph is also effused between the coats of the artery, and among the parts surrounding its extremity. In a little time, the ligature makes the part on which it is directly applied ulcerate ; and, acting as a tent, a small aperture is formed in the layer of lymph effused over the artery. Through this aperture, a small quantity of pus is discharged, as long as the ligature remains ; and, finally, the ligature itself also escapes, and the little cavity which it has occasioned, granulates and fills up, and the external wound heals, leaving the cellular substance a little beyond the end of the artery, much thickened and indurated. (*Jones, p. 159, 161.*)

In short, when an artery is properly tied, the following are the effects, as enumerated by Dr. Jones :

1. To cut through the internal and middle coats of the artery, and to bring the wounded surfaces into perfect apposition.

2. To occasion a determination of blood to the collateral branches.

3. To allow of the formation of a coagulum of blood just within the artery, provided a collateral branch is not very near the ligature. It merits particular notice, however, that though the nearness of a collateral branch prevents the formation of a coagulum, it cannot always prevent the completion of the adhesive process. In the experiments made on the arteries of horses and dogs by Mr. Travers, the ligature was purposely applied close to large collateral branches, yet the vessels were safely obliterated. (*See Med. Chir. Trans. Vol. 6, p. 658, 660.*)

4. To excite inflammation on the internal and middle coats of the artery, by having cut them through, and, consequently, to give rise to an effusion of lymph, by which the wounded surfaces are united, and the canal is rendered impervious; to produce a simultaneous inflammation on the corresponding external surface of the artery, by which it becomes very much thickened with effused lymph; and, at the same time, from the exposure and inevitable wounding of the surrounding parts, to occasion inflammation in them, and an effusion of lymph, which covers the artery, and forms the surface of the wound.

5. To produce ulceration in the part of the artery, around which the ligature is immediately applied, viz. its external coat.

6. To produce indirectly a complete obliteration, not only of the canal of the artery, but even of the artery itself, to the collateral branches on both sides of the part which has been tied.

7. To give rise to an enlargement of the collateral branches. (*Jones, p. 163, 164.*)

Every part of an artery is organized in a similar manner to the other soft parts, and its coats are susceptible of the same process of adhesion, ulceration, &c. as the other parts are. Hence, the precautions taken to secure the adhesion of other parts, should be observed for the same purpose with regard to an artery. The vessel is put in a state to admit of adhesion by the ligature, which, when properly applied, cuts through its internal and middle coats, keeps their cut surfaces in contact, and affords them an opportunity of uniting by the adhesive inflammation, as other cut surfaces do. The immediate stoppage of the bleeding is merely the incipient and temporary part of what the ligature has to accomplish; it has also to effect the adhesion of the internal and middle coats of the artery, which being the thing on which the permanent suppression of hemorrhage depends, is the most important. The size and form of the ligature, whether completely flat or irregular, have not been, as Dr. Jones remarks, sufficiently attended to; nor is the degree of force employed in tying the artery, often considered. Some surgeons, wishing to guard against the ligature's slipping off, tie it with very considerable force; while others, apprehensive lest they should cut through the artery, or occasion too early a separation of the ligature, draw it only sufficiently tight to prevent the escape of any blood. A broad flat ligature is not likely to make such a wound in the internal and middle coats of the artery, as is most favourable to adhesion, because it is scarcely possible to tie it smoothly round the vessel, which is very likely to be thrown into folds, or puckered by it, and, consequently, to have an irregular bruised wound made in its middle and internal coats. By covering also a considerable space of the external coat, it may destroy the very vessels which pass on it in their way to the cut surfaces of the inner coats, and thus render them incapable of inflaming. Even supposing the wound to unite,

still such a ligature may cover that part of the external coat which is directly over the newly-united part, and, consequently, as soon as it has produced ulceration through the external coat, it will cause the same effect on the newly-united parts, and, of course, secondary hemorrhage. (*Jones, p. 168.*)

When a ligature is of an irregular form, it is apt to cut through the internal and middle coats of an artery more completely at some parts than others; but these coats must be perfectly cut through, in order to produce an effusion of lymph from the inside of the vessel, which seems to adhere most securely at its cut surfaces.

Also, when the ligature is not applied with sufficient tightness, the inner coats of the artery will not be properly cut through. Dr. Jones thinks, that the ligature being sometimes put on so as to deviate from a circle, has a tendency to produce secondary hemorrhage.

Dr. Jones conceives that ligatures are best when they are round, and very firm, and he adds, that though a very slight force is necessary to cut through the internal and middle coats of an artery, it is better to tie the vessel more tightly than is necessary, merely to cut through its inner coats, because the cut surfaces will thus be more certainly kept in contact; the separation of the ligature expedited; and the danger of ulceration spreading to the newly-cicatized part diminished. The external coat will never ulcerate through, before the inner ones have adhered. The limb, however, should be kept in a perfectly quiet state.

I am sincerely glad to find, that so accurate an observer as Dr. Jones, has refuted the idea, that ligatures occasionally slip off the vessels, in consequence of the violent impulse of the blood. In fact, the blood does not continue to be impelled against the extremity of the artery with the same impetuosity with which it circulated through the vessel before it was tied. The blood is immediately determined into the collateral branches, nor is there any pulsation for some way above the ligature.

Dr. Jones much more rationally imputes this occasional accident, either to the clumsiness of the ligature, which prevents its lying compactly and securely round the artery; or to its not having been applied with sufficient tightness; or to its having that very insecure hold of the vessel, which the deviation from the circular application must occasion. (*P. 173.*)

Dr. Jones is of opinion, that in cases of aneurism, in which the artery has only been tied with one ligature, and left undivided, and in which secondary hemorrhage has arisen, that this has most probably been owing, either to a diseased state of the artery; to various contrivances for compressing a large portion of the vessel; to having a loose ligature above the one which is tied; or, lastly, to not tying the artery sufficiently tight to cut through the internal and middle

coats, so as to fit them for adhesion, but so as to cause a gradual ulceration through them, and, of course, bring on hemorrhage, which returns with greater violence as the ulceration advances. (P. 176.)

These reflections must also obviously explain why Scarpa's practice of using a largish ligature, with the intervention of a piece of cloth between the cord and the vessel, for the express purpose of hindering the inner coats of the vessel from being divided, must be objectionable, because it may be set down as an axiom in all operations, where large arteries are to be tied, that the quantity of extraneous substances in the wound, and particularly of such as are in contact with the artery, should be diminished as much as possible. And though I may be disposed to go so far with Scarpa as to believe, that the interposition of a piece of cork or wood is worse than that of a cylinder of linen, I cannot accede to the proposition, that the latter is free from objection, because it rather acts as a cushion, than as a body likely to bruise. (See *Mém. On the Ligature of Arteries*, p. 44.)

With the differences in the constitutions of man and animals, I know that the results of experiments on the latter can never be looked upon as a positive proof of what would happen from the same experiments performed on the human subject. The stronger or weaker impulse of the heart, the more or less coagulable nature of the blood, the greater or lesser degree of general and local irritability; the more or less quick tendency to adhesive inflammation and ulceration; are circumstances which must make in different animals the same experiments lead to opposite results. The question, whether a small round ligature, or a larger flat one, with a piece of linen between it and the vessel, be best, must therefore after all be decided, not by Dr. Jones's experiments, nor those of Scarpa, or Mistei, but by the practice of surgery on the human body; and that the principles defended in this Dictionary are on the whole to be preferred, can hardly be questioned by any man, who knows how much less frequent secondary hemorrhage now is in this metropolis, than it was formerly when those principles were neither observed, nor comprehended. (See *Amputation, Aneurism, Arteries, and Ligature*.)

Dr. Jones seems to consider, that the advantage of the retraction of the divided artery within the cellular membrane, is compensated, in the case of the undivided artery, by the speedy and profuse effusion of lymph, which takes place over and round the vessel, at the tied part, and even covers the ligature itself. Another cause of secondary hemorrhage, is the including of other parts in the ligature, together with the artery, by doing which, the division of the inner coats of the vessel may be prevented.

In the valuable publication of Dr. Jones, to which I have so freely adverted, some secondary hemorrhages are also imputed to the hidden separation, or laceration of the

recently united parts of an artery, by premature and extraordinary exertions of the patient. Hence, he strongly insists on keeping a limb, in which a large artery has been tied, perfectly at rest.

I shall conclude these remarks on the ligature with a few practical rules.

1. Always tie a large artery as separately as possible, but still let the ligature be applied to a part of the vessel, which is close to its natural connexions.

Besides the reasons for this practice, already specified, we may observe, that including other substances in the ligature causes immense pain, and a larger part of a wound to remain disunited. The ligature is also apt to become loose, as soon as the substance between it and the artery sloughs, or ulcerates. Sometimes the ligature thus applied, forms a circular furrow in the flesh, and remains a tedious time, incapable of separation.

The blood-vessels being organized like other living parts, the healing of a wounded artery can only take place favourably, when that part of the vessel, which is immediately contiguous to the ligature, continues to receive a due supply of blood through its vasa vasorum, which are ramifications of the collateral arteries. Hence, the disadvantage of putting a ligature round the middle of a portion of an artery, which has been separated from its surrounding connexions; and hence, the utility, of making the knot as closely as possible to that part of the vessel which lies undisturbed among the surrounding flesh.

Small arteries neither allow, nor require, these minute attentions to the mode of tying them.

2. When a divided artery is large, open-mouthed, and quite visible, it is best to take hold of it, and raise its extremity a little way above the surface of the wound with a pair of forceps. When the vessel is smaller, the tenaculum is the most convenient instrument.

3. While the surgeon holds the vessel in this way, the assistant is to place the noose of the ligature round it, and tie it according to the above directions. In order that the noose may not rise too high, and even above the mouth of the artery, when it is tightened, the ends of the ligature must be drawn as horizontally as possible, which is best done with the thumbs. A knot is next to be made.

4. As ligatures always operate in wounds as extraneous bodies, and one half of each is sufficient for the removal of the noose when detached, the other should always be cut off close to the knot, and taken away.

As we have explained in the article *Amputation*, and as we shall notice again in speaking of the *Ligature*, trials have of late years been made of the practice of cutting off both ends of the ligature close to the knot, with a view of diminishing, as far as possible the quantity of extraneous sub-

stances in the wound. This plan requires the use of very small silk ligatures, in order to be duly judged of. (See *Mr. Lawrence's Obs. in Medico-Chir. Trans. Vol. 6, p. 156, et seq.*)

5. When a large artery is completely divided, two ligatures, one to the upper, the other to the lower part of the vessel, are commonly necessary, in consequence of the anastomosing branches conveying the blood very readily into the part of the artery most remote from the heart, as soon as the first ligature has been applied.

6. When a large artery is only punctured, and compression cannot be judiciously tried, the vessel must be first exposed by an incision, and then a double ligature introduced under it, with the aid of an eye-probe. One ligature is to be tied above; the other below the bleeding orifice; with due attention to the principles explained in this article, and that on *Aneurism*.

7. Ligatures usually come away from the largest artery ever tied, in about a fortnight, and from moderate-sized ones, in six or seven days. When they continue attached much beyond the usual period, it is proper to draw them very gently every time the wound is dressed, for the purpose of accelerating their detachment. Great care, however, is requisite in doing this; for, as Dr. Jones remarks, as long as the ligature seems firmly attached, pulling it rather strongly must act, more or less, on the recently cicatrized extremity of the artery, which is not only contiguous to it, but is still united to that portion of the artery, (the external coat) which detains the ligature. (*Jones, p. 162.*)

In particular individuals, there appears to be an extraordinary tendency to profuse hemorrhage from very slight injuries. An instance of this kind was lately recorded by Mr. Blagden, where a fatal hemorrhage arose from the extraction of a tooth. The patient, who was twenty-seven years of age, had had a tooth extracted when a boy, in consequence of which operation, the bleeding continued for twenty-one days, from the socket, before it ceased. A very slight cut on the head was also followed by an alarming bleeding, which could not be stopped by pressure, styptics, or the ligature, so that it became necessary to apply the *Kali purum*, which succeeded. On his having another carious tooth taken out, a profuse bleeding followed, which resisted the effect of styptics, caustic, and every means adopted to stop up the socket. The actual cautery was tried in vain. The dangerous condition of the patient seemed to leave no other resource, but that of tying the carotid artery, which was done by Mr. Brodie. But even this proceeding failed to suppress the hemorrhage, which proved fatal. (*Vid. Med. Chir. Trans. Vol. 8, p. 224, London, 1817.*) On the mode of stopping hemorrhage from the sockets of the teeth, the reader may find some remarks in the *Einb. Med. and Surg. Journ. No. 58, p. 157.*

The hemorrhage from the bites of leeches sometimes proves exceedingly obstinate, and

instances of death from this cause have occasionally happened, particularly in children. When common methods fail, the plan has been recently tried of passing a fine sewing-needle through the skin on one side of the wound, and then another through the skin on the opposite side, and then twisting some thread round the needles, so as to draw them together, and close the bite. The experiment fully answered. (*See Lond. Med. Repository, January, 1819, p. 23—26.*)

A Case of Amputation, with some Experiments and Observations on the securing of Arteries with minute silk ligatures, in Lond. Med. Repository, Vol. 7, p. 353.* The author relates several experiments for the purpose of ascertaining the utility of tying arteries with such ligatures, and cutting the two ends off close to the knot. They were performed on the carotids of dogs and asses. The conclusions are unfavourable to the practice. After one case of amputation, where the method was tried, the stump healed slowly, and for several months small abscesses repeatedly formed.

HEMORRHOIDS. (from *αιμα*, blood, and *ρῆμα*, to flow.) *Piles*, divided into such as do not bleed, and termed *blind*, and into others

subject to occasional hemorrhage, and distinguished by the epithet *open*. The etymological meaning of the word is evidently only a discharge of blood. Surgeons, however, sanctioned by long custom, have generally implied, by the term *hemorrhoids*, either a simple bleeding from the veins of the lower part of the rectum recurring more or less frequently, yet not accompanied with any distinguishable permanent tumours, within, or on the outside of the anus; or else swellings formed by a varicose distention and morbid thickening of those vessels, either with, or without occasional hemorrhage; or lastly, tumours, originally produced by effused blood, which is sometimes converted into an organized substance. (*Abernethy, Surgical Works, Vol. 2, p. 234.*)

According to Richter, blind hemorrhoids consist of preternatural cysts, or sacs, at the lower extremity of the rectum, from the size of a pea to that of an apple. Sometimes they are distended with blood, and very much swelled; and, at other periods, entirely subside; though, when they have been often considerably swelled, they never quite disappear, but are alternately in a full enlarged state, and empty and flaccid. Indeed, the more frequent and considerable the enlargement has been, the greater is their size. It is generally supposed, that these tumours, or cysts, are varicose expansions of the veins of the rectum; and probably, says Richter, this may sometimes really be the case; but the disease is not always of this nature. In particular instances, and perhaps, in most cases, they arise from an extravasation of blood under the inner coat of the rectum; and then the cyst is altogether formed by this membrane, and not by the vein. The following circumstances furnish proof of what has been here observed. Hemorrhoids are sometimes as large as a walnut, or apple; yet it is scarcely credible, that a mere varix could attain such a size. When cut away, the bleeding is often very slight, even when they are large. Surely, if the tumours were varices, there would always be profuse hemorrhage. Sometimes the cyst is found quite empty; but how can a varix be supposed to be in this state? The shape of hemorrhoids is also remarked to be subject to greater variety, than can hardly attend dilations of veins: thus, they are sometimes oblong, sometimes cylindrical, like a finger, &c. Lastly, when cut away, the sac is plainly seen to consist only of a single membrane. (*Anfangsgr. der Wundarzn. B. 6, p. 395, Ed. 2, Göt. 1802.*)

At the same time it should be recollected, that "the blood sometimes coagulates in the dilated vein, and the swelling becomes hard, inflamed, and very painful. The coagulum is subsequently absorbed, but the thickened coats of the vein, and the surrounding parts, form a tumour, which is little liable to inflame, and afford great distress." (*Hodgson on Diseases of Arteries, &c. p. 566.*) In short, all surgeons, who consider the disease as varices, admit with Sir E. Home, that in cases of long standing,

the contents of hemorrhoidal tumours "coagulate, and become solid; their coats increase in thickness, and they resemble pendulous excrescent tumours in other situations in the body." (*On Ulcers, &c.*) Availing himself of the extensive opportunity afforded by his dissecting room, Mr. Kirby has taken some pains to ascertain the nature of these tumours; and he observes, "I cannot say, that they seemed to be formed of a varicose distention of the great hemorrhoidal vein, even in a single instance. In every case of external hemorrhoids, the tumour appeared to be composed of a prolongation of the cellular substance in a state of unusual firmness, surrounded by some veins, and covered by the integuments. The veins were branches of the internal iliac. In every case of internal hemorrhoid, the structure was pretty similar: the veins, however, seemed enlarged, and were branches of the hemorrhoidal." (*On certain severe Forms of Hemorrhoidal Excrescence, p. 40.*)

The opinion, that piles are formed of cells filled with blood, is also adopted by Dr. Ribes. The distention of the hemorrhoidal veins with blood, he observes, gives rise to varices; but, if any of their blood is extravasated in the cellular membrane, at the inferior and internal part of the anus, hemorrhoids are the result. If the inferior mesenteric vein be dissected in hemorrhoidal patients, the ramifications of the vessel are seen terminating in the cysts of blood, and, on completely removing the whole, the hemorrhoids appear suspended from the branches of the vein, as grapes from the vine. (See *Révue Méd. T. 1, Ser. 1820.*) Montegre, well known as the author of a copious treatise on the present subject, is the only writer who defines a hemorrhoid to be a preternatural determination of blood (*fluxion sanguine*) to the extremity of the rectum, because he conceives, that hemorrhage, swelling, &c. are accidental circumstances, not constantly attending the disease. (See *Dict. des Sciences Méd. T. 20, p. 445.*)

Whether the account of some piles being formed of distinct cysts, or sacs of blood be correct, or not, there is no doubt, that the tumours sometimes consist of a varicose enlargement of the branches of the hemorrhoidal veins. Were this not the fact, how could cases like the following ever take place? "One of my patients (says M. Delatour) had several of these tumours of very large size, and at every contraction of the sphincter ani, the blood issued from them *per saltum*." (*Hist. Phil. Obs. 212.*) Montegre has likewise seen two instances, in which the blood spouted out of the tumours in a continued stream. (*Dict. des Sciences Méd. T. 20, p. 453.*) And Richerand mentions a merchant who lived to the age of eighty-nine, quite free from infirmity, and whose good health was ascribed to periodical bleedings from piles, during fifty years of his life; the evacuation being very regular, and so profuse, that the blood was thrown some distance, as from a vein opened in

phlebotomy. (See *Nosogr. Chir.*) If many piles were not either varices, or cysts in direct communication with the large veins of the rectum, Petit would not have succeeded in taking blood from them by puncture, as he often did in lieu of the ordinary mode of venesection. (*Mal. Chir. T. 2, p. 134.*)

Hemorrhoids vary in number, size, form, and situation; some being *external*; others, *internal*; and some hardly larger than a pea, while others exceed a hen's-egg in size. Sometimes they bring on very serious complaints, either by bursting and discharging blood so profusely as dangerously to reduce the patient; or by exciting inflammation of the adjacent parts, and causing abscesses and fistulæ; or, lastly, by becoming strangulated by the contraction of the sphincter ani, so as to occasion severe pain. Piles, which bleed but little, are not of much consequence; but those which bleed profusely, cause violent pain, or which induce inflammation, and all its effects, demand the greatest attention. Lieutaud mentions a person, who lost three quarts of blood from some piles in the course of a couple of days; and the heretic Arius, and the celebrated philosopher Copernicus, are said to have bled to death in this manner.

I do not know what credit ought to be given to the extraordinary case cited by Panaroli, in which a Spanish nobleman voided every day for four years a pint of blood from some hemorrhoids, and yet enjoyed perfect health! (See *Obs. Chir. Pentec. 2, Obs. 46.*) For other curious facts of this nature, see *Dict. des Sciences Med. T. 20, p. 458.*

In general, when piles are situated far up the rectum, they are less painful than when low down. In the former case, the veins or tumours are surrounded by soft and yielding substances, which do not make any painful pressure on them; but when they are situated towards the anus, they often suffer painful constriction from the action of the sphincter muscle. In fact, when they are quite within the rectum, the patient has sometimes no warning of his disorder, till he discharges blood from the anus.

With regard to the cause of hemorrhoids, any thing capable of retarding the return of blood through the hemorrhoidal veins, may occasion the disease. The pressure of the gravid uterus, costiveness, and the frequent retention of hardened feces in the rectum, are very frequent causes. Persons, who lead sedentary lives, are often troubled with the complaint. Hence, women are more subject to piles, than men.

The pressure of an enlarged liver, or of water accumulated in the cavity of the peritonæum, it is said, may occasion piles.

I have adverted to the opinion of Montegre, that hemorrhoids depend upon a determination of blood to the lower part of the rectum, which sentiment is perhaps correct in cases, where the disease arises from irritation in that bowel, or the neighbouring parts.

When these tumours are produced by the

pressure of the gravid uterus, no cure can be expected till after delivery, when one generally follows spontaneously. Also, when piles are an effect of dropsy, they cannot get well before the pressure of the fluid in the abdomen has been removed by tapping. Gently laxative medicines, and an horizontal position of the body, commonly alleviate the uneasiness resulting from hemorrhoids. The application of an ointment, composed of equal parts of the powder of oak-galls, and of elder-ointment, or hog's-lard, contribute to the same beneficial effect. The application of warm water by means of a bidet, or semicupium, is also frequently productive of great ease. When piles are constricted by the sphincter ani muscle, the pain may often be at once removed, by pushing the swellings up the rectum. When the disease is in a state of inflammation, leeches applied to the vicinity of the anus, and puncturing the dilated hemorrhoidal vessels with a lancet, for the purpose of taking away blood, and the application of cold lotions, are measures occasionally employed to procure ease. The usefulness of leeches was particularly noticed by Schmucker. (*Vermischte Chir. Schriften, B. 1, p. 107.*) Petit preferred the lancet.

When the number and size of hemorrhoids are so considerable, as materially to obstruct the discharge of the feces; when they are severely painful, and subject to profuse bleedings; when the patient is disabled from following his usual occupations; and when the above means afford insufficient relief, the surgeon should recommend their removal.

The extirpation of piles with the actual cautery and caustics, as practised by the old surgeons, is now altogether relinquished. The only plan, ever followed in the present state of surgery, is either to cut the tumours off with a pair of scissors or knife, or to apply a tight ligature round their base, so as to cause them to slough away. If possible, the opportunity of doing either of these operations should always be taken when the disease is in a tolerably quiet state.

When piles are to be cut off, and they are not sufficiently visible, the patient must first strain, as at stool, in order to make the swellings more apparent. With the aid of a pair of dissecting forceps, the skin, covering the hemorrhoids, is then to be separated from them with the knife, but not cut away, and the tumours, being taken hold of with a tenaculum, are to be removed. Sabatier states, that saving the skin is very essential; for any hemorrhage which may arise, can then be more easily suppressed; and, when there are several hemorrhoids to be extirpated, the loss of substance about the anus will be less, and of course, the patient will not be so liable to a contraction of this part, which is sometimes a very great affliction.

Previously to the performance of any operation, Mr. Abernethy endeavours to bring the bowels into a more regular state, and takes care to clear them with any medi-

cine, found by experience to answer the purpose without inducing a continuance of irritation and purging. "The bowel being everted to the utmost by the efforts used in evacuating the feces, and the parts cleansed by bathing with tepid water, the piles should be taken hold of with a double hook, and removed by a pair of scissors. A protruded and thickened plait of the bowel may be removed in the same way; but I think it is best to use the bistoury in removing it, because the depth, to which the scissors may cut, is uncertain. The incision, made by the knife, resembles two curved lines, joined at each extremity." The direction of the incision, both for the removal of piles, and that of plaits, he says, should be longitudinal, in the direction of the bowel. When there is a transverse fold of the bowel of considerable extent, he prefers taking away two elliptical portions in the long axis of the rectum. (See *Abernethy's Surgical Works*, Vol. 2, p. 239.)

As I have explained in the former part of this work, (see *Anus, Prolapsus of*) the late Mr. Hey used to remove these extensive diseased folds, about the verge of the anus, with great success. J. L. Petit used to follow the same practice, (*Mal. Chir. T. 2, p. 134*;) and more recently, Mr. Kirby. (*Obs. on the Hemorrhoidal Excrescence*, Lond. 1817.)

The late Mr. Ware, published some remarks on the present subject, and the tenor of what he says is to prove, that when there are several hemorrhoids, the removal of one, or two of the most painful of them, with a pair of scissors, will afford effectual relief. The same author asserts, that when the pain of hemorrhoids is not violent, but there is a constant distressing uneasiness, with frequent returns of a profuse debilitating hemorrhage, this method will frequently produce a radical cure.

The excision of piles is occasionally followed by dangerous bleeding, as a case, related by Petit, confirms. A patient had some hemorrhoids, which were supposed to be external, while they were only temporarily protruded. Almost immediately after they had been cut off, the skin which had supported them, was drawn inward. An internal hemorrhage ensued, which could not be suppressed, and proved fatal in less than five hours. The rectum and colon were found full of black, coagulated blood. Sir E. Home speaks also of some instances within his knowledge, where after the removal of internal piles with the knife, the bleeding endangered life. (*On Ulcers*, p. 365.)

If the bleeding should prove troublesome, and proceed from vessels within the rectum, the best plan would be to distend the gut with a suitable piece of sponge, so as to make pressure on the wound. Cold should also be applied to the sacrum and nates.

The removal of hemorrhoids, with a ligature, may generally be done with sufficient safety; but still it has its inconveniences, though they are not constant. Petit frequently practised this method, without any

ill effects. In other instances, he had reason to repent of having adopted it. A woman, for whom he had tied three hemorrhoids with narrow pedicles, which were favourably situated for this operation, did not at first experience a great deal of pain. However, five hours afterward he was informed, that she suffered violent colic pains, which extended along the colon. She was bled four times, without material relief. At last, Petit cut the ligatures, which could not be loosened, in consequence of their being concealed so deeply in the substance of the swollen parts. The pain very soon subsided. The ligatures had only been applied four and twenty hours, but the piles had become black, and the skin covering their bases was cut through. Petit then removed them, without the least effusion of blood.

Petit also relates a case, in which a patient, after having had some piles tied, died of symptoms resembling those which take place in cases of strangulated herniæ, notwithstanding the ligatures were cut as in the foregoing instance. After these two cases, Petit abandoned the practice of tying hemorrhoids. Mr. Kirby has mentioned two cases, proving the ill effects sometimes arising from the ligature of piles: in one of these examples, the patient's life was saved with great difficulty; and in the other, the operation was followed by tetanus and death. (*Obs. on the Treatment of certain severe Forms of Hemorrhoidal Excrescence*, p. 1—3, 8vo, Lond. 1817.)

I believe, on the whole, that it is best to remove hemorrhoids with a knife, unless they are situated high up the rectum, where the veins are of large size, and likely to bleed profusely. If a tumour so situated should absolutely require removal, which can rarely happen, a ligature might be put round its base with the aid of a double canula, as is sometimes done in cases of uterine Polypi. When the base of the tumour, however, is large, admits of being brought into view, and the surgeon prefers tying it, he should pass a needle, armed with a strong double ligature, through the root of the hemorrhoid, and tie one part of this ligature firmly over one side of the swelling, and the other over the opposite side. When the base of the tumour is narrow, and the ligature is preferred, the part may be tied at once, without passing a double ligature through its middle.

Old hemorrhoids, which have been repeatedly in a state of inflammation, at length acquire a considerable degree of hardness. The internal membrane of the rectum becomes thickened, loses its natural softness, and forms a kind of cyst, which prevents the tumour from bursting and bleeding. (See *Theben, Progrès de la Chirurgie*, Sect. 4, p. 73.) In the end, it ulcerates, and pours out a fetid discharge. Its size cannot now be lessened by the use of emollient applications; and its excision is indispensably necessary. (See *Lassus, Pathologie Chir. T. 1, p. 336*.)

An opinion has commonly prevailed, that

the bleeding from piles is of a salutary, or critical nature; an evacuation, by which some peccant, or morbid matter, is thrown off from the body. Hence, many patients have been advised to submit to all the pain and uneasiness which the disease occasions, rather than seek a cure. If the fact that some patients lose their health after their piles have been cured, be received as sufficient proof of the disease having had a salutary effect, the doctrine must remain fully established. But before this inference should be drawn, it ought to be known, whether the frequency of the fact is such as to warrant the conclusion; for it is not to be supposed, that the removal of piles places the patient altogether beyond the reach of disease and illness; and no one will deny, that such operation frequently leads to improvement of the health. Were a patient to appear to suffer from the cessation of an habitual bleeding from piles, fomentations and leeches should be applied.

APPENDIX.

ABDOMEN. Our author in his description of the abdominal cavity, seems to give an incorrect idea of the distribution and connexions of the peritoneum. He would convey, that this substance had within it all the viscera, except the kidneys and contents of the pelvis. Strictly speaking, however, there is nothing within the bag of the peritoneum save a vapour, the secretion of exhalent arteries, which opening upon its inner surface, pour out this fluid to prevent the effects of friction during the motions of the several viscera.

The peritoneum is a membrane, forming a circumscribed cavity, on the outside of which are situated all the viscera; and divided into its visceral and reflected portions. The visceral portion is made up of the back part of this bag, which, after closely enveloping the several viscera, except the kidneys, rectum, and urinary bladder, that are but partially covered, passes toward the posterior abdominal parietes, and there forms the mesentery, mesocolon, and mesorectum, with the broad suspensory and lateral ligaments of the liver, &c. Afterward it becomes attached to the walls of the abdomen, constituting its reflected portion, which becomes a general lining to the whole parietes. Thus, the viscera are all without the peritoneal cavity. We do not consider the abdominal cavity opened, until this bag shall have been cut into; hence, by the cavity of the abdomen, is really meant, the space within the peritoneum; for if a wound had been inflicted upon the abdomen, and the peritoneal lining remained sound, we would not call it a wound of the abdominal cavity. The water of *ascites* is contained within the bag of the peritoneum, and the operation of *paracentesis* or *tapping*, consists in penetrating the cavity of the peritoneum, to allow its escape.

When, however, we speak of the *cavity* of the abdomen, without immediate reference to the bag of the peritoneum, we conceive of it as being a large cavity having certain boundaries containing large and important viscera; and withal lined by the peritoneum. So that there is still an ambiguity in the customary expression, *Abdominal Cavity*, which should be removed, as the student is often led astray, by what appears a contradiction in terms.

ACUPUNCTURE. Notice having
Vol. I.

been taken by some of the journalists of this country, of a work lately issued by Mr. Churchill, of the London College of Surgeons, upon the subject of Acupuncture, it may be expected that I should enlarge a little upon the article in this appendix. This I shall do by a few extracts from that publication.

The subject is introduced, by presenting the manner of performance among the Darien Indians, as related by the Surgeon of Dampier, Mr. Wafer.

The patient is taken to a river, and seated upon a stone in the middle of it. A native, dexterous in the use of the bow, now shoots a number of small arrows into various parts of the body. These arrows are prepared purposely for this operation, and are so constructed that they cannot penetrate beyond the skin, the veins of which, opened by the puncturation, furnish numerous streams of blood, which flow down the body of the patient.

The operation, as practised in Japan, is stated to be as follows.

The place made choice of for the puncture, is commonly at a middle distance between the navel and the pit of the stomach, but often as much nearer to, or farther from, either, as the operator, after a due scrutiny, thinks most proper; and in this, and the judging rightly how deep the needle must be thrust below the skin, so as to reach the seat of the *morbific matter*, and giving it a proper *vent*, consists the main skill of the artist, and the success of the operation is said to depend. Each row hath its particular name, which carries with it a kind of direction with regard to the depth of each puncture and the distance of the holes from each other, which last seldom exceeds half an inch in grown persons, in the perpendicular rows, though something more in those which are made across the body, thus,

. . .
: : :
: : :
.

The needles which perform the operation, are made, either of the finest gold or silver, and without the least dross or alloy. They must be exquisitely slender, finely polished, and carry a curious point, and with some degree of hardness, which is given by the maker by tempering, and not by any mixture, in order to facilitate their entrance, and penetrating the skin.

But though the country abounds with expert artists, able to make them in the highest perfection, yet none are allowed but such as are licensed by the emperor.

After a further introduction, by recording the opinions and practice of Mr. Berlioz of Paris, and of Dr. Haime of Tours, upon this important operation, Mr. Churchill ventures to exhibit his own experience in regard to acupuncturation.

The first case is that of a bricklayer, of thirty years of age, who he describes as truly halt; having come to the house of the Doctor supporting himself with a stick in one hand, and resting the other against the wall.

"The body was bent at nearly right angles with the thighs, and his countenance indicated acute suffering. He had been attacked, he said, three days before with darting, excruciating pains in the loins and hips; every motion of the body produced an acute spasmodic pain, resembling an electric shock; and the attempt to raise the body to an upright position, was attended by such insupportable agony, as obliged him to continue in this state of flexion, rather than encountering it by altering his position. There was no more constitutional disturbance than was to be expected from three days and nights of constant pain; the pulse was a little quickened, and the tongue white, but I attributed this derangement to the irritation set up by the pain and loss of rest. I directed him to place himself across a chair, for support during the operation, and I immediately introduced a needle of an inch and a half in length into the lumbar mass, on the right side of the spine; in two minutes time I observed that he seemed to rest the weight of his body more on his limbs, and in the next instant, without any inquiries being made, he observed that he felt his limbs stronger, from the 'pain having left his hips.' He next plainly indicated that the disease was lessened, by raising his body, from which he only desisted by being desired to remain at rest, through fear of the needle being broken. The instrument having remained in its place for about six minutes, the patient declared that he felt no pain, and could, if he were permitted, raise himself upright; it was then withdrawn; the man arose, adjusted his dress, expressed his astonishment and delight at the sudden removal of the disease, and having made the most grateful acknowledgments, left the house with a facility as though he had never been afflicted."

Another case is one wherein Mr. Churchill succeeded in curing in the same astonishing manner. A young man who had been rendered unable to raise himself, being seized by violent pain in the loins whilst in the act of lifting a very heavy piece

of mahogany. Although two days were devoted to try the effects of cupping and blistering, which had been immediately administered, and which time passed without much relief, yet by the aid of the operation of the acupuncture, the patient was soon rendered fit for his usual employment.—The case is as follows.

"On the third day, the operation of acupuncturation was performed upon the part of the loins pointed out as the seat of the injury, which, as in the former case, dissipated the pains in five or six minutes, and restored the motions of the back. He returned, however, the next day with the same symptoms as at first, but in a mitigated degree. A needle was now passed to the depth of an inch on each side of the spine, which, as I expected, terminated the disease in a few minutes; and it was with pleasure that I understood the next morning that the man had gone to his usual employment."

But the Climax!—Mr. Jakes, of Westminster, (the gentleman who is said to have first introduced the operation into England) received an urgent message from Mr. Scott, to visit him immediately. Mr. J. found him in bed, with a countenance expressive of much anguish, having suffered, for three days, from severe pain in the loins, which he attributed to a sudden transition from a warm room to a foggy nocturnal atmosphere.

"Within the last twelve hours it had acquired such a degree of violence, that even respiration was insupportable, except the body were fixed in such positions as permitted the least possible motion. An attempt to resume the erect posture, produced violent spasmodic action of the muscles of the back, which appeared to be communicated by sympathy to those of the abdomen and chest, impeding respiration with a convulsive effort; nor could any motion of the body be made without producing this effect. Neither fever nor general derangement was present, the secreting organs of the body properly performing their functions, proved the external locality of the disease. In this state of things, acupuncturation presented itself to us, as likely to afford relief, and it was therefore immediately resorted to.

"I applied an exhausted cupping-glass upon the integuments, opposite the second lumbar vertebræ, and midway between this bone and the edge of the latissimus dorsi muscle, which was the part referred to as the most concentrated spot of the disease. As soon as a needle had penetrated to the depth of an inch, a sensation arose, apparently from the point of the instrument, which the patient described as resembling that which is produced by the passage of the electric aura, when directed to a metallic point, diffusing it-

self at first to some distance around the part, and then extending itself to some distance up the side to the axilla. This sensation continued to be felt for the space of a minute, when a violent pain struck into the right iliac region, immediately above, and corresponding with the line of the crista of the ilium. No pain was now felt in the back, except a dull aching of about two inches in breadth on the right side of the spine, extending from the lower part of the neck to the sacrum, corresponding with the situation and course of the longissimus dorsi muscle. The pain above the hip now began to subside, and in the space of *three minutes* from its commencement, had ceased altogether.

"The uneasiness along the course of the spine still remaining, a needle was introduced about an inch from one of the dorsal vertebræ, and another in a corresponding situation, to one of the lower lumbar vertebræ. The pain in the right side was in a few minutes entirely dissipated, and the patient arose, declaring that, excepting a slight degree of uneasiness on the posterior part of the chest, near the angles of the inferior ribs, he was completely relieved from the disease. He, however, requested I would pass a needle in this last situation; on effecting which, the pain soon left its last refuge, and the patient dressed himself, and left his house in the most perfect health. I have this day seen him, and he assures me that he has not experienced any return of the affection."

Mr. Churchill's manner of operating is in this wise.

The handle of the needle being held between the thumb and fore-finger, and its point brought into contact with the skin, it is pressed gently, whilst a rotatory motion is given it by the finger and thumb, which gradually insinuates it into the part, and by continuing this rolling, the needle penetrates to any depth, with facility and ease. The operator should now and then stop, to ask if the patient be relieved; and the needle should always be allowed to remain five or six minutes before it is withdrawn. This mode of introducing the needle, neither produces pain (or at least very little,) to the patient, nor is productive of hemorrhage, which Dr. Haime says arises from the fibres being separated, rather than divided by the passing of the needle; the former of which, (the absence of pain) is a point in its favour which few surgical operations possess.

I must say, that I conceive this operation to be an improvement on that of Perkins's celebrated Metallic Tractors, having its beneficial effects upon the same principle.

AMAUROSIS. In the last American edition of this Dictionary, Dr. Dorsey

states, that Dr. Physick has punctured the cornea, and evacuated the aqueous humour in some cases of gutta serena, with *temporary advantage*; having been induced to the step from an idea that pressure from an inordinate secretion of the humours might have occasioned the paralysis of the retina. Mr. Ware, in like diseases, also has punctured the sclerotic, as mentioned under the article gutta serena, where also it is affirmed, that in several of the cases the proceeding was attended with almost immediate good effect. Now, by a reference to the structure of the globe of the eye, we are enabled to judge of the comparative benefit to be expected from the puncture in each situation.

It is clear, advantage cannot follow such an operation, unless in cases wherein the disease is kept up by pressure upon the filaments of the retina, and which was occasioned by a watery fluid thrown out by the vessels of the choroid coat, among the reticular membrane connecting the retina to its inner surface, in the manner found by Mr. Ware, upon examination of the dead subject. Under such a view of the case, it is obvious, that a puncture into the globe, through the sclerotic coat, would afford opportunity for the escape of this fluid. And as far as it was the cause of the disease, the immediate good effects happening in Mr. Ware's cases would follow, and unless there was a disposition in the parts for its reproduction, which the operation might not overcome, a permanent cure would be accomplished. When, however, in such cases, the puncture is made through the lucid cornea, this watery fluid is not evacuated; the aqueous humour from the eye only escapes. For, in consequence of the connexions of the ciliary processes with the tunic of the lens, a complete partition exists between the chambers of the eye, and the site of the morbid watery accumulation. Nevertheless, by the escape of the aqueous humour, the lens is allowed to be projected somewhat forward against the pupil by the compressed vitreous mass, and until the chambers of the eye become filled again, the retina may be susceptible of impressions from the rays of light, but will soon, on the reproduction of the aqueous humour, be returned to its former state of paralysis:—hence the temporary advantage spoken of in reference to Dr. Physick's cases.

AMPUTATION.

OF LIGATURES FOR THE ARTERIES.

The size and material for ligatures, for the arteries on the face of a stump, will be, in a great measure, regulated by what is the intention of the surgeon. Whether he designs to cut them close to the stump previous to dressing, and at the time

of the operation, or allow their ends to hang from the lips of the wound, to be removed when the arteries which they embrace shall have been divided by ulceration. If the latter is the intention, then it matters little of what substance they are composed; perhaps the common white sewing silk, waxed and flattened, will answer every purpose. But when the surgeon wishes to have a union effected speedily and throughout, by what has been called the first intention, and cuts the threads close to the knot, for the purpose of bringing together the parts over them, then it is expedient that the material of which the ligature is composed, be one which will not act as an offending substance, at the bottom of the wound, and by eliciting the suppurative process, defeat the intention. To forward this end, such ligatures have been recommended, of substances of the nearest ally to animal matter, for the purpose of their more ready absorption; and accordingly, they have been proposed of raw silk, carefully put together and waxed; or of doe skin, of glove leather, or of catgut, &c. If we examine into what must take place from such knots, so shut up in a wound, of whatever material they are composed, we shall be made acquainted how far the practice is to be approved.

All consent, that the ligature around the vessel, effects adhesion of its sides, by the pressure it makes upon the tube at that part; and, as applied in amputation, this is so great, that the ulcerative process supervenes, and is carried on until the artery is rid of this now offending substance. This process of ulceration is accompanied with a free supply of pus, in which the ligature lies until it is removed. If the ends of the ligature have been cut off close to the knot, at the time of the operation, the process just spoken of will nevertheless have gone on thus far. Matter will now continue to be thrown out, in quantity proportionate to the power of the substance composing the ligature to cause irritation, and to the time required for its complete solution; for the ligature must be dissolved before it can be absorbed, and the excess of pus required for its solution, must be absorbed also before the stump can be pronounced healed; and it is still a query, whether, notwithstanding how rapidly all this may have been accomplished, it can be called a healing by the first intention. More frequently, however, the pus in such a case is found to disturb the newly cicatrized integuments,* and be the cause of one or more troublesome little abscesses

on the face of the stump, either in the course of the cicatrix or through the skin at other parts, (for I have seen them in both situations,) that may be referred to unauthorized attempts, on the part of the surgeon, to produce a too speedy union after amputation.

Mr. Lawrence, in favour of this practice, has recommended very small and thin ligatures, of what is called *dentist silk*; but the inconveniency and trouble which must attend the tying of a large vessel with such small thread, must, in my opinion, overbalance any advantage that may have been attributed to the measure; besides, the same process of solution, previous to absorption, must take place in these cases; so that even here we cannot have an absolute union by the first intention.

In the last instance I witnessed this practice, the ligatures were made of doe skin, and cut off close to the knot, in amputation below the knee. At the end of a week, a most alarming secondary hemorrhage took place, which nearly carried off the patient, having been with much difficulty arrested. This I immediately attributed to the circumstance of thus disposing of the ligatures, and the surgeon, who operated was so convinced of the force of the remark, that he resolved never to deal in the practice again.

I can imagine that when the knots are made by small thread or silk, they may become encysted, after the manner of some foreign bodies in wounds, and soon cease to be offending causes, but this must be a rare occurrence in comparison to the other issue. Upon the whole, I think, that the method of cutting off one end of the thread close to the knot, and letting the other pass beyond the lips of integument, opposite the vessels to which they are applied, and so distributing the adhesive straps at the dressing as to allow such accommodation, is a practice that cannot be improved upon.

OF DRESSING THE STUMP.

I have the pleasure to record an important feature in the practice of American surgery, which is a very effectual preventive of secondary hemorrhage, after the operation of amputation. I allude to a delay in dressing the stump, from half an hour to an hour after the ligatures are applied. During this time the patient is put to bed, the paraphernalia of the operation removed, and every ordinary means afforded for the reaction of the system, after the effects of fear, loss of blood, &c. By this plan, those small vessels which might have bled, without discovery, had the wound been immediately dressed, will show themselves, and the surgeon will have an opportunity of securing them by ligature, before the plasters and bandages are applied. He will be

* It is found, that the process for dissolving the ligature, does not retard the entire union of the integuments of the stump, by the first intention; if it did, there might be, perhaps, less danger in trying these experiments.

able, also, to remove all the clotted blood, derived from an oozing from the capillaries; and in this way, give facility for adhesion by the first intention. I am confident, that most of the cases of secondary hemorrhage, after amputation, which I have seen, and they were many during the late war, might have been prevented by this precaution. And I feel assured, that most of those instances that were attended with extensive suppuration and delay, nay, sometimes followed by convulsions and death, are to be attributed to irritation, kept up by the presence of blood, which had oozed from the small vessels, succeeding a too early dressing after the operation. I have to state, that I first witnessed this excellent caution in the practice of Dr. Parish, of Philadelphia.

In regard to the direction of the line, made by bringing together the common integuments over the face of the stump, I believe it altogether unimportant what is the course given to the cicatrix, as to the ultimate shape of the stump. What is called a *good* and *handsome* stump, is not derived, in my opinion, from attention to this particular; but from the circumstance of preserving sufficient integument to cover the muscles and bone. I also think, that if the flap operations had nothing else to recommend them than making a well-shaped stump, it would be better the practice was laid aside. I believe there is little danger to be dreaded from leaving too much integument for this purpose, but that there is every thing to be feared from leaving too little. In amputations below the knee, however, it may be of consequence to bring the integuments together in a particular manner; but then there is a different motive that directs the indication, than that of giving shape to the stump. It is expedient that this stump should be covered in a way that the bones may be least likely to make an injurious pressure against the skin; and for this end, the union of integument should be directed downward and outward, which is in conformity to the line made by the ends of the divided bones, in relation to each other; for we have many times seen the end of the tibia find its way through the ulcerated integuments, in a different situation than where they were divided at the time of the operation. It may be recollected likewise, that this line will be in a perpendicular direction, when the limb is placed on its side in bed, as effected by separating it from the other, and putting pillows under the outside of the thigh; by this also a ready outlet is afforded for pus, as it may be formed during the cure.

FLAP OPERATIONS.

The many objections that are now con-

firmed against the great variety of flap operations, and that have been opposed to amputation by the circular incision, have, I believe, pretty well succeeded in making the latter the general practice at the present day. The greater extent of wounded surface, the oblique division of blood-vessels, the difficulties experienced while searching for arteries in secondary hemorrhage, not being the least among the objections that have prevailed against flap operations in amputation. I have, however, witnessed, in Philadelphia, what might perhaps bear the name of a flap operation, by Drs. Parish and J. R. Barton, which for aught I know, is original with them; and from not being subject to the weighty objections to flap operations generally, I think is, upon the whole, to be advised in all cases where it is practicable, in amputations below the knee. The manner of the performance is as follows.

The surgeon, in making the first incision, does not carry it circularly round the limb, but gives it an oblique direction, so that the incision round the limb is of an oval shape; the lesser diameter of which is from side to side, and the place where the integuments are cut on the forepart of the leg, is much higher than where they are divided behind. The whole of this incision is done by one sweep of the knife, and perhaps is not giving more pain in its performance to the patient, than that through the skin in the circular direction. The integument is then dissected back at the front of the limb, from the forepart of the tibia for about half an inch, and for a considerable extent behind, to prepare for the second incision, or that through the muscles, which is made in a circular direction, after the manner of the second cut in the operation by the triple incision. The rest of the performances is gone through as in the old way. The benefit of this method is ascribed to the neat manner in which the face of the stump can be covered, by bringing forward the flap of skin which had been left at the back part of the leg. In this case, also, the line by which the integuments are brought together, will be somewhat perpendicular when the limb is placed in bed, with the outside of the thigh against a pillow.

SHOULDER JOINT OPERATION.

In reference to amputation at the shoulder joint, I shall not presume to add much, but when parts will permit, it is undoubtedly the best method to amputate by making a flap of the deltoid muscle. The excellent covering afforded to the glenoid cavity, the permanent fleshy padding over the bone, are advantages which I would value above any derived from the other methods. Another benefit which I believe will accrue from this me-

thod, is, that the stump will be by it more likely to heal by the adhesive process. There is in these cases a strong exciting cause to suppurative inflammation, which I will undertake to say is owing to the presence of the cartilaginous covering, or lining of the glenoid cavity. Hence, it has been recommended to scrape the glenoid cavity, as a necessary step to this operation, although Mr. Cooper thinks the advice of little value, except when it is under disease. From the particular structure of interarticular cartilages, they will not granulate, and are insusceptible of the adhesive inflammation, but are to be removed through a process of absorption, effected by the inflammation of the surrounding parts. It is their presence which makes wounds of joints so dangerous, from the irritation they afford to the constitution, through the medium of a highly susceptible synovial membrane. There was lately a case in this city, which was not well in twelve months after the operation; and from the information I collected respecting it, I believe that the omission of scraping the cartilage from the glenoid cavity, was not the least among the causes that did protract the cure.

I cannot imagine any case wherein an amputation of the shoulder joint might be deemed advisable, that it would be necessary or proper to secure the subclavian artery, by ligature, previously to the performance of the operation. The situation of the subclavian artery, where it lies upon the first rib, just above the middle of the clavicle, is peculiarly convenient for pressing the vessel, either by the thumb, or a pad, easily contrived on the handle of a key, &c. if the surgeon should not choose to secure it first in the axilla, or if the state of the disease prevented him.

AMPUTATION OF THE THUMB.

When it is necessary to remove with the thumb the metacarpal bone, a very pretty operation can be performed in this manner. An incision is to be begun up the inner part of the hand, opposite the os trapezium, and carried on each side of the metacarpal bone of the thumb, in shape of letter V. These two lines are to meet under the root of the thumb, at the junction of the first phalanx with the metacarpal bone. The bone is then to be separated from the trapezium, and with the whole thumb to be taken away. The adductor muscles and fleshy belly of flexor pollicis brevis, form a fine cushion, so that when the parts are brought together, any great loss of substance will not be perceived.

ANASTOMOSIS. Under this head, might with propriety be introduced the result of the several *post mortem* examina-

tions, instituted for the purpose of discovering the route of the circulation of the blood, in cases wherein some of the principal arteries had been tied, for the cure of aneurism, as well as from diseased obstructions. A knowledge of the dilatable power of the arteries, however, is now so well confirmed, that the record at this time might be considered more a matter of curiosity than for direction to the surgeon, as to what arteries he might attempt to tie. For since the human subject has undergone the sudden interruption in the course of the blood, through the aorta, by an operation by Sir Astley Cooper, and through the arteria innominata, by one performed by Professor Mott, without exhibiting any unpleasant symptom from the circumstance of the sudden suspension of the natural course of the blood. No surgeon need now hesitate, on this account, in tying these or lesser arteries. As the *post mortem* appearances, however, in the case in which the carotid artery was tied by Professor Mott, previously to extirpating a large tumour from the side of the neck, has not been recorded by the author of this Dictionary, I shall extend this article, by giving it a place.

John McGarrigle, born in Ireland, aged forty-nine years, was admitted into the New York Hospital, on the 10th of November, 1818, with a carcinomatous fungus, situated on the right side of the face and neck, occupying a considerable portion of each. From its highly vascular appearance, as well as other reasons, it was, in a consultation of the surgeons of the Hospital, agreed, that an operation, which would lessen the flow of blood to the fungus, and permit as much of the tumour to be removed as possible, would afford the only possible means of prolonging the patient's life, and of mitigating his sufferings. With these views, on the 14th of the same month, the right carotid was taken up, about an inch below the cricoid cartilage, and secured by two ligatures, but not divided in the interspace, in consequence of the depth of the artery, occasioned by the swelling of all the parts surrounding the disease. And such was the enlarged size of the vessels, that it became necessary to take up several arteries and veins before the carotid could be exposed. The tumour was now removed in a manner detailed in the second number of the Register of Medical and Surgical Cases in the New-York Hospital, which can be referred to; suffice it to say, that the operation was completely successful, but he died from a pulmonary disease on the following March 3d, having been greatly emaciated and worn out by a succession of hectic symptoms.

By this, an opportunity was afforded for an examination into the new route

the blood had taken, succedent to the obliteration of the carotid artery, and having seen the preparation, and compared it with the description by Dr. Mott, in the Hospital Register, I shall give the detail of the dissection, as it is there delineated.

"As this afforded me an excellent opportunity of examining the arteries on the right side of the head and neck, after the carotid had been tied, and not knowing that any such case had been recorded, I gladly availed myself of it, and separated the head, neck, and shoulders in the following manner.

Having sawed through the sternum at the upper part, so as to leave the clavicles attached, the superior extremities were removed from the trunk, and the dorsal vertebræ and ribs divided between the second and third, so as to leave it of a bust-like shape. This preserved the shoulders in such a way, that the subclavians and their branches might be injected. The ascending arch, and a portion of the descending aorta, were also included in the preparation.

To secure the filling of the arteries of the head and neck, a long pipe was passed up the aorta, into the left carotid, and a fine wax injection was thrown in with great care, and as the subsequent account will show, with great success. The aorta was next injected, to fill the subclavians and their branches. In the dissection, which was conducted with the greatest care and attention, I was assisted by David L. Rodgers and Alexander Vaschè, two of my pupils, ardent in the pursuit of anatomical and surgical knowledge.

1st. *The arteries that supplied the right side of the head and neck, after the carotid had been tied.*

To give a regular description of these arteries, would be incompatible with the principle of collateral circulation, inasmuch as they are found to vary in different subjects, for, "the circulation is never carried on by any particular set of vessels, but by all the arteries of the neighbouring parts."

Upon removing the integuments on the forepart of the neck, and laying bare the carotid artery, from the innominata to the angle of the jaw, its calibre was found completely obliterated from its origin to its bifurcation; leaving a firm, ligamentous chord, which was divided into two parts, showing the place where the ligatures had been applied.

The vein and nerve were perfectly natural. The right subclavian was much enlarged, being equal in size to the innominata, from its origin to the scaleni muscles.

The left carotid was enlarged to twice its natural diameter, its branches increased

in the same ratio, and assumed a tortuous and irregular course.

When we take into consideration the connexion which the arteries of the left have with those of the right side of the head, and their free inosculation with the subclavian, we can have in our imagination the branches that must necessarily supply the place of the right carotid. First, we have the branches arising from the subclavian, which are very numerous; secondly, those arising from the left carotid, which are still more numerous.

A minute detail of the numerous vessels which communicate with the carotid, would be tedious and uninteresting, and would, perhaps, be impracticable, were it deemed expedient. Suffice it to notice the principal branches, and to give a general description of the smaller, but not less beautiful inosculations. We find them arising from the right subclavian; first, the arteria thyroidea inferior, secondly, the cervicalis profunda, thirdly, the cervicalis superficialis, and fourthly, the vertebral arteries.

The inferior thyroid, as it arises from the subclavian, divides into four branches; two passing downwards and outwards, and the other two passing upwards; the latter are called the ramus thyroideus and the thyroidea ascendens. These require particular attention from their large size, and the important supply of blood which they furnish for the support of the arteries of the neck. While the superior arteries are enlarged to twice their natural diameter, the two inferior ones, viz. the transversalis colli, and the transversalis humeri, although arising from the same trunk, and receiving their currents of blood in the most favourable direction, still retained their natural dimensions. But this phenomenon usually occurs in the circulating system. John Bell observes, "that in whatever way the demand of blood, upon an artery, or set of arteries, is increased, the effect is an accelerated motion of blood towards that artery." And again, "any demand of blood causes an enlargement of the arteries, leading to the part which demands the blood."

Guided, then, by this principle, we need not be surprised, that the subclavian is so much enlarged from its origin to the scaleni muscles, for here it affords a supply of blood to new and important parts. The ramus thyroideus passing upwards to the thyroid gland, and anastomosing with the superior thyroideal artery, was one great source of blood, its branches were large and tortuous, forming communications in every direction, with those from above.

The thyroidea ascendens, naturally a small and unimportant branch; it was here three times its usual size, mounting

up the neck in a zigzag direction, lying close to the vertebræ, forming frequent communications with the vertebral artery, dividing into many small branches at the upper part of the mastoid muscles, forming a beautiful plexus of vessels, with the mastoid branch of the occipital artery, and sending branches to all the muscles on the upper part of the neck.

The *cervicalis profunda* and *superficialis*, were much enlarged, sending frequent branches upwards to anastomose, with the descending branches of the occipital artery. By far the most important and interesting part of the circulation yet remains to be described.

2dly. *The arteries of the left side of the head and neck.*

The left carotid, passing up the neck, equal in size to the *arteria innominata*, furnished the greatest part of the blood for the right side.

In order to determine what particular arteries were enlarged, it is necessary only to enumerate the branches given off from the carotid, and more particularly those which arise from its forepart. Below the jaw there are four, *to wit*, the superior thyroid, the lingual, pharyngeal, and the *maxillaris interna*, which inosculate with open mouths, having the appearance of continuous trunks, and sending a plentiful supply of blood to the neck, and internal parts of the face.

The labial and temporal arteries leaving the axilla under the angle of the jaw, passing upwards upon the face, send off small branches in a beautiful and fantastic manner. Branches, which before were considered unworthy the attention of the anatomist, now rise into importance. The plexuses and inosculation formed by these branches excite alike our surprise and admiration, and elucidate, in the most beautiful manner, the principles of collateral circulation. These arteries in general are large and tortuous, and have frequent communications among themselves. The arteries most enlarged, were the mental, the inferior labial, the coronary, and the angularis. The optic artery was likewise much enlarged, beautifully anastomosing with the angularis.

So freely did these arteries inosculate with those of the right side, that before the operation was finished, it was found necessary to secure the labial artery in a ligature. This was clearly illustrated by the retrograde course of the injection, after death, which passed freely from the arteries of the opposite side, filling the superior portion of the labial, to the point at which the ligature had been applied. The temporal artery was of its natural size, receiving its blood from "all the arteries of the neighbouring parts, from the ascending branches of the occipital, the

left temporal, the ophthalmic, and the transverse facial. This free communication was distinctly shown by injection, which passing down the temporal, completely filled the external and internal carotids, and several of their branches; particularly the inferior portion of the labial, which is seen emerging from under the jaw to pass upon the face. The labial terminated at that point, where the mental is given off. The mental itself passed on to its usual destination, and received blood from its fellow from the opposite side."

ANEURISM. I was not a little surprised, when, upon a close inspection of this edition of the Dictionary, I found that the author had altogether omitted the case in which the *arteria innominata* was tied, in this country, for the purpose of diverting the blood from an aneurismal cyst, which occupied the subclavian artery. This case having been on record sufficiently early, must have met the industrious eye of Mr. Samuel Cooper, but I cannot account why its detail, or a bare mention of it had been neglected. I am aware, however, that the critics of this country did, in a great measure, succeed in establishing, for a time, an unbelief in what had been alleged by the operator: having presumed to assert, that *the operation was unauthorized; that the disease which was said to call it forth, was not an aneurism of the subclavian artery; and that the method adopted to get at the artery, was attended with an unnecessary violence to the surrounding parts, from which it was probable that the patient lost his life.*

Having seen the preparation, and carefully examined into the history of the case, it does appear to me, that malevolence had dictated for the critics, and jealousy prescribed for the reviewers. But truth will be established and must out, although for a time its influence may be suspended by the ephemeral effects of ignorance, impudence, and folly.

If the limits of this Appendix had permitted, it was my intention to present a general examination into the merits of this very important and singular operation; but I must content myself by merely offering the case, and subjoining a reference to the several reviews; by which may be seen the motives of those who have declaimed against it, all which, with an appeal to the reader's own knowledge of the anatomy of the part, I feel assured will be sufficient to substantiate, that the disease was an aneurism of the right subclavian artery, that the *arteria innominata* had a ligature placed around it in the most apt manner, by Professor Mott, and that although the patient died on the 26th day after the operation, yet that his death was not the necessary consequence of its performance.

I shall transcribe Dr. Mott's communi-

cation, from the New-York Hospital Reports.

"Since the publication of Allan Burns's invaluable work on the Surgical Anatomy of the Head and Neck, I have been in the habit of showing in my surgical lectures the practicability of securing in a ligature the arteria innominata; and I have had no hesitation in remarking that it was my opinion, that this artery might be taken up for some condition of aneurisms; and that a surgeon, with a steady hand and a correct knowledge of the parts, would be justified in doing it. I felt myself warranted in this, from the singular success which this celebrated anatomist informs us attended his injections, and from my own investigations of this subject. If the right arm, right side of the head and neck, can be filled with injection, after interrupting its passage through the innominata, as we believe they can, who can doubt the possibility of the blood to find its way there also, as it will pass through thousands of channels, which art could not penetrate even by the finest injections? The well-known anastomoses of arteries, and the great resources of the system in cases of aneurism, encouraged me to believe, that this operation might be performed with reasonable prospects of success. With all this sanction, and the analogy of the other great operations for aneurism, I could not for a moment hesitate in recommending and performing the operation.

"The following operation, as the steps of it will show, was performed with the two-fold intention: 1st, of tying the subclavian artery before it passes through the scaleni muscles, if it should be found in a fit state; and 2dly, to tie the arteria innominata in case the former should be diseased or too much encroached upon by the aneurismal tumour.

"Michael Bateman, aged 57 years, was born in Salem, Massachusetts, and by occupation a seaman. He was admitted into the New-York Hospital on the 1st of March, 1818, for a catarrhal affection, having at the same time his right arm and shoulder much swollen. At the time of his admission the catarrh being thought the most considerable disease of the two, he was received as a medical patient, and placed under the care of the physician then in attendance. During the three first weeks of his residence in the house, the catarrh had greatly yielded to the remedies prescribed. The inflammation, which had produced an enlargement of the whole superior extremity, extending itself to the muscles of the neck on the right side, was also gradually subsiding.

"A tumefaction, however, situated above and posterior to the clavicle, at first involved in the general swelling, and not to be distinguished from it, began to show

itself. This resisted the remedies which were effectual in relieving the other, and became more distinct and circumscribed as the latter subsided; at length assuming the form of an irregular tumour.

"The history which he gave of the case is as follows: He said, about a week before he entered the hospital, while at work on ship-board, his feet accidentally slipped from under him, and he fell upon his right arm, shoulder, and the back part of his head; that he felt but little inconvenience from the fall, and after a short time returned to his duty. Two days subsequent to this, however, he felt pain in the shoulder, and the succeeding night was unable to lie upon it in bed. The whole arm and shoulder then began to swell, and became so painful that he was unable any longer to perform his duty as a seaman. The ship having arrived in New-York, he was admitted into the hospital.

"For some time after the general swelling had subsided, leaving the tumour distinct and circumscribed, no circumstance occurred which gave rise to a suspicion of its being aneurismal. The enlargement was thought to be a common indolent tumour, and was repeatedly blistered, with a view to discuss it. The tumour gradually diminished under this treatment; though a considerable time elapsed before any very striking change took place.

"At length a faint and obscure pulsation was perceived; still it was a matter of doubt whether the tumour was aneurismal, or whether the pulsatory motion was communicated to it by the subclavian artery, immediately over which it was situated. From its firm unyielding nature upon pressure, the latter was considered as the most probable, and the blisters were continued as before. During the whole of this time the patient had worn his arm in a sling, the motions of it being very limited, and always attended with pain.

"The patient remained in this state for several days, without any marked change either in his feelings or in the appearance of the tumour.

"On the 3d of May, at 6 o'clock in the afternoon, the patient complained that he "felt something give way in the tumour,"* that his shoulder was very painful, and that he was able to raise it only a few inches from his side. The tumour at this time suddenly increased about one-third, and a pulsation was distinctly perceptible. Its most prominent part was below the clavicle; at which place the pulsation was most distinct. The portion above the clavicle was also much enlarged; it still,

* In the preparation, the clavicle is to be seen divided about its middle, which from its appearance is shown to have been effected by absorption. This Dr. M. seems to have omitted to mention.

however, had its usual firmness, except in one point near its centre.

"May 4th.—The tumour is evidently increased, that portion of it more particularly which is below the clavicle; it is not as firm and resisting as it has been. Pulsation is not so distinct as yesterday, but appears to be more diffused.

"He was this day transferred to the surgical side of the house, and became my patient. The cough having become comparatively slight, the tumour appeared to be the most urgent disease, and, in my opinion, to call for prompt attention. The arm is now perfectly useless, and any motion at the shoulder joint gives him severe pain. The patient is naturally of a spare habit, and from the nature of his disease, and the confinement to which he has been subjected, has become much reduced in strength.

"May 5th and 6th.—The tumour is still progressing, and the pain in the shoulder is also more severe. During the three last days his medicines have been discontinued, except that he is allowed to rub the parts about the clavicle with volatile liniment.

"On the 7th I directed a consultation of my colleagues to be called, consisting of Drs. Post, Kissam, and Stevens. I now stated to them that I wished to perform an operation which would enable me to pass a ligature around the subclavian artery, before it passes through the *scaleni* muscles, or the *arteria innominata*, if the size of the tumour should prevent the accomplishment of the former. This I was permitted to do, provided the patient should assent, after a candid and fair representation was made to him of the probable termination of his disease; and that the operation, though uncertain, gave him some chance, and, as we thought, the only one of his life.

"Dr. Post, at my request, communicated with him privately on this subject, and after a full explanation of the nature of the case, my patient requested to have any operation performed which promised him a chance for his life, saying that in his present state he was truly wretched.

"May 8th, 9th, and 10th.—The tumour is acknowledged by all to be increasing, and it is thought proper not to defer the operation any longer. I therefore requested that preparation be made for performing it to-morrow.

"It is difficult to give an idea of the size of a tumour so irregular in its form, and so peculiarly situated. A thread passed over it, from the lower part of that portion of it which is below the clavicle, extending upward obliquely across the clavicle toward the back of the neck, will measure five and a quarter inches. Another crossing this at right angles one inch above the clavicle, will measure four inches: two and a half inches of the thread

are on the sternal side of the former, and one and a half on the acromial. It rises fully an inch above the clavicle, which, added to the depression below the clavicle on the opposite shoulder, will make the size of the swelling above the natural surface about two inches.

"May 11th.—One hour before the time assigned for the operation, the patient appeared perfectly composed, and apparently pleased with the idea that the operation afforded him a prospect of some relief. He was directed to take of *Tinct. Opii*. 70 drops.

"No difference can be perceived in the pulsation of the arteries in the two extremities; his pulses are uniform and regular, each beating 69 in a minute.

"He was placed upon a table of the ordinary height, in a recumbent posture, a little inclining to the left side, so that the light fell obliquely upon the upper part of the thorax and neck. Seating myself on a bench of a convenient height, I commenced my incision upon the tumour, just above the clavicle, and carried it close to this bone and the upper end of the sternum, and terminated it immediately over the trachea; making it in extent about three inches. Another incision about the same length, extended from the termination of the first along the inner edge of the *sterno cleido mastoid* muscle. The integuments were then dissected from the *platysma myoides*, beginning at the lower angle of the incisions, and turned over upon the tumour and side of the neck.

"Cutting through the *platysma myoides*, I cautiously divided the sternal part of the *mastoid* muscle, in the direction of the first incision, and as much of the clavicular portion as the size of the swelling would permit, and reflected it over upon the tumour. The internal jugular vein was encroached upon by the swelling, which made this part of the operation of the utmost delicacy, from the morbid adhesion of that part of the clavicular portion of the muscle to it, which was detached. I separated this portion of the muscle to as great an extent, however, as the case would possibly allow, to make room for the subsequent steps of the operation; only a part of the vein was exposed. The *sterno hyoid* muscle was next divided, and then the *sterno thyroid*, and turned upon the opposite side of the wound, over the trachea. This exposed the sheath containing the *carotid* artery, *par vagum*, and internal jugular vein. A little above the sternum, I exposed the *carotid* artery, and separated the *par vagum* from it; then drawing the nerve and vein to the outside, and the artery towards the trachea, I readily laid bare the subclavian about half an inch from its origin. In doing this, the handle of a scalpel was principally used, nothing

more being required but to separate the cellular membrane, as it covers the artery. I judged it would be very imprudent to introduce a common scalpel into so narrow and deep a wound, especially as it would be placed between two such important vessels or parts, as the carotid and par vagum, and where the least motion of the patient might cause a wound of one or the other of them. The proper instrument, in my opinion, for this part of the operation, is a knife, the size of a small scalpel, with a rounded point, and cutting only at the extremity; this was used, and found to be very convenient for this stage of the operation. It can be introduced into a deep and narrow wound, among important parts, without the hazard of dividing any but such as are intended to be cut. This knife is contained in a set of instruments admirably calculated for this and other operations on arteries deeply seated, and which I shall mention more particularly hereafter.

"On arriving at the subclavian artery, it appeared to be considerably larger than common, and of an unhealthy colour; and when I exposed it to the extent of about half an inch from its origin, which was all that the tumour would permit, to ascertain this circumstance more satisfactorily, my friends concurred with me in opinion that it would be highly injudicious to pass a ligature around it. The close contiguity of the tumour would of itself have been a sufficient objection to the application of the ligature in this situation, independent of the apparently altered state of the artery. Art in this case could not anticipate any thing like the institution of the healthy process of adhesive inflammation in an artery in the immediate vicinity of so much disease. The Pathology of arteries has long since taught us, that ulcerative inflammation, and all its train of consequences, would have been the inevitable result. This was the fate of the only case, in which a ligature has been applied to the artery in this situation. The operation was performed by that eminent Surgeon of Dublin, Dr. Colles.

"While separating the cellular substance from the lower surface of the artery, with the smooth handle of an ivory scalpel, a branch of artery was lacerated, which yielded for a few minutes a very smart hemorrhage, so as to fill the wound perhaps six or eight times. It was about half an inch distant from the *innominata*, and from the stream emitted, was about the size of a crow-quill. It stopped with a little pressure. I can scarcely believe this to have been the internal mammary, from the hemorrhage ceasing so quickly; though, from its situation, it would appear so; and if from some irregularity it were not the superior intercostal, it must

have proceeded from an anomalous branch.

"With this appearance of disease in the subclavian artery, it only remained for me either to pass the ligature around the *arteria innominata*, or abandon my patient. Although I very well knew, that this artery had never been taken up for any condition of aneurisms, or ever performed as a surgical operation, yet with the approbation of my friends, and reposing great confidence in the resources of the system, when aided by the noblest efforts of scientific surgery, I resolved upon the operation.

"The bifurcation of the *innominata* being now in view, it only remained to prosecute the dissection a little lower behind the sternum. This was done mostly with the round-edged knife, taking care to keep directly over and along the upper surface of the artery. After fairly denuding the artery upon its upper surface, I very cautiously, with the handle of a scalpel, separated the cellular substance from the sides of it, so as to avoid wounding the pleura. A round silken ligature was now readily passed around it, and the artery was tied about half an inch below the bifurcation. The recurrent and phrenic nerves were not disturbed in this part of the operation.

"As most surgeons who have performed operations upon large arteries, in deep and narrow wounds, complain of the embarrassment which has attended the application of the ligature, I am happy in the present opportunity to have it in my power to recommend an instrument, or contrivance, which, in my opinion, is calculated to surmount all difficulties. This set of instruments consists of several needles of different sizes and curvatures, with sharp and blunt points, and having in each two eyes. The needles screw into a strong handle or shank of steel: two strong instruments in handles, with a ring or eye in the extremity similar to a tonsil iron, and perhaps they may be called ligature irons: a small knife rounded at the extremity like a lancet for scarifying the eyes, and a small hook at the extremity of a steel shank, also fixed in a strong handle. These instruments are the invention of Drs. Parish, Hartshorne, and Hewson, of Philadelphia. They are the result of investigations made upon the dead body, as to the best mode and place for tying the subclavian artery on the *acromial side of the scaleni muscles*.*

"With the ligature introduced into the eye of one of the smallest blunt needles, which was nearest the shank of the instrument, I pressed down the cellular substance and pleura with the convex part, and very carefully insinuated it from

* See Dr. Parish's Paper, Eclectic Rep. vol. III. p. 229.

below upwards, under the artery. The point of the needle appearing on the opposite side of the artery, I introduced the hook into the other eye of it; then unscrewing the shank, the needle was drawn through with the utmost facility, leaving the ligature underneath the artery.

"In the application of the ligature to this artery, I would invite the attention of those who perform it, to a circumstance which, in my opinion, is somewhat important: it is to pass the ligature from below upwards, in order to prevent the pleura from being wounded. From the use of these instruments repeatedly, I would also recommend that the hook be fixed in the eye of the needle before the shank is unscrewed, otherwise very considerable difficulty will be experienced in finding it, and even when felt, not easily introduced, from the want of firmness which the handle part of the instrument would afford.

"I now made a knot in the ligature, and with my forefingers carried it down to the artery, and drew it a little so as partly to close its diameter and arrest the column of blood gradually. This was continued for a few seconds to observe the effect produced upon the heart and lungs; when no change taking place, it was drawn so as to stop the circulation entirely, as was shown by the radial artery of the right arm, and the right temporal immediately ceasing to pulsate. The knot was drawn more firmly by the ligature irons, and a second knot applied in the same manner.

"In no instance did I ever view the countenance of man with more fluctuations of hope and fear, than in drawing the ligature upon this artery. To intercept suddenly one-fourth of the quantity of blood, so near to the heart, without producing some unpleasant effect, no surgeon, *a priori*, would have believed possible. I therefore drew the ligature gradually, and with my eyes fixed upon his face, I was determined to remove it instantly if any alarming symptoms had appeared. But, instead of this, when he showed no change of feature or agitation of body, my gratification was of the highest kind.

"Dr. Post now asked him if he felt any unpleasant sensation about his head, breast, or arm, or felt any way different from common, to which he replied, that he did not.

"Immediately after the ligature was drawn tight, the tumour was reduced in size about one-third, and the course of the clavicle could be distinctly felt.

"The parts were now brought into coaptation, and the integuments drawn together by three interrupted sutures and straps of adhesive plaster; a little lint and additional straps completed the dress-

ing. Three small arteries were tied in the course of the operation: the first was under the sternum, and divided with the sternal part of the mastoid muscle, and from its course may have been a branch of the internal mammary reflected upwards; the second, in raising the inner edge of the mastoid muscle, about the upper angle of the longitudinal incision, and must have been the most descending branch of the superior thyroid; and the third was a branch of the inferior thyroid, and cut while raising the sterno thyroid muscle. The patient lost perhaps from two to four ounces of blood, most of which came from the ruptured branch of the subclavian. The operation occupied about one hour.

"The curved spatulas recommended by Dr. Colles, I found of great use in the operation. I provided three for this purpose, two broad, and one narrow, bent at right angles, and sufficiently firm. After raising the muscles, they were of the greatest advantage in keeping separated the carotid artery and par vagum, as likewise the divided muscles; they served also another very useful purpose, that of preventing by their equable pressure the constant oozing from the smaller vessels; and the little room taken up in a small and deep wound, will give them a great superiority over the fingers introduced.

"Ten minutes after the operation the pulse is regular, and not the least variation can be perceived; it beats 69 strokes in a minute; the patient says he is perfectly comfortable, and has no new or unnatural sensation, except a little stiffness of the muscles of the neck, which he thinks is owing to the position in which his head was placed during the operation; the temperature of the right arm is a little cooler than the left; his breathing has not been the least affected by the operation, but is perfectly free and natural.

"2 o'clock, P. M.—Patient expresses a desire to eat, and is directed a little thin soup and bread; the temperature of both arms is very nearly the same; breathing perfectly natural; pulse as before.

"3 o'clock, P. M.—There is still a trifling difference in the temperature of the two arms; ordered the right to be wrapped in cotton wadding; not the least unpleasant symptom has as yet made its appearance.

"6 o'clock, P. M.—Complains of a little pain in his head, not more on one side however than the other; describes it as a common headach: the pain of the shoulder and arm much less than before the operation: no difference can now be perceived in the temperature of the two arms; pulse a little accelerated, and perhaps a little full.

"9 P. M.—Patient complains of headach; skin is rather hotter than natural;

pulse strong and full, and beats 75 in a minute; the carotid on the left side of the neck is observed to be much dilated and in strong action; tongue moist and clean.

" 9 1-2 P. M.—Symptoms continuing the same, directed him to be bled from the left arm to ℥ssj . After bleeding the pulse fell 7 beats, and was less full. Complains of some thirst; let him drink common tea.

12 P. M.—Patient has slept a little; is free from pain; pulse full and less frequent, beats 60; skin moist and of a natural temperature.

" *Second day*, 2 o'clock A. M.—Patient enjoys a natural and undisturbed sleep; respiration free, and performed without the least difficulty.

" 5 A. M.—He has rested well the last three hours. Says he has a slight head-ach, and a little pain in the right elbow: the latter he attributes to the position in which his arm has lain during sleep; pulse full, but not so tense as before the venesection; skin natural and moist; temperature of both arms the same. He states that he can now incline more upon the right shoulder than he has been able to do since the second day after he received the injury.

" 9 A. M.—Pain in the head no way troublesome; skin moist and of natural temperature; tongue clean; says his neck feels stiff, but is not painful; has no difficulty in swallowing. His cough has thus far been much less frequent than before the operation: expectoration is also attended with less difficulty; pulse 75, full, but not tense; has taken a dish of coffee, and some bread; complains of some thirst; directed a solution of super-tartrate of potass to be drank occasionally.

" 10 A. M.—Symptoms as before; the veins of the fore-arm and hand since the operation have been as much distended as previous to it, and upon compressing them so as to stop the circulation, and allow the vein to become empty for some distance above, the column of blood is seen to distend the vein immediately upon the removal of the pressure, plainly showing that the circulation is going on with considerable rapidity, although no pulsation has been felt in the brachial or radial arteries. The radial artery can be easily distinguished by the fingers, and seems to be filled with blood. There is evidently a pulsation in the anterior branch of the temporal artery, just as it is passing a little above the exterior canthus of the orbit; the left external carotid is beating with increased action, and appears larger than natural.

" 3 P. M.—Has taken a light dinner, and complains of a little headach; pulse has become tense, and is also increased in frequency; skin is considerably hotter

than natural; tongue too indicates a febrile action: was bled to ℥viij . and directed to drink freely of a solution of the super-tartrate of potass.

" 10 P. M.—Since the last report he has become more comfortable; complains of no pain, and says he lies perfectly easy; pulse increased in frequency to 78, but of the natural soft feel; the right side of the face has been at times a little cooler than the left, and is so at the present time: it is, however, not so much so as to be perceptible to the patient; temperature of the right arm natural: that of the left, and the whole body, is above the natural standard, but it is moist; tongue is clean: having had no evacuation from his bowels since the operation, is directed to take a saline cathartic, in divided doses.

" 1 A. M.—Complains of nothing; has not slept any; cathartic has operated twice.

" *Third day*, 5 A. M.—Has had no sleep in consequence of the operation of the medicine, it having produced free evacuations in the course of the night; skin not so moist, but of natural temperature; the two arms have equal warmth; pulse full, and rather more frequent than last evening: says his right elbow is a little painful, and the arm feels tired. The complete flexion of the arm at the elbow is prevented by a little rigidity of the extensor muscles.

" 9 A. M.—He is now comfortable, has slept a little, and feels refreshed; pulse is full, and rather more frequent than natural; skin natural and moist: the size of the tumour is considerably diminished; has taken a dish of chocolate and some rusk.

" 11 1-2 A. M.—Patient still free from pain, or any uneasiness; medicine has operated seven times; skin not hotter than natural, and moist; tongue clean; the right facial and anterior temporal arteries communicate a distinct pulsation to the fingers: having slept but little during the last night, directed him to take an anodyne of Tinct. Opii. gtt. xxx. and to have the room made dark, and kept quiet, in order to procure him some sleep: let him have sago or panada as often as he inclines to take nourishment.

" 4 P. M.—Has slept the last two hours, and is still sleeping; respiration free and easy; nothing the least unnatural in his appearance.

" 10 P. M.—He has slept four hours, and is much refreshed; is free from pain, except a little in the elbow; pulse small and soft, beating 105 strokes in a minute; tongue clean; feels a little soreness in the wound when swallowing; has taken a considerable quantity of sago and panada; his appetite is good; temperature natural and uniform in both arms.

" 12 P. M.—Patient has slept the greater

part of the time; is free from pain, and perfectly comfortable: skin moist and natural; pulse soft, small, and frequent.

"Fourth day, 6 o'clock A. M.—Patient has passed a good night; says his right elbow gives him some uneasiness, but complains of nothing else; tongue is clean; skin moist and natural; can move the right arm with considerable ease; says he takes as much light nourishment as he has been accustomed to for some time past: no unfavourable symptom has as yet made its appearance.

"11 A. M.—Symptoms continue much the same; tongue slightly furred; pulse comparatively small and soft, beats 105, and regular; respiration has been uniformly natural since the operation; suppuration has begun to appear through the dressings, and is attended with a little fœtor; let them be covered with a yest poultice: it is thought that a faint pulsation, or undulation, is at intervals felt in the radial artery of the right arm: the left external carotid continues its increased action.

"6 P. M.—No change is observable in the patient's symptoms; he still continues comfortable, and complains of nothing.

"Fifth day, 11 1-2 o'clock A. M.—The wound was dressed to-day: on removing the poultice the dressings were soft, and easily came away; the suppuration was considerable, and of a healthy appearance; it was found that the extremities of the two incisions were united as far as the sutures, each about one inch in extent; one suture at the angle of the wound was removed; the wound was dressed with dry lint, gently pressed into it; adhesive straps and a compress; his pulse beats 110, is fuller and stronger than yesterday.

"5 P. M.—Patient is very comfortable, subject to no pain or unnatural sensation; pulse still 110, but softer.

"Sixth day, 6 A. M.—Patient sleeps; respiration not attended with the least difficulty; skin moist and natural.

"9 A. M.—He has rested well during the night, and is perfectly free from pain; pulse 110, and soft; skin moist; tongue clean: having had no alvine evacuation since the 13th, directed to take of sulphate of soda $\frac{z}{j}$, in divided doses.

"11 A. M.—The dressings were again removed, and the discharge seemed more considerable than at the former dressing; the sides of the wound are granulating, and appear perfectly healthy; on the ends of the muscles that were divided in the operation, there are small sloughs which are beginning to separate, leaving a healthy surface underneath; wound was dressed with lint spread with Ung. Res. Flav. and adhesive straps: pulsation is now perfectly distinct in the branches of

the right external carotid artery: complains a little of the back part of his head, which he says is sore from lying; in other respects is comfortable.

"6 P. M.—Has no pain, and is in every respect much as usual; tongue clean; skin natural; says he feels "no weaker than before the operation."

"Seventh day, 6 A. M.—He has passed a comfortable night, and is free from pain or any uneasiness; pulse regular and soft, and beats 105 in a minute; skin moist, and of natural temperature.

"11 A. M.—The wound was again dressed; suppuration considerable and healthy; some of the small sloughs came away, leaving a healthy and florid surface beneath: sprinkled the wound with powdered carbon, then filled it lightly with lint, and over this applied the yest poultice, which was secured with adhesive straps: temperature of the two arms is the same, cathartic having produced no effect, *Habeat enema purgans statim*.

"9 P. M.—Symptoms have not varied materially: the enema has produced a copious evacuation: says he feels more comfortable, and desires to sit up in bed, which was allowed, taking care to have him raised up very cautiously, in order to prevent any exertion being made with the right arm and shoulder.

"Eighth day, 6 A. M.—Patient has rested well during the night; says he feels some pain on swallowing, and that when the attempt is made, it gives rise to a fit of coughing, which fatigues him; it also occasions some soreness in the wound; pulse still soft, and less frequent than yesterday: he takes a reasonable quantity of light food every day:—Directed a cetaceous mixture for his cough, and is permitted to sit up for a short time, if he feels disposed.

"11 A. M.—Pulsation of the radial artery of the right arm to be felt occasionally pretty distinct; cough has become more troublesome; pulse 100; skin natural and moist. The dressings were again removed, and the suppuration is more profuse, apparently healthy, though attended with considerable fœtor; appearance of the wound every way favourable; small portions of the sloughs are removed at each dressing, and the sides of the wound look perfectly healthy; the same dressings to be continued.

"6 P. M.—Complains only of his cough, which troubles him frequently; can move his arm with much more facility, and has no pain in it; circulation as before, and the temperature uniform and natural. The wound was dressed this evening in consequence of the fœtor being unpleasant to the patient: continue the dressings.

"Ninth day, 7 A. M.—Patient was found sitting up in bed, supported by a bed-chair, having passed a good night; is in

good spirits, and expresses his gratitude for the relief afforded by the operation; says he can move the arm with greater ease, and it gives him no pain; pulse 105, regular and soft; skin natural; every symptom as favourable as could be wished.

"10 A. M.—Pulse less frequent, regular and soft; temperature perfectly natural; wound has a more favourable appearance, discharges less in quantity, and it possesses less fœtor: dressed the wound as yesterday; tumour has diminished two-thirds, is soft, and less florid. The apex of the tumour is now below the clavicle.

"6 P. M.—Patient still in every respect as comfortable as at the last report.

"9 P. M.—Pulse 110, regular and soft: the dressings were removed this evening; the wound is much contracted in size, and is perfectly healthy, except a small slough which still remains in the deepest part of the wound: granulations are shooting up rapidly from the sides.—When preparing to renew the dressings, an unexpected and unaccountable hemorrhage took place, which suddenly filled the cavity of the wound. The rapidity with which the blood flowed, and the size of the stream, gave rise to fearful apprehensions for the man's safety: dry lint was immediately placed in the wound, and as much pressure made as the patient could conveniently bear, which quickly stopped it. After continuing the pressure for a short time, the lint was removed, when no hemorrhage recurring, the usual dressings were repeated: the patient experienced no ill effects from the bleeding, nor did he seem to be much agitated. At 10 o'clock P. M. has no pain, nor has he as yet had any sleep.

"Tenth day, 7 A. M.—Has passed a comfortable night, except that he has been frequently disturbed by his cough: tongue clean; skin moist; pulse soft, and has much less strength than before.

"11 A. M.—The dressings were again removed, and the wound made clean; its appearance is in every respect favourable; does not appear to have been the least injured by the hemorrhage: the dressings were renewed as before: he is directed to take half an ounce of the cold infusion of cinchona every hour, and to drink occasionally of ale when thirsty: has had an evacuation from his bowels to-day.

"6 P. M.—Symptoms much as before; complains a little of his elbow, and a numbness in his hand, to relieve which, he is directed to have the arm and hand rubbed well, and wrapped in wadding.

"Eleventh day, 6 A. M.—Patient has rested well during the night; cough has not been so troublesome; says he has no pain, and feels perfectly comfortable;

pulse better than yesterday; other symptoms as before.

"11 A. M.—The wound is dressed daily at this hour; its appearance is still very favourable, although there is still some fœtor in the suppuration: the wound has contracted perhaps one-third: the tumour is also considerably diminished, and softer than before; pulsation in the right temporal and radial arteries as before: the same dressings to be continued.

"6 P. M.—No change in the patient's general symptoms; pulse soft, and rather more frequent; appetite is as good as usual.

"9 P. M.—Appearances have not varied.

"Twelfth day, 6 A. M.—Our patient was visited as usual this morning, but there is no evident change in any of his symptoms; says he now rests well at night.

"11 A. M.—To-day, when the dressings were removed, that portion of the slough which occupied the bottom of the wound (apparently a portion of the sheath of the vessels) came away: every part of the wound now, where its surface can be seen, has a healthy look: the most depending part is obscured by a quantity of pus, which cannot be wholly removed by lint, and it is not thought safe to permit the patient to lie in such a position as will allow it to be discharged: with the slough came away the ligature which had been applied to an artery under the lower portion of the sterno-thyroid muscle; it was followed by no hemorrhage: the wound was now dressed with pledgets of lint, spread with Ung. Resinæ Flavæ and adhesive straps. He remains much as yesterday, has drank freely of ale; pulse rather stronger than yesterday.

"Thirteenth day, 7 A. M.—No perceptible change in his symptoms; complains of no pain, and says he feels very comfortable; cough has given him very little trouble for the last two days; he is evidently considerably weaker than before the operation, but is not sensible of it himself.

"11 A. M.—The wound was again exposed; it is not as florid as yesterday, and there is a greater secretion of pus; the cavity of the wound was filled with dry lint only; the pus appears well formed, and has very little fœtor.

"The same dressings were repeated in the evening; there is still a quantity of pus at the bottom of the wound, which rises and falls at each inspiration and expiration; it continues to contract above, leaving us uncertain of its extent beneath: during the last three days, the patient has sat up for several hours each day.

"9 P. M.—Pulse and skin perfectly natural; has had a natural evacuation from his bowels to-day; continues the infusion of bark as prescribed before.

"Wound was again dressed, and is as healthy as usual; suppuration just sufficient to moisten the lint: the same dressings to be continued.

"*Fourteenth day, 7 A. M.*—Patient has slept well during the night, and is as well as usual; complains of soreness of the ulcer which he has had for some time between his shoulders; it is improving in its appearance, and is directed to be dressed as usual with Ung. Resinæ Flavæ. The erysipelatous blush which surrounded it, is not as florid as heretofore; it is beginning to granulate, and assume a healthy appearance: in other respects he is perfectly comfortable: he is now able to raise the right arm to his lips, which he has not done since the fourth day after the accident by which his shoulder was injured; says, too, that he is getting stronger, and that he walked across the floor this morning without any assistance.

"*11 A. M.*—On removing the dressing, the granulations appear perfectly florid and healthy: the bottom of the wound is not visible, owing to the small quantity of matter which collects there, and from its depth cannot be easily removed, and perhaps not altogether safely: the position of the patient in bed must necessarily make the bottom of the wound the lowest: when he coughs or swallows, a small quantity of fluid pus at the bottom of the wound is seen to rise and fall; from the general appearance however of the wound, the man's feelings, and many other circumstances, it is not probable that there is any considerable quantity: the large ligature lying very loose in the wound was taken hold of, merely however to see if it was separated; no force was used: pulsation of the right radial artery more distinct than heretofore: countenance of our patient is improving; says he feels more comfortable than before the operation: he can now straighten his arm, and raise it to his mouth with facility. as yet he has not recovered his strength, but is improving daily; has been sitting up all day: directed him when lying down to assume a more recumbent posture; continue the sulphuric acid and infusion of cinchona, as before: complains of the ale being too strong; let it be diluted and made pleasant with sugar and nutmeg.

"*9 P. M.*—The large ligature, since the operation, has been confined upon the upper part of the sternum by a piece of adhesive plaster, to prevent any accident during the dressings. Upon dressing the wound this evening, the large ligature, as it lay in the wound, appearing to be loose, was again taken hold of with the forceps, and found floating upon the pus, being completely separated from the artery below. The ligature was drawn so firmly upon the artery, that the noose

was only large enough to admit the rounded end of a common probe. The wound looks healthy, and is contracting rapidly; it is now perhaps not more than one-third of its original size. Suppuration is now only sufficient to moisten the lint through.

"*Fifteenth day, 12 o'clock.*—The patient is comfortable in every respect; pulse and skin perfectly natural; is sitting up in bed, and occasionally amusing himself with a book; not the least symptom about him indicating indisposition: wound is healthy, and continues to improve in appearance. The right arm at intervals gives him a sensation of numbness: not more, however, than can be accounted for from the uniform position in which the arm rests, and no doubt a more languid circulation, as it is readily removed by a little friction and motion of the arm. His appetite improves, and he expresses a desire to walk about the room. The bark and sulphuric acid to be continued.

"*9 P. M.*—In the afternoon he was removed down stairs, from the private room in which he was placed immediately after the operation, to the ward in which he formerly lay, and appeared highly gratified with the idea of again seeing his friends, whom he had left with very little hope of ever returning to. The wound, upon being dressed, did not appear to have undergone any perceptible change.

"*Sixteenth day, 11 A. M.*—Our patient's strength is improving. To-day he made an effort, and with success, to visit his friends in Ward No. 7, where he lay previous to his being transferred to the surgical department, and returned, without having any support; pulse as strong as before the operation, and in every respect natural; appetite better than before the operation; cough a little troublesome, but less so than for several days previous; wound dressed with dry lint.

"*9 P. M.*—Dressings removed; patient as before; suppuration small in quantity, and appears to be well-formed pus, and is not attended with the least fœtor.

"*Seventeenth day, 11 o'clock.*—The ends of the divided muscles are nearly in contact, and the surfaces of the wound are rapidly granulating, and in every respect look well: patient's health continues to improve; he walks about the room with perfect ease, and into several wards in the same story; the ability to move the arm increases; pulse and skin natural. The dressings were removed at 4 P. M., and also at 10. P. M.

"*Eighteenth day.*—The patient's strength continues to improve; every symptom remains highly flattering; cough less troublesome. The dressings were again removed to-day three times.

"*Nineteenth day.*—Continues the same as yesterday; wound dressed three times.

"*Twentieth day.*—To-day he passed down two pair of stairs, and walked several times across the yard, and was highly delighted with his performance, and felt not the least inconvenience from it; sleeps uniformly well during the night, and takes more food during the day than he did previous to the operation; continues the infusion of cinchona and sulph. acid as before, and directed to use dry lint as the dressing.

"*Twenty-first day.*—Dressed the wound three times again to-day; it is nearly closed at the bottom; the power of motion in the right arm continues to increase: he can now move it with as much facility as the left, though not to the same extent: his strength is daily improving, and the operation is considered by all to have been completely successful; size of the tumour continues the same, no diminution of it having been perceived for the last week; the most prominent part of the tumour is yet below the clavicle, that above rises to about the height of the clavicle, which gives a little convexity to the place between the clavicle and trapezius muscle.

"*Twenty-second day.*—Continues to improve in every respect; dressings renewed as often as yesterday; owing to the weather, he has not left his ward to-day; pulse full and strong; temperature of both arms the same.

"*Twenty-third day.*—A few minutes before the hour of visiting, to-day, a message was brought, that the patient was bleeding from the wound. The dressings were immediately torn off, and dry lint crowded into the wound, and slight pressure applied for a few minutes, when the hemorrhage ceased. The patient lost at this time, perhaps, about 24 ounces of blood, and was very much prostrated. Pulsation ceased in the radial artery of the left arm, and the countenance, gasping, and convulsive throes of the patient, threatened immediate dissolution: all present apprehended the instant death of the patient. The first impression was, that the trunk of the arteria innominata had given way. The conjecture afterward was, that the subclavian artery, from the diseased state of it, had not united by adhesion, and that the fluid blood from the tumour had regurgitated through its ulcerated coats. This appeared to be the most probable, both from the suddenness with which the blood ceased flowing, and the cause the patient assigned for the hemorrhage. He says that he felt weary of lying on his left side and back; that he had just turned on the right, which he had not done before since the operation, agreeable to my re-

quest. At the instant of turning over, something arrested his attention, which caused him to turn his head to the opposite side suddenly, and he felt the gush of blood from the wound.

"He was directed some wine and water frequently, which soon revived the circulation. The wound was dressed with dry lint and a compress. Pulse as frequent as natural, but very small and soft: he appears very languid, and complains of a numbness and painful sensation in his hands; says also that his back aches. During the last twenty-four hours he has taken a pint and a half of Madeira wine: he also took occasionally some egg and wine, which was immediately rejected from the stomach.

"9 P. M.—Patient has lost his appetite, and appears considerably depressed; circulation very languid in the right arm; temperature of it is a little less than the left: directed a hot brick to be wrapped in flannel, and placed close to the arm. For a profuse perspiration which he has been in for the last three hours, he was ordered to be bathed with cold rum.

"*Twenty-fourth day, 6 A. M.*—Slept the greater part of the night, and feels comfortable; is still languid, and has no disposition to eat any thing; says he feels sick, and once last evening vomited after drinking some wine and water.

"Wound looks exceedingly pale, and the discharge is thin and fetid, for which the carbon and yest dressings were applied. He has vomited several times to-day, and has some considerable difficulty in swallowing, and complains of a soreness in the wound upon pressure.

"9 P. M.—Dressings removed; wound very pale; right arm of the natural temperature; feels occasionally a little numbness in the hand; has taken very little nourishment during the day; pulse natural, as to frequency, but small and feeble; a few minutes after dressing the wound, information was brought that hemorrhage had ensued, and before it could be commanded, he probably lost four ounces of blood. For his restlessness and pain in the bones he was ordered two grains of opium.

"*Twenty-fifth day.*—Has rested well during the night, and is perhaps a little better this morning. The repeated hemorrhages have debilitated him exceedingly, and from the irritable state of the stomach he can take only a very little nourishment. In the morning he was directed the effervescing draught to be repeated every two hours; this allayed the irritability of his stomach, and enabled him to take a little breakfast.

"His countenance has altered since the first bleeding surprisingly, his eyes are now heavy, and for the most part fixed; his cheeks are sunken, and an universal

palor has spread itself over his countenance; and, from every appearance, a short time will terminate his existence. He has not vomited since early in the morning; is advised to take a little soup, and to drink freely of wine and water; dressings were renewed at 3 o'clock P. M., shortly after which the patient again bled, but not to exceed, however, an ounce. He was dressed with dry lint, as usual.

"11 P. M.—Patient has not as yet had any sound sleep, is restless, and apparently distressed, although he says he feels no pain: breathing is attended with some difficulty; his hands and legs are continually in motion; pulse small and feeble.

"*Twenty-sixth day, 6 A. M.*—Patient has not rested well; is occasionally falling into little slumbers, but is awaked by the least motion: pulse small and feeble; respiration somewhat laboured; appears to be sinking; seems disinclined to take any thing; legs and arms constantly in motion.

"11 A. M.—More feeble than before: has been forced to take a little chocolate; is evidently sinking; wound was dressed, but there was no secretion of pus in it; countenance of the patient foretells his approaching dissolution.

"6 P. M.—Is extremely low; respiration very much laboured: is not able to articulate: for the last three hours there has not been such continued throwing of the legs and arms about the bed: he lays in a state of insensibility; *temperature of the two arms the same to the last.*—My pupil, Abraham I. Duryee, the House Surgeon (to whom I am indebted for the correct reports, and the most unwearied attention to this case, and whose ingenious application of means, for the recovery of many of my patients, will long be held by them in grateful remembrance,) having for a few minutes left the patient, he was sent for immediately, as there was another bleeding from the wound, by which he lost probably eight ounces of blood: during the whole time he did not manifest the least appearance of consciousness, nor was the least motion perceptible, except that necessary for respiration and circulation: the hemorrhage was stopped with lint, after removing the former dressings; respiration is now performed with the utmost difficulty, and the patient appears as if every respiration would be the last: he expired at half past six in the afternoon: the temperature of the right arm, after death, appeared by the touch to be the same as the left; it was as natural and uniform as other parts of the body.

EXAMINATION OF THE BODY.

About eighteen hours after death, I opened his body; there was considera-

ble emaciation, and the surface of the wound was of a dark-brown colour, and fetid; the wound was perhaps about one-third of its original size; it had been enlarged by the pressure of lint into it, and other means to arrest, from time to time, the hemorrhage: the ulcer between his shoulders was ill-conditioned.

"For the purpose of examining the condition of the aorta, where the arteria innominata is given off, as also the origin of the latter vessel, as well as the state of the pleura at the part about which the ligature had been applied around the artery, the chest was opened in the following manner: after removing the integuments and muscles from the forepart of the chest, the sternum was carefully sawed through, about an inch from its upper extremity, and raised by sawing through the ribs below the junction of the cartilages: this removed so much of the front part of the chest as to facilitate and expose fully to view the subsequent steps of the dissection; by thus leaving the clavicles attached, every part connected with the ulcer and great vessels could be seen and examined in situ.

"The arch of the aorta and origin of the innominata being fairly exposed, not a vestige of inflammation or its consequences could be discovered, either upon them, the lungs, or the pleura, at any part. An incision was next made longitudinally into the aorta, opposite the origin of the innominata, and upon introducing a probe cautiously up the latter vessel, it was seen to pass into the cavity of the ulcer; the innominata was then laid open with a pair of scissors into the ulcer; the internal coat of this vessel was smooth and natural about its origin, but for half an inch below where the ligature had cut through the artery, it showed appearances of inflammation, and there was a coagulum adhering with considerable firmness to one of its sides; showing that nature had made an effort to plug up the extremity of so large a vessel, after the adhesion, which no doubt had been effected by the ligature, was swept away by the destructive process of ulceration. The upper extremity of this vessel was considerably diminished in its diameter by the thickened state of its coats, occasioned by the surrounding inflammation. The innominata, about half an inch from the aorta, and a little to the left side, gave off an anomalous artery, large enough to admit a small size crow-quill.

"The ulcer at the bottom was more than twice the size of the wound in the neck; it extended laterally towards the trachea and under the clavicle towards the tumour. The tripod of great vessels, consisting of the innominata, subclavian, and carotid arteries, to the extent of

nearly an inch, was dissolved and carried away by the ulceration. The extremities of the two latter vessels were found also to open into the cavity of the ulcer. The upper surface of the pleura was very much thickened by the deposit of newly organized matter, for the safety and protection of the cavity of the thorax. Indeed, instead of having increased the danger of penetrating this membrane, the adhesive inflammation which preceded the ulcerative, seemed, by the consolidation of cellular membrane, and the addition of new substance, to have more securely and effectually shielded it from danger.

"The internal surface of the carotid artery was lined with a coagulum of blood, more than twice the thickness of its coats, and extending above the division into internal and external, so as almost to give them a solid appearance, insomuch that a probe could barely be introduced. The subclavian artery, internally and externally to the disease, was pervious. The brachial and other arteries of the right arm were of their common diameter, and in every respect natural. The external thoracic or mammary arteries, as they went off from the subclavian, were larger than natural: the right internal mammary was pervious, and of the usual appearance. Upon opening into the tumour, which now gave (from its small size) no deformity to the shoulder, the clavicle was involved in it, and found carious, and entirely disunited about the middle. A number of lymphatic glands under the clavicles, and particularly the left, were considerably enlarged, and, when cut into, very soft, and evidently in a state of scrofulous supuration.

"Where the subclavian artery opened into the ulcer left from the wound of the operation, it appeared not only pervious, but of the natural size, and the coats free from any diseased appearance. Externally towards the axilla the artery was somewhat enlarged in diameter, but exhibited no appearance of disorganization of its coats either externally or internally. About an inch from the ulcer, or just as the artery had passed between the scapular muscles, there was an irregularly shaped elliptical opening upon its upper side, though large enough to receive the extremity of the fore-finger. The edges of this opening were jagged and uneven, and the surface of the artery internally was of a brownish yellow colour to the extent of half an inch on the inside of the opening, and more than an inch towards the axilla. The internal coat of the artery had a rugous or puckered appearance, separated a little from the muscular coat, very friable, and evidently in a degenerated state. This opening of the artery communicated directly with the an-

terior extremity of the sac, which contained the coagula; and upon removing these, the surface of the sac was seen puckered, or thrown into a great number of little folds, giving it at first sight the appearance of containing a number of holes.

"Several very important facts are established by this operation—facts which no surgical operation has ever before confirmed. It proves very conclusively, that the heart, the brain, and the right arm, were not the least injured by it in any of their functions. To tie so large a vessel so near the heart, might very reasonably be expected to occasion some immediate derangement in the actions of that organ: but it was neither increased nor diminished in its contractions, nor did it give rise to the least visible change in his respiration. All this could not have been anticipated. I apprehend there are no ingenious surgeons, who would not have expected quite a contrary result. For my own part, I must confess, that this was to me an anxious moment, when I drew the ligature upon this artery. Indeed, so apprehensive was I that some serious, if not almost immediately fatal consequences, would follow, from arresting so large a proportion of the whole mass of blood suddenly, that I drew the ligature very little at first. But when no change took place in the actions of the heart, or respiration, I felt a confidence in completely intercepting the whole current of blood through this great vessel.

"The brain in no operation has been deprived of so large a quantity of blood as in this, and yet it suffered no inconvenience: from the effect of experiments however upon animals, I entertained no fear as to the consequences of my operation upon this organ.

"The right arm, as the reports of the case from day to day will show, was in no want of a sufficient supply of blood for the purposes of its economy. That circulation went on to a degree adequate to its wants, the natural warmth and function of the skin fully prove; and although at no time could all be satisfied that a pulsation was perceptible in the radial artery, yet many at times were of the opinion, that an occasional undulatory motion was very evident: every one was confident of the distended and elastic feel of this artery, and could plainly see, from pressing on the distended veins upon the back of the hand, that a free circulation of blood was going on: but independent of these evidences, the natural warmth and free perspiration would alone be sufficient to establish the fact.

"The route of circulation to the right arm was somewhat different, at first, from what took place after the ulceration had extended. The musculature of the

epigastric and internal mammary must have thrown a considerable retrograde current of blood through the latter vessel into the subclavian directly, and which in all probability passed on into the arm: after the ulceration had extended, this communication was cut off by the destruction of the subclavian to some distance. It was now that the principal supply of blood to the arm must have been derived from the free communication of the intercostals with the thoracic arteries. From the large size of these, as found in the dissection, I apprehend they must have afforded the principal channels through which the blood was conveyed to the arm after the operation: the anastomoses of the infra scapular and other arteries of the axilla, more or less with small branches of the intercostals, as also the occipital, with small ascending branches from the subclavian, may have given some trifling assistance.

"The ulceration which went on so insidiously at the bottom of the wound, was the sole cause of the death of my patient. While the upper part of the wound put on a favourable appearance, and seemed healing, mischief was extending below. The separation of the ligature on the fourteenth day, spontaneously, without being followed by any hemorrhage for a number days, and not until ulceration had extended, conclusively proves to my mind, that all the purposes of the ligature were completely answered—that adhesion was fully effected. Had it not been for the ulcerative inflammation, no doubt will be entertained, I think, by surgeons, but that my patient would have recovered. From occupation, his constitution was indeed very old, and with an ill-conditioned habit, every thing favoured the process of ulceration. The position of the wound may be said by some to favour this process, but in a sound healthy habit it would only retard the wound in its recovery, but would never promote ulceration.

"The practicability and propriety of the operation appear to me to be satisfactorily established by this case: and although I feel a regret, that none know who have not performed surgical operations, in the fatal termination of it, and especially after the high and just expectations of recovery which it exhibited; yet I am happy in the reflection, as it is the only time it has ever been performed, that it is the bearer of a message to Surgery, containing new and important results."

I have now to refer the reader to the several periodical publications which have cavilled at this operation, when he will, by viewing their criticisms, have further confirmed the splendid nature of this surgical performance. See *American Medi-*

cal Recorder, Vol. 2, p. 73. *London Medical and Physical Journal*, Vol. 42, p. 145. *New-York Medical Repository*, (new series,) Vol. 5, p. 162.

INGUINAL ANEURISMS.

When we compare the method for taking up the external iliac artery, as performed by Sir Astley Cooper, with that practised by Mr. Abernethy, we are at no loss to which to give the preference. The trifling disturbance of parts in the one case, contrasted to the extensive division of muscular structure in the other, will induce us to decide in favour of the former plan.

It appears, that the principal indications to be fulfilled in the performance of this operation, are, first, to preserve the peritoneum from an unnecessary disturbance; and, secondly, to avoid detracting from the support afforded the abdominal contents by the muscular parietes.

In the method practised by Sir A. Cooper, the incision through the tendon of the external oblique muscle is carried in a direction nearly parallel to its fibres; from which circumstance, the action of the muscle after the operation, has a tendency to close the wound; and from the internal oblique and transversalis remaining uncut, the least possible weakening of the walls of the abdomen ensues. But in the first mode practised by Mr. Abernethy, and followed by most of the surgeons who afterward undertook the operation, the three abdominal muscles were divided to the extent of about three inches, and in some cases four inches, in a perpendicular line from Poupart's ligament, by which the abdominal muscles were cut in a direction at right angles with their fibres, from which a great gap must have immediately followed from the contraction of those muscles, that would have remained, so far as regards the presence of muscular substance: and that this space is not filled afterward by a substance equal to give as much strength and support to the contained viscera, is proved by the supervention of hernial protrusions at these very parts. Such an instance is recorded by Mr. Kirby, of Dublin, in a case wherein he tied the external iliac artery according to Mr. Abernethy's plan. He adds to the detail of that case, "A hernia prevails where the abdominal muscles were divided." In the case operated on by Mr. Stevens, of Santa Cruz, a very large hernia exists, protruding at the part where the parietes were cut to get at the internal iliac artery. He made an incision five inches in length parallel to the epigastric artery, which was almost at right angles with the fibres of all the muscular struc-

ture in that situation, and the consequence was as I have stated.

Having had opportunity to operate in two instances in the living subject, for securing the external iliac artery within a ligature, and adopting the method of Sir Astley Cooper, as described by Mr. Hodgson, and quoted in the text of this dictionary, I was struck with the facility with which the artery could be surrounded, by introducing the needle through the natural opening in the fascia transversalis. I have since taken many opportunities to exhibit this operation in the dead subject, and have informed myself that it can be taken up at a distance of nearly two inches from where it lies under Poupart's ligament, by seeking for it through the internal abdominal ring, and without disturbing the fibres of the internal oblique or transversalis. I have found also, that a very slight division of these would give room to reach it nearly to where the internal iliac is given off. I have moreover tied the internal and common iliac arteries with the greatest ease in the dead subject, after separating the internal oblique and transversalis muscles from Poupart's ligament as far as the anterior superior spinous process of the ilium, by cutting outwardly from the internal abdominal ring.

In this way can these operations be performed, and the division of the parietes from the ring will not exceed two and three quarters inches in the adult subject. The opening, however, through the tendon of the external oblique muscle will be somewhat greater, by being extended through that part of it which covers the spermatic chord, and is over the oblique canal; yet the incision will be in the direction of its fibres.

This method will be found in detail in the first part of my *Surgical Anatomy*, published this year, accompanied by a plate, which is the fifth in the series; showing a ligature around each of these vessels, in situations in which they had been applied after the arteries had been got at by prosecuting the dissection as recommended. (*Surgical Anatomy*, part first, p. 147.)

AORTA. The circumstance of the constitution sometimes suffering comparatively little injury under wounds of the peritoneum, is not sufficient to lead us to feel safe when accidents occur to this structure. And to avoid wounding that highly sensible and delicate membrane, must be held an established maxim in surgery, when operating near the abdominal cavity.

I will hardly presume to think that Sir Astley Cooper's patient, in whom the aorta was tied for aneurism, might have died from peritoneal inflammation; yet that event, perhaps, might be as readily

inferred, as that the man's death, within forty hours after the operation, was to be attributed "to the want of circulation in the aneurismal limb." And although "on opening the abdomen there was not the least appearance of peritoneal inflammation, *except at the edges of the wound*, and" though "the omentum and intestines were of their natural colour," might he not have sunk pursuant to the shock experienced by the nervous system, in the demand made upon it to support a general inflammation of the abdominal cavity; even such an one as was to be expected, *a priori*, upon the slightest wound into the peritoneum? Or in other words, might not the patient have undergone the constitutional symptoms attending peritoneal inflammation, and to an amount to have produced death; notwithstanding evident marks of that inflammation were not observable among the *post mortem* appearances; from having been withheld, owing to the excess of impression upon the nervous system, in the first instance? Be that, however, as it may, it requires little argument to prove, that in performing so great an operation as that of surrounding the aorta with the ligature, the safest method is to be adopted: and if it is possible to get at the vessel as easily to the surgeon, and as safely to the patient, without wounding the peritoneum, such a plan should certainly be resorted to. I have accordingly taken the liberty to propose a method for securing this vessel, which I have frequently practised on the dead subject; and if it ever fell to my lot to tie that artery in the living, should prefer it to any other.

I would commence an incision beginning over the extremity of the last or twelfth rib of the left side, and continue it through the common integuments as far as the anterior superior spinous process of the ilium. Thus I would lay bare the external oblique muscle, which I should divide for the same extent; this incision would be almost in the course of its fibres. The internal oblique and transversalis muscles I would also divide in the line and to the extent of the first incision. These muscles readily retracting, would expose the fascia transversalis, which part I would lift with a pair of dissecting forceps, and open it as directed in the case of a hernial sac. I would then introduce my finger, and extend its division by means of a bistoury as far as the first cut through the common integuments; being cautious to avoid any injury to the peritoneum underneath. I would after this, elevate the peritoneum from the posterior abdominal parietes, by insinuating two fingers, while I supported with the other hand the part raised, until I had separated as far as the attachment

of the mesentery, at the forepart of the lumbar spine. I should now see and feel the artery above its bifurcation, and be able, with a properly curved aneurismal needle, to pass a ligature around it, and to draw the knot by the contrivance made use of for the extirpation of the tonsils.

To facilitate such an operation, as remarked in Sir A. Cooper's case, it would be expedient to approximate the shoulders to the pelvis, that the abdominal muscles might be relaxed; and also, previously, to empty the intestinal canal, that no difficulty should be experienced in elevating the peritoneum, from the pressure of the abdominal viscera.

BLEEDING.

ARTERIOTOMY.

Every one must have witnessed the trouble and embarrassment that frequently attends the attempt to draw blood from the temporal artery. It is always difficult to succeed by simply striking the artery with a lancet; for although the vessel itself is pretty firmly bound down to the fascia over which it has its course, yet the common integuments at this part of the head are very loosely connected; so that it is hardly practicable to make at once, the cut through them and that into the artery, opposite each other; and retain them in that relative situation. Hence we have, as a frequent attendant on this operation, an extensive ecchymosis, the existence of which hinders the application of the necessary pressure; which that kind of performance requires, or preventing an after hemorrhage. And when, from the difficulty experienced in stopping the bleeding, it becomes expedient to cut the vessel across to restrain it, a new embarrassment presents itself, from the trouble of finding the vessel among such extensive ecchymosis.

To avoid this evil, then, to be enabled to command a certain quantity of blood, and the more easily to restrain the hemorrhage when enough has been extracted, I have been in the practice of first cutting down by the side of the vessel with a scalpel or lancet; of separating it from its attachments; then lifting it upon a probe, after which, of opening it obliquely with a lancet, and taking as much blood as was required. The vessel lying upon the probe; I cut the vessel across, when it would immediately retract, and the bleeding instantly cease. After this a piece of adhesive plaster without pressure will be generally all that would be required. The probe being under the artery while the bleeding is going on, I should, by cutting it free, be under no doubt of having completely divided the vessel.

BRONCHOCELE. The following is from the Quarterly Journal of Foreign Medicine and Surgery, No. 11, p. 348; being an extract from a Memoir which M. Coindet published in the February number of the *Bibliothèque Universelle*, on the subject of Iodine as a remedy in this disease.

"Of all the preparations of iodine, that of the hydriodate of potash with a superabundance of iodine is the most manageable, and the one which produces the fewest accidents. For its preparation, 36 grains of the hydriodate of potash, and 10 grains of iodine are dissolved in an ounce of distilled water. From 6 to 10 drops are at first prescribed three times a day, and the dose is increased or diminished according to the effects produced. M. Coindet is of opinion, that it is necessary to observe the time when the iodine is about to manifest its action, so as immediately to suspend its exhibition, and resume it eight or ten days afterward, that is, at the moment when the action of that before administered must terminate; again to suspend it and resume it, in observing nearly the same rules as every prudent practitioner follows in the administration of mercury, rules which have not always been kept in view by those who have made use of iodine, and the neglect of which diminishes the success of the remedy.

The following are the alarming symptoms observed by the author:—Acceleration of pulse, palpitation, dry cough, watchfulness, marasmus, and prostration of strength; sometimes swelling of the legs, tremours, painful hardness of the bronchocele, diminution of the breasts, or a remarkable augmentation of appetite, supervene; and, he adds, that in almost all the instances which he has observed, to the number of five or six, a very rapid diminution, or a disappearance, more or less complete, has taken place during those symptoms, even in hard, bulky, and old bronchoceles. On some patients the medicine acts almost immediately, while on others no apparent effect is produced, even after they have taken it for several weeks in succession. An example of its quick action is related, which occurred in a man who had had an enormous bronchocele in the two lobes of the thyroid body for a long series of years. Its increase was progressive, and it was very hard to the touch; the patient complained of choking and oppression when he walked, stooped, or went up stairs, but in other respects he enjoyed good health. He took thirty drops of the medicine daily, but on the fifth day complained of an increase in the size of the bronchocele, aphony, and rather severe pains, which required the suspension of the iodine, and the repeated applica-

tion of leeches and poultices to the part. In fifteen days he had recovered his former state, with the exception of hoarseness: the bronchocele was also considerably diminished and softened. Two months after the commencement of the treatment, the remedy having been again administered during four days, and again discontinued, the bronchocele was sufficiently diminished to free the patient from all inconvenience.

"M. Coindet considers that the iodine is contra-indicated when the constitutions of patients are remarkably delicate, nervous, or weak. But he has seen its exhibition attended with admirable success when the precautions he recommends have been observed, and the patients were affected with no other complaint than bronchocele; but above all, when they were at an advanced period of life. The following is an example of its beneficial operation; it occurred in a woman, seventy-five years old, who was affected with pains in the head, a tendency to drowsiness, and so great a weakness and numbness of the right arm, that she thought she touched every thing through a glove. These symptoms increased as an immense bronchocele was developed in the right side of the thyroid body, as it were in an acute manner; for although it had commenced thirty years before, it had during three months been increased in bulk nearly as much as the size of the fist. It evidently interfered with the circulation in the brain, and compressed the brachial plexus. By the employment of the iodine, the disease was arrested after a fortnight; in thirty days the bronchocele and bad symptoms were diminished. In a month afterward the swellings, paralysis, and affection of the head, were all entirely dissipated.

"The credit of the remedy is supported by other authorities besides that of M. Coindet; and the name of Breschet is mentioned as having communicated the results of his practice on this point to the Société Médicale d'É. ulation, coinciding with the above stated facts."

BRONCHOTOMY. I had lately handed me, by Professor Mott, the memorandum of an interesting case, wherein this operation had been successfully performed by him; and of which the following is a summary.

He was called to the child of Mr. B. of this city, of the age of ten months, in August, 1820, at about forty hours after the half of a peanut-shell had found its way into the larynx. The child at this time was nearly suffocated, having the symptoms of croup in a most aggravated degree. Having been made acquainted with the circumstances of the case, the only method that could be pursued immediately presented itself, to wit, the

performance of bronchotomy. The neck of the child being short and fat, with the high irritation under which it laboured, the operation in this instance was neither desirable, nor did the operator, by it, anticipate any permanent advantage. Yet, however, as the case admitted no delay, he began by making a longitudinal incision of about an inch and a half in length upon the trachea perpendicularly to the sternum through the common integuments. This bled freely and increased much the restlessness of the child; so that the operator was half inclined to hesitate any further proceeding. However, after a cautious use of the sponge, he at length ventured to pass a lancet between two rings of the trachea, just below the cricoid cartilage and the joining of the lobes of the thyroid gland. This was immediately followed by a great gush of bloody mucus of a brownish colour, and the breathing became immediately relieved. The next step was to withdraw the nut-shell; to effect this two probes were bent at their blunt extremities and passed between the rings of the trachea, for the purpose of giving an opportunity of seeing, if possible, the situation of the extraneous substance. There was great difficulty, however, in applying the probes, for, during the efforts of respiration the opening into the trachea was drawn alternately under the integuments above and below, beyond the extremities of the first incision. But the part being at length caught by the probes, it was held in a fit situation, so that the piece of nut-shell was seen within the larynx, opposite the cricoid cartilage. The probes being held by an assistant, the doctor, with the forceps, easily extracted it. The part being still retained by the probes, he had an opportunity of seeing within the tube above and below, and found an effusion of coagulable lymph, as observed in croup, lining the larynx and trachea above the wound. A probe passed upward produced excessive irritation and coughing, with suspended respiration during the intervals, but when passed downward, even as far as the division at the bronchiæ, the child showed no signs of irritation. The doctor now attempted to peel off the exuded coagulable lymph, which he did by aid of a probe, then withdrew it with the forceps. The layer of lymph was firm, and of much tenacity in itself, but was easily separated from the side of the larynx. The membrane of the larynx, where the lymph was situated, was observed highly florid, marking high inflammation, the effect of the presence of the extraneous body. At the end of the operation the breathing was found additionally relieved by the removal of the layer of coagulable lymph from the larynx. The doctor, now much satisfied

with the result of the operation thus far, prepared to dress the parts, which he began by applying strips of adhesive plaster; but he had no sooner closed the wound than the child's immediate death was threatened, which obliged him quickly to tear away the dressing, and allow the infant to breathe again by the opening he had made in the trachea. In this state the patient was permitted to remain for eight days, in which time the side of the neck, and the breast were blistered, and an active antiphlogistic treatment made use of for subduing the inflammatory symptoms. After this he was able to bring the parts together; upon which the child did well. This, I am informed, is the first instance of the successful performance of this operation in New-York.

It does appear to me, that the circumstances attending this operation are very decisive in favour of the operation of bronchotomy as a remedy for croup.

CARBUNCLE. I have to add to the value of this article, by inserting from the experience of Dr. Physick in Anthrax. It will have been observed, that Mr. Cooper speaks in the most decided manner against the use of caustics in this disease; and seems to depend solely upon constitutional treatment for the removal of this complaint. But Dr. Physick is of opinion, that the common caustic vegetable alkali, as a local application, is highly beneficial, provided it is made use of at a proper period of the malady. In elucidation of this sentiment, he has given an instance, in which is detailed the progressive treatment towards a cure of an inveterate case of carbuncle; and afterward explains the rationale of the practice.

He considers, that the disease is rightly divided into three stages, which require to be traced, in order that the application of the caustic may be regulated and used to advantage.

"The first stage to be that in which the disease is forming, and in which the peculiar inflammation exists in the cellular texture, under the skin, that ends in its death or mortification. This is attended by a burning pain, and sometimes by fever."

"The second stage, that in which pimples appear with orifices through the skin, which, gradually increasing, join, and eventually form one or more large openings, through which the mortified parts and ærial fluids pass out. These effects are produced by the ulcerative process, which, during the whole time of its continuance, is attended with the most severe and distressing pain that is experienced in the course of the disease. The patient's constitution also suffers so materially, owing to loss of appetite, want of

sleep, and fever, that death is the consequence in severe cases." And

"The third stage, is that in which an ulcer remains, attended, however, with no peculiarity from its cause."

Dr. Physick, therefore, has found all stimulating applications in the first stage of the disease highly improper; and considers the use of caustics at that period as particularly injurious. He had, however, once thought, from what he observed as the effect of blisters in checking mortification proceeding from some kinds of inflammation, that they would be useful in arresting the progress of carbuncle. Yet in his experience they have not shown any power in counteracting its progress to mortification. But it is in the second stage that he recommends the caustic, for the purpose of facilitating the discharge through the skin of the mortified cellular membrane, in which the inflammation had originally been situated. And adds, in all cases in which he had used it, at this period of the disease, the sufferings of the patient ceased as soon as the pain from the caustic had subsided. Its operation being, by accomplishing in a few minutes, what, if left to the process of ulceration, would require several days, to the great suffering and consequent loss of the powers of the constitution of the patient. (*See Philadelphia Journal of Medicine, Vol. 1, No. 3, p. 172.*)

FISTULA IN PERINEO. I enlarge upon this article, not for the purpose of introducing any new practice, but for recording a curious case, which turned out to be a very complicated instance of fistula in perineo.

Mr. W. a gentleman of Elizabethtown, N. J. of forty years of age, and who had lived freely, began about eighteen months before his death to complain of an almost constant pain in his back, which appeared like a rheumatic affection; after some weeks' treatment by the usual means for that disease, the symptoms were in a measure subdued, but there still remained a febrile disposition which could not be got under. About a year after this period Dr. Mott was sent for from New-York, in consequence of a peculiar discharge accompanying the flow of urine, this he soon found to be of the nature of *scæces*, which, however, the patient was most unwilling to believe. Examination was made by the rectum, to ascertain if there was any communication between that gut and the urinary bladder; but none could be found; neither was there any tumefaction or tenderness at the perineum, that would indicate the forming of a fistula in that situation. He was directed to pay attention to the state of his bowels, in order that the *scæculent* discharge might be as much as possible in a fluid state. He passed a number of weeks

after this under a constant hectic irritation, until at length an uneasiness was felt in perineo, then a tumour, and quickly a spontaneous opening was formed, which discharged matter, urine, and feces. By an examination through this new-formed opening no communication could be traced with the rectum, but the cavity of the fistula was found supplied with urine and feces from an opening through the membranous part of the urethra. From this time until the patient was carried off, he spent his life in great distress, becoming much emaciated, with continued hectic; the fistulous orifices in perineo amounting to four or five in number, from each of which extensive excavations were made between bladder and rectum, and these parts and the sides of the pelvis.

At about two months before his death, a fish-bone was discharged by perineum, incrustated with calculous matter.

At his decease, the Doctor having much anxiety to inspect the body, obtained permission for an examination, and found upon searching the abdominal cavity, that the rectum descended the hollow of the sacrum far to the right side, and opposite the right ileo-sacral articulation; while the sigmoid flexure of the colon was in its usual place. But there was a straight portion of the colon connecting the sigmoid flexure with the beginning of the rectum, and placed before the base of the sacrum. This was an anomaly, called by Dr. Mott, in his communication to me, a *pelvic arch* to the colon. I believe such a variety has been before noticed by an European author, whose name I have not at present in mind. Between this portion of the colon and the urinary bladder, there was an opening by which the two cavities were connected, but not in a simple manner. There was a sac placed between them, as if the fish-bone, in its effort to escape, had projected the side of the gut towards the fundus of the bladder, previously to any adhesion being formed; after which the communication was effected with the vesica urinaria.

I have been made acquainted with another case something like the one sketched; but as the patient is at this time in life, I do not know that it would answer any useful end to give a detail of his ambiguous symptoms.

FRACTURE.

FALSE JOINTS, OR UNUNITED FRACTURES.

There is something yet to be learnt upon this subject, as to the rationale of the operation of setons, sawing off the ends of bones, &c. as means produ-

cing cure in this form of disease. I will contend, that, when a want of union exists between the broken extremities of a bone in any part of the body, owing to a deficiency in the constitution to form osseous matter; that, taking out the ends of the bone, and sawing them off; saying nothing of the formidable nature of such an operation; or *sewing* the ends of the bones with caustic potash; is more calculated to confirm such *deficiency* than to renovate the constitution. I need not explain why; for a knowledge of the laws of the animal economy will answer for me. Also, how keeping up a puriform discharge for ten or twelve months, through means of a seton, from a limb under such circumstances of constitution; will lead the vessels of the broken ends of the bone to an osseous deposit, is to me inexplicable; and I will affirm, that no conclusive evidence, that it is so, can be drawn from any of the cases on record where a cure has taken place.

When means then, applied to the part, have beneficial tendency, (I intend the means hitherto made use of;) they must have influence upon some local cause preventing union. To be brief, for my limits oblige me, I will assume, that an insulated or loose splinter of bone, void of periosteum, acting as an extraneous body in the wound, is the only *local* cause which is preventing union and producing a hinge joint. Now, if we present this idea to the several recorded cures, we will find a ready explanation for the success of the different plans of treatment.

"Stephen Hammond," some three years ago, "was admitted into the New-York Hospital, with lameness, in consequence of a fracture of the leg about seven months previous. Upon examination, the tibia was found ununited, and to admit of very free motion between its ends; the fibula was entire, and the patient believed it never had been broken. From the account which he gave, it appeared he had been subjected to the proper treatment for the restoration of a broken bone, but he stated that it never showed any disposition to unite under the course which was pursued.

"As his general health was not good, he was put upon tonic medicines, and invigorating diet, and was directed a stimulating plaster of gum ammoniac and mercury should be applied over the part with the many-tailed bandage; and splints to reach above the knee and below the ankle, and to be very firmly secured; he was also advised to walk upon it with the assistance of his crutches, as much as the pain would any way permit, informing him that the object in wishing this exercise, was to inflame and irritate the ends of the bone; and that

he must not desist, even though considerable pain should accompany it. This was persevered in for several weeks, but finding little or no pain to attend it, and no appearance of inflammation in or about the fracture, and no hope of amendment, it was discontinued. Blisters were next repeatedly tried, but to no purpose. Very powerful shocks of electricity also were passed in different directions through the part, but they produced no beneficial effects.

"A seton was next introduced: this was done by making a small incision upon the outside of the tibia, down to the fractured ends, then passing between the bones the stilette of a small trocar, and pushing it out on the opposite side, the seton was readily introduced with an eyed probe.

"In a few days considerable inflammation and pain supervened, which required emollient poultices and the antiphlogistic treatment to subdue it. This was soon followed by a copious discharge of matter from the seton, and a collection of pus on the anterior part of the tibia, which was evacuated by a small incision. After five or six weeks, he became sensible of an increase of firmness in the leg, and from this time he was directed to diminish the size of the seton one thread every other day, until it was all removed. It continued to grow stronger every day, and in a short time after the wounds healed, he was permitted to walk a little upon it, when splinted and tightly bandaged, and in about three months the bone was firmly united."

"John Smith, aged forty-one years, became a patient in the hospital in 1819, in consequence of an ununited fracture of the thigh bone, of twelve months standing. It occurred at sea, and at the same time several of his ribs were fractured. Thirty-six days after the accident, he arrived at Halifax, without having had any attention paid to the adjustment of the bones. After his arrival, he states, that little notice was taken of his thigh, and no attempt was made to reduce it. He recovered without difficulty from the fracture of his ribs. The several means mentioned in the preceding case were tried, but without benefit. The limb was considerably shortened from the obliquity of the fracture and ends of the bone overlapping. No advantage attending the use of the means referred to, a seton was recommended. In the introduction of this, much more difficulty was experienced than in the case of Hammond.

"An incision was made on the inside of the thigh, a little to the outside of the artery, so as to come down upon the centre of the ends of the bones, where they overlapped. The stilette was then

attempted to be passed between the bones, but this was found altogether impracticable, from their very close contact, even though the limb was changed from one position to another. Instruments of different sizes were resorted to, but they could only be made to pass a very small distance. A *gimblet* was tried, but very little progress could be made. Having provided for the occasion a *carpenter's bit*, about the size of a large trocar, I found with this a passage could be made with the greatest facility. Then, by making an incision down to the end of the instrument, on the outside of the thigh, a large seton was readily conveyed through between the bones, by means of a long-eyed probe.

"After the expiration of three months, the thigh becoming firmer, and much less motion being felt between the ends of the fracture, he was permitted gradually to lessen the size of the seton. The firmness continued regularly to increase, but it was not until after eight months had elapsed, that the thigh had acquired sufficient firmness to enable him to support the weight of his body by the aid of a crutch.

"It is now more than twelve months since the seton was introduced, and the bone appears to be firmly united. The shortening of the limb does not exceed three inches and a half."

These were cases in which I should say, the spicula of bone had either escaped the limb by the course of the seton, was pushed out by the *carpenter's bit*, or had found its way along the muscles, at some distance from its former situation; so that it ceased to prevent union between the broken bones; or perhaps it might have been dissolved and absorbed pursuant to the inflammation, the consequence of the seton; but this last result I should be less inclined to believe.

I have observed, and I believe it is the fact, that the seton is of more doubtful success in cases of hinge joint of the humerus, than even of the femur, or either of the bones of the lower extremity; and I am satisfied with this explanation, why it is so, viz. that the patient will keep his bed, no doubt, when the seton is in the thigh or leg, by which the spiculae will find a more ready escape; but, when in the upper arm, the course of the seton may not be such as to invite the spicula outwardly: especially when the patient walks about with his arm in a sling. While I was at Philadelphia, I saw a man in the Alms-house who had, I think, for three years been under a hinge joint of the humerus, and from the nature of the cause producing the fracture, I was convinced the bone had been comminuted. He had had the

seton, as I was informed, applied twice, being kept in several months each time, under the special direction of Dr. Physick himself; yet the bone was still ununited. The patient was a good-looking fellow, a young man, and acknowledged by all to have got remarkably fat while in hospital. I expressed a great desire to the attending surgeons to have the bones cut down upon, and the spicula, which I felt assured was present, removed. I do not know whether it has yet been done.

I have just met with a case of hinge joint of the humerus, by Mr. Earle, in the 12th vol. (just published) of the *Medico-Chirurgical Transactions of London*, which is not in contradiction to the opinion I hold of this disease.

"Mr. C. of Teignmouth, fell from his horse in August, 1820, and fractured his left humerus, near the insertion of the deltoid muscle. He felt very little pain at the moment of the accident, and none at all after the limb had been placed in splints. Nothing worthy of remark occurred during the early treatment of the case; but, at the usual period, on removing the splints, it was found that no union had taken place. After a lapse of some months he consulted an eminent surgeon at Exeter, who wished him to submit to an operation, with a view to excite ossific inflammation. This, however, he declined; and the following May he came up to London, and placed himself under my care. His age was about thirty, and he stated that he had generally enjoyed good health. In his infancy he had suffered from fits, which had caused a paralytic state of the right arm, which was wasted, and nearly useless. This circumstance rendered it more important to endeavour to restore the left, which had been fractured. On examining it, I found the broken ends perfectly moveable, one upon the other, and the superior portion was drawn in towards the axilla, and did not appear in close coaptation with the inferior. While I was examining him, I was surprised to find that the integuments of the arm and forearm, in the space of a few minutes, became covered with urticaria. On remarking this to him, he stated, that he had been subject to this affection for many years; that he never suffered in his health from it; and that the slightest irritation, and even the friction of his clothes, would at any time produce it. This led me to be very particular in my inquiry into the state of his general health, and his various secretions. He had an unhealthy, sallow aspect; he perspired profusely, and his perspiration had a peculiar fœtid smell, and stained his linen of a brownish tint. His appetite was good, and he slept well; but his bowels were very irritable.

Fermented liquors, such as beer and cider, or any irregularity of diet, produced a copious deposit of lithate of ammonia in his urine; although he was not sensible of any dyspeptic feelings, and conceived himself in health. His common beverage was cider. I recommended him to have a seton passed through the arm, between the ends of the bone; which, on a revision of all the circumstances of the case, I was led to hope might be attended with success. I further recommended him to take the opinion of Mr. Brodie, who concurred with me in the propriety of the measure.

"On the 16th of June the operation was performed. An incision was made down to the bone, along the outer edge of the biceps, when I found that the fracture had been oblique, and that there was a projecting point occupying the outer part of the inferior portion; behind this I passed the needle, directing it through the interval between the ends of the bone. There was but little resistance to its progress. Considerable inflammation and a copious discharge of offensive matter followed; and, for some days, there was a good deal of fever and constitutional disturbance. The soft parts around the fracture became much thickened, and some hopes of union were entertained from this circumstance. After a time, however, this thickening subsided, leaving the limb quite as moveable as before the operation. The discharge became thin and ichorous, and excoriated the surrounding skin. The greatest attention was paid to maintain the ends steadily in contact, and his diet and general health were strictly regulated during the whole treatment of the case. At the end of seven weeks the seton was withdrawn, having totally failed in producing any bony deposit, though it had certainly caused considerable inflammation in the soft parts immediately around the bone. On mentioning the case to some medical friends, and considering with them the propriety of any further attempts to produce the union, Mr. Green suggested an operation which he had seen successfully practised by the late Mr. Henry Cline, which consisted of applying caustic potash to the ends of the bone. On considering the subject, the practice appeared to afford some probability of success in the present case; and the age of the patient, and the useless state of his other arm, fully warranted any attempt. The nature of the operation, and the possibility of its failure, were fairly represented to him, and on the 2d of August he submitted to the trial, on which occasion I was favoured with the assistance of Mr. Green.

"An incision, about four inches in length, was made through the integu-

ments, over the broken part, the broken ends of the bone were laid bare, and were found to be separated by a small detached portion of bone and a fibro-cartilaginous deposit. A small quantity of pus was still in the tract of the seton. The intervening substance was freely removed with a scalpel, but owing to the irregular surface of the bone it could not be entirely separated. A stick of caustic potash was then rubbed upon the ends of the bone, until the whole appeared black. I was in hopes, by thus producing artificial necrosis, to call forth into action the ossifying powers of the surrounding bone and periosteum. In performing the operation much caution was required, as the upper part of the bone lay close to the humeral artery. This rendered the operation rather more tedious, but the patient endured it with much fortitude, and afterward declared that he would rather submit to a repetition of it, than have another seton passed. Very little constitutional irritation followed, and no more inflammation in the part than was desirable. Considerable thickening took place round the bone, and the patient expressed a consciousness of returning strength and power in the limb. The sloughs of the softer parts came away in about a week, and two trifling exfoliations at the end of about six weeks. The wound granulated kindly, and was only kept from closing by the exfoliations. While there was a free discharge from the wound the disposition to urticaria ceased, but it returned as soon as the wound was healed. The thickening round the fracture had a very firm feel, and bore all the character of a callus. The consciousness of returning strength, and the increased firmness of the limb, were very encouraging, and induced Mr. Brodie, Mr. Green, and myself, to entertain very sanguine hopes of success. In the beginning of October I constructed an apparatus, calculated to give very firm and steady support to the limb, which was applied before he left town, at which time there was only a very slight degree of yielding, in one direction, towards the wound. I recommended him to be very careful, and to continue to wear the apparatus for some time. I have since had the mortification to hear from him, stating that he continued to wear the apparatus until Christmas, and on leaving it off, he found that the whole of the callus had been absorbed, and the limb was as weak and useless as before.

"On reflecting on this case, the following question suggests itself:—Did the want of union depend on any peculiarity of constitution in the individual, arising from causes over which we have no control? All the circumstances of the case seem to favour such an opinion. In the first place, although the ends of the bone

were not in very close adaptation, *and a small piece of detached bone was interposed*, the space between them was not sufficient to prevent union in a healthy person, and the separate portion of bone was not deprived of vitality. Next, although he was certainly not in a good state of health; yet, any flesh wounds which he had met with accidentally, and those which were inflicted in the operations, healed without difficulty; which proves that his vital powers were sufficiently active; of which, indeed, the state of his pulse, his time of life, and his power of enduring fatigue, afforded satisfactory evidence. It was clearly then not from debility that the bones would not unite. How far it may have been connected with the state of his skin, and digestive organs, must be determined by further experience. Another question suggests itself, which may be worth mentioning. Would it have been better to have left off the support earlier? To employ the language of Hunter, would the stimulus of necessity have called forth greater activity, which was not roused so long as the artificial support was employed?"

I hope the stimulus of necessity, or some other cogency, will soon direct to a decision in favour of a true pathology for this disease.

GONORRHOEA. In the New-York Hospital Reports, there are eight cases recorded of the use of cubebs in gonorrhœa, by Dr. Stevens. In all except one the cubebs cured the disease; in some cases in four days, in others within the month. In the case wherein it failed, it had been used for four weeks, beginning with a dessert spoonful, and ending with an ounce a day, without the least abatement of the discharge; but by having recourse to an ordinary injection, he was discharged from the hospital in four days, "nearly or entirely cured." The doctor states, that although unwilling to believe it a specific, he is unable to point out any stage of the disease in which it does not appear to be generally beneficial. In discharges from the urethra, attended with stricture, he had not occasion to try it; neither had he ventured to prescribe it during the presence of high inflammation.

I think I shall render a service to the American student, by giving a transcript of a paper of surgeon T. D. Broughton, of the St. George's and St. James' Dispensary, London, upon the efficacy of Cubebs, or Java Pepper, just published in the 12th volume of the Medico-Chirurgical Transactions. He proceeds,

"The history of this plant, its nature and tendency, and the best modes of preparing and exhibiting it, being already before the public, I shall confine myself altogether to a summary account of the

results of my exhibition of Cubebs in fifty cases of gonorrhœa; the largest proportion of which were those of soldiers, and the remainder dispensary and private patients.

"The preparations employed were the powder, and the wine or tincture; the former in doses of from half a drachm to two, the latter from one drachm to half an ounce, twice or thrice a day.

"The following statement will exhibit a concise and general view of the results: Patients cured in from two to seven

days,	10
eight to fourteen,	17
fifteen to twenty-one,	18
twenty-two to thirty,	1
in fifty-five days,	1
Patients in whom no sensible effects were produced,	8
Total,	50

"In five of the above cases, though the relief obtained was immediate and decidedly marked, the final cure was completed under the use of copivy in four of them, and an astringent injection in the other.

"In one case, the complaint having been arrested, returned again, and was eventually removed by copivy.

"Two cases, solely removed by the cubebs, were attended with swelling of the testicles, and one was accompanied by severe chordees, for which the usual remedies were used, in conjunction with cubebs. A small proportion of these cases only were of the severer kind, and two such were among the failures.

"The greater part were recent cases; but one of six months' existence yielded to cubebs in as many days, while the case of fifty-five days' cure had existed no more than a fortnight.

"Among fifty cases treated with cubebs, there were, therefore, three total failures, five relieved, and one suffered a relapse; leaving forty-one cases cured under the use of the pepper, in less time than a month, with one exception; the largest proportion in less than three weeks, and several in a few days, among which latter some were well in eight-and-forty or thirty-six hours; and, the failures excepted, the relief in all cases, where the symptoms were urgent, was very sudden; and only two instances of swelling of the testicles occurred, and one of chordees continuing after the exhibition of the pepper, although in other respects the clap was relieved directly.

"The account may therefore stand thus:

Cured,	41
Relieved,	5
Cured and relapsed,	1
Failed,	8
Total,	50

"It may be said that other plans of treatment are capable of affording similar results, especially that of injecting. But there are some points of view in which I cannot avoid looking at the cubebs pepper more favourably than any other remedy. It seems to possess the power of allaying irritation beyond that of alkalies, or the nitre and gum powders, and also of diminishing the discharge. Over balsam of copivy it seems to hold an advantage, in being admissible in the earliest and worst stages of the severest gonorrhœa, without being productive of inconvenience to the patient; while I have not found its continuance attended with that injury to the functions of the stomach which so frequently arises from full and continued doses of copivy.

"It appears to be superior to injections in not possessing any one of their injurious effects; and a remedy which is equally effective, and introduced into the general system, is, I think, more valuable than one applied topically to such a membrane as that of the urethra.

"As to the time which is usually consumed in removing a clap with cubebs, I think it might challenge most remedies in this respect, and is not more fickle in its operation. And, at the same time, we must take into consideration its negative qualities, which, rendering it a perfectly safe remedy, would naturally induce an inclination to sacrifice a little time, were it necessary, for the sake of avoiding the chances of a ruder, though a quicker plan of cure.

"Upon the whole, considering the effects in general of medicines on the human constitution, the resistance which the latter often opposes to the former, and the variable state of medicines, there are grounds for presuming that the cubebs pepper, though certainly not a specific, is as worthy of being relied upon, in removing gonorrhœa, as any other remedy, while its exhibition is unattended with any dangerous or disagreeable consequences; and it is frequently a quicker remedy in its action than those usually employed.

"As to the general use of this pepper, I agree with others in thinking, that when it does not seem to act in three or four days, it should be superseded by some other remedy; and as soon as (having relieved the urgent symptoms) it appears to cease exerting its influence on the constitution, the balsam of copaiva may be employed advantageously.

"Although no general rule can be laid down, yet it appears to me that those cases in which most benefit may be expected to arise from the use of cubebs, are the most recent, and perhaps not the severest cases; in short, those case^c

which are most usually met with in practice.

"As a farther advantage of this medicine, it may be added, that the habits of life and mode of diet need not to be infringed upon any further than such as common sense would dictate to every individual labouring under a local inflammatory affection, which, in every instance must be aggravated by exercise and intemperance; and recovery assisted by means of rest and abstinence, proportionate to the degree of the existing inflammation; the neglect of it would be opposed to the beneficial influence of any remedy whatsoever."

HEAD, INJURIES OF. There is a circumstance connected with the after treatment in these cases, which, if made general practice, would, I think, soon be conspicuous among remedial means in injuries of the head. I allude to a long interval between the first and second dressings, after operations, or wounds of the cranium or scalp.

I have frequently witnessed persons in low life, even bruisers and drunken people, having an extensive injury of the scalp, or even fracture of the cranium; from circumstances neglected for a week or ten days, and recover without any bad symptom. I have, even at this period, been sent for; and carefully cutting off the matted hair which covered the wound, and which was not easily removed, have dressed with adhesive plaster and a neat bandage. But by next morning, symptoms have supervened which required bleeding, and a most active antiphlogistic treatment; which I now feel assured would not have occurred, had I left the parts to themselves. I have been led to remark, moreover, that when wounds of the scalp and cranium have taken place in persons of a better standing, and who have been dressed daily from the commencement, especially if I had been joined by some formal consultants; that they have generally been troublesome to manage. Every practising surgeon, must be sensible of this fact. But how is it to be accounted for?

It does appear to me, that these parts, and especially those within the cranium, are induced to accommodate themselves to the pressure of the first dressing; and that, by it the inflammation, supervening to the injury, is moderated and regulated. But when the dressings are removed daily, there is as often a reaction in the vessels set up, under which they receive more blood for a time, which becomes a new excitant to inflammatory action. The delay between first and second dressings, after the operation of the trepan, is no doubt of decided advantage, and from this cause; by preventing an excess

of inflammation in the vessels of the pia mater.

In the 1st vol. of the *Physico-Medical Transactions of New-York*, published in 1817, we have three cases recorded by Dr. Mott, to illustrate this practice. The first was a boy of fifteen years of age, who underwent the operation of the trephine, for an extensive fracture and depression of the cranium, accompanied with a laceration of the dura mater, and a wound of the arteria meningeal media; he was dressed the *fifteenth* day after the operation, and did well without a bad symptom.

The second case I shall transcribe:

"I was requested early this morning to visit Thomas Williams, aged ten years, who had fallen from a stoop leading into the second story of a house, about fifteen feet high. He struck upon some round paving stones which covered the yard, with his side, and the side and back part of his head. When taken up he was entirely insensible, and appeared to his friends to be dead. It was about three-fourths of an hour after the accident, before I saw him. I found him lying on his side, and when an attempt was made to move him he appeared very much offended, though he did not speak. The pulse, breathing, and eyes, were all natural; and there was no vomiting.

"On the lower and middle part of the left parietal bone was a considerable tumour of the scalp, and a very small wound. The sensation to the feel around the tumour and wound, left no doubt (as far as the feel can be depended upon in these cases,) that there was a fracture, with considerable depression of the cranium. At this kind of treatment he complained a good deal, and requested to be left alone; the stupor which was first produced having now entirely gone off.

"To ascertain the state of the skull, I made an incision to the extent of about two inches, which enabled me to introduce my finger, and even see the fracture and depression.

"It became necessary in order to make the requisite divisions of the scalp, and to ascertain the extent of the depression, to request the assistance of five of the bystanders, in order to confine him.

"The depression was such, that with the elevator several pieces of bone were removed. The trephine was applied three times before all the depressed part could be elevated or removed, so as to take off all the pressure from the brain. The trephine was applied twice to the parietal bone, and once upon the os occipitalis, opposite the posterior and inferior angle of the parietal bone. Eighteen pieces of bone were saved during the operation, and no doubt some of the smaller were lost. Two large pieces were ele-

vated, and appeared so firm that it was not deemed necessary to remove them. A large crack, (for it would admit the handle of a scalpel,) extended from the anterior part of the depressed portion, and, from the size of it, and the distance it was traced, it in all probability was continued into the left orbit.

"Another fracture, not so wide as the first, went through the squamous part of the temporal bone, and may have terminated in the petrous part of the same. It was extremely difficult to remove and elevate the injured portions of the bone, owing to the extent of the surrounding injury, and motion, as it were, of the whole side of the cranium. The fulcrum of the old cases, would have been an excellent instrument in this operation, by resting at a distance upon the sound bone.

"The dura mater under the os occipitis was lacerated about an inch in extent.

"The head having been extensively shaved, the wound of the scalp was nicely drawn together, and retained by straps of adhesive plaster. The incision in the scalp resembled an inverted T; it was easily made to coaptate, except that part which extended transversely across the temporal muscle. At this place there was a trifling retraction of the edges, notwithstanding the plasters. The hemorrhage was considerable from the necessary division of the posterior branch of the temporal artery, and a large branch, if not the trunk, of the occipital artery. Over the straps of adhesive plaster, a large quantity of soft scraped lint was applied, with a thin compress, and the whole secured by a night-cap, so as to avoid all pressure upon the brain.

"He was now conveyed to bed, the room was darkened, and all noise directed to be guarded against. When told that the operation was over, and he was to be dressed, he was pretty easily controlled. His hands were secured together to prevent him from tearing off the dressings.

"Before the operation was completed, the pupils of both eyes were considerably dilated, and almost motionless, and continued so for two days.

"The night after the operation, he was very restless, constantly tossing himself about the bed. The following morning, and occasionally during the next and succeeding days, he was affected with retching, but it did not amount to complete vomiting. He appeared to understand when spoken to, but could not articulate a word for two or three days; and when he began, it was in a low whisper, and with an awkward and clumsy motion of his tongue. Indeed it was evident that he understood before this, when spoken to, as he would an-

swer by a significant motion of his head.

"The arterial system was very little affected; his pulse, for eight or ten days after the operation, was about a hundred strokes in a minute, but not the least tense. His tongue was moist and clear, from the beginning to the end of his confinement. He did not complain of any thing but a soreness in his head, at any time, from the operation; his bowels were kept open by the daily use of an enema. His diet was of the mildest kind, consisting of gruel, barley, and toast-water: this course was rigidly observed.

"On the twelfth day from the operation, he was walking about the room, and did not complain of any thing but weakness.

"On the morning of the *sixteenth day* from the injury, I dressed the head. Every part of the wound was healed by the first intention, except about half an inch of that part which went through the temporal muscle:—here were two granulations, each about the size of half a pea, which was the only suppurating surface to be seen. It was dressed with a small pledget of simple cerate.

"The head was again dressed on the nineteenth day from the operation, when it was completely healed at every point of the incision. The faculties of his mind and the functions of his body did not appear to be in the least impaired. For the general debility, he was recommended a more generous diet, and directed to take a little cinchona daily."

The third case was wherein the os frontis was extensively depressed, accompanied with a laceration of the dura mater in several situations. The meninges in the whole were torn to the extent of nearly two inches, from which the cerebrum was constantly discharging; and it is said, from the appearance there must have been nearly two tea-spoonsful of this substance lost. After the operation of the trephine, the wound was dressed with adhesive straps, lint, and a nightcap, in the usual way, and the patient put to bed.

"On the *sixteenth day* from the operation, the wound was dressed. It had all united by the first intention, except about half an inch in extent, which cicatrized in a few days by the use of a little argenti nitratum, to repress the exuberant granulations. He sat up in a chair, to have the first dressing removed, and had been walking about the chamber for several days previously."

The author says, "If renewing the dressings were entirely free from danger, there is another important reason why they should not be removed at this time; and particularly if a large portion of the

cranium has been taken away. The brain, by this time, has become accommodated to the pressure of the first dressing, and feels no way impatient under it; therefore, besides the irritation attendant upon the removal of the first: the pressure of the second cannot be so nicely graduated as the tender brain, at this time, so imperiously demands.

END OF THE FIRST VOLUME.
