DICTIONARY OF **Practical Surgery :**

COMPREHENDING

ALL THE MOST INTERESTING IMPROVEMENTS, FROM THE EARLIEST
TIMES DOWN TO THE PRESENT PERIOD ;

AN ACCOUNT OF THE INSTRUMENTS, REMEDIES, AND APPLICATIONS
EMPLOYED IN SURGERY ;

THE ETYMOLOGY AND SIGNIFICATION OF THE PRINCIPAL TERMS ;

AND

Numerous References to Ancient and Modern Works, forming together a "Catalogue
Raisonné" of Surgical Literature :

WITH

A VARIETY OF ORIGINAL FACTS AND OBSERVATIONS.

BY SAMUEL COOPER.

FORMERLY SURGEON TO THE FORCES ; MEMBER OF THE ROYAL COLLEGE OF SURGEONS ;
OF THE MEDICAL AND CHIRURGICAL SOCIETY OF LONDON ; AND
OF THE MEDICAL SOCIETY OF MARSEILLES.

WITH

NOTES AND AN APPENDIX,

BY WILLIAM ANDERSON,

OF THE COLLEGE OF SURGEONS OF EDINBURGH ; PROFESSOR OF ANATOMY AND
PHYSIOLOGY TO THE VERMONT ACADEMY OF MEDICINE ; AND
LECTURER ON SURGICAL ANATOMY IN NEW-YORK.

IN TWO VOLUMES.

VOL. I.

FROM THE FOURTH LONDON EDITION.

NEW-YORK :

PUBLISHED BY COLLINS & HANNAY, 230 PEARL-STREET.

J. & J. Harper, Printers.

1823.

WO
C 787d
v. 1
1823

Southern District of New-York, ss:

BE IT REMEMBERED, That on the second day of December, in the forty-seventh year of the Independence of the United States of America, COLLINS & HANNAY, of the said District, have deposited in this office the title of a book, the right whereof they claim as proprietors, in the words following, to wit :

"A Dictionary of Practical Surgery : comprehending all the most Interesting Improvements, from the earliest times down to the present period ; an Account of the Instruments, Remedies, and Applications employed in Surgery ; the Etymology and Signification of the Principal Terms, and Numerous References to Ancient and Modern Works, forming together a "Catalogue Raisonné" of Surgical Literature ; with a Variety of Original Facts and Observations, by Samuel Cooper, formerly Surgeon to the Forces ; Member of the Royal College of Surgeons ; of the Medical and Chirurgical Society of London ; and of the Medical Society of Marseilles. With Notes and an Appendix, by William Anderson, of the College of Surgeons of Edinburgh ; Professor of Anatomy and Physiology to the Vermont Academy of Medicine ; and Lecturer on Surgical Anatomy in New-York."

In conformity to the Act of the Congress of the United States, entitled "An Act for the encouragement of Learning, by securing the copies of Maps, Charts, and Books, to the authors and proprietors of such copies, during the times therein mentioned." And also to an Act, entitled "An Act supplementary to an Act, entitled An Act for the encouragement of Learning, by securing the copies of Maps, Charts, and Books, to the authors and proprietors of such copies during the times therein mentioned, and extending the benefits thereof to the arts of designing, engraving, and etching historical and other prints."

JAMES DILL,
Clerk of the Southern District of New-York.

Dr. JOHN MILLER
LANCASTER

ADVERTISEMENT

OF

THE AMERICAN EDITOR.

THE high celebrity which this Dictionary has already attained renders encomium unnecessary on the present occasion. As an apology, however, for reprinting the fourth edition in this country, it may be urged, that seven years have nearly elapsed from the last publication of this work in America, the second edition being then issued under the auspices of the late Professor Dorsey of Philadelphia. Since that time much has been done, both in Great Britain and on the continent of Europe, to add to the stock of surgical knowledge; all which Mr. Cooper has carefully recorded; posting to the present period the improvements that have been made in this department of Science. In this labour his wonted candour is eminently conspicuous, and not to the exclusion of those other qualities which have been ranked among the excellencies of his former writings.

It may nevertheless be asked, Why the necessity of an Appendix? In answering this, the Editor will not plead a custom in the country; but allege, that upon a close perusal of this edition, he has discovered, with surprise, an entire omission of some brilliant surgical achievements, that have their origin on this side the Atlantic. These having been long ago before the public, he is unable to explain why their record has escaped the author's eye. The expediency of their having a place in a book of this nature, he offers, therefore, as one excuse for the appearance of the Appendix.

Another motive not less specious, is founded upon the propriety of giving information of some new surgical operations that have been performed in this country with success, but which have occurred so recently, that any notices respecting them could not have reached our author in time to have had them inserted.

And lastly, as there have been lately presented to the public some new ideas relating to the anatomical structure of the parts within the pelvis, which are supposed will influence the method of operating in lithotomy; the Editor ventures to place them in an appendix, by way of making more known what he considers of the highest importance in this department of operative surgery.

To further these designs, he has taken occasion to extend the article

ANASTOMOSIS—That he might exhibit what he believes to be the only instance on record, wherein opportunity was afforded, of examining into the circulation by anastomosis on the side of the neck and face, after the carotid artery had been tied in the human subject.

ANEURISM—This has been also enlarged to detail the paper by Professor Mott on the arteria innominata in 1818, per the purpose of interrupting the blood in its course to an aneurism of the subclavian artery. Under this head also the Editor has proposed a manner of operating for securing the common and internal iliacs, which is easy of accomplishment, and does not endanger the peritoneum, nor give so great opportunity for hernial protrusions as the methods which have been heretofore practised.

AORTA—Under this head the Editor has in view to submit a method of securing the aorta by ligature, without wounding the peritoneum, and with the least disturbance of that membrane.

HYDROPHOBIA—This article has been extended to give place to a paper, read Oct. 1821, by Dr. Michael Marochetti, to the Medico-Physical Society of Moscow, "Upon the hydrophobic virus, and the means of discovering its presence, and destroying its activity on an infected subject." Although we have not yet had an opportunity in this country to test the doctrine, we give it a place on account of the respectable source whence the information has emanated.

LITHOTOMY—What is found in the Appendix relating to this subject is intended to fix the surgeon's attention to the line for the incision through the prostate and neck of the bladder, in this operation.

OSTEO-SARCOMA—Under this head is detailed three cases of operation upon the lower jaw by Professor Mott, of this city, for the removal of this disease. In two of these nearly one half of the bone was successfully taken away. In the third case, the bone was taken from the socket on the one side, and cut through just before the masseter muscle on the other; and although the patient survived but until the evening of the fourth day, yet the circumstances were found to be such upon dissection, which forbid accounting for his death from the operation. These cases evince the high surgical talent of the operator. They must remain on record, and become lasting memorials to the honour of American surgery.

In addition to these, several other articles have been enlarged upon in the Appendix.

New York, 1822. }

PREFACE

TO THE FOURTH LONDON EDITION.

THE flattering reception with which this work has been honoured ; its extensive circulation, not only in this country, but abroad, and in the colonies ; the influence, which it may therefore be presumed to have over the judgment and practice of some thousands of surgeons in different parts of the world ; and the quantity of good, or harm, which it may thus be the means of doing to society ; are reflections, which would not suffer its author to hesitate a moment about conscientiously doing every thing in his power for its completion and improvement. And, were not writers frequently the worst judges of their own productions, his ambition would lead him to hope, that he has not laboured in vain, and that at all events, if he has not been able to make the book in every respect complete and satisfactory, he has succeeded in bringing together a mass of valuable information, constituting a nearer approach to a full and correct history of the Theory and Practice of Surgery, than any other previous undertaking. Throughout the book, he has avoided a blind deference to great names, knowing that experience is the only infallible authority, and, upon every proposal, whether made in ancient or modern times, he has delivered his own sentiments with the same freedom and impartiality, which he would always court for opinions professed by himself. One thing is certain ; viz. that, as he is unconscious of personal dislike to any man in the profession, if he occasionally differs from his brethren wrongly, he may be accused of ignorance, or want of judgment, but never of envy, or private animosity. His steady wish has been to offer an exposition of surgery, where right and wrong doctrines, and good and bad methods, are so contrasted, that the impression in favour of what seems best for the relief of the patient, and the credit of the surgeon, may be rendered as plain and striking as possible. And, upon all controverted and doubtful points, he has uniformly endeavoured to let cases and facts weigh more, than any speculative considerations.

To numerous friends and correspondents, who did the author the honour to notify to him various suggestions for the improvement of the work, he returns his grateful acknowledgments ; and, wherever it has been possible for him to avail himself of these welcome intimations, the opportunity has not been neglected, and the credit of them given to the gentlemen from whom they were derived.

Some of the following cases, proposals, and references, have been inadvertently omitted ; but others unavoidably, in consequence of the articles, to which they relate, having been printed at too early a period for the necessary insertions to be made in them.

AMPUTATION—*Case of Amputation at the Hip-Joint, for the Removal of an Osteosarcomatous Tumour, by R. Carmichael. Vid. Trans. of the Fellows, &c. of the King's and Queen's College of Physicians, Ireland, Vol. 3,*

8vo. Dublin, 1820. The patient, a girl nineteen years of age. The operation was followed by her death on the fifth day.

ANEURISM—*R. Carmichael, Observations on Varix and Venous Inflammation, with Instructions for operating with safety to the Femoral Vein in Popliteal Aneurism.* See *Trans. of the Fellows, &c. of the King's and Queen's College of Physicians, Ireland, Vol. 2, p. 357, &c.* "The only part of the thigh, from Poupart's ligament to the tendon of the triceps, in which the femoral vein is not completely covered by the artery, lies within the space which extends from Poupart's ligament to where the artery meets the sartorius muscle. At the part of this space, most distinct from Poupart's ligament, the vein begins to disclose itself at the pubal side of the artery, from beneath which it emerges more and more as it ascends." Mr. Carmichael's plan is to introduce the needle on the pubal side of the artery, where the vein presents itself to view, and can be most easily avoided.

ANUS, ABSCESSES OF—*T. Ribes, Recherches sur la Situation de l'Orifice Interne de la Fistula de l'Anus, et sur les parties dans l'épaisseur desquelles ces ulcères ont leur siège.* See *The Quarterly Journal of Foreign Medicine and Surgery, No. 8, Oct. 1820.* In fistula in ano, the internal orifice, when there is one, is stated to be always within five or six lines above the point, at which the lining of the gut, and the skin conjoin, and generally capable of being seen, when the patient gently strains. This is an important observation, if correct. The advice of M. Ribes never to cut a fistula, unless the inner orifice can be found, is quite repugnant to the doctrines of Mr. Pott, with whom the author of this Dictionary is still disposed to concur.

ANUS, ARTIFICIAL—Cured by Mr. G. F. Collier, on the Taliacotian principles. See *Med. and Physical Journ. for June, 1820.* In this case, the feces used to escape chiefly when the patient was costive.

BRONCHOCELE—The Memoirs of Dr. Coindet on iodine, should have been mentioned in the references. The earliest of these interesting papers was read to the Helvetian Physical Society, July 25, 1820.

BURSÆ MUCOSÆ—Some interesting pathological and practical remarks on inflammation of bursæ mucosæ are contained in *Brodie's Obs. on Diseases of the Joints, p. 305, &c. 8vo. Lond. 1818.*

GRANULATIONS—*Sir Everard Home in Philosophical Trans. for 1819.* The discovery, here alluded to, is briefly noticed in the account of the properties and uses of pus, in the article SUPPURATION.

FRACTURES—A new method of treating old fractures, which have lost all tendency to unite, was successfully tried by the late Mr. Henry Cline, and has been recently practised by Sir Astley Cooper. It consists in cutting down to the ends of the fracture, scraping them well with a scalpel, and then rubbing them with a piece of caustic potassa, so as to destroy the parts of the bone indisposed to union, and at the same time excite such changes in the adjacent portions of bone, as will lead to an attempt at reparation, the formation of callus, and a reunion of the living bone after the detachment of the dead fragments. A few weeks ago, the author of this work was present at an operation of this kind, done by his friend Mr. Earle; but as the case is now under treatment, and this gentleman will probably soon favour the public with the particulars himself, it is judged unnecessary to offer here any premature observations on the merits of the practice, of which no just estimate can yet be formed, on account of the very small numbers of trials hitherto made of it. Like other methods, however, it appears not always to have suc-

ceeded ; but, whether it will do so more frequently, than the plans, for which it is substituted, and with less suffering than the seton produces, time and experience must determine.

LITHOTOMY THROUGH THE RECTUM—It appears from a recent statement, that altogether 15 patients have been operated upon in this way, and that only one case terminated fatally, ten being completely cured, and four quite well, with the exception of trivial urinary fistulæ. See *Journ. Complem. du Dict. des Sciences Med.* T. 10, p. 180, 8vo. Paris, 1821.

VENEREAL DISEASE—Recent investigations into this difficult subject tend to confirm an observation, made by Fallopius, Palmarius, and other writers of former times, that when mercury is not administered, the bones are seldom affected with nodes, or caries. However, it is not to be supposed, that the non-mercurial treatment is never followed by swellings of the bone, or periosteum. In Mr. Abernethy's Works, Vol. I. or in Vol. II. of this Dictionary, a case is recorded, where a young medical student, in consequence of the infection of a scratch on his finger with the matter of a bubo, had a variety of secondary symptoms, and among them, a thickening of the periosteum on the forehead, and a true corona veneris. The case was treated from the beginning to the end without mercury, and every symptom disappeared. Mr. Abernethy, according to the doctrines formerly in vogue, supposed that the disease could not be syphilis, because the recovery was effected without the reputed specific ; but as this criterion is now proved to be erroneous, the above case would be set down as venereal by the generality of modern surgeons. A day or two ago, Mr. M'Gregor, senior surgeon to the Lock Hospital, mentioned to the author two decided examples of nodes in patients, who had never used any mercury from the commencement of their cases ; but who were obliged to have recourse to this medicine for the cure of these and other secondary complaints. In Mr. Abernethy's case, it has been stated, that the corona veneris, as well as the other symptoms, yielded without mercury. Mr. M'Gregor inclines to the opinion, that syphilis is capable of a spontaneous cure only where the constitution is good ; yet, as the army reports include some thousands of cases, taken promiscuously and cured without the specific, there is some difficulty in explaining the invincible resistance of a few cases to the non-mercurial practice by any supposition of badness of constitution, in the general sense of the expression ; and it must be presumed, that, where many thousands of individuals are treated promiscuously without mercury, and ultimately recover, their constitutions could not all have been healthy. Mr. M'Gregor, however, may be correct, inasmuch as some uncommon peculiarity of constitution may sometimes present itself, in which the use of mercury is *absolutely* necessary for the removal of syphilitic complaints. As far as the experience of the author of this work goes, the frequency of nodes and caries has been considerably lessened since moderate courses of mercury have been substituted for violent salivations ; an opinion, in which he is happy to find himself joined by his friend, Mr. M'Gregor.

South Crescent, Bedford-Square,
Dec. 11, 1821.

A
DICTIONARY
 OF
PRACTICAL SURGERY.

This mark () will signify, that the Word which it precedes is further spoken of in the Appendix.*

ABD

A BAPTISTON, or **ABAPTISTA** (from α , priv. and $\beta\alpha\pi\tau\iota\varsigma$, *immergo*, to sink under.) Galen, Fabricius ab Aquapendente, and especially Scultetus, in his *Armamentarium Chirurgicum*, so denominate the crown of the trepan, because this part of the instrument formerly had a conical shape, which kept it from penetrating the cranium too rapidly, so as to plunge the teeth in the dura mater and brain. It would be quite superfluous here to inquire, whether there was any ground for this apprehension in the ruder periods of the surgical art, when the skilful management of the trepan might not be so well understood as at the present day. While it is admitted by modern surgeons, that mischief may be done by letting the saw penetrate too deeply, they do not find it necessary or adviseable, to obviate the possibility of such an accident, by using a conical trepan, with which it would be difficult to make any perforation at all; but guard against the danger by observing particular rules and cautions laid down in another part of this book. (See *Trephine*.)

It is remarked by Mr. S. Sharpe, that the great labour of working so slowly and difficultly (with a conical saw) is not only very inconvenient to an operator, but by no means serviceable to the operation; for, notwithstanding the saw be cylindrical, and works without any other impediment than what lies before the teeth, yet, even with this advantage, the operation goes on so gradually, that, in all his experience, he never found the least danger of suddenly passing through to the brain, when care was taken not to lean too hard on the instrument at the period of the bone being almost sawn through. (*Operations of Surgery*, p. 151, Ed. 3; also *l'Encyclopédie Méthodique*, *Partie Chir. art. Abaptiston*.)

***ABDOMEN**. **THE BELLY**. The term is said to be derived from the Latin verb *abdo*, to hide, because many of the chief viscera of the body are here concealed.

When a surgeon speaks of the cavity of the abdomen, he confines his meaning to the space, which is included within the bag of the peritoneum. Hence, neither the

ABD

kidneys, nor the pelvic viscera, are, strictly speaking, parts of the abdomen.

Anatomists have distinguished this large cavity into different regions, the terms allotted to which are so very frequent in the language of surgical books, that some account of them in this Dictionary seems indispensable.

The middle of the upper part of the abdomen, from the ensiform cartilage as low down as a line drawn directly across the greatest convexity of the cartilages of the ribs, is called the *epigastric region*.

The spaces at the sides of the epigastric region are termed, the *right and left hypochondria*, or *hypochondriac regions*.

The *umbilical region* extends from the navel upwards to the line, forming the lower boundary of the epigastric region, and downwards to a line drawn across from one anterior superior spinous process of the ilium to the other.

The middle space, below the last line, down the os pubis, is named the *hypogastric region*.

The parts of the abdomen, situated on the outside of the umbilical region to the right and left, or externally with respect to two perpendicular lines drawn from the greatest convexities of the cartilages of the seventh true ribs, are named the *ilia*, or *flanks*. On each side of the hypogastric region is situated the *inguinal region*, or *groin*. The whole of the back part of the abdomen has only one technical appellation, viz. the *lumbar region*, or *loins*.

The abdomen is a part of the body claiming the particular attention of every practical surgeon; for, it is the frequent situation of several of the most important surgical diseases. It is also very much exposed to wounds, and various operations on different parts of it are often indispensable. One of the most common afflictions, to which mankind are subject, is that in which some of the bowels protrude, pushing out before them a portion of the peritoneum. This disease is called *hernia*, and ought to be well understood by every practitioner, who, however, can never acquire the necessary

knowledge, without being perfectly and minutely acquainted with the anatomy of the abdomen. In dropsical cases, it is frequently proper to tap the abdomen, and this operation, named *paracentesis*, simple as it may seem, requires more consideration, and attention to anatomy, than surgeons often bestow on the subject. The abdomen is also exceedingly liable to be wounded. See *Hernia*, *Paracentesis*, and *Wounds*.

Abdomen, abscesses of the. These may take place either within the cavity of the belly, or at some point of its circumference, and may be either of an acute, or chronic nature. Women are generally considered more liable, than men, to abscesses in and about the abdomen: the abscesses named *lumbar* being elsewhere treated of, are here excluded from consideration. Collections of purulent matter, resembling turbid whey, and containing whitish or yellowish flakes, are not unfrequently formed in the cavity of the peritoneum, as one of the effects of inflammation accompanying puerperal fever. —(Stoll, *Rat. Med.* 4. p. 103; Lassus, *Pathologie, Chir.* T. 1, p. 137, *Nouvelle Edit.* 8vo. Paris, 1809.)

In lying-in women, abscesses frequently form between the abdominal muscles and the peritoneum, especially just above the groin. They are cases, which have been very correctly described by Conradi. Before the integuments project, the diagnosis is often attended with difficulty, and sometimes an obscurity prevails several weeks; for, the patients seem as if affected with slight colic pains, which yield to common treatment, particularly external applications, but soon return. Thus, unless the vicinity of Poupart's ligament be carefully examined, in which situation some very painful point, or a hardness, or elevation can be detected; the abscess may remain concealed until a large prominence, or the extension of the matter down the thigh, lameness, &c. make the nature of the case completely manifest. As the peritoneum, adjoining the abscess, is always thickened by the preceding inflammation, Conradi assures us, that there is no danger of the collection of matter bursting inwards. Some abscesses indeed have been so enormous, that the matter actually pushed the viscera out of their places, yet all this happened without being followed by any inward bursting of the disease. The whole danger depends upon the duration of the complaint, and the extent to which the matter spreads. A timely detection of the nature of the case, the use of emollient applications, and the making of an early opening, generally brings the disease to a speedy and favourable termination. —(See *Arnemann's Magazin für die Wundarzneiwissenschaft*, 1 B. p. 175. 8vo. Göt. 1797.)

Chronic tumours of the mesentery, which, in scrophulous children, sometimes slowly terminate in suppuration, and the diseases of the ovary, and other abdominal viscera, bringing on the formation of matter, are often the cause of purulent extravasation,

great emaciation, hectic symptoms, and death. However, sometimes salutary adhesions are produced between the viscera, by which means an outlet is obtained for the matter through the bladder, anus, or vagina. Thus (says Lassus) in the case of a woman who had had for a long while pains in the right lumbar region, which were supposed to proceed from suppuration of the kidney, because pus was voided with the urine, the right kidney was found after death in the natural state; but an abscess existed in the right ovary, that was adherent to the bladder into which the pus had passed through an ulcerated communication. In another patient, who had voided pus by the anus, the right kidney was suppurated, and adhered to the colon, with which it communicated by a preternatural aperture. A woman had for many years a hard considerable tumour in the abdomen: at length the pain, which she suffered from the disease, became intolerable; and just at the moment when her death was apprehended, an immense quantity of pus was suddenly discharged from the vagina. The pain abated; the swelling of the belly subsided; merely the remains of the obduration were now perceptible; and the woman's health became perfectly re-established. (Lassus, *Pathologie, Chir.* T. 1, p. 138.)

The abscesses, which sometimes form between the peritoneum and abdominal muscles, or between the layers of these muscles, or under the integuments of the abdomen, are attended with considerable variety, according as they happen to be chronic, or acute; circumscribed, or diffused; small, or extensive. Those of the acute or phlegmonous kind sometimes follow stabs and contusions, and are particularly noticed in the article *Wounds*. These are cases, which demand especial care, because, if not checked and kept within certain limits, they may prove fatal, many examples of which are upon record. (See *Commerc. Literar. Noric.* 1741, P. 100; Eller, *Medic. and Chir. Anmerkungen*, P. 108, &c.) As for chronic external abscesses of the abdomen, they should be opened early, and treated on the principles explained in the article *Lumbar Abscess*.

For further information, respecting abscesses of the parietes of the abdomen, the reader may consult *Commerc. Literar. Noric.* 1735, hebd. 37; C. Bell, *System of Dissections*, Tab. 1. Bourienne, in *Journ. de Médecine*, T. 43, P. 64; Collomb, *Med. Chir. Werke*, Obs. 28; J. H. Furstenau, *Diss. Abscessuum musculorum abdominis, &c. lata tristiaque exempla*, Rintel, 1742; Hoffmann, *de Feere Tertiana*, Obs. 7. vid. Op. 2. P. 20; Heuermann, *Vermischte Bemerkungen*, 2. &c. Kite, in *Medical communications*, 2. No. 6, and app. to *Essays on submer-sion*, &c.; Riverus, *Obs. Communicat.* Obs. 2. 3; Winship, in *Memoirs of the Medical Society of London*, 2. No. 52; Wrede, *Collectanea Chir.* T. 1.

Hard indigestible substances, after being swallowed, are not unfrequently dis-

charged from abscesses formed in some of the abdominal regions. (See *De La Grange, in Museum der Heilkunde*, 4. B. P. 154: a fishbone, which had been swallowed, found in the abscess; *Petit, Trait. des Mal. Chir.* T. 2, p. 226: awl, without a handle, extracted from an abscess of the abdomen; and many other analogous cases.)

Encysted tumours sometimes form between the peritoneum and abdominal muscles, and attain an immense size, before they burst; a remarkable specimen of which is detailed by Gooch. (*Chirurgical Works*, Vol. 2. p. 144. &c. 8vo. Lond. 1792.) In this case, the spontaneous opening of the navel was enlarged with caustic, and the cyst extracted; but, before a cure could be effected, it became necessary to make a depending opening, and introduce a seton. Swellings of this nature, however, are only noticed here, on account of their resemblance to circumscribed chronic abscesses of the parietes of the abdomen.

Abdomen, Pulsations in the. From the article *Aneurism*, the reader will understand, that, though it be the common nature of this disease to be attended with throbbing, it is not every pulsating tumour, which is an aneurism. The cases, usually called *abdominal or epigastric pulsations*, often furnish a proof of the correctness of the preceding remark. The authors, who have treated of the latter affection with the greatest discrimination, are Dr. Albers, of Bremen, and Mr. Allan Burns, of Glasgow. Some of the pulsations here referred to are a consequence of organic disease, capable of demonstration on dissection; while the rest are not attended with any such appearance, and have therefore been regarded as nervous. The pulsation is not always produced by the impulse communicated to some solid tumour, or substance between the hand and the artery, but is sometimes certainly dependent on a nervous affection of the vessel itself. (*On Diseases of the Heart*, p. 263.) Hippocrates, in his book "*De Morbis Popularibus*," makes mention of three patients, affected with extraordinary pulsations in the abdomen. As one of these cases originated from obstructed menses, it was probably not the result of any organic disease. (*Hippocratis Opera Omnia, ex edit. Fæsi. Francof.* 1621. lib. 5. sect. 7. p. 1144.) In order to remove a difficulty, which may be at first experienced in believing how an artery, not affected with aneurismal enlargement, can communicate to the parts which lie over it such movements as are frequently remarked in cases of abdominal pulsations, a fact pointed out by Mr. Hunter, should be remembered: in speaking of the actual dilatation of an artery, he says, that when the vessel is "covered by the integuments, the apparent effect is much greater than it really is in the artery itself; for, in laying such an artery bare, the nearer we come to it, the less visible is its pulsation; and when laid bare, its motion is hardly to be either felt or seen." (*Treatise on the Blood, &c.* p. 175. 4to. Lond. 1794.)

And this observation will apply to all tumours and indurations situated over a large artery. In the epigastric region of a certain patient, Taberranus felt not only a pulsation, but a tumour as large as the fist, with all the other usual symptoms of an aneurism. On opening the body after death, he was therefore surprised to find, instead of this disease, a considerable scirrhus tumour in the middle of the mesentery, so closely connected to the large vessels, as to compress the aorta, by the pulsations of which it had been lifted up. (*Obs. Anat. ed. 2. No. 9.*)

Dr. Albers quotes an extraordinary case from Tulpus: the patient, a laborious man, but subject to bilious attacks, was sometimes affected with violent throbbings of the spleen. These pulsations were not only very painful, but could be heard at a distance, and their number distinctly counted, when the hand was applied to the part. What seems almost incredible, it is alleged, that Tulpus could hear them at the distance of thirty feet! Their violence increased, or diminished, according as the patient was more or less bilious, and sometimes they entirely ceased, when his health improved; but always recurred, as soon as the chylopoietic organs got out of order again. After the patient's death, permission could not be obtained to open the body. (*Tulpii Observationes Medicæ. Amst.* 1652. lib. 2. cap. 28.)

The case of a female, recorded by Pechlin, is then adduced, which consisted of a complication of symptoms, amongst which the only one, claiming attention here, was an annoying throbbing in the abdomen. The pulsation, which was quite evident, was felt by Pechlin when he placed his hand upon the linea alba, and corresponded to the pulse at the wrist. The patient fancied, that a monster was in her abdomen; but Pechlin comforted her with the assurance, that the throbbing was only the motion of the large artery, rendered perceptible by her extreme emaciation. She lived three years with this disease, suffering at times severely from convulsions, of which she at last died. Pechlin was informed, that before her death, her body was shortened two feet, the ribs being bent down to the ossa pubis, and the whole vertebral column curved forwards. (*Pechlini Observationum Physico-Medicarum, libri tres. Hamburgi*, 1691, lib. 2, Obs. 6.)

According to Bonetus, pulsations in the left hypochondrium are not unfrequent, and it was his belief that they were produced by the celiac artery. He cites several cases of this disorder from other writers, the tenor of which is to prove, that the celiac artery and mesenteric vessels must have been affected, as they were found after death dilated and filled with black blood. (*Sepulchretum Anatomicum, lib. 1. sect. 9. Obs.* 9, 25, 27, 30, 38, 42, 44, 45, and 46.) The conjecture of Bonetus and others, however, respecting the frequency of abdominal pulsations from dilatation of the celiac and mesenteric arteries, by no means coincides with the results of modern observa-

tions. Mr. Wilson, whose dissections have been very numerous, says, that he has met with only one instance of true aneurism, affecting any of the branches of the aorta, which are distributed to the abdominal viscera. This case was an aneurism of the left branch of the hepatic artery. (*Lectures on the Blood, and on the Anatomy, Physiology, and Surgical Pathology of the Vascular System, &c. p. 379. Sec. Lond. 1819.*) Bontius was present at the opening of an inhabitant of Batavia, who had been afflicted three years with a disease, the exact nature of which could never be made out during life. When the hand was applied above, or below the navel, a pulsation was felt like that of the heart, or an artery, and as forcible as the motion of a child in the womb. It was synchronous to the pulsation of the heart and arteries. Hence, Bontius concluded, that the case was owing to some affection of the heart. The vena cava, instead of containing blood, was filled with a medullary substance, which, pressing against the aorta, is supposed to have excited the extraordinary pulsations in that vessel. The heart was unusually dilated, and flabby. The two ventricles were very large, and filled with dark-coloured blood. The liver was of nearly twice the natural size, its substance being of a light colour. The gall-bladder resembled that of a bullock, and was filled with viscid bile nearly as thick as an extract. (*Jacobi Bontii de Medicina Indorum, libri 4. Lugd. 1718. Obs. 8. p. 101.*)

Lewenhoeck met with an instance of a similar pulsation, which he imputed to irregular action of the diaphragm, the pulse at the wrist not being affected. The disorder lasted three days, during which the functions of the alimentary canal were so much interrupted, that the patient was expected to die. (*Philosophical Trans. from 1719 to 1733, abr. by J. Eames, &c. Lond. 1734. vol. 7. p. 683.*)

Ballonius recites the case of a man, affected with a quartan fever, gout, and other complaints, who had so violent a pulsation in the left hypochondrium, that it was supposed to originate from an aneurism. The patient died suddenly (as Ballonius imagined) of a rupture of one of the vessels of the spleen. (*Ballonii Epidemicorum et Ephemeridum, libri 2. Venetiis, 1734. Consiliorum Med. Lib. 1. p. 379.*)

Dr. Albers has also described the particulars of a man's case, recorded by Burggraf, and entitled "Diuturna, magna, et valde molesta pulsatio in epigastrio." (*Vid. Acta Natur. Cur. Norimb. 1740, Vol. 6, Obs. 131.*) Burggraf gives his reasons for believing, that, in this instance, the pulsation arose neither from the aorta nor from the celiac artery; and suspects that it was caused by a dilatation of that considerable branch of the inferior mesenteric artery, which inosculates with the branch of the superior mesenteric. This idea, however, which was merely surmise, could not be correct, as the patient was cured by taking in the form of pills, every morning and even-

ing, half a dram of a mass composed of equal parts of Gum Ammoniac, extr. Centaur. Minor, and Venice soap.

Then follows an example taken also from Burggraf. (*Anserlesene Med. Falle und Gutachten, Frankf. Am. M. 1784, S. 300.*) A young man, after experiencing some complaints of the stomach, began to feel pain and tenderness about the scrobiculus cordis. At length a pulsation was detected just below the ensiform cartilage. It was not very considerable when the stomach was empty, but always increased after a meal. In the course of the disease, the patient had various symptoms of dyspepsia, and became so constipated, that he had a motion only once in three or four days. Various opinions were given by the physicians concerning the nature of the disease, about which, however, Burggraf finally leaves the reader in the dark.

Dr. Albers details the particulars of another case from the work last quoted. (*p. 310.*) The patient, a young woman, three and twenty years of age, whose menses had been obstructed five months, became affected with violent throbbings in the epigastric region, which were synchronous to the pulsations of the heart, and so forcible, that they seemed as if they proceeded from a displacement of the latter organ into the upper part of the abdomen. Dr. Massuet of Amsterdam considered the affection altogether as an effect of obstructed menstruation and hysterics, and of course, prescribed medicines calculated to re-establish that evacuation. Some physicians of Leipsic, however, who were probably quite mistaken, looked upon the case as an aneurism either of the arteria gastrica, or gastro-epiploica, and ordered repeated venesection, aperients, and a bandage.

In the valuable essay of Albertinus, on diseases of the heart, as a cause of difficult respiration, there is a passage where he is speaking of the diagnosis of enlargements of the heart, aneurism of the curvature of the aortæ, &c., which Dr. Albers cites, as deserving attention in the present subject. "Verumtamen extra pectus ubi deficiente solido arcu costarum, tantum difficultatis in hac indagine non ostenditur, me satis scio pluries indicavisse ex eo, quod vasis diametrum non auctum perceperim validas, assidueque arteriæ celiacæ, vel aortæ in abdomine pulsationes fuisse sine dilatatione, nec judicium meum eventus fefellit." (*De Bononiensi Scientiarum et Artium Instituto, atque Academia Comment. Bononiæ, 1748, T. 1. p. 387.*)

An example follows from the writings of the celebrated Störk. After death, the symptoms were found to have arisen from disease of the pancreas, which weighed thirteen pounds, and contained a large cyst filled with lamellated blood. (*Annus Medicus, Vindob. 1760, p. 245.*)

The subsequent case, somewhat analogous to the former, is from a different author.

A man, aged 60, complained of pain in the left side of the abdomen, midway between the umbilicus and crista of the iliuni.

Emaciation, weakness, distress of countenance, anorexia, constipation succeeded. At length, a large pulsating tumour was discovered in the epigastric region. The case was now pronounced aneurism of the abdominal aorta. There was no nausea, nor vomiting, except that some days before death, a quantity of fetid, blackish fluid was twice or thrice voided. No fever. The swelling caused a sense of constriction rather than pain, and the throbbings became more perceptible. The pulse was feeble, but slow and regular. After death, the stomach was found adhering to the liver, pancreas, and abdomen; and a cancerous tumour occupying its internal surface from the duodenum to the insertion of the œsophagus, the coats of the stomach being an inch thick. The surface of the pancreas was also diseased, and the pylorus, situated in the midst of the cancerous mass, was contracted by the thickening of the parietes of the stomach, and obstructed by numerous fungi. The liver was large, but apparently sound; the spleen small. The aorta, the celiac trunk, and its branches were quite natural. (See *Journ. de Med. per Leroux*, Oct. 1815, and *Medico-Chir. Journ. Vol. I. p. 289.*)

Morgagni describes the case of a woman, 44 years of age, who, after a suppression of the menses for some months, was attacked with palpitations in the epigastrium. Morgagni, on applying his hand to the part, felt a large hard body moving forcibly. At first, it was regarded as an aneurism in the abdomen; but, as there were no similar throbbings in the chest, and there was nothing extraordinary in the pulse at the wrists, Morgagni concluded, that the movements in question could not depend upon the heart. Neither did he take the disease for an aneurism, because the throbbings did not correspond to the pulse. As for the large indurated mass, it appeared to him more easy to say what it was not, than what it was: it could not be merely a *globus hystericus*, which never beats like an aneurism. Morgagni considered the case as an hysterical spasmodic complaint, ordered the patient to be bled, and the following day the pulsations ceased. (*Morgagni, de Sedibus et Causis Morborum*, T. 2, Epist. 39, 18.)

Aaskow relates a case, in which, after the subsidence of a hard painful swelling under the upper false ribs of the right side, a peculiar throbbing movement presented itself in the same part. The phenomenon was imputed to the diaphragm: "et in loco dolente singularis motus palpitantis instar, evidenter enim conspiciebatur, quasi musculus diaphragmatis se constringendo partes vicinas comprimeret et extrorsum protruderet." (*Acta Societatis Medicæ Havnensis. Havnæ, 1777, Vol. 1, p. 208, &c.*)

Senac has spoken of these abdominal pulsations, as sometimes occurring in hypochondriacal and chlorotic patients; and as they frequently subside, without leaving any vestige behind, he sets them down as nervous affections. (*Traité des Mal. du Cœur.*)

De Haen had under his care a hypochon-

driacal patient, affected with pulsations in the abdomen; which, with other complaints, were dispelled by means of brisk opening medicines. (*Heilung's Methode Überseist von Plattner, Leipz. 1782. 2. B. S. 29.*)

Thilenius observed a flatulence of the stomach, which he represents as having been epidemic, and attended, in some patients, with pulsations at the scrobiculus cordis. (*Med. Chir. Bemerk. Frankf. 1789. S. 211,—217.*)

My friend, Mr. Hodgson, also, in speaking of pulsations in the epigastrium, which are not the consequence of organic disease, and occur in irritable hypochondriac subjects, states his opinion, that, in some instances such pulsations were a consequence of distention of the stomach with air, which was thrown against the abdominal muscles by the pulsation of the great blood vessels; and in these cases, the throbbing was diminished by the eructations. (*On the Diseases of Arteries and Veins*, p. 96.)

These abdominal pulsations are also described by Zuliani, as a symptom of hypochondriasis and hysteria. (*De Apoplexia, Lips. 1790. p. 79.*) They also happen in certain febrile diseases. (*Versuch über den Pemphigus und das Blasenfieber von C. G. C. Braune, Leipz. 1795, S. 23; and Dr. R. Jackson on the Fevers of Jamaica, 8vo. Lond. 1791.*)

In a dissertation on cramp in the stomach, Haü remarks. "Quin immo, ubi diutius vexavit gastrodynia, continuos ægotans persentit spasmos, ut et haud raro pulsationem quandam plane singularem, in cardia et ventriculo, pulsui autem cordis minime synchrone." (*Diss. de Gastrodynia, Upsal. 1797.*) In the same essay is also given an account of a man, who had violent palpitations in the epigastric region, apparently first excited by the larva of the musca penula, many of which were vomited up.

Pinel is another writer who describes these abdominal pulsations, as an occasional symptom of hypochondriasis. "Palpitations du cœur, et quelquefois une sorte de pulsation irrégulière, dans quelque partie de l'abdomen." (*Nosographie Philosophique. T. 2, p. 25, Paris, an. 6.*)

Dr. Albers details some cases which fell under his own notice. A young woman, whose menses were upon her, and who had been for some days constipated, was seized with frequent fainting fits and febrile symptoms, occasionally voiding from the bowels a quantity of dark matter, each evacuation of which was followed by a swoon. One morning at five o'clock Dr. Albers was sent for, as it was feared the patient was about to die. She was extremely exhausted, and the fainting fits followed each other, with hardly any intervals. She could just say, "I feel a throbbing in the belly;" and, when Dr. Albers applied his hand to the part, he felt a violent pulsation, extending from the ensiform cartilage down to about the bifurcation of the aorta. The action of the heart was weaker than natural; the pulse at the wrist very small, but not quicker than it had been on the preceding day, and

was not synchronous to the throbbing in the abdomen. Dr. Albers confesses, that at first he took the case for an aneurism. Dr. Meyerhoff was of the same opinion. Another physician, however, Dr. Weinhold, entertained doubts of the complaint being aneurismal, saying, that he recollected having read some similar cases in Morgagni. These gentlemen decided to persevere in the employment of opening medicines and clysters, combining opium with the former. Under this plan, the pulsations in the abdomen and tightness of the chest diminished in a few days. The stools were at first of the colour of chocolate, but afterwards resumed their natural appearance. The throbbings, in a weakened form, however, were perceptible for six weeks longer. The patient at length got quite well, and was remaining so four years afterwards.

A man, about 40, severely afflicted with hypochondriasis, great oppression of the chest, constipation, and tension of the abdomen, tendency to fainting, &c., complained to Dr. Albers, that he felt as if his heart had fallen down into his belly, where he was annoyed with an incessant throbbing. Indeed when Dr. Albers examined the abdominal parietes, he could feel a very strong pulsation, and, what is curious, could trace it not only along the track of the aorta, but in the course of the left iliac artery. The pulse at the wrist, which was small, frequent, and hard, did not correspond with the abdominal pulsations. For several days, the evacuations from the bowels had been as black as pitch. After the employment of gentle purgatives, all the complaints quickly abated, though the throbbings were feebly perceptible for nine months afterwards.

The next case, which Dr. Albers met with, is very interesting. A robust sailor, whose bowels were so constipated, that hardly the strongest purgative could affect them, was seized with constant pain in the left hypochondrium. With this complaint were soon joined great pain in the back, and a sensation as if something alive moved about in the belly from one side to the other, and thence extended up to the neck, followed by the vomiting of a greenish matter. At the same time, he felt in the left side a pulsation, which he took for that of the heart, and which continued the whole of his illness. The pulse at the wrist was natural, and synchronous with that in the abdomen. In the beginning of the disorder, the patient was obliged to sit with his body very much inclined forward, as no other posture could be endured. For the first week opening medicines afforded so much relief, that he was sometimes quite free from pain for six or eight hours. After a time, a round swelling formed in the left hypochondrium, and reached to the navel, and attained with incredible quickness the size of a child's head. Indeed, it could now be traced beyond the umbilicus to the right side. The motions were quite of a dark colour, or else red blood and a puriform matter was discharged. Sometimes the blood voided was

of a bright red colour, sometimes it was dark, coagulated, and mixed with bile. The patient was at length worn out with febrile symptoms, and died. On opening the body, Dr. Albers found a swelling in the middle of the mesentery, the texture of which cannot be easily described, and the circumference of which was 16 French inches. The stomach was filled with coagulated blood. The spleen, pancreas, and liver were sound; but the gall-bladder was of prodigious size, and contained a very thick viscid bile. The arteria cœliaca, arteria coronaria ventriculi, and the arteria mesenterica, were preternaturally dilated, and full of dark coloured blood. He speaks of them, however, only as being in an enlarged, not an aneurismal state. Dr. Albers thinks it highly probable that it was one of these vessels, by which the pulsations had been occasioned.

Dr. Albers has also seen these abdominal pulsations in a paralytic female; and in a lunatic, who was afterwards seized with apoplexy. He likewise met with a married woman, the mother of several children, in whom these throbbings took place invariably at the commencement of pregnancy, and were a surer sign of this state than other usual effects, as stoppage of the menses, &c. After the third month, however, they used to cease altogether.

Many valuable practical observations on cases attended with hemorrhages from the intestinal canal, my limits here oblige me to pass over. According to Dr. Albers, hemorrhoidal patients, especially when put to inconvenience by compression of the tumours, often complain of throbbings about the spleen, which are plain even to the hand.

The same gentleman says, that he has often remarked these pulsations in hypochondriacal and hysterical patients, who were put to much distress by the occurrence, as they supposed their hearts were out of their right places. (*J. F. Albers, über Pulsationen im Unterleibe, Sro. Bremen, 1803.*)

The differences pointed out by this able physician, between these pulsations and those of internal aneurism, will be presently noticed.

Dr. Parry makes a few interesting remarks on such abdominal pulsations as excite apprehensions of aneurism. In any persons not very fat and lying upon their backs, he says, the pulse of the aorta can easily be felt, if strong pressure be made a little to the left of the median line, about half way between the navel and scrobiculus cordis. In certain instances, the pulsation is painfully felt by the patient himself. In many cases of this kind, particularly in nervous individuals, the sense of pulsation is merely the effect of preternatural action of the heart. While, in other examples, it is the effect of the pressure of some hard substance upon the descending aorta, determining a disproportionate quantity of blood to the head, "and giving to the hand placed on the abdomen, and sometimes even to

the eye, the appearance of a beating so near the surface, as to lead inexperienced observers to conclude, that the aorta is morbidly dilated." According to Dr. Parry, the most common causes are collections of feces in the colon, requiring repeated and active purgatives, which must bring away almost incredible discharges of stercoraceous matter before the aortal pulsation subsides. (See *Parry's Elements of Pathology*, &c. and the *Medico-Chir. Journ. and Review*, Vol. 1, p. 157.)

Another cause of a temporary appearance of pulsation or movement in the abdomen, not mentioned by any of the preceding authors, is the power which some persons have of putting portions of the recti muscles separately into strong convulsive action. I have seen a large abscess of the loins, attended with distinct and forcible pulsations, corresponding to those of the aorta.

According to Mr. Allan Burns, a beating is generally felt about the pit of the stomach, in the advanced stage of chronic inflammation of the heart: in this case, when the pericardium is closely adherent to the latter organ, it is corrugated at every contraction of the ventricles, and the diaphragm and liver are elevated. The ventricle, however, having completely emptied itself, is again distended, and, in proportion to the degree of dilatation, the liver and diaphragm descend, whereby an impulse is communicated in the epigastric region. (*On Diseases of the Heart*, p. 263.) This valuable writer cites the remark of Morgagni, (*Epist. 17, art. 28*), that sometimes in dilatation of the heart, this organ descends so far as to push the diaphragm into the hypochondrium, and pulsate in that situation, so that the disease is mistaken for an aneurism of the celiac artery. In Mr. Burns's work, a memorable case of this description is related. An erroneous judgment is the more likely to be formed in such examples, because the pulsations of the heart and tumour are not exactly simultaneous; for, it is not the heart which is felt directly beating, but the liver, which, by the action of the heart, is thrown forwards. Hence, the palpable interval between the stroke of the heart, and the movement of the liver.

Preternatural pulsation about the epigastrium is also stated by Mr. A. Burns, to be sometimes occasioned by encysted tumours, attached either to the lower surface of the diaphragm, or formed between the layers of the pericardium towards the diaphragm, as happened in an instance recorded by Lancisi.

Another cause specified by Mr. A. Burns, is enlargement of the vena cava, or of the right auricle of the heart. Senac describes a case, in which the vena cava was as large as the arm, and there had been a violent pulsation in the epigastrium.

The next cause, enumerated by the same gentleman, is increased solidity of the lungs, more especially of their lower acute margins, where they overlap the pericardium.

In this case, the pulsation is about the scrobiculus cordis.

Mr. A. Burns likewise comprises several other causes of epigastric or abdominal pulsations, already illustrated in the foregoing part of this article, indurations of the pancreas, scirrhus of the pylorus, tumours in the mesentery, or any solid increase of substance about the abdominal aorta, or its principal branches; and, lastly, it is called a peculiar affection of the vascular system itself.

The following observations, on the criteria between various abdominal pulsations and those of aneurism, appear interesting.

According to Dr. Albers, an internal aneurism originates gradually, and the pulsations increase in strength by degrees. Other abdominal pulsations, on the contrary, begin suddenly, and are more violent in the beginning, abating after they have lasted some time.

In an aneurism, the pulsation is synchronous with the stroke of the artery at the wrist; but this is not regularly the case with other pulsations.

Should the patient be affected with melancholia, hypochondriasis, hysteria, or other nervous complaints, void blood from the stomach, or a black matter from the bowels; should there be any hardness or swelling of any of the abdominal viscera discoverable by the touch, the probability is, that the pulsations are not owing to an internal aneurism.

With the exception of cases, in which these pulsations are owing to mechanical impediments to the circulation, Dr. Albers believes, that they are mostly a symptom of some nervous affection. He also thinks that the surprise, excited by these throbbings, arises only from their strength and situation, other analogous, strong pulsations, as for instance, those of the heart, or of the carotids, being common enough in hypochondriacal and hysterical persons. The same gentleman also adverts to the increased action, which, in inflammation and fevers, is often more conspicuous in some parts of the sanguiferous system, than in others. (*Über Pulsationem im Unterleibe*, p. 63, &c. *Bremen*, 8vo. 1803.) Much important additional information on this subject may be found in *Observations on some of the most frequent and important Diseases of the Heart; on Aneurism of the Thoracic Aorta; on Preternatural Pulsation in the Epigastric Region*, &c. By Allan Burns, p. 262., &c. 8vo. *Edinb.* 1809.

ABSCESS. This term signifies a tumour containing pus, or a collection of purulent matter. Authors differ about the original derivation of the word. The most common opinion is, that it comes from the Latin *absedo*, to depart, because parts, which were before contiguous, become separated, or depart from each other.

Abscesses are divided into two principal kinds, viz. *acute* and *chronic*. For every thing, relative to the former, see *Suppuration*; and, for information concerning the

latter, refer to *Lumbar Abscess*. See also *Abdomen*, *Antrum*, *Anus Abscesses of*, *Bubo*, *Empyema*, *Hypopium*, *Mammary Abscess*, *Whilow*, &c.

ACETIC ACID, Vinegar. *Distilled Vinegar. Acetum.* Vinegar is an article of very considerable use in surgery. Mixed with farinaceous substances, it is frequently applied to sprained joints, and, in conjunction with alcohol and water, it makes an eligible lotion for many cases, in which it is desirable to keep up an evaporation from the surface of the inflamed parts. Vinegar was once considered as useful in quickening the exfoliation of dead bone, which effect was ascribed to its property of dissolving phosphate of lime. Its application to this purpose, however, seems hardly admissible, for reasons, which will be well understood, from a perusal of what is said on the subject of *Necrosis*. The excellent effects of vinegar, when immediately applied to burns and scalds, were taken particular notice of by Mr. Cleghorn, a brewer in Edinburgh, whose sentiments were deemed, by Mr. Hunter, worthy of publication. (See *Med. Facts and Observations, Vol. II. and the Art. Burns.*)

In chronic inflammations of the eyes, and eyelids, and in certain instances, in which the eyes are weak and watery, vinegar is sometimes recommended as an useful ingredient in the collyrium. After general and topical bleeding, it is said to be an efficacious remedy even in cases of acute ophthalmia. Whenever vinegar is applied to the eye, it is in a diluted state, as may be seen in another part of this work. (See *Collyrium Acidi Acetici*.) In the form of a collyrium, it is alleged to be the best lotion for clearing the eye of any small particles of lime which happen to have fallen into, and become adherent to it, on the inside of the eyelids. (See *A. T. Thomson's Dispensatory, p. 8. Ed. 2.*)

Very strong vinegar may be obtained by freezing and separating the water, which is mixed with the acid. When concentrated, either in this manner, or by distillation, it is said to be an excellent styptic for stopping violent hemorrhage from the nose. With this view, it may be used either as an injection or a lotion, in which lint is to be dipped, and introduced up the nostril.

Vinegar in all its forms is sometimes employed for obviating the smell of sick rooms. The strongest acetic acid which can be made, is found also to be one of the most certain and convenient applications for the destruction of warts, and corns, care being taken not to injure with it the surrounding skin.

ACHILLES, Tendon of. See *Tendons*.

ACIDS. See *Acetic Acid*; *Muriatic Acid*; and *Nitrous and Nitric Acids*.

ACTUAL CAUTERY. A heated iron, formerly much used in surgery for the extirpation and cure of diseases. The instrument was made in various shapes, adapted to different cases, and it was often applied through a canula, in order that no injury

might be done to the surrounding parts. *Actual* cauteries were so called in opposition to other applications, which, though they were not really hot, produced the same effect as fire, and consequently were named *virtual* or *potential cauteries*. The actual cautery is still in use upon the continent; and by foreign surgeons, we are not unfrequently criticised for our general aversion to what they distinguish by the appellation of an *heroic* remedy. Pouteau, Percy, Dupuytren, Larrey, Roux, and Maunoir, are all advocates for the practice; and the latter gentleman, when he was lately in England, took the opportunity of reminding British surgeons of their error, in totally abandoning, as they now do, the employment of heated irons in the business of their profession. (See his *Observations on the Use of the Actual Cautery, Med. Chir. Trans. Vol. IX. p. 364, &c.*)

***ACUPUNCTURE** (from *acus*, a needle, and *pungo*, to prick.) The operation of making small punctures in certain parts of the body with a needle, for the purpose of relieving diseases, as is practised in Siam, Japan, and other oriental countries, for the cure of headaches, lethargies, convulsions, colics, &c. (See *Phil. Trans. No. 148*; and *Wilh. Ten. Rhyne, de Arthritide, Mantissa Schematica, &c. 8vo. Lond. 1683.*) The practice of acupuncture is not followed in England. In a modern French work, it has been highly commended; but, the author sets such a rash example, and is so wild in his expectations of what may be done by the thrust of a needle, that the tenor of his observations will not meet with many approvers. For instance, in one case, he ventured to pierce the epigastric region so deeply, that *the coats of the stomach were supposed to have been perforated: this was done for the cure of an obstinate cough, and is alleged to have effected a cure!* But if this be not enough to excite wonder, I am sure the author's suggestion to run a long needle into the right ventricle of the heart, in cases of asphyxia, must create that sensation. (See *Berlioz, Mém. sur les Maladies Chroniques, et sur l'Acupuncture, p. 305-309, 8vo. Paris, 1816.*)

ADHESIVE INFLAMMATION. That kind of inflammation, which makes parts of the body adhere, or grow together. It is the process, by which recent incised wounds are often united, without any supuration, and it is frequently synonymous with union by the first intention. (See *Union by the First Intention.*)

ÆGYLOPS (from *αἴς*, a goat, and *ὄψ*, an eye.) A disease so named from the supposition that goats were very subject to it. The term means a sore just under the inner angle of the eye.

The best modern surgeons seem to consider the ægylops, only as a stage of the fistula lachrymalis. Mr. Pott remarks, when the skin covering the lachrymal sac has been for some time inflamed, or subject to frequently returning inflammations, it most commonly happens, that the punc-

ta lachrymalia are affected by it, and the fluid, not having an opportunity of passing off by them, distends the inflamed skin, so that, at last, it becomes sloughy, and bursts externally. This is the state of the disease, which is called perfect *aigylops*, or *agylops*. (*Pott on Fistula Lachrymalis*.)

Aegylops was a very common term with the old surgical writers, who certainly did not suspect, that obstruction in the lachrymal parts of the eye, is so frequently the cause of the sore, as it really is. The skin over the lachrymal sac must undoubtedly be, like that in every other situation, subject to inflammation and abscesses; but, we do not find, that sores unconnected with disease of the lachrymal sac, are here so frequent, as to merit a distinct appellation.

ÆRUGO (*Subacetas Cupri*.) Prepared verdigris is occasionally employed by surgeons as an escharotic. Mixed with an equal quantity of powdered lytta, it is sometimes used as an application for destroying warts and other excrescences. At present, the old practice of attempting to destroy the surface of chancres with it, with the view of hindering the absorption of the venereal poison, and rendering the exhibition of mercury needless, appears to be exploded.

AGARIC. A species of fungus growing on the oak, and formerly much celebrated for its efficacy in stopping bleeding. (See *Hæmorrhage*.)

ALBUGO (from *albus*, white.) A white opacity of the cornea, not of a superficial kind, but affecting the very substance of this membrane. The disease is similar to the leucoma, with which it will be considered. (See *Leucoma*.)

ALPHONSIN is the name of an instrument for extracting balls. It is so called from the name of its inventor Alphonso Ferrier, a Neapolitan physician. It consists of three branches, which separate from each other by their elasticity, but are capable of being closed by means of a tube in which they are included.

ALUM. (An Arabic word.) Alum, either in its simple state, or deprived of its water of crystallization, by being burnt, has long been used in surgery. The ingenious author of the *Pharmacopœia Chirurgica* remarks, that except for external use, as a dry powder, the virtues of alum are not improved by exposure to fire. Ten grains of alum, made into a bolus with conserve of roses, are given thrice a day at Guy's Hospital, in such cases, as demand powerful tonic, or astringent remedies. In a relaxed state of the urinary passages, or want of power of the sphincter vesicæ, small doses of alum have been found of service. Alum is employed as an ingredient in several astringent lotions, gargles, injections, and collyria.

It is also recommended by Dr. Perceval as a remedy for counteracting the poison of lead. Burnt alum is a mild caustic, and is a principal ingredient in most styptic powders.

ALVINE CONCRETIONS. Compre-
VOL. I. 3

hending under this head both gall-stones and intestinal concretions, an interesting subject presents itself, certain parts of which have been chiefly elucidated in modern times, as will be hereafter explained: where the concretions voided are very numerous, they are generally gall-stones. Thus Dr. Coe relates an instance in which seventy were discharged in one day. In the same short time Petermann knew of seventy-two being voided from one individual; Birch, one hundred; Barbette, Sloane, and Vogel, two hundred; and Russell, four hundred. A patient, under the care of Van Swieten, had voided two hundred, and was still continuing to expel others. Riverius speaks of another patient, who had voided calculi from the bowels for several years whenever he went to stool. (*Observ. Commun.*) Fernelius likewise adverts to cases, in which the concretions evacuated were innumerable. (*Pathol. lib. 6. cap. 9.*) But if we take a view of alvine concretions generally, and include all their different kinds, we shall find that they are of various sizes. Most of them are not larger than a pea or nut; but others are as large as an orange, and weigh four pounds. (See *Monro's Morbid Anat. of the Human Gullet, &c. and Medico-Chir. Journ. vol. 4. p. 188.*) Morgagni saw one, which equalled in size a moderate finger, and Gooch, Guettard, Heuermann, Maréchal, *Mém. de l'Acad. Royale de Chir. t. 3. p. 55.* and others have seen concretions of this nature, which were too voluminous to pass out of the rectum without surgical aid. In certain examples, recorded by Heuermann and Maréchal, the passage of the concretion outward lacerated the sphincter ani. Horstius speaks of one concretion, which was as large as an apple. (*Epist. l. 2. sect. 2. Opp. 2. p. 237.*) and Marcellus Donatus, Schwind, (*Schmucker's Verm. Schriften, 2. b. p. 129.*) Hooke, Vennette, and Hecquet, give the particulars of other examples, in which the concretions discharged were as large as a hen's egg. Mr. Charles White extracted two from the rectum which were nearly as big as the first; (*Cases in Surgery, p. 18.*) and in a boy, who had died in an emaciated state, after continued pain in the abdomen, attended with frequent attacks of ileus, Mr. Hey found in the transverse arch of the colon so large a concretion, that it could not pass any further along the bowel, and appeared to have been the sole cause of the boy's death. (*Practical Observations in Surgery, p. 509, ed. 2.*) An analogous case is also reported by White (*p. 28.*) It is stated, in the *Mém. de l'Acad. de Chir.* that Duhamel saw a concretion that had been discharged, which was two inches and a half in length, one inch and a half in diameter, three inches and a half in circumference, and the weight of which was three drams and a half. But, judging by their weight, how much larger those must have been, which were seen by Scroekius and Lettsom, and weighed ten drams; that reported by Doléus, which weighed two ounces; that recorded by

Orteschi, which, besides weighing two ounces, two drams and a half, is said to have been eight inches in circumference, and to have been taken out by force; that recorded by Schaarschmidt, which weighed four ounces; and lastly the specimen cited by Plouquet, (*Literatura Med. Dig.* vol. 1. p. 171.) the weight of which is alleged to have been half a pound. (*Samml. Med. Wahrnehm.* 9. b. p. 231.) It is observed by Rubini, that although examples of alvine concretions being discharged by vomiting are not so frequent as the foregoing cases; yet they are tolerably numerous. Many of them have been collected by Schenck; and others are recorded by Breyn (*Phil. Trans.* No. 479;) by Orteschi in his Journal; by Moreali (*Dell' Uscita di una Pietra, per la Via del Esophago. Modena, 1781*;) by Borsieri; and by a long list of other writers, whose names and publications are specified by Plouquet. (*Lit. Med. Dig. art. Calculus, Vomitus, &c.*) With this class of substances, says Rubini, may also be arranged those concretions which are found upon dissection, either in the intestines or stomach, whence, probably, in time they might have been expelled. Facts of this description are recorded by Portal, Vicq d'Azyr, Jacquinelle, Chandron, &c. The cases recited by White and Hey, in which the colon was completely obstructed, I have already mentioned; and to these may be added the instance quoted by Rubini, in which Professor Meckel found the jejunum entirely blocked up by a similar substance. (See *Pensieri sulla varia origine e natura de corpi calcolosi, che vengono talvolta espulsi dal tubo gastrico, Memoria, p. 5 and 6. 4to. Verona, 1808.*)

Rubini observes, that, with respect to the origin of alvine concretions, whether discharged from the alimentary canal upwards or downwards, some of them appear to be formed in that canal itself, while others pass into it from other situations; and they all admit of being distinguished according to the place of their origin and formation into three kinds: 1. *hepatic, or biliary*; 2. *gastric, or intestinal*; and 3. (what this author terms) *mixed or hepatico-gastric*. *Hepatic alvine concretions*, as the name implies, are derived from some point of the hepatic system; the *gastric, or intestinal*, are formed within the alimentary canal; and the *mixed* commence in the hepatic organs, but afterwards get into the bowels, where they acquire an increased size.

On the subject of hepatic concretions, or biliary calculi, or gall-stones (as they are usually named,) there is no point of this system in which they do not occasionally form. Riedlin found them in the surface of the liver. Sorbait met with a biliary calculus, as large as a goose's egg, adhering to the peritoneal covering of the liver; and a similar case is recorded by Benivenio. Tallon, Pomme, Saurau, and Heberden have seen calculi within the substance of the liver; while Blasius, Fallopius, Columbus, Ruysch, Henricus ab Heers, and Morgagni, record examples in which the concretions

were in the parenchyma of that organ. Plater, Reverhorst, Glisson, Morgagni, and Walther have seen them in the biliary ducts, as probably were those which Columbus and Camenicus say they found in the vena portæ. Walther and Dietrick found calculi in the ductus hepaticus; Ruysch and Soemmering in the ductus cysticus; and Dietrick, Galeazzi, and Richter in the ductus choledocus. Greisel, Benivenio, Eller, Morgagni, Dargeat, and D'Hervillay have seen calculi included in morbid cysts, attached either to the liver or the gall-bladder. The place, however, where calculi are found in the greatest number, and with most frequency, is the cavity of the gall-bladder itself. Here they are sometimes single, their size varying up to that magnitude which completely fills that cavity, as Saye, (*Journ. de Savans, Sept. 1697.*) Halle, and Isenflamm have noticed; while sometimes their number amounts to a hundred, or even a thousand, of different sizes. Rubini possesses a gall-bladder which contains above a hundred small calculi; and formerly I had a similar number, which I found in the body of a female. Van Swieten met with a hundred; Haller, a hundred and forty; Stieber, two hundred; F. Plater, three hundred; Walther, five hundred; Mentzki, seven hundred; Baillie, a thousand; Hunter, eleven hundred; Paré, sixteen hundred; Stork, two thousand; and Meckel, several thousands. (*Handb. der Pathol. Anat. b. 2. p. 460.*)

All hepatic concretions, however, are not calculated to pass from the place of their origin into the intestines, but only such as are situated in the ductus hepaticus, or its main branches, in the gall-bladder, the ductus cysticus, or the ductus choledocus. When their size is not disproportionate to the diameter of the ducts, they pass with facility; but when their dimensions are larger than those ducts can naturally admit, the latter become stretched and dilated, whence arise the sharp pains and colic which attend the disorder, analogous to the sufferings produced by the descent of large calculi from the kidneys to the bladder. The reality of these dilatations of the hepatic ducts is proved by dissection. Heister found the orifice of the ductus choledocus, which is usually very small, so much enlarged that it could receive a finger; and Vicq d'Azyr saw this duct enlarged through its whole extent in a similar degree. (*Hist. de la Société Royale de Médecine, an. 1779, p. 220.*) Galeazzi, in dissecting a body, found the ductus choledocus so dilated that it resembled a kind of bag, in which several calculi were included. Mr. Thomas has likewise seen two cases, in which the point of the forefinger readily passed from the duodenum into the gall-bladder. (See *Med. Chir. Trans. Vol. 6. p. 105.*) Morgagni saw this duct in one instance large enough to hold a couple of fingers; and he quotes many similar instances from Bezold, Trew, Verney, and others. We may conceive how dilated this tube must have been in a case re-

corded by Richter, where, though it was not completely obstructed, a calculus weighing three ounces and a half was lodged within it. (Rubini, *op. cit.* p. 7—10.)

With regard to those concretions which are distinguished by the epithet *gastric* or *intestinal*, some are formed in the cavity of the stomach; the rest in one or other of the intestines. They remain for a greater or lesser period in the place of their formation, according as they happen to be lighter or heavier, smoother or rougher, more or less adherent, or as local or general circumstances are more or less favourable to their retention or expulsion. Sometimes they continue undischarged until they have attained a very considerable size. In particular instances, instead of remaining constantly in one place, they successively pass through the whole length of the intestinal tube, lodging at different points for a greater or lesser time. In the works of Haller and Conradi may be seen representations of the points of the intestinal canal where these concretions have been found. The alvine concretion, of which Maréchal has given an account, was some years in traversing all the convolutions of the bowels. These gastric or alvine concretions, which are very common in animals, are less frequent in the human subject, as the observations of Fourcroy and Vauquelin prove; which are inserted in their valuable essay on this subject in the *Annales du Museum Nationale d'Histoire Naturelle de Paris*. In the horse they are sometimes of an enormous size, as we may learn from an instance on record, in which the concretion weighed thirteen pounds. (Voigt, *Magazin für das Neueste der Naturkunde*, 3 B. p. 578.)

As for the third species, which Rubini names *mixed* or *hepatico-gastric*, they have their beginning in the hepatic organs, and augment in the intestinal tube. Here, if the extraneous body be detained, and the contents of the bowels have a disposition to become thickened and condensed round it as a nucleus, it may be rendered larger by additional strata of matter, and would increase *sine fine*, if a stop were not put to the augmentation by the narrowness of the canal, or an effort made for the expulsion of the concretion. Morgagni cites two instances of this sort of concretion: one from Gemma, the other from Bezold; and he gives his opinion, that another alvine calculus spoken of by Vater must have been of the same nature. Dr. Coe describes another interesting specimen; and others are referred to by Vandermonde, Moreali, Portal, &c. Perhaps, says Rubini, the instances of this kind would have been more numerous if all the concretions discharged from the bowels had been noted with greater attention, and the hepatico-gastric substances not confounded with the hepatic. The lodgment of these concretions in the intestinal canal is of uncertain duration, and depends upon a variety of circumstances. Vandermonde gives the history of a calculus, which, as far as could be judged of by

the pain in the right hypochondrium, and the change of symptoms, must have passed into the duodenum in the month of January, and then continued in the bowels until August, when it was discharged from the rectum.

The crystallized appearance of alvine concretions is generally so conspicuous that it has not escaped the attention of several of the old writers, as we may convince ourselves of by referring to the works of Corn. Gemma, Greisel, Baglivi, Scultetus, &c. It was noticed by Haller in his *Elementa Physiologiae*, vol. 6, and by Morgagni in his *Epist.* 37, de *Sedibus et Causis*, &c. If, says Rubini, these crystallizations are not always plainly visible, distinct, and regular, this depends either upon their imperfection; the heterogeneous nature of the accumulated matter; or particular unfavourable circumstances, which equally affect the process of crystallization out of the body.

Now, as all crystallizations depend upon the fluids, in which they form, and from which they receive their crystallizing elements, it must be evident that, inasmuch as the fluids of the hepatic organs differ in their constituent principles from the fluids contained in the intestinal canal, the concretions produced in the first system must differ from those which originate in the second; whilst the hepatico-gastric calculi will combine the nature and properties of both together.

The fluid from which hepatic concretions are formed is unquestionably the bile, either some or all its ingredients entering into their composition. Indeed, previously to the new chymical doctrines, hepatic calculi were generally considered as being simply condensed indurated bile.

From investigations made in more modern times, however, when the art of analysis has attained a precision of which the old chymistry was not susceptible, it appears, that, although human biliary calculi yield the same products as the bile, there is contained in them more or less of a peculiar substance, which was named by the celebrated Fourcroy, *adipocire*. (*Mém. de l'Acad. des Sciences*, 1789. p. 323.) The presence of this substance in the concretion is of such importance, that, when it is abundant and in large proportion, the calculus is regular, and the crystallization well finished; and when it is in small quantity, the crystallization is confused and disordered, the calculus only exhibiting an irregular misshapen concretion, more like a clot than true crystals. The kind of *adipocire*, which constitutes the base of all human biliary calculi, has some resemblance to *spermaceti*. Both Fourcroy and Dr. Bostock, who analyzed it, found it composed entirely of carbon, hydrogen, and oxygen. It melts, but requires a heat superior to that of boiling water: in fusion it has a smell like wax; and on cooling, forms a substance which breaks into crystalline laminæ. It is not soluble in alcohol in the cold; but when the alcohol

is boiled on it, it is dissolved in a proportion, according to Fourcroy, of one part in nineteen; according to Dr. Bostock, one in thirty. (*Nicholson's Journ. Soc. vol. 4. p. 137.*) The solution when it cools, deposits light brilliant scales. It is soluble in ether in the cold, and more abundantly if the ether be heated. Oil of turpentine dissolves in general biliary calculi; and, according to Green, it dissolves those which consist almost entirely of this peculiar matter; yet Dr. Bostock has remarked, that oil of turpentine acts on it with difficulty, and even when digested with it, at a boiling heat, dissolves it only in a small degree. Pure soda, and potassa dissolve it completely, and reduce it to a saponaceous state. Ammonia, as Dr. Bostock has remarked, exerts little action on it, except when boiling. Nitric acid dissolves it, and, according to Fourcroy, converts it into a species of liquid similar to the oil of camphor. This, as Dr. Bostock has remarked, becomes concrete, but without any crystalline structure, and is more soluble in ether and the alkalis, than the original matter.

"This substance (Fourcroy has observed,) is contained in greater or less quantity, in nearly all the human biliary calculi, more or less intermixed with other matter, but still so far predominant as to form their basis. Hence, they partake of its properties; are fusible, inflammable, and more or less soluble, in the agents which dissolve it." (*See Murray's Syst. of Chymistry, vol. 4, p. 594, Ed. 2.*) Fourcroy, on exposing the above peculiar substance to the action of oxygenated muriatic acid, saw it whitened, and afterwards resume its former silvery hue. However, Rubini repeated this experiment, and found that the whiteness, which was contracted, remained permanent.

While the hepatic system contains a fluid which is always nearly of the same quality, viz. the bile, the alimentary canal, as Rubini observes, contains a hundred different fluids, and is continually occupied by substances, of various natures, kinds, and properties, consisting of food, drink, and several secretions. All the principles, which are to serve for the formation and renewal of the different species of living solids, and of the many kinds of fluids, at first remain more or less time in the alimentary canal, and there undergo peculiar changes. All the principles, which, under different circumstances, may contribute to the production of morbid concretions, either in the gall-bladder, the urinary bladder, the kidneys, or in any other part of the body, where they ever occur, pass at first into the intestinal canal, where they continue for some time. Such a multiplicity of principles, disposed to crystallize, and be converted into calculi, would very often, almost daily, produce these concretions in the bowels, were there not many circumstances, which counteract this tendency, as, for instance, exercise, the incessant motion of the matter

itself along the intestinal tube, the variety of these elements, whereby their requisite tendency to unite is disturbed, and the decomposing and recomposing influence of the gastric secretions, whereby parts are united, disposed of, dissolved, and analogous matter kept divided, &c. But, whenever these circumstances are not actively operating, as may be the case in a noose, or fold of the bowels, or in some preternatural cyst belonging to them; whenever the intestinal fluids undergo such an alteration, that the production of these concretions cannot be prevented; or, lastly, whenever some favourable circumstance, such as an extraneous nucleus, forms a centre of reunion for particular elements; then the saline matter, which is most disposed to crystallize, and the earthy and mucilaginous substances, &c. are attracted together, and produce more or less perfect crystallizations. A chymical analysis of some intestinal calculi, first made by Konig, and afterwards by Slare, (*Philosophical Transactions*) proves that when they are exposed to a strong heat in distillation, they yield water, ammonia, and a lixivious salt, a caput mortuum remaining behind. Cadet, in analyzing a similar concretion, found, in addition to the above products, phosphorus. The muriate of ammonia was afterwards discovered; and Gioberti, Fourcroy, and Vauquelin, in their histories of the intestinal concretions, met with in animals, describe them as composed of the acidulous phosphate of lime, phosphate of magnesia, and of the ammoniacal-magnesian phosphate.

Some specimens, contained in the Edinburgh museum, were very carefully examined by Dr. T. Thomson: they at first swam in water, but afterwards sunk; the specific gravity varying from 1.376 to 1.540. Cold water, acquired from them a brownish tinge, and took up albumen, which separated in white flakes by boiling. There was also a peculiar brown substance, at first dissolving in water, but rendered nearly insoluble by slow evaporation; soluble in alcohol; and most nearly resembling vegetable extract. The specimens likewise contained muriate of soda, crystallizing on spontaneous evaporation of the water: phosphate of lime, precipitated by ammonia; sulphate of soda in minute proportion; and, perhaps, sulphate of lime. Alcohol dissolved the peculiar brown matter and some of the salts; caustic potash, the albumen, brown matter, and perhaps some of the salts; and muriatic acid a proportion of phosphate of lime. After all, there remained a peculiar substance, having the colour and texture of the calculus; in very short threads, light, resembling cork, or rather agaric; tasteless, insoluble in water, alcohol, ether, potash-ley, and muriatic acid; being blackened, and partly reduced to charcoal by sulphuric acid; slowly dissolving by heat, without effervescence, in nitric acid; and leaving on evaporation a whitish residue, of bitter taste, and imperfectly soluble in water;

burning with a bright flame; but differing from all other animal and vegetable substances hitherto examined, and distinguishable from wood, by its insolubility in potash-ley. The calculi consisted of alternate layers, or intimate mixtures of this substance and phosphate of lime, to which the albumen and brown matter served as a cement, the other substances being in small proportions. Phosphate of lime, mixed with a brown animal matter, formed the external crust of some of the specimens. On the surface of a few were noticed crystals of phosphate of ammonia and magnesia. The presence of neither potash, ammonia, carbonate of lime, uric acid, nor urea, could be detected.

Varieties have also been found by Dr. Henry and Mr. Brande, which were exclusively composed of magnesia, of which the patients had been in the habit of taking vast quantities. (See *Thomson's Obs. in Monro's morbid Anatomy of the human Gullet*, &c. p. 36, or in *Medico-Chir. Journ.* vol. 4, p. 188, 189.)

From some recent observations made by Dr. Wollaston, it appears probable, that the above fibrous light thready substance is derived from oats, which are so commonly taken as food in Scotland.

"If the oat-seed be divested of its husk, minute needles or beards, forming a small brush, are seen planted at one of its ends. Dr. Wollaston, on examining these needles, and comparing them with similar ones detached from the calculi, and forming the velvet substance in question, satisfied himself beyond all doubt of their perfect identity." (*Marsell on calculous Disorders*, p. 130, *Edo. London*, 1817.)

As for the mixed, or hepatico-gastric calculi, they have for their nucleus a biliary concretion, round which other substances contained in the bowels adhere: hence, it is evident, that as they are formed at two distinct periods, in two different situations, and among various fluids, two distinct compositions must be the result. Although, says Rubini, there has hitherto been no scientific analysis of this species of calculus, excepting the very imperfect one by Moreali, reason shows clearly enough that, if two separate analyses were made, one of the nucleus, the other of the surrounding matter, there would be obtained from the nucleus the same elements, as those of an hepatic calculus, and from the rest those of an intestinal concretion. (See *Pensieri sulla Varia Origine, &c. de' Corpi calcolosi che vengono espulsi dal tubo gastrico*, p. 15—17.)

As the same author remarks, the foregoing principles will enable us to determine with greater precision, than formerly, the characters, which appertain to the several classes of calculi, liable to be voided from the intestinal canal; characters, by means of which there can be no difficulty in deciding, from the appearance of one of these concretions, the place of its origin, and its peculiar nature. The hepatic calculus, being composed of bile, and also of *adipocire*,

its characters will be such as indicate the predominance of an uniform, oleaginous, and (what Rubini terms) a well *animalized* principle. The gastric, or intestinal calculus, arising from the union of various salts, earths, and other principles, which happen to be in the alimentary canal, will have very different characters, generally indicating its earthy, saline composition. Lastly; the hepatico-gastric calculus will present an union of the different characters; viz. in the centre, the characters of the hepatic calculus; more externally, those of the gastric.

The criteria for distinguishing the several kinds of calculi from each other, may be divided into two classes; those which may be termed *external*, being derived from accidental circumstances attending the foreign body; and others, which may be called *internal*, being deduced from the inherent characters, belonging to the composition and nature of these concretions.

The first of these external criteria, is the age of the patient. C. Stephanus, Hoffmann, Durande, and Morgagni all agree, that biliary calculi seldom occur, except in subjects of advanced age, and never in youth. And Haller writes, "*Juniores et pueros, quantum novi, numquam adfligit morbus.*" Morgagni states, that he has met with sixty-one old persons who had alvine concretions, but only eight young persons, not one of whom was a child, the youngest being twelve years of age, and the eldest twenty-nine. To these I may add the instance, reported by Saye, in which a stone as large as a hen's egg, was found in the gall-bladder of a young female aged only twelve. (See *Journ. des Savans*, Sept. 1697.) The cause of this difference is attempted to be explained by Morgagni; but probably a more rational explanation than that suggested by him, will be found in the analysis of the bile of old and young subjects, as made by Fourcroy and other modern chymists. From these and other observations, collected by Rubini, it is rational to conclude, that when an alvine concretion is discharged from a young subject, the chances are that it is not a biliary one; though, if the patient be of advanced age, it is not to be inferred, that the foreign substance expelled must certainly be hepatic, because gastric or intestinal concretions are common to individuals of every age. (*Rubini, op. cit.* p. 18.) Indeed, with the latter kind of calculi, men of advanced age and women are said to be most frequently afflicted; children and young persons rarely suffering, unless the formation of such bodies has been produced by the presence of fruit-stones, or other indigestible substances which serve as nuclei. (See *Richerana's Nosographic Chir.* T. 3. p. 433, Ed. 4.) These concretions have likewise been noticed in patients, who have been confined by disease a long while in a recumbent posture.

With respect to another criterion, deduced from the patient being also afflicted with urinary calculi, there cannot be a doubt of

its invalidity, though proposed by so great a man as Morgagni. The concurrence of the two disorders in the same individual, when it happens, is purely accidental. Suffice it to add, that Haller, in his pathological works, expressly mentions the rarity of urinary calculi at Gottingen, where cases of gall-stones are extremely frequent.

A third criterion is drawn from the symptoms which precede or accompany the expulsion of the calculus. Sense of heaviness, irritation, and pain in the region of the liver, pain about the ensiform cartilage and navel, bilious vomiting, jaundice, and either looseness of the bowels or constipation, are the symptoms, which (especially when they frequently occur) indicate the hepatic origin of the calculus, and proceed from its passing through the narrow ducts of the liver or gall-bladder towards the intestines. The most careful observations have proved, however, that these symptoms are only to be depended upon when taken collectively, and that no single one gives any certain information. Also, if their presence be sufficient to prove the hepatic origin of the calculus, their absence can by no means be regarded as a proof of the concretion being of the intestinal kind. (Rubini, p. 19.)

Fourth criterion. A calculus voided may be set down as undoubtedly hepatic, if accompanied by others, which are unequivocally of this nature. In a case recorded by Brunner, and in another by Vater, the absence of certain symptoms in the first, and the magnitude of the calculus in the second, created doubts whether the concretions were not more likely to be of the intestinal kind, than of the hepatic. At length, the bodies having been opened, the presence of other similar calculi in the gall-bladders afforded an adequate criterion.

Morgagni lays down a fifth criterion, deduced from the number of the calculi voided; which, if very numerous, are to be considered as biliary. Rubini points out, however, the fallacy of this test; both hepatic and gastric concretions being sometimes single, sometimes in various numbers, even up to a thousand; and he refers to a case where a very large number of concretions of the gastric description were voided, as reported by Konig. The test, here suggested, however, may be considered as generally valid; for, the number of intestinal concretions is rarely more than two, though sometimes very considerable. (T. Thomson. See *Med. Chir. Journ.* Vol. 4, p. 189.)

I shall now follow Rubini, and notice those characters of alvine concretions, which he calls *internal*, and are deduced from their quality and composition, beginning with the criterion furnished by the size of the extraneous substance voided. As the biliary ducts are narrow, it is obvious that, if the calculus be above a certain size, it cannot have passed through those narrow tubes, and consequently must be either of the gastric description, or mixed, having quitted the hepatic system when it was

small, and afterwards increased within the alimentary canal. Unquestionably, as Rubini admits, this criterion has considerable weight, especially when the discharge of the calculus has not been preceded by pain, or other symptoms indicating such violent distension, as the above ducts must have suffered from the passage of the foreign body. These may certainly be dilated in a remarkable degree; but, it can never happen without pain, irritation, and a serious train of sympathetic effects. The case in which the dilatation takes place slowly and insensibly, if not hypothetical, is uncommon. This criterion is adopted by Moreau in the *Mem. de l'Acad. de Chirurgie*; and Bonté has availed himself of it in *Vandermonde's Journal*, for determining, that a calculus, of which he has published an account, was first formed in the hepatic organs, and then attained a larger size in the intestinal canal. As Rubini remarks, however, it is plain, that this criterion will only apply to large, and not to diminutive concretions.

A second criterion is the colour of the calculus; a test admitted by Moreau; who asserts, that biliary calculi are yellow, or green, and intestinal ones grayish brown, or black. But, says Rubini, one need only look at various specimens of alvine concretions, and read the statements of authors, who have seen a great many of them, particularly Morgagni and Soemmering, to comprehend, that any criterion, deduced from their colour, is most fallacious. every species of them presenting great variety in this particular. And, it is to be remembered, that the bile and the intestinal fluids, whence these concretions are formed, differ in colour in different individuals, according to a variety of circumstances, in health and disease. The smaller intestinal concretions, examined by Dr. T. Thomson, destitute of coating, resembled bad yellow ochre; the larger were encrusted with an earthy matter, of a coffee colour, and purple, or sometimes white. (See *Monro on the Human Gullet, &c. and Med. Chir. Journ.* Vol. IV. p. 188.)

Third criterion. The presence or absence of a nucleus will enable one to judge, whether a calculus be gastric, or hepatic. A biliary concretion has no nucleus, properly so called; that is to say, it has no foreign body in its centre. When a transverse section is made of such a calculus, one either finds a cavity in its middle, or else nothing, by which this part of its substance can be distinguished from the rest; or, if a nucleus, different from the other part of the concretion, be apparent there, it consists merely of bile, either grumous, differently coloured, or more or less fluid, than the rest of the calculus, but which is nevertheless invariably bile. On the contrary, every gastric concretion has, as it were, an extraneous nucleus, as Fourcroy and Vauquelin have explained in their essay upon the intestinal calculi met with in animals. Ruysch in the *Phil. Trans.* gives an account of some alvine concretions

which were formed round grains of seed. Birch records an example of a crystallized calculus, formed round a leaden bullet. Haller met with a calculus, in the centre of which was an iron nail. Concretions, formed upon fruit-stones, are recorded by Clarke, White, and Hey, and also in the *Edinb. Med. Essays*. Instances, in which the nucleus was a small portion of bone, are related in the latter work, and also by Hooke, and Coe. Homberg and others describe alvine concretions, formed round indurated excrementitious matter; and many similar cases are specified by Vallisneri, Vanswieten, and others. In the hepatico-gastric calculus, the biliary concretion serves as a nucleus for the gastric. According to Dr. T. Thomson, the nucleus is commonly a cherry-stone, a small piece of bone, or a biliary calculus. (*See Med. Chir. Journ. Vol. IV. p. 188.*)

A fourth criterion is deduced from a certain unctuousity, which belongs to biliary calculi, but not to those of the gastric class. This character is more palpable, when the calculus has been recently voided, or when it is handled with warm fingers. The unctuousity is still more evident, when the concretion is cut, or sawn, as then the knife, saw, or fingers, become smeared with saponaceous particles, which adhere to them. In order to denote an hepatic calculus, however, the unctuousity must pervade its whole substance, and not merely appear towards its outside; for, a gastric, earthy, saline concretion may by accident become coated, as it passes through the bowels, with a stratum of bile, or saponaceous matter. When the unctuousity is deficient externally, or in the outer laminae of a calculus, but is found in its interior, when cut, it is a clear indication of the hepatico-gastric formation of the concretion.

Fifth criterion. The specific gravity of a calculus, the property which it has of floating or sinking in water, has been long considered as a test of its species. The hepatic calculus is generally specifically lighter than water, as most oily substances are; on the contrary, gastric calculi are specifically heavier than water, like all earthy saline matter, and of course sink in that fluid. This criterion was often employed by Reverhorst, Fernelius, and others, for distinguishing various concretions. But, it is by no means regular, as many biliary calculi swim only a little while, and then sink. The specific gravity of that analyzed by Dr. Ure of Glasgow, was 1.0135. (*See Med. Chir. Journ. Vol. IV. p. 179.*) Rubini observes, this test will not answer for hepatico-gastric calculi, which are subject to great anomalies. (*Pensieri, &c. p. 22.*) Nevertheless, the most correct modern examinations prove, that gastric concretions have a specific gravity, varying from 1.376 to 1.540, (*Dr. T. Thomson in Monro's Morb. Anat. &c.*) and, consequently, their general character is to be heavier than biliary calculi.

A sixth criterion is that proposed by Vicq d'Azyr, in the *Mém. de l'Acad. Royale*

de Med. and deduced from the figure of the crystallization. According to this writer, intestinal concretions crystallize in concentric laminae, shaped like a cock's comb, while the crystallizations of biliary calculi are radiated and needle-shaped. Although this criterion is ingeniously founded upon the known laws, by which every crystallized substance assumes a peculiar and determinate shape, yet it may be generally observed, with respect to the mark of distinction here proposed, that the concretions, of which we are now speaking, are usually too compound, and too much disturbed in their crystallization, to exhibit a regularity, for which simplicity and quietude are indispensable. Hence, many of these concretions do not present the slightest vestige of crystallization, while others scarcely show a trace of it, in the midst of a large misshapen mass. With respect to the special shape assigned by Vicq d'Azyr, to the two classes of alvine concretions, it may be observed, that his specimens were taken from animals, and that consequently, the inferences made from them are not applicable to substances of an analogous nature, discharged from the human body; because, as the bile varies in different animals, so must the formative principles of the calculous crystallizations. It is further remarked by Rubini, that the substance termed *adipocire*, which is the basis of biliary concretions, was not found by Poulletier in hepatic calculi taken from horned cattle.

A seventh criterion is founded upon the inflammability of an alvine calculus. A biliary concretion being commonly made up altogether of unctuous matter, liquefies when subjected to heat, smokes, emits a flame, and burns. When this experiment is made in close vessels, the products are hydrogen, carbonic acid gas, oil, and ammonia; some carbon and earth remaining behind. An intestinal concretion, on the other hand, decrepitates, or turns black, but does not burn.

The eighth criterion depends upon the solubility of calculi in an oily menstruum. Haller dissolved biliary calculi in oil of turpentine; Dietrick found them soluble in oil of sweet almonds; and Gren in oils in general. But, intestinal calculi are not so readily dissolved by any of these menstua.

The ninth criterion is founded upon the solubility of the calculus in alcohol. In biliary calculi, this solubility is not always the same. Having already spoken upon this point, however, it is unnecessary to dwell upon it; and I shall merely add, that while hepatic concretions are always more or less dissolved by alcohol, those of the gastric kind resist this menstruum.

Though the above criteria are interesting, as tending to establish distinctions betwixt the different species of alvine concretions, it merits attention, that not one of them, taken separately, is at all certain and pathognomonic. It may happen, says Rubini, that some peculiarity in the biliary secretion, and an irregularity in the crystalli-

zation and accumulation of the matter, may cause salts and earths to predominate in hepatic concretions, in which circumstance, their usual oily quality will be defective. On the other hand, in the formation of an intestinal concretion, oily adipose matter may accidentally adhere to it, so as to disguise its wonted character. If uniformity of characters and physical properties depend upon uniformity of elementary constituent principles, it can hardly happen even in the natural healthy state of the secretions, because age, sex, and other particular circumstances of the individual, will always make a difference in the proportions of those principles. How then can identity of results be expected in a diseased state of the process of secretion?—Such reflections may explain, how Morgagni, among others, met with many biliary calculi, which were not inflammable; with others, which did not give a yellow tinge to water; and with some which floated, or sunk in water, according as they had been recently, or long discharged; while Gren found some of these calculi insoluble in alcohol, &c. (Rubini, p. 24, 25.)

Moreali put a piece of the outer part of an alvine concretion into nitrous acid, when a considerable effervescence took place, and the substance afterwards completely dissolved. Now, as this calculus had a nucleus, it must have been of the hepaticogastric kind, and the experiment was therefore made only with the intestinal part of it. Should the experiment be often repeated with the same result, says Rubini, it would furnish another criterion for distinguishing the two species of calculi; those being intestinal, which effervesce, and others being hepatic, which do not effervesce, but yield globules of wax-like oily matter. (p. 28.)

For additional chymical observations on biliary and other alvine concretions, the reader is particularly referred to Rubini's interesting memoir, Vicq d'Azyr's essay in the *Hist. de la Société Royale de Médecine*, an. 1779; the writings of Fourcroy and Vauquelin; Thomson's account of the subject in *Monro's Morbid Anatomy of the Human Gullet*, &c.; Marcet on calculous Disorders; and some interesting experiments by Dr. Ure, related in a paper by Mr. Kennedy, in *Medico-Chir. Jour.* Vol. 4. p. 177, &c.

With respect to the treatment of cases of biliary calculi, the subject not being generally one, for which any surgical proceeding is advisable, I may be very brief. The medicine, which is alleged by Durande, a physician at Dijon, to be the best solvent for them, consists of three parts of sulphuric ether, and two parts of oil of turpentine. It is to be given in the dose of $\mathfrak{z}\text{ij}$ every morning; purgatives being previously exhibited for a few days. The efficacy of this medicine is also corroborated by Soemmering and Richter. To these statements, however, some doubts must be attached, because what symptoms and cir-

cumstances will ever unequivocally prove, that there were biliary calculi in the bowels; and that they have been dissolved by this medicine? And how can the product of such solution be got at and examined? But, admitting the authenticity of the cases, doubts must exist of the solvent action of the remedy, since at a temperature, below that of the human body, the ether separates from the turpentine and is volatilized. (See *Diet. des Sciences Med.* T. 3, p. 464. 465.)

A calculus in the gall-bladder, or one of the biliary ducts, sometimes produces so much irritation, that inflammation and suppuration take place, and if the abscess point outwardly, the stone may escape externally, and a termination be put to the patient's sufferings. Heberden records a case of this description; and another is given by Mr. Blagden. (See *Med. Trans. of the College of Physicians*, Vol. 5. and *Thomas in Med. Chir. Trans.* Vol. 6. p. 106. And for other instances, the following works referred to by Plouquet: *Acret. Diss. de Cholelithis*, Upsal, 1788. p. 204; *Act. Natur. Cur.* Vol. 6. Obs. 69; *Bartholinus, Act. Hafn.* 4, Obs. 46; *Block, Med. Bemerk.* p. 27; *Gooch's Works*, Vol. 2, 157—161; *Johnson in Phil. Trans.* Vol. 50, p. 2, 548; *Petit, Mém. de l'Acad. de Chir.* 1, p. 182—185; *Sandisfort, Tab. Anat. Fasc.* 3; *Schlichting in Bald. N. Magaz.* 9 b. p. 210; *Vogler in Museum der Heilkunde*, 4 b. p. 91; *Haller, Collect. Diss. Pract.* 3, No. 107.)

The eminent J. L. Petit, as is well known, suggested the bold practice of making, under certain circumstances, an incision into the gall-bladder, in order to extract biliary calculi. This proceeding is liable to serious objections, arising not only from the usual difficulty of knowing positively that there is a calculus in the gall-bladder, but also from the difficulty of ascertaining that this viscus is adherent to the peritoneum, without which state of things, the operation would cause an extravasation of bile, enteritis, and death. Petit himself, indeed, mentions three cases, in which distention of the gall-bladder was mistaken for an abscess, and punctured. In two of these examples, the consequences were fatal, there having been no adhesion between that organ and the peritoneum to prevent the bile from getting amongst the bowels; the other patient was saved by this fortunate circumstance. (See *Traité des Mal. Chir.* T. 1, 262, &c.) However, if a case were to present itself in which an abscess had formed, and broken, leaving an aperture in which the calculus could be plainly felt, the surgeon would be justified in attempting to make a sufficient opening for its extraction.

The symptoms, induced by the lodgment of large concretions in the bowels, are of a formidable description: severe pains in the stomach and bowels, diarrhoea, violent vomitings of blood and mucus, a discharge of thin fetid matter from the rectum, a difficulty of voiding the excrement, an afflicting

tenesmus, extreme emaciation, and debility.

That the foregoing account is not at all exaggerated, may be seen by a perusal of the cases, and remarks published by Mr. C. White of Manchester, and Mr. Hey of Leeds.

In cases, like that reported by Mr. Hey, (*Pract. Obs. P. 509. Ed. 2.*) where the colon was entirely obstructed, surgeons have been advised to cut into that bowel, and extract the foreign body. Let the inexperienced admirer of curious feats with the scalpel, however, pause a little, before he ventures to make up his mind upon this matter; and, at all events, let him know that some serious mistakes have nearly been made "upon the very bold operation of cutting out these concretions, when lodged in the colon, proposed by Dr. Monro senior, (See *Monro's Morbid Anatomy of the Human Gullet, &c. P. 63.*) we think it our duty to state, that the diagnosis is so difficult, that, in one case, where the operation was strongly advised, it turned out, upon dissection, that the disease was a *scirrhus pylorus*." (See *Edinb. Med. and Surg. Journ. No. 33. P. 112.*)

Sometimes patients ultimately get well by voiding the concretions either by vomiting or stool. Mr. Charles White gives us an account of some such instances; in one fourteen concretions on plum-stones were discharged from the anus; in another twenty-one similar bodies were ejected from the stomach.

When such concretions are not particularly large and indurated, they sometimes admit of expulsion by doses of castor oil, oleaginous clysters, &c. But, in other instances, their extraction must be attempted, if their situation in the rectum will permit. It may be done with a pair of lithotomy forceps, or with the sort of scoop used for taking fragments of stone out of the bladder. In this manner Mr. C. White succeeded in removing two alvine concretions from the rectum, nearly as big as his fist. When the sphincter ani will not allow the concretion to be taken out, the muscle should be divided at its posterior angle. According to Richerand, such a division does not permanently weaken its fibres in a perceptible degree, and its paralysis never originates from this cause. (*Nosogr. Chir. T. 3, p. 434. Edit. 4.*) Maréchal, after a proper dilatation with a scalpel, extracted from the rectum an alvine concretion, which weighed two ounces and a half, and was of an ovoid form, its greatest diameter being two inches eight lines, and its smaller one inch seven lines. (See *Mém. de l'Acad. de Chir.*)

*AMAUROSIS (from *αμαυρος*, to obscure.) *Gutta serena. Suffusio nigra.* Fr. L'Amalrose; Germ. Schwarzer Staar. According to Beer, the term amaurosis properly means that diminution or total loss of sight, which immediately depends upon a morbid state of the retina and optic nerve, whether this morbid state exist as the only defect, or be complicated with other mischief; whether it be a primary affection, or a secondary

one, induced by previous disease of other parts of the eye.

From this definition, which comprehends every form of amaurosis, it is evident that this affection does not uniformly take place as a single independent disorder; but not unfrequently presents itself as a symptomatic effect of some other disease of the eye; a fact exemplified in cases of hydrophthalmia, cirsophthalmia, glaucoma, &c. And as Mr. Wardrop observes, amaurosis, in its usual acceptation, signifies a symptom of disease, as well as a distinct affection. (*Essays on the Morbid Anatomy of the Human Eye*, vol. 2. p. 165. 8vo. Lond. 1818.) With respect to the mere name of the kind of disease, which is here implied by amaurosis, its correctness will remain the same, whether the iris be moveable or immovable; whether the pupil be preternaturally enlarged or contracted; and whether it be perfectly clear and transparent, or more or less turbid; for the name only refers to the morbid state of the retina and optic nerve, and not to the condition of the sight in general. When the long-established name of *amaurosis* is received with this precise meaning, there will not be the slightest danger of confounding this disease with other affections of the eye. However, when it is wished to make out the very different forms and kinds of amaurosis, the foregoing appearances of the iris and pupil are considerations of great importance. (See *Beer's Lehre von den Augenkrankheiten*, b. 2. p. 420, &c. Wien. 1817.)

Amaurosis does not constantly attack both eyes at the same time. Frequently one is attacked some time after the other; and it is not unusual even for one eye to remain sound during life, while the other is completely blind. This depends in part upon the disposition to the disease in one eye being quite local, and in part upon the causes giving rise to the complaint extending their operation only to the eye affected. Where, also, the origin of amaurosis seems to depend altogether upon constitutional causes, as in gouty and syphilitic patients, &c., one eye is not unfrequently attacked much sooner than the other; though, in these examples, it is more rare to find the eye, which does not suffer at first, continue perfectly unaffected. (*Beer*, b. 2. p. 422.) As a general observation, Mr. Wardrop thinks it may be remarked, that, when only one eye becomes at first amaurotic, from a sympathetic affection, there is little danger of the other eye becoming blind; but, that when amaurosis is produced by any organic change in one eye, the other is in danger of becoming sympathetically affected. (*Essays on the Morbid Anatomy of the Human Eye*, vol. 2. p. 190.) Amaurosis does not completely hinder vision, a diminished power of seeing often remaining during life. Hence the division of cases into *perfect* and *imperfect*, which latter, however, sometimes attain a degree in which the patient is only just able to

distinguish light, the direction of its rays, and its degree.

Imperfect amaurosis, besides being characterized by a considerable weakness of sight, approaching to real blindness (*Amblyopia Amaurotica*), is mostly complicated with a greater or lesser number of other morbid appearances, which merit serious attention.

Among the most important of these symptomatic appearances of imperfect amaurosis, is a defective interrupted vision (*visus interruptus*.) For instance, when the patient is reading, single syllables, words, or lines, cannot be seen, unless the eye be first directed to them by a movement of the whole head, and greater or lesser portions of other objects are, in the same manner, undistinguishable. Sometimes amaurotic patients can see only the upper or lower, or the left or the right half of objects. (*Visus dimidiatus*; *Amaurosis dimidiata*; *Hemiopia*; *Hemiopsia*.)

Sometimes, when the patient shuts one eye, he can only distinguish the halves of objects; but, if he open both eyes, he sees every thing in its natural form. In this case, according to Schmucker, one eye is sound, and only some fibres of the nerve of sight are injured in the other. (*Vermischte Chir. Schrift*, b. 2. p. 12.)

There are likewise some not very uncommon cases of imperfect amaurosis, in which the patient cannot see an object, unless it be held in a particular direction before the eye; but when the eye or head is moved in the least, he loses all view of the thing, and cannot easily get sight of it again. (*Beer, Lehre von den Augenkrankheiten*, b. 2. p. 424.) On this part of the subject, it is remarked by Richter, that patients who may be said to be entirely blind, sometimes have a small part of the retina which is still susceptible of the impression of light, and is usually situated towards one side of the eye. This obliquity of sight was long ago pointed out by the late Mr. William Hey of Leeds, as common in the present disease. (See *Med. Observations and Inquiries*, vol. 5.) Richter mentions, that, in one man, who was in other respects entirely bereft of vision, this sensible point of the retina was situated obliquely over the nose, and so small, that it was always a considerable time before its situation could be discovered. He adds, that it was so sensible, as not only to discern the light, but even the spire of a distant steeple. According to this author, it is the centre of the eye that seems to be the first and most seriously affected in the gutta serena. Hence, the generality of patients, who have a beginning imperfect amaurosis, can always see objects laterally situated better than those which are immediately before them. (*Anfangsgr. der Wundarzn.* b. 3. Kap. 14; also *Hey in Med. Obs. and Inq.* vol. 5.)

One of the most common symptoms of a beginning amaurosis is an appearance in the patient's fancy, as if gnats or flies were flying about before his eyes. (*Visus Mus-*

carum, Myodesopsia.) Sometimes transparent, dark-streaked, circular, or serpentine diminutive bodies appear as if flying in greater or lesser numbers before the eyes, often suddenly ascending, and as quickly falling down again, and chiefly annoying the patient and confusing his sight when he looks at strongly illuminated or white objects. The substances thus appearing to fly about before the patient's eyes are termed by writers *Scotomata, Muscæ volitantes, Mouches volantes*. (Beer, *Lehre*, &c. B. 2. p. 424.) The term *scotoma*, however, is not always received exactly in the foregoing sense; for, Richter says, sometimes the malady seems to be confined to a single little spot in the eye, in which case, the patient is conscious of having before the retina an immoveable black speck. It is to this particular instance that some pathologists apply the term *scotoma*.

These scotomata gradually increase, become less and less transparent, and at length, are so connected together, that they form a kind of network, or gauze, by which all objects are more or less obscured. This is another symptom of amaurosis, technically called *visus reticulatus*. The network commonly has the peculiarity of being black in very light situations, or when white substances are before the eye; while, in dark places, it is quite shining, and, as it were, of a bluish white hue, like silver, though sometimes of a red-yellow, golden colour.

A not uncommon symptom of imperfect amaurosis is the patient's seeing every object indistinctly in a rainbow-like, sometimes tremulous, and generally very dazzling light; while, in the dark especially, blue or yellow flashes, or fiery balls seem suddenly to pass before his eyes when the eyelids are shut, and excite considerable alarm. (*Visus lucidus; Marmoryge Hippocratis; Photopsia*.)

In imperfect amaurosis, the sensibility of the retina may be so augmented, that the patient shuns all very light places, particularly those in which the light is strongly reflected into the eye, and, in order yet to discern in some measure large objects, he feels himself obliged always to seek shady, darkish situations, or to screen his eyes, out of doors, with a green shade, or green glasses. This state is termed by Beer, *Lichtscheue*. (*Photophobia*.) Under these circumstances, it sometimes happens, that the patient for a very short time, for example a few moments, or (what is very uncommon) for a more considerable period, is able of himself to discern the smallest objects in a very weak light more plainly and accurately than the best eye can hardly do in a good light. Yet, excepting at such period, the patient with the above degree of light is not capable of seeing even larger objects. This infirmity of sight receives the name of *oxyopia*.

Sometimes, in the early stage of amaurosis, all objects seem covered with a dense mist; while, in other instances, this mist first presents itself as a simple, continually

increasing scotoma, and rarely in the form of a network, or gauze; but to the patient, when his blindness commences with the *visus nebulosus*, the mist usually appears for a day or two of a light gray colour, and then for another day or two very black, every thing appearing as if looked at through a dense sooty smoke. (Beer, *Lehre von den Augenkrankheiten*, B. 2, p. 422—26.)

To an eye affected with imperfect amaurosis, all objects frequently appear indistinct, but double. (*Visus duplicatus; Diplopia*.) It is remarked by Schmucker, that, in the *gutta serena*, which comes on gradually, the patient sometimes sees double, with both eyes. Some years ago, Schmucker cured a major of huzzars, who saw the three lines of his squadron double; and the same surgeon was ordered by the king of Prussia to attend a gentleman, who was afflicted in a similar way. In the opinion of this eminent surgeon, such cases are brought on by a violent distention of the vessels of the choroides, where he thinks, that varices may easily arise, in consequence of the weak resistance of that membrane. In this manner, the filaments of the retina suffer pressure, and the rays of light are broken. Under these circumstances, if prompt assistance be not afforded, total and frequently incurable blindness may be the consequence. Schmucker met with an example of such an irremediable amaurosis (the only instance in his practice,) in a young man, twenty-six years of age. When the patient made application for the advice of the foregoing surgeon, he had been blind a year. Before he lost his sight, he remarked, that, after any violent emotion, his sight at first grew weak, and that objects afterwards appeared double. When his circulation was at all hurried, he saw black spots before his eyes, and at length was quite blind. The vessels of the choroides were as large, as if they had been injected with wax, and every kind of surgical assistance proved ineffectual. (*Vermischte Chir. Schriften*, B. 2, p. 12, &c. 8vo. Berlin, 1786.) In some cases, according to Beer, double vision only occurs, when the patient looks at objects with both eyes, and it ceases as soon as he shuts either the diseased or the sound eye. In the last of these circumstances the double vision only originates from the deviation of the unsound eye from the axis of vision; but in the first instance, it arises from the morbid state of the retina itself of the diseased eye. For the purpose of distinguishing both these examples of diplopia from every other species of symptomatic double vision, Beer applies to them the name of *diplopia nervosa*. A degree of squinting, *strabismus*, therefore, is a very common symptom of incipient amaurosis, particularly when only one eye is affected: for, this always deviates more or less from the axis of vision. It is less usual for imperfect amaurosis to be accompanied with what Beer terms obliquity of the eye, (*Lusitas*;) either a paralysis of one or other of the muscles of the eye, or a ceaseless, irregu-

lar action of one or more of the same muscles, being evidently a condition of this symptomatic appearance. (See Beer's *Lehre von den Augenkrankheiten*, B. 2, p. 427.)

Beer has often met with patients labouring under imperfect amaurosis, who could plainly distinguish all objects, which were not very small; but saw them of a different colour from their real one; for instance, yellow, green, purple, &c. (*Visus coloratus; crupsia*.) He had under his care an amaurotic woman, who at midday could discern even the smallest objects in a strong light; but, they all appeared yellow, though no marks of jaundice were perceptible.

Sometimes, in the early stage of amaurosis, all objects appear quite distorted, bent, shortened, and, in rarer instances, inverted. (*Visus defiguratus; Metamorphosis*.) Thus the flame of a candle appears very long, but all awry. This is constantly an unfavourable omen, as the cause of it lies in the brain itself.

Imperfect amaurosis is sometimes attended with considerable shortsightedness (*Myopia*;) and sometimes with the opposite affection (*Presbyopia*;) an infallible proof that essential changes have happened either in the transparent media or in the muscles of the eye.

Many patients, when first attacked with amaurosis, every where testify a partiality to a great quantity of light, employing several candles at night, and sitting the day-time with their backs against a sunshiny window, in order to let whatever they are reading have a very strong light upon it. This symptomatic appearance of incipient amaurosis is termed by Beer, *Lichthunger*.

Amaurosis may either take place in an instant, even so as to be attended with entire blindness; or it may come on quickly, that is, it may be complete in a few days or weeks; or, lastly, what is most frequently the case, it may be produced gradually, and several years elapse before it attains its utmost degree; circumstances of great moment in the diagnosis and treatment.

The type, which the disease assumes in its course and development, is also subject to great variety, and claims the utmost attention; for, amaurosis may either be permanent, or temporary. The gutta serena is sometimes an intermittent disorder, making its appearance at regular or irregular intervals. In certain examples, as Richter remarks, the disease prevails at particular times, commonly all day, till a certain hour; or from one day till the next; or at a stated time every month. The attacks of the complaint sometimes take place at indeterminate periods. In particular cases, another morbid affection is associated with the impairment of sight. Richter mentions a man, who became blind at twelve o'clock in the day, when the upper eyelid used also to hang down, in consequence of being affected with paralysis. The attack always lasted twenty-four hours. On the following day, at twelve o'clock, the sight used

to return, and the patient then suddenly regained the power of raising the upper eyelid. He would continue thus able to see for the space of the next twenty-four hours. Whenever he took bark, the disease was regularly doubled; that is to say, the man then alternately remained blind forty-eight hours, and recovered the power of seeing for only twenty-four. In another patient, cited by this experienced surgical writer, the aqueous humour, during the blindness, always became discoloured, whitish, and turbid; but its transparency regularly returned on the cessation of the attack. According to Richter, the periodical amaurosis commonly depends upon irritation affecting the digestive organs, the stimulus of worms, or irregularity in the menstrual discharge. Sometimes, it is plainly a symptom of a confirmed ague, the patient being attacked with an ordinary intermittent, and blind during each paroxysm, but always regaining his sight as soon as each fit is over. (See Richter's *Anfangsgr. der Wundarzn.* B. 3, Kap. 14.) Beer believes, however, that the periodical gutta serena is chiefly observed in chlorotic, hemorrhoidal, hysterical, and hypochondriacal subjects. Dayblindness (*Cæcitas Diurna; Nyctalopia*;) and nightblindness (*Cæcitas Crepuscularis; Hemeralopia*;) are nothing more than cases of periodical amaurosis. But sometimes the frequently recurring form of the disease confines itself to no determinate type; and, on account of its irregularity, it is then termed by Beer, *Amaurosis Vaga*, which he says is often of spasmodic origin, and therefore principally met with in persons liable to hysteria, hypochondriasis, convulsions, or epilepsy. Periodical amaurosis, after remaining uncured a certain time, often becomes permanent. (Beer, *Lehre*, &c. B. 2, p. 429.)

In amaurosis in general, but particularly when no material knowledge can be acquired of causes, and the treatment must of necessity be conducted on empirical principles, it is of the highest importance to recollect what Richter has pointed out, namely, that amaurosis sometimes commences with several symptoms, which seem to betray an increase of sensibility in the eye, or some irritation affecting this organ. In moderately light places, the patient can discern things very well; but, in a great light, he is not able to see at all. The eye is sometimes so sensible, that a strong light will make it weep and become painful. Patients of this description ought always to wear a shade, however bad their sight may be. Sometimes the gutta serena originates with symptoms of weakness and diminished irritability. The sight is cloudy, and the patient finds that he can see better in a light than a dark situation. He feels as if some dirt, or dust, were upon his eyes, and is in the habit of frequently wiping them. His power of vision is greater after meals than at the time of fasting. His sight is always, for a short time, plainer, after the external use of tonic remedies,

such as hartshorn, cold water, &c. Richter informs us of a person, who was nearly quite blind, but was constantly able to see very well, for the space of an hour, after drinking champagne wine. He also mentions a woman entirely bereft of sight, who was in the habit of having it restored again for half an hour, whenever she walked a quick pace up and down her garden. This author likewise acquaints us with the case of a lady, who had been blind for years; but, experienced a short recovery of her sight, on having a tooth extracted. (*Anfangsgr. &c. B. 3. Kap. 14.*)

When the disorder is accompanied with a diminished sensibility in the eye in general, Professor Beer joins Richter, with respect to the temporary improvement of the sight after a nourishing meal, or drinking spirituous liquors; or when the patient's mind is elated with joy, or anger, though such melioration of sight, it is true, is but of very short duration.

On the other hand, it may be remarked, that every thing, which tends to depress the passions and spirits, augments the imperfection of sight. Where marks of increased sensibility prevail, the above-mentioned circumstances exercise a transient disadvantageous operation; the patient carefully retires from every strong light, and frequently shelters his eye with his hand, &c. (*Lehre von den Augenkr. B. 2, p. 430.*)

Amaurosis either presents itself as a genuine uncomplicated affection, or, at least, with the appearance of such a form of disease of the eye, depending solely upon a morbid state of the optic nerve, and cognizable by a diminution, or complete abolition, of the power of vision; or the disease is coexistent with other diseased appearances either in the eye, its vicinity, or some other organs at a distance from the eye, or in the general constitution. These appearances merit the most earnest consideration, because they are for the most part connected with the cause of amaurosis. According to this statement, then, there is a *genuine local amaurosis*, and a *complicated amaurosis*, which last may be either *local*, or *general*, or of both descriptions together, and therefore named by Beer, *perfectly complicated*. (*Vol. cit. p. 431.*)

On the whole, genuine local amaurosis, that is to say, a diminution or total loss of the eyesight, unattended with any other apparent local or constitutional defect, may be said to be a very rare case, the disorder being usually more or less complicated.

To the hitherto ascertained local complications, says Beer, belong the cataract; glaucoma; a general varicose state of the eyeball (*circsophthalmia*); exophthalmia; atrophy of the eye; spasms in the organ and surrounding parts; paralysis of one or more muscles of the eye (*ophthalmoplegia*); paralysis of the eyelids; ophthalmia in general, and internal ophthalmia in particular; a scorbutic blood-shot appearance of the eye; (*Hypaemia Scorbuticum*); and, finally,

wounds or contusions of the eye or adjacent parts. From this simple enumeration of local complications, one may see how frequently, under such circumstances, amaurosis is only a symptomatic effect of another disorder of the eye, with which it is conjoined, and how often it is connected with the same common causes, which pertain to another or several other diseases of the eye, as for instance, in gouty subjects, with glaucoma, cataract, circsophthalmia, &c.

Among the general complications, Beer enumerates those which are purely nervous; impairment of the health in various forms by infection, contagion, or miasmata; a bad habit of body; typhoid fevers; asthma; internal and external hydrocephalus; organic defects of the abdominal viscera; worms; chlorosis; consumption; old ulcers of the legs; organic disease of the brain and skull; complaints arising from pregnancy; hemorrhage, &c. In these general complications, Beer remarks that the casual connexion between amaurosis, and some other remote disease of another organ, or of the whole constitution, cannot be mistaken; and, says the same author, in these cases, we often see the disease of some other distant part from the eye, suddenly or gradually diminish, and immediately appear again as a sympathetic action in the form of amaurosis, of which the most remarkable instance is seen after the sudden healing of old ulcers of the legs. (*Beer, Lehre von den Augenkr. B. 2, p. 433.*)

From the above general remarks upon amaurosis, it is quite manifest, that the objective and subjective symptoms of the disease vary considerably according to the violence of its causes, and of the local and general complications, though the seat of the disease, and what is particularly the proximate cause of the loss of vision, be in the optic nerve; and it depends especially on the nature of the causes, whether this or that morbid appearance take place in the eye.

One may consider as the only real inseparable subjective symptom of amaurosis, that weakness of sight, (*Amblyopia*) or that complete blindness, in which neither with the unassisted nor assisted eye the least defect can be perceived in the structure and shape of the affected organ. Hence, Beer names such impairment of vision, or blindness, *amaurotic*. But how seldom this subjective symptom of amaurosis exists alone, and how frequently it is obscured by some other defect in the structure and form of the eye, is proved by daily experience.

The objective symptoms of amaurosis have hitherto been set down as merely consisting of a considerable dilatation of the pupil, and immobility of the iris, because these appearances are indeed the most frequent; but, as Beer observes, this is another proof what ignorance has prevailed respecting the true nature of that disease of the eye, and its modifications, which are usually termed amaurosis; the objective symptoms of the complaint being, accord

ing to the nature of the causes, as numerous as the subjective.

First; the objective symptoms of amaurosis may consist in the faulty size and shape of the pupil. In many cases, the pupil is very much dilated, immoveable, and possesses its natural black colour, and usual transparency. It cannot be denied, that this is the state of numerous cases; but, it is equally true, that there are many exceptions. Sometimes, according to Richter, in the most complete and incurable cases, the pupil is of its proper size, and even capable of very free motion (*Tarbes, Recueil Periodique, &c. T. 2, p. 319*;) and, occasionally, it is actually smaller, and more contracted, than natural. This aperture often continues extraordinarily large in the strongest light; but in some instances it is unusually small in every kind of light. (*Arrachard, Recueil Period. &c. T. 1, p. 273.*—*Richter, Anfangsgr. &c. B. 3, p. 424*; *Beer, Lehre, &c. B. 2, p. 435.*) According to the latter writer, the pupillary edge of the iris rarely has its primitive shape, being generally more or less angular; either at some indeterminate point; or above and below, so as to resemble in some measure the pupil of the cat-race; or towards the nose, or temple, so as to have some similitude in its form to the pupil of ruminating animals. These appearances are highly important, having great influence over the diagnosis.

Frequently not only the size and shape of the pupil are faulty, but the position of that opening is quite unnatural, being inclined either upwards or downwards, or outwards or inwards; but most commonly in a diagonal line between inwards and upwards, and, in these cases, the pupillary margin of the iris never describes a regular circle, but is always more or less angular. (*Beer, Vol. cit. p. 436.*)

The pupil of an eye affected with amaurosis (as Richter remarks) seldom exhibits the clear shining blackness, which is seen in a healthy eye. In general it is of a dull, glassy, hornlike blackness, which symptom alone is frequently enough to apprise a well-informed practitioner of the nature of the disease. Sometimes the colour of the pupil has an inclination to green; while, in other examples, this aperture seems to be dense, white, and cloudy, so that the complaint might easily be mistaken for the beginning of a cataract. This error, into which inexperienced surgeons are liable to fall, may readily be avoided by attention to the following circumstances. The misty appearance is not situated close behind the pupil, in the place of the crystalline lens; but, frequently, is manifestly deeper in the eye. Nor is it in proportion to the impairment of sight, the patient being quite blind, while the misty appearance is so trivial, that, if it arose from the opacity of the crystalline lens, it could at most only occasion a slight weakness and obscurity of vision. At the same time, Richter acknowledges, that it must be more difficult to

avoid mistake, when a beginning amaurosis is accompanied with this cloudiness in the eye, and, consequently, when the degree of blindness seems to bear some proportion to the degree of mistiness in the pupil. However, in this case, if we are to credit Richter, the true nature of the disease may generally be known by comparing the ordinary symptoms of the two diseases. (*Anfangsgr. B. 3, p. 14.*) And, according to Professor Beer, when the pupil is of a true dark gray, or greenish gray colour, a lateral inspection of the eye will show plainly enough, that the cloudiness is in the vitreous humour, or behind it. Sometimes, the pupil appears reddish, quite red, or of a yellowish white colour; (*Lehre von den Augenkr. B. 2, p. 436.*) while in other cases, the interior of the eye, a good way behind the pupil, seems quite white, and a concave light coloured surface may be observed, upon which the ramifications of blood-vessels can be plainly seen. In particular instances, this white surface extends over the whole back part of the eye; while, in other cases, it only occupies a half or a small portion of it. This peculiar appearance has been ascribed to a loss of transparency in the retina itself, and a consequent reflection of the rays of light. (*Haller, Element. Physiol. Tom. 5, p. 409.*)

There can now be no doubt, that such whiteness behind the pupil must sometimes have originated from the diseased mass, which, in cases of fungus hæmatodes of the eye, grows from the deeper part of this organ, and gradually makes its way forward to the iris, being always attended with total loss of sight. Putting out of present consideration the change of colour within the eye, produced by fungus hæmatodes, the other palish changes behind the pupil are not confined, as Kieser supposes, to very old cases of amaurosis, because the alteration is described by Schmucker as taking place especially in examples, the formation of which has been quite sudden; (*Vermischte Chir. Schrift. B. 2.*) and Langenbeck has recorded cases, in which the same appearance happened in the early stage of the disease. (*Neue Bibl. B. 1, p. 64, &c.*)

Besides the above appearances in the pupil itself, and in the pupillary margin of the iris, Beer adverts to several important phenomena, with respect to the motion of the iris. Sometimes the iris moves but very inertly, and frequently not at all, though the light be strong, and the upper eyelid be rubbed over the eyeball. While, in other examples, a very moderate light will bring on such a rapid contraction of the iris and closure of the pupil, as are never witnessed in a healthy eye.

We have also the authority of Richter for asserting, that, in particular instances, the iris not only possesses a power of motion, but is capable of moving with uncommon activity, so that, in a very moderate light, it will contract in an unusual degree, and nearly close the pupil. (*Anfangsgr. der Wundarzn. B. 3, p. 424, Edit. 1796.*)

Two or three remarkable instances of the

active state of the iris, in cases of amaurosis, were some years ago shown to me by Mr. Albert, then staff surgeon of the York Hospital, Chelsea, and I have seen some other similar cases in St. Bartholomew's Hospital. Most of the patients in question had not the least power of distinguishing the difference between total darkness and the vivid light of the sun, or a candle placed just before their eyes. Janin and Richter have likewise seen the pupil capable of motion in this disease, and Schmucker has twice seen the same fact.

In some anomalous cases, when the strength of the light is suddenly increased, the pupil expands with more or less celerity.

I have already adverted to the occasional moveableness of the iris, notwithstanding the insensible state of the retina. Let me next take notice of a case which sometimes presents itself, and is quite the reverse of this last. The nerves of the iris may be paralytic, while those of sight continue unimpaired. Schmucker tells us, he was acquainted with a woman, whose pupil was uncommonly distended, and totally incapable of motion. Her sight was very weak, and spectacles were of no use to her. She could scarcely discern any thing by day, or in a strong light; but she could see rather better at night and in dark places. This infirmity of sight depended upon the dilated paralytic state of the pupil, by which too many rays of light were admitted into the eye; and the reason why the patient could see better at night was, because the pupil, in its natural state, always becomes widened and dilated in a dark situation. (See *Vermischte Chirurgische Schriften, Von J. L. Schmucker, Band 2, p. 13, 14.*)

Frequently, in amaurosis, when the sight of only one eye is lost, and the other retains its full power of vision, not the slightest defect can be discovered, as long as the patient keeps both eyes open; but the instant the sound eye is completely covered, the iris becomes perfectly motionless, its pupillary margin assumes an angular shape, and the pupil expands, being sometimes evidently drawn towards the edge of the cornea. (Beer, *Lehre von den Augenkrank. B. 2. p. 438.*)

Besides the above appearances of the pupil and iris, amaurosis is attended with other characteristic phenomena, which occur, under certain circumstances, in the form, texture, and state of other parts of the eye, and adjoining organs. Thus, the patient often complains of a peculiar troublesome dryness of the eye, or of a sensation as if the eyeball were about to be pressed out of its socket; and, indeed, says Beer, one may sometimes hear a grating noise, and distinguish a fluctuation in the orbit behind the eye-ball, when this organ is pressed upon by the finger, or moved in various directions, though neither its circumference be enlarged, nor any tendency to exophthalmia be really present. Nor is it very uncommon to find the affected eye

preternaturally hard, soft, or even quite flaccid; but it is less common to find the dimensions of the globe of the eye increased, or the organ affected with atrophy. (Beer, *Vol. cit. p. 438.*)

The principal subjective morbid effects, which appertain to amaurosis, have been already described in speaking of the several defects of vision, which accompany an amaurotic weakness of sight. Besides these, however, there are other subjective symptoms, which merit attention. For instance, the patient feels in the eye and surrounding parts an irksome sensation, without any actual pain, and complains of a remarkable sense of fulness, or weight in the organ. Amaurotic patients are also frequently attacked with sudden violent giddiness, which usually ends in a considerable diminution of the eyesight, and sometimes in severe general headach. Occasionally they fancy that small atoms of dust are lodged under the eyelids, and are fearful of moving either these parts or the eye. It is also well known, that many persons become amaurotic, while labouring under severe hemicrania, which either extend from or to the diseased eye; while, on other occasions, the most violent pains are confined particularly to the region of the eyebrow, and have the appearance of being strictly periodical. In certain other cases, the pain is wandering, and shoots in every direction about the eyebrow. These painful feelings often precede the amaurotic blindness a considerable time, and often first take place when one or both eyes are already blind; but the pains and loss of sight are not unfrequently produced together. Lastly, some patients are met with, in whom the worst pains only last until the amaurosis is perfectly formed, when they gradually and permanently cease. In all these painful cases of amaurosis, the pain and the blindness chiefly depend upon the same cause, and one is seldom the occasion of the other. Sometimes amaurotic patients experience such violent pain, that they lose their senses, and grow delirious; but in these cases, if we can credit the assertion of Beer, important morbid changes in the bones of the skull, or the brain itself, are invariably noticed after death. (See *Lehre von den Augenkr. B. 2, p. 439.*) In some amaurotic patients, lethargic symptoms may be remarked: in others restlessness; and, more rarely, delirium in all its degrees, either as a transient or permanent affection.

Paralytic appearances may precede amaurosis, either in the vicinity of the eye, or in the muscles of the face, or in a distant situation, as the extremities. Sometimes they accompany the disease, and sometimes closely follow the amaurotic amblyopia; such a case of amaurosis being not unfrequently the forerunner of a fatal attack of apoplexy.

In the same way convulsive symptoms may be conjoined with amaurosis, and when they first occur in the complete stage

of the latter disease. Beer pronounces them a very unfavourable omen for the patient's life.

But, according to the same experienced oculist, when in a case of perfect amaurosis, several of the other external senses are affected; and lastly, when the internal senses begin to suffer, when, for instance, the hearing, and then the smell, and taste are lost, and afterwards the memory and other intellectual powers fail, the patient's speedy dissolution may be expected. (See *Lehre, von den Augenkrankh. B. 2, p. 441, Wien. 1817.*)

As Professor Beer correctly observes, age cannot be considered a predisposing cause of amaurosis, as it is of a cataract; for there are many more blind persons who have been deprived of their sight by amaurosis in their best days, than of old persons thus attacked. Amaurosis spares no age, not even the new-born infant.

Neither does sex nor race appear to have any influence over the origin of the complaint; but it would seem that dark eyes, especially those which are called black, are more disposed to amaurotic blindness than such as are light coloured. According to Beer's experience, for every gray or blue eye affected with amaurosis, there are five and twenty or thirty brown or black ones, thus diseased. In the peculiar constitution of the eye, then, as well as in a sanguineous and choleric temperament, there exists a tendency to the disorder.

More frequently than cataract, amaurosis is found to be a true hereditary disease. This is so much the case, that most of the members of a family, for more than one generation, may lose their sight from amaurosis at a certain period of life. Beer says, that he is acquainted with more than one family in which this has happened; and, what merits attention, the women of one of these families, down to the third generation, became completely and permanently blind from amaurosis on the cessation of the menses, while all the others, who had had children, were unaffected. But the males of this unfortunate family, who, as well as the females, have very dark brown eyes, all seem to be weak-sighted, though none of them are yet blind. (*Lehre von den Augenkrankheiten, b. 2. p. 443.*)

In women, especially those with black eyes, the time when the menses stop is a dangerous period for the commencement of amaurosis, particularly that form of it which Beer chooses to denominate *gouty*.

According to the same writer, patients, whose piles used to bleed periodically for a long time, but are now suddenly stopped, and whose eyes are dark, are often attacked with amaurosis.

One of the less common causes of amaurosis is an idiosyncrasy in relation to this or that sort of nutriment or medicine, or this or that particular state of the body. Here is to be reckoned the amaurotic weakness of sight, or the perfect amaurosis, which

comes on at the very commencement of pregnancy, and subsides after delivery, but always attended with dyspepsia and insuperable vomiting. This species of amaurosis, however, should be carefully distinguished from that which sometimes first originates in the final months of pregnancy, and chiefly from strong and long-continued determination of blood to the head and eyes, particularly when the bowels are at the same time loaded, and the patient constipated. This latter case usually continues till after delivery; or, if the labour be tedious, difficult, and attended with considerable efforts, the blindness may first attain its complete form at the time of delivery, and not afterwards subside.

Beer saw a young Jewess, who at the very beginning of her first three pregnancies, which followed each other very quickly, regularly used to lose her sight, becoming completely amaurotic between the third and fourth months; and, on the two first occasions, she continued blind till after delivery; but, in the third instance, the power of vision never returned at all. Beer twice had under his care another woman, who was attacked with amaurosis whenever she drank chocolate; but, upon leaving off that drink, she never afterwards had any complaint in her eyes.

If we are to believe Professor Beer, the abuse of bitter substances, as of chicory in coffee, bitter malt liquors, and bitter medicines, especially quasia, is unquestionably a predisposing cause of amaurosis.

The abuse of narcotic poisonous substances may induce amaurosis; immoderate doses of opium, hyoscyamus, belladonna, &c. Lead will do the same thing. Beer mentions a case in which the only assignable cause was the exhibition of pills, containing the extractum cynoglossi.

One not unfrequent and very important cause of amaurosis is hysteria and hypochondriasis, with which must be included infarction generally, and induration of one or more of the abdominal viscera, especially the liver. (*Beer, Lehre, &c. B. 2. p. 444-46.*)

According to Richter, the remote causes of gutta serena may be properly divided into three principal classes, the differences of which indicate three general methods of treatment.

It is alleged, that the first class of causes seem to depend upon an extraordinary plethora and turgidity of the blood-vessels of the brain, or of those of the optic nerves and retinae, upon which last parts a degree of pressure is thereby supposed to be occasioned. A considerable plethora, especially when the patient heats himself, or lets his head hang down, will frequently excite the appearance of black specks before the eyes, and sometimes complete blindness. A plethoric person (says Richter,) who held his breath, and looked at a white wall, was conscious of discerning a kind of network, which alternately appeared and disappeared with the diastole and systole of

the arteries. This phenomenon, it is conjectured, originated from the plethoric state of the vessels of the retina. Boerhaave mentions a man, who always lost his sight on getting tipsy, and regained it on becoming sober.

Richter thinks it likely, that it is in this manner that the disease is produced, by the suppression of some habitual discharge of blood, by not being bled according to custom, by the stoppage of the menses, and by the cessation of hemorrhage from piles; circumstances, which, if we can give credit to all the accounts of Richter, Scarpa, Schmucker, and other experienced writers on the subject, frequently give rise to gutta serena. In the same manner, the complaint may be brought on by great bodily exertions, which must determine a more rapid current of blood to the head. Richter informs us of a man who became blind all on a sudden, while carrying a heavy burden up stairs. He tells us of another man, who laboured excessively hard for three days in succession, exerting his strength very much, and who became blind at the end of the third day. Pregnant women, in like manner, are sometimes bereft of their sight during the time of labour. Schmucker has recorded a remarkable instance of this in a strong young woman, thirty years old, and of a full habit. Whenever she was pregnant, she was troubled with violent sickness till the time of delivery, so that nothing would stop in her stomach. She was bled three or four times without effect. Towards the ninth month her sight grew weak, and for eight or ten days before parturition she was quite blind. The pupil of the eye was greatly enlarged, but retained its shining black appearance. She recovered her sight immediately after delivery, and did not suffer any particular complaints. Schmucker assures us, that he has been three times a witness of this extraordinary circumstance. (*Vermischte Chir. Schriften, Band 2, p. 6, edit. 1786.*) Richter speaks of a person who lost his sight during a violent fit of vomiting. Schmucker acquaints us, that it is not uncommon for soldiers, who are performing forced marches in hot weather, to become blind all on a sudden. All great exertions of strength, when the body is plethoric, or heated, or bent forwards with the head in a low posture, are usually attended with some danger of bringing on amaurosis.

The blindness which follows external injuries of the head, is ranked by Richter among the preceding class of cases. A man who received a smart box on the ear, says this author, lost his sight on the spot. Richter conceives it probable, that a concussion of the head may sometimes produce an atony of the blood-vessels, giving rise to their dilatation, and consequent pressure on the adjacent nerves: perhaps, it is more likely, that the blow itself actually ruptures them, and produces an effusion of blood. Richter suspects that the gutta serena,

which originates during a violent ophthalmia, or during a severe inflammatory fever, may be of the same nature. He thinks it probable, that persons, who become blind while exposing themselves to the burning sun, with their heads uncovered, have their sight impaired in a similar way.

Beer also coincides with Schmucker, Richter, and others, in regarding as a frequent cause of amaurosis, repeated and long continued determinations of blood to the head and eyes, produced by various circumstances,—viz. by pregnancy; a tedious and difficult labour; lifting and carrying heavy burdens, especially with the arms raised up; all kinds of work in which the eyesight and intellectual faculties are intensely exerted, with the head bent forwards, and the abdomen compressed, as is the case with shoemakers, tailors, &c.; every sudden stoppage of natural or preternatural long established discharges of blood, as that of the menses, lochia, or hemorrhoids; the omission of an habitual venesection at some particular season of the year; severe and obstinate vomiting; forced marches in hot dry weather; scrofulous and other swellings of considerable size in the neck, pressing upon the jugular veins, and obstructing the return of blood from the head; the use of a pediluvium, or warm bath, the water of which is of high temperature; hard drinking; violent gusts of passion; frequent and obstinate constipation; and hard straining at stool. These causes are more likely to occasion amaurosis, in proportion as the individual is young and plethoric. (*Beer Lehre von den Augenkr. B. 2. p. 446.*)

The second class of causes are supposed to operate, by weakening either the whole body, or the eye alone, and they indicate the general or topical use of tonic remedies. In the first case, the gutta serena appears as a symptom of considerable universal debility of the whole system; in the second case, the disease is altogether local. Every great general weakness of body, let it proceed from any cause whatsoever, may be followed by a loss of sight. The gutta serena, if we can give credit to the statement of Richter, has sometimes been the consequence of a tedious diarrhoea, a violent cholera morbus, profuse hemorrhage, and immoderate salivations. He informs us of a dropsical woman, who became blind on the water being let out of her abdomen. According to the same author, no general weakening causes operate upon the eyes, and occasion total blindness so powerfully and often, as premature and excessive indulgence in venereal pleasures.

The causes are various which operate locally in weakening the eyes. Nothing has a greater tendency to debilitate these organs than keeping them fixed very attentively, for a long while, upon minute objects. But, however long and assiduously objects are viewed, if they are diversified, the eye suffers much less than when they

are all of the same kind. A frequent change in the objects which we look at has a material effect in strengthening and refreshing the eye. The sight is particularly injured by looking at objects with only one eye at a time, as is done with telescopes and magnifying glasses; for when one eye remains shut the pupil of that which is open always becomes dilated beyond its natural diameter, and lets an extraordinary quantity of light into the organ. The eye is generally very much hurt, by being employed in the close inspection of brilliant, light-coloured, shining objects. They are greatly mistaken, says Richter, who think that they save their eyes when they illuminate the object which they wish to see, in the evening, with more lights, or with a lamp that intercepts and collects all the rays of light, and reflects them upon the body which is to be looked at. Richter makes mention of a man, who, in the middle of winter, went a journey on horseback, through a snowy country, while the sun was shining quite bright, and who was attacked with amaurosis. He speaks of another person, who lost his sight, in consequence of the chamber in which he lay being suddenly illuminated by a vivid flash of lightning. A man was one night seized with blindness, while he had his eyes fixed on the moon in a fit of contemplation. Richter also expresses his belief, that a concussion of the head, from external violence, may sometimes operate directly on the nerves, so as to weaken and render them completely paralytic.

Professor Beer corroborates the foregoing statement; for, he says, among the most frequent causes is to be considered every abuse of the eyesight, especially in dark-eyed persons, as a long and close inspection of one object, particularly with a microscope, when the thing examined is very brilliant, or reflects back much light into the eye. Hence, the view of jewels at night, and long journeys through snowy countries, &c. are conducive to the disease. In this respect, every kind of employment which strains the eyes much, and requires a strong reflected light, must be considered injurious. Thus reverberating lamps, like Argand's; a white wall opposite the windows, and illuminated with the sun's rays, and looking a long while at the moon, or more especially the sun, with the unassisted eye, are circumstances likely to bring on the disease. That a flash of lightning, especially when it suddenly wakes a person in the night-time out of a sound sleep, may produce an amaurotic amblyopia in an irritable eye, or even perfect blindness, is a well-known fact; and, it is on the same principle, that going suddenly out of a dark bed-room immediately after waking in the morning into an apartment that commands an open extensive prospect, must be hurtful to an irritable eye, though the bad effects may only be very slow. Here is also to be included every kind of over irritation of the eye by light, as happens to typhoid pa-

tients, when they lie with their eyes open all the day in a large sunny chamber.

Very often the cause of amaurosis consists in local or constitutional debility, proceeding from impairment of the nerves in general, or of the nerves of the head, especially those of the forehead and eyebrow; either from a concussion of the spinal marrow, falls from a considerable height with the weight of the whole body upon the heels; concussions of the eye-ball, sometimes caused by violent artificially excited sneezing, but more generally by contusions of the eye with blunt weapons, &c. If we are to believe Beer, and other foreign practitioners, considerable direct weakness may arise from cholera, long-continued diarrhoea, salivation, and the incessant spitting of tobacco-smokers; bleedings; injudicious tapping of the abdomen; excessive indulgence in venery, and the misemployment of issues. A general debility, which has the worst effect on the eyes, may also arise from long trouble; tedious vexation, and worldly cares, especially when the diet is poor and bad; also from a deficiency of proper food; long watching; violent and sudden fright; imprudently washing the eyes with very cold water, especially when they are already weakish and irritable; and keeping them long in a dark place, particularly when they are also exerted a good deal in some particular kinds of labour, a case which Beer says is very frequent in Vienna. The amaurosis, following typhus, without any unusual irritation of the eye by light. Beer also refers to general debility. (*Lehre von den Augenkr. B. 2. p. 449.*)

The third class of causes consists of irritations, which in some inexplicable way affect the optic nerves, and render them insensible of the impression of the light. Most of these irritations are asserted to lie in the abdominal viscera, whence they sympathetically operate upon the eyes. The observations of Richter, Scarpa, and Schmucker, all tend to confirm, that amaurosis more frequently arises from irritation in the gastric organs than any other cause whatever. It may often be ascertained, that patients with amaurosis have suffered much trouble, and long grief, or been agitated with repeated vexations, anger, and other passions, which are supposed to have a great effect in disordering the bilious secretion, and the digestive functions in general. Richter tells us of a man, who lost his sight a few hours after being in a violent passion, and recovered it again the next day, upon taking an emetic, by which a considerable quantity of bile was evacuated. A woman is also cited, who became blind whenever she was troubled with what are termed acidities in the stomach. (*See Anfangs. der Wundarzn. B. 3, Kap. 14.*) However, according to Beer, the imperfect amaurosis seldom depends upon disorder of the gastric organs, excepting the case from worms: (*Lehre von den Augenkr. B. 2. p. 456.*) a very important difference of opi-

nion from that entertained by Schmucker, Richter, and Scarpa.

The continental surgeons are excessively comprehensive in their ideas of the causes of gutta serena, and, with many truths, they blend an evident quantity of unestablished conjectures, and palpable absurdities. I believe, it will generally be found, that, when surgical writers assign a multitude of causes for any disease, they deal very much in mere supposition. It would be idle credulity, indeed, to put faith in the assertions concerning amaurosis being occasioned by the bad treatment of particular fevers, suppressed diarrhoeas, the repulsion of eruptive complaints, &c. There is no reason why a person should not become blind about the time when another disorder gives way; but we ought to have some other ground for the doctrines, to which allusion is made, before we can presume to offer them as entitled to confidence. These observations apply to some of the causes of amaurosis enumerated by Beer, of whose sentiments I mean presently to give a full account.

Worms in the alimentary canal are alleged to be sometimes the cause of amaurosis; and, since a disordered state of the gastric organs is universally acknowledged to be frequently concerned in the production of blindness, we can have no difficulty in conceiving that worms may likewise have the same effect. Besides gastric irritations, there are some others which class as causes of this disease. A violent fright, which is considered as being a frequent remote cause of gutta serena, is supposed by Richter to operate chiefly by irritating the nerves.

The blindness sometimes proceeds from a mechanical kind of irritation. A man received in his right orbit a small shot, which pierced the upper eyelid, and lodged at the upper part of the socket, between the eyelid and eyeball, so that it could be felt externally. Richter adds, that this patient shortly afterwards became blind in the left eye; but recovered his sight in it again upon the excision of the shot. (*Anfangsgr. der Wundarzn. Band 3, p. 439.*)

Sometimes, says this experienced surgeon, the irritation, exciting amaurosis, seems to have its seat in the mucuous membrane of the nose and frontal sinuses. We have already adverted to the unusually dry state of the nostril, that has been suspected of being occasionally conducive to this species of blindness.

According to Beer, several constitutional disorders, but more especially gout, are frequently concerned in the production of amaurosis.

Respecting the causes of amaurosis, the following remarks by Beer claim attention. Various swellings in the orbit, as, for instance, encysted tumours, tophi, hydatids in the sheath of the optic nerve, may, and must gradually produce complete amaurosis by their pressure upon the optic nerves and retina. These cases are usually

characterized by a protrusion of the eye from its socket. (See *Exophthalmia*.)

In the same manner, different morbid changes in the brain itself, and in the bones of the cranium in particular, may be the direct cause of amaurosis: for example, hydrocephalus internus, caries, and exostoses at the basis of the skull.

Just as amaurosis is frequently a pure symptomatic effect of various disordered states of the constitution, so may different morbid changes, occasioned in the eye by those states of the health, become the proximate cause of amaurosis, as hydrophthalmia, cirsophthalmia, dissolution of the vitreous humour, glaucoma, &c.

From a contagious atmosphere, which is generally injurious to the eyes, an amaurotic blindness may originate, though but very rarely, and, as it would seem, only through the powerful influence of such state of the air over the whole sanguiferous and nervous system. Debilitated, nervous, weak-sighted persons, by remaining long in the atmosphere of a privy (*Chomel, Mém. de Paris, 1711, Obs. Anat. 5. and Ramazzini, De Morbis Artificum, c. 13.*) that of a deep cellar, or exposed to coal-smoke, may be suddenly attacked with amaurosis; and Beer assures us, that his experience confirms the truth of these reports. (*Lehre, &c. b. 2. p. 452.*) A sympathetic affection of the nerves of the eye, with a carious grinder in the upper jaw-bone, is one of the most uncommon causes of amaurotic blindness.

A case, not yet duly considered, and very like the amblyopia senilis, consists of an incessantly diminishing secretion of the pigmentum nigrum upon the tunica Ruyschiana, choroidea, and uvea, which secretion indeed, in some individuals, earlier and more considerably; in others, later and in a slighter degree, recedes with other secretions of a different nature. In consumptive persons, this change happens in a remarkable degree, so that the patients are gradually quite bereft of vision. (See *Beer's Lehre von den Augenkr. B. 2. p. 451, &c.*) For a variety of additional facts and observations respecting the causes of amaurosis, I would advise the reader to consult *Wardrop's Essays on the Morbid Anatomy of the Human Eye, vol. 2. chap. 45*; a work replete with valuable information.

It is remarked by professor Beer, that amaurosis, when completely formed, has hitherto been but rarely cured. This (says he) may depend, in the first place, upon our far too imperfect knowledge of the nerves, and of their genuine and complicated disorders. Secondly, it may equally depend upon the present very defective etiology of amaurosis. Thirdly, the frequent incurability of amaurosis also very materially proceeds from the causes of the disease being, in most instances, not only obscured, but exceedingly complicated; and even when detected, many of them will not admit of removal, because they have their foundation either in the constitution

of the eye, long existing defects of physical and moral education, protracted bad habits of youth, or the unmanageable behaviour of the patient. Fourthly, we must take into the account the unconscientious indolence of the practitioner, who so often positively declines rendering the patient any assistance at all; or, if for the sake of lucre he attempt any thing, it is only an empirical mode of treatment, by which means every chance of benefit is annihilated, while an active and intelligent surgeon might perhaps preserve vision, and bring it to perfection again.

When there is a probability of relieving amaurosis, the cure is mostly tedious, and beset with many difficulties, though the blindness has originated and formed suddenly, the utmost attention, and the greatest practical skill, being requisite on the part of the surgeon. Hence, as Beer observes, even in favourable cases, either the patient himself, the surgeon, or both of them, lose all inclination to persevere in the treatment, and the unfortunate victim is either left to his fate, or consigned to impudent, mercenary quacks.

In amaurosis, the difficulty of cure is naturally in proportion to the variety and number of causes of the complaint; and the more readily the surgeon makes himself acquainted with them, and the more certainly he obviates them, the more surely and quickly does the cure follow.

It may be considered as generally true, that every amaurotic weakness of sight, and every completely formed amaurosis, are attended with the greatest probability of cure, where they began suddenly, and were quickly developed; for experience proves, that, in these cases, the whole of the causes of the disease are much more frequently and earlier comprehended than when the complaint has been several years in forming. — (Beer, *Lehre von den Augenkr. b. 2. p. 454—56.*) This observation perfectly coincides with the account given by Schmucker, who says, that many of these suddenly formed cases have fallen under his notice, and been more easy of cure, than when the disorder had come on in a more gradual way. (See *Vermischte Chir. Schriften, b. 2.*)

A case may happen, nay, it happens not unfrequently, says professor Beer, (which, considering the imperfect etiology of amaurosis, cannot be wondered at,) that the surgeon, after the most careful investigation, can absolutely detect no particular cause of the existing amaurotic blindness, in which event, the prognosis must in every respect be very uncertain and unfavourable, since only empirical treatment can be tried, which rarely answers; and, even when a cure in this manner does follow, it is frequently quite accidental.

As will be seen in the account of each particular species of amaurosis, the affected eye is sometimes so conditioned, that the complete incurability, sooner or later, may be prognosticated with entire certainty, and

this even though a degree of vision may now be enjoyed.

There are amaurotic patients, in whom every treatment does harm, the disease making uninterrupted advances to perpetual blindness. This observation especially refers to local remedies, of the danger of which, under certain circumstances, the patient should be carefully warned.

In general, the more complete the amaurosis is, and the longer the patient has been deprived not only of vision, but of all sensibility to light, the less hope is there of sight being ever re-established.

When one eye has been completely bereft of sight by amaurosis, and the surgeon can find out little or no cause for the infirmity, there is strong reason for apprehending that the other eye will sooner or later become blind. This is a fact amply proved by experience, and the exceptions are very rare.

According to Beer, the idea entertained by some writers is not built upon experience, that amaurotic patients, in whom the iris is still moveable, and the pupil not very much dilated, are more easily and frequently cured than others in whom the iris is perfectly motionless, and the pupil exceedingly dilated. For sometimes, during the treatment, or even spontaneously, the iris, after being quite immoveable, recovers its power of motion, yet the patient may not, at the same time, regain the slightest degree of vision; and on the other hand, many cases of perfect amaurosis are cured, without the iris recovering any of its mobility, and the pupil remains dilated during the remainder of the patient's life. (*Lehre von den Augenkr. b. 2. p. 458.*) Richter also thinks, that the moveable or immoveable state of the pupil can neither be considered as a favourable nor unfavourable circumstance. Sometimes, says he, an amaurosis may be cured, which is attended with a pupil extraordinarily dilated, and entirely motionless; and sometimes the disorder proves incurable, notwithstanding the pupil be of its proper size, and capable of motion. There are likewise examples, in which the pupil recovers its moveableness, in the course of the treatment, although nothing will succeed in restoring the eyesight. (*Anfangsgr. der Wundarzn. b. 3. p. 424. 8vo. Gott. 1795.*)

In some very rare instances, says Beer, amaurotic blindness has been cured by some apparently accidental, or indeed morbid effect, without any assistance from art; by hemorrhage from the nose, an intermittent fever, a blow on the head, &c. The same experienced writer operated successfully upon both eyes of a patient with cataracts, which had been previously depressed too far against the retina, so that their pressure gave rise to amaurosis, which, after continuing eight years, was suddenly removed by the patient's accidentally falling out of bed, and pitching upon the top of his head. (*Lehre von den Augenkr. b. 2. p. 458.*)

The following observations, made by professor Beer, respecting the prognosis, can-

not fail to prove interesting. There is a species of amaurosis, which gradually diminishes of itself; for instance, that which arises from hard drinking, or the effect of narcotic poisons, belladonna, opium, hyoscyamus, &c.

Sometimes imperfect amaurosis goes away, without any assistance from art, in consequence of the accession of some other disease, as an eruption, a discharge of matter from the ear, bleeding from piles, the menses, &c.

Also, in most cases, when the surgeon is so fortunate as to cure amaurosis, either by scientific or empirical methods, there still continues, for life, a considerable degree of amblyopia, more especially if the amaurosis has been complete.

Sometimes, by successful treatment, vision is in a great measure, or even entirely, restored in one eye; yet the other remains completely blind; or one eye sees again much sooner than its fellow, although they were both affected together with an equal degree of blindness.

It often happens that, though a material degree of vision returns in the course of the treatment, the faculty is restricted to a circumscribed point of the retina, so that the patient is enabled to see objects plainly only when they are held in a particular direction before him; while, in other directions, they are either quite invisible, or very indistinct. (*Beer, Lehre von den Augenkr. b. 2. p. 459, 60.*)

Professor Scarpa, of Pavia, has given an excellent account of the prognosis in cases of amaurosis. Some of his doctrines, however, founded on the humoral pathology, are hypothetical, and therefore purposely omitted in the following account. It also deserves notice, that the case supposed to originate from injury of the supraorbital nerve, is not always incurable. Scarpa only knows of one such cure, viz. the example recorded by Valsalva. (*Dissert. 2. § 11.*) But additional instances are reported by Hey (*Med. Obs. and Inq. vol. 5.*) by Larrey (*Mém. de Chir. Militaire, t. 4. p. 181.*), and Dr. Hennen (*Principles of Military Surgery, p. 346. ed. 2.*) According to Mr. Wardrop, it is only when this nerve is wounded, or injured, and not divided, that amaurosis takes place; for the blindness may sometimes be cured by making a complete division of the trunk nearest its origin. (*Essays on the Morbid Anatomy of the Human Eye, vol. 2. p. 180.*)

Amaurosis is divided by Scarpa into the perfect, or imperfect; inveterate, or recent; and continued, or periodical.

The perfect, inveterate amaurosis, attended with organic injury of the substance, constituting the immediate organ of sight, says Scarpa, is a disease absolutely incurable. The imperfect, recent amaurosis, particularly that which is periodical, is commonly curable; for it is mostly sympathetic with the state of the stomach and primæ viæ, or

dependent on causes which, though they affect the immediate organ of sight, are capable of being dispersed, without leaving any vestige of impaired organization in the optic nerve or retina.

When amaurosis has prevailed several years, in persons of advanced age, whose eyesight has been weak from their youth; when it has come on slowly, at first with a morbid irritability of the retina, and then with a gradual diminution of sense in this part, till total blindness was the consequence; when the pupil is motionless, not circular, and not much dilated; when it is widened in such a degree, that the iris seems as if it were wanting, and the margin of this opening is irregular and jagged; and, when the bottom of the eye, independently of any opacity of the crystalline lens, presents an unusual paleness, like that of horn, sometimes partaking of green, and reflected from the thickened retina, the disease may be generally set down as incurable. Kieser joins Scarpa in representing this alteration as an unfavourable omen, adding, that it only takes place in examples of long standing, and, that when it is considerable, the disease is incurable. Langenbeck differs, however, from both these authors, and particularly from Kieser, assuring us, not only that he has often seen this discolouration of the bottom of the eye in the early stage of amaurosis, but seen patients in this state soon cured. The cases which he has published, in proof of this statement, I have read with care, and find them completely satisfactory. Langenbeck agrees with other writers in imputing the appearance to a morbid change of the retina, and the treatment which he prescribes consists in the internal exhibition of the oxymuriate of mercury in small doses, and friction with mercurial ointment on the eyebrow and temple. (*See Langenbeck's Neue Bibl. für de Chirurgie, 1 b. p. 64—69, &c. Göttingen, 1815.*)

Cases, says Scarpa, may be deemed irremediable, which are attended with pain all over the head, and a continual sensation of tightness in the eyeball; which are preceded by a violent, protracted excitement of the nervous system, and then by general debility, and languor of the constitution, as after masturbation, premature venery, and hard drinking. There is no remedy for cases connected with epileptic fits, or frequent spasmodic hemicrania; nor for such as are the consequence of violent, long-continued, internal ophthalmia. Cases are incurable, also, when produced by violent concussions of the head, direct blows on the globe of the eye, or a violent contusion, or other injury of the supraorbital nerve, and this, whether the disease take place immediately after the blow, or some weeks subsequently to the healing of the wound of the eyebrow. Amaurosis is also incurable, when occasioned by foreign bodies in the eyeball, lues venerea, or exostoses about the orbit. Lastly, amaurosis is absolutely irremediable, when conjoined with a

manifest change in the figure and dimensions of the eyeball.

On the contrary, all cases of imperfect, recent amaurosis, whether the blindness be total or partial, are mostly curable, when not produced by causes, capable of contusing or destroying the organic structure of the optic nerve, and retina. This is especially true when the retina is in some degree sensible to the impression of light. Recent, sudden cases, in which the pupil is not excessively dilated, and its circle remains regular, while the bottom of the eye is of a deep black colour; cases, unaccompanied with any acute, continual pain in the head and eyebrow, or any sense of constriction in the globe of the eye itself; cases, which originate from violent anger, deep sorrow, fright, excessive fulness of the stomach, a foul state of this viscus, general plethora, or the same partial affection of the head, suppression of the menses, habitual bleedings from the nose, piles, &c. great loss of blood, nervous debility, not too inveterate, and in young subjects, are all, generally speaking, curable. Amaurosis is also, for the most part, remediable, when produced by convulsions, or the efforts of difficult parturition; when it arises during the course, or towards the termination of acute, or intermittent fevers; and when it is periodical, coming on at intervals, such as every day, every three days, every month, &c. (*Scarpa, Osservazioni sulle Malattie degli Occhi. cap. 20. Venez. 1802.*)

In general, when the treatment proves successful, the return of the power of vision is accompanied with a regression of the same characteristic effects, which were disclosed in the gradual advance of the disorder, viz. appearances as if there were before the eyes flashes of light, a cobweb, network, mist, or flaky substances. (*Beer, Lehre von den Augenkr. b. 2. p. 460. Wien. 1817.*)

Upon the commencement of the cure, there is also a return of the obliquity of sight; one of the most constant symptoms of imperfect amaurosis. This is a circumstance, which Mr. Hey took particular notice of in some cases, which fell under his observation many years ago: he says, that it was most remarkable in those persons who had totally lost the sight in either eye; for, in them, the most oblique rays of light seemed to make the first perceptible impression upon the retina; and, in proportion as that nervous coat regained its sensibility, the sight became more direct and natural. (*See Med. Obs. and Inq. vol. 5.*)

TREATMENT OF AMAUROSIS, OR GUTTA SERENA.

Where amaurosis is to be fundamentally cured, not upon empirical, but scientific principles, all the causes of the disorder must be ascertained, and, if possible removed, as in the treatment of every other complaint. How often, however, it is impossible to accomplish the one or other of

these objects, must be clear enough from the preceding observations, particularly those concerning the etiology of the disease; and hence it is not surprising that amaurosis should so frequently resist every endeavour to cure it.

The plan of treatment is to be regulated, first by the number and kinds of circumstances, which determine the form of the disorder; secondly, by its presence, degree, and duration. When only the chief causes can be ascertained, a scientific mode of treatment may always be instituted; though here it is very necessary to pay the utmost attention to those morbid effects in the constitution, and in the eye in particular, which appear to have no connexion with the causes of amaurosis, and merely exist as accidental cotemporary defects.

If no particular circumstances can be assigned as the cause of amaurosis, the surgeon has no alternative but the adoption of some empirical method of treatment; but, exclaims professor Beer, wo to the patient whose surgeon, under these circumstances, draws from a heap of what are considered remedies for amaurosis, as from a lottery, the first as the best!

In order to avoid this erroneous method; at all events, to do no harm, if no good be practicable; and not perhaps to render a half-blind person completely blind, instead of improving, or at least preserving, whatever remnant of vision there may be; the surgeon should act with great caution, and constantly bear in his mind, first, the constitution, sex, and age of the patient; secondly, his ordinary employments, and general mode of living; and, thirdly, the principal morbid appearances under which the amaurosis originated and was developed. (*Beer, Lehre von den Augenkr. b. 2. p. 462.*) But, what will be of the greatest assistance, is a correct acquaintance with the remedies for amaurosis in general, and the circumstances under which the use of this or that particular means is likely to be useful or detrimental. I know of no writer who has been so minute on this part of the subject as professor Beer, whose sentiments (be it also remarked) are here in many respects different from those of Richter and Scarpa; for, like the surgeons of this metropolis, he rarely employs the emetic plan of treatment, which, according to his principles, is not only ineffectual, but hurtful, whenever the blindness is attended with determination of blood to the head and eyes, plethora, an accelerated circulation, or (what is understood by) a phlogistic diathesis. Beer's opinions, respecting the employment of emetics, and other means for the cure of amaurosis, may be partly collected from the sequel of this article; but, more especially, from the fuller statement which will be made at a future opportunity. (*See Gutta Serena.*) In the mean time, I shall endeavour to offer a general account of the practice recommended by Schmucker, Richter, and Scarpa, according to the arrangement of causes adopted by

the second of these valuable writers, and already detailed in the foregoing pages; for I need not repeat that, whenever the method of cure can be directed against the causes of the disease, it is the most proper and scientific. The present article will, then, close with a description of the four forms into which Professor Beer divides amaurosis, and a history of their varieties, symptoms, and treatment, according to the doctrines and experience of this eminent oculist.

In that species of amaurosis, which arises from the first class of causes specified by Richter, namely, from those which seem to induce the disease, by means of a preternatural fulness and dilatation of the blood-vessels of the brain, or eye, the indication is evidently to lessen the quantity of blood, and diminish the determination of it to the head. For this purpose, the patient may be bled in the arm, temporal artery, or foot. This evacuation is to be repeated as often as seems necessary; and it will be better to begin with taking away from twelve to sixteen ounces. We are also advised by Schmucker to apply ten or twelve leeches to the neck and temples. The efficacy of bleeding, in the cure of particular cases of gutta serena, is strikingly exemplified by numerous well authenticated observations. Richter informs us of a woman, who, on leaving off having children, lost her sight; but recovered it again by being only once bled in the foot. A spontaneous hemorrhage from the nose also cured a young woman, who had been blind for several weeks. (*Anfangsgr. der Wundarzn. b. 3. p. 442.*)

General bleeding sometimes proves ineffectual, unless assisted by topical. Leeches may be applied to the temples, or cupping glasses to the back part of the neck. When the disorder is connected with chlorosis, or the cessation of bleeding from piles, leeches may be put on the perinæum, the inside of the thigh, or the sacrum. Local bleeding, however, seldom avails, except the whole mass of blood has been previously diminished by the prudent employment of the lancet. Besides bleeding, the surgeon may advantageously have recourse to other means at the same time; as, for instance, emollient clysters, purgatives, blisters, bathing the feet in warm water, &c.

In some cases all the foregoing means fail in producing the desired benefit, even when they have been followed up, as far as the state of the pulse and strength of the constitution will allow. Here the continuance of the disease may depend, either upon the stoppage of some wonted evacuation of blood, or else upon some other cause of the first class. In the first of these cases (says Richter,) experience proves, that the disease will sometimes not give way before the accustomed discharge is re-established, on which the malady depends, notwithstanding evacuations may be employed in any way whatsoever. A woman, who (as this author acquaints us) had lost

her sight, in consequence of a sudden suppression of the menses, did not recover it again till three months after the return of the menstrual discharge, notwithstanding every sort of evacuation was tried. He also tells us of another woman, who had been blind half a year, and did not menstruate, and to whose external parts of generation leeches were several times applied. As often as the leeches were put on (says Richter,) the menses in part recommenced; and, as long as they made their appearance, which was seldom above two hours, the woman always enjoyed a degree of vision. (*Anfangsgr. der Wundarzn. b. 3. p. 443.*)

For the amaurosis, arising from suppression of the menses, Scarpa recommends leeches to the labia pudendi, bathing the feet in warm water, and afterwards exhibiting an emetic, and the resolvent pills, of which I shall presently speak. If these means fail in establishing the menstrual discharge, he says, great confidence may be placed in a stream of electricity, conducted from the loins across the pelvis, in every direction, and thence repeatedly to the thighs and feet. He enjoins us not to despair at want of success at first, as the plan frequently succeeds, after a trial of several weeks.

For the amaurosis, proceeding from the stoppage of an habitual copious bleeding from piles, Scarpa recommends the application of leeches and fomentations to the hemorrhoidal veins, then giving the patient an emetic, and afterwards the opening pills hereafter described. (*Saggio di Osservazioni e d'esperienze sulle principali molattie degli occhi, cap. 19.*)

When the disease does not originate from the stoppage of any natural or habitual discharge of blood, and does not yield to the evacuating plan, Richter thinks, that the surgeon is justified in concluding, that the preternaturally dilated vessels have not regained their proper tone and diameter, and that he ought to employ topical corroborant remedies, particularly cold water. In this kind of case, Richter is an advocate for washing and bathing the whole head with cold water, especially the part about the eyes: a method, he says, which may often be practised after evacuations, with singular and remarkable efficacy.

When the return of sight cannot be brought about in this manner, Richter advises us to try such means, as seem calculated to stimulate the nerves, and remove the torpid affection of the optic nerves in particular. Of these last remedies, says he, emetics are the principal and most effectual. Soldiers, who lose their sight in performing forced marches, in hot weather, very commonly have it re-established again, by being immediately bled, and taking an emetic the next day. (See *Schmucker's Chir. Wahrnehmungen 1. Theil.*)

We come now to the consideration of that species of the gutta serena, which is regarded as the effect of some unnatural irri-

tation. Here, according to the precepts delivered by Richter, we should endeavour to discover what the particular irritation is, and then endeavour to effect its removal. When it cannot be exactly detected, we are recommended generally to employ such remedies, as will lessen the sensibility of the nerves, and render them less apt to be affected by any kind of irritation.

Sometimes the irritation is both discoverable and removeable, and still the effect, that is to say, the blindness, continues. In this circumstance, Richter thinks, that the surgeon should endeavour to obviate the impression, which the irritation has left upon the nerves, by the use of anodynes; or else, try to remove the torpor of the nerves by stimulants.

But, according to Schmucker, Richter, and Scarpa, the curable imperfect amaurosis commonly depends on some disease, or irritation, existing in the gastric system, occasionally complicated with general nervous debility, in which the eyes participate. Hence, in the majority of cases, we are assured, that the chief indications are, to free the alimentary canal from all irritating matter, improve the state of the chylopoietic viscera, and invigorate the nervous system in general, and the nerves of the eye in particular.

For an adult, dissolve three grains of antimonium tartarizatum in four ounces of water, and give a spoonful of this solution, every half hour, until nausea and copious vomiting are produced. The next day some opening powders are to be exhibited, consisting of an ounce of the supertartrate of potash, and one grain of antimonium tartarizatum, divided into six equal parts. The patient must take one of these in the morning, another four hours afterwards, and a third in the evening, for eight or ten days in succession. They will create a little nausea, a few more evacuations from the bowels than usual, and, perhaps, in the course of a few days, vomiting. If the patient, during their use, should make vain efforts to vomit, complain of bitterness in his mouth, loss of appetite, and no renovation of sight, the emetic, as at first directed, is to be prescribed again. This is to be repeated a third and fourth time, should the morbid state of the gastric system, the bitter taste in the mouth, the tension of the hypochondria, the acid eructations, and the inclination to vomit, make it necessary. The first emetic often produces only an evacuation of an aqueous fluid, blended with a little mucus; but, if it be repeated, a few days after the resolvent powders have been administered, it then occasions a discharge of a considerable quantity of a yellow, greenish matter, to the infinite relief of the stomach, head, and eyes.

The stomach having been thus emptied, Schmucker's or Richter's resolvent pills are to be ordered.

These are composed as follows:

R Gum. Sagapen. }
Galban. } an. ʒj
Sap. Venet.
Rhei optim. ʒiss
Tart. Emet. gr. xvi.
Suc. liquerit ʒj. fiant pilulæ gran. quinque.

Three of these pills to be taken every morning and evening for a month, or six weeks.

R Gum. Ammoniac. }
Ass. foetid. } an. ʒij
Sap. Venet.
Rad. Valer. s. p.
Summit. Arnicae.
Tart. Emet. gr. xvij. fiant pilulæ gran. quinque.

Six to be taken thrice a day for several weeks.

The pills are here directed to be made larger, than Schmucker and Richter order, so that the number in one dose may be diminished; for, to prescribe 15 pills, three times a day, might seem absurd to the generality of patients in this country.

When the above plan has rectified the state of the stomach, and partly effected the restoration of sight, such remedies must be employed, as strengthen the digestive organs, and excite the vigour of the nervous system in general, and of the nerves of the eye in particular. A powder is to be prescribed, composed of an ounce of bark, and half an ounce of valerian, divided into six equal parts, one of which is to be taken in the morning, and another in the evening, in any convenient vehicle, for, at least, five or six weeks. During this time, the patient's nourishment must consist of tender succulent meat, and wholesome broths, with a moderate quantity of wine, and proper exercise in a salubrious air. For exciting the action of the nerves of the eye, the vapour of liquor ammoniac, properly directed against the eye, is of the greatest service. This remedy is applied by holding a small vessel, containing it, sufficiently near the eye to make this organ feel a smarting, occasioned by the very penetrating vapours, with which it is enveloped, and which cause a copious secretion of tears, and a redness, in less than half an hour after the beginning of the application. It is now proper to stop, and repeat the application three or four hours afterwards. The plan must be thus followed up till the incomplete amaurosis is quite cured. The ammoniacal vapours should be used as soon as the stomach has been freed from all irritating matter, and they should not be discontinued, till long after the eye has been cured.

The operation of these vapours may be aided by other external stimulants, applied to such other parts of the body as have a great deal of sympathy with the eyes. Of this kind are blisters to the nape of the neck; friction on the eyebrow with the anodyne liquor; the irritation of the nerves of the nostrils by sternutative powders, like that composed of two grains of turbith mineral, and a scruple of powdered betony leaves;

and, lastly, a stream of electricity. For some additional observations on the effect of electricity in cases of amaurosis, see *Gutta Serena*.

Bark, which is efficacious in intermittent fevers, and other periodical diseases, far from curing the periodical amaurosis, seems to exasperate it, rendering its return more frequent, and of longer duration. On the other hand, this disease is most commonly cured, in a very short time, by exhibiting first emetics, then opening pills containing antimonium tartarizatum, and gummy saponeous substances, and lastly, corroborants, and even bark, which was before useless and hurtful.

Such is the statement of Professor Scarpa, which agrees with the sentiments already cited from Richter, respecting the effect of bark in periodical amaurosis. As if, however, practitioners were doomed always to differ, and learners to be puzzled, Beer tells us, that he has seen only two cases of periodical intermittent amaurosis, both of which were soon perfectly cured by large doses of bark. Other periodical amaurotic affections he has seen, however, attendant on intermittent fever, but they spontaneously subsided with the febrile paroxysms, without any particular treatment being applied to the eyes. Sometimes, when the paroxysms recurred frequently, a considerable weakness of sight remained after them; but, this always went off of itself, except in a single instance, in which the functions of the eyes were perfectly re-established by the exhibition of arnica, joined with bitters. (See *Beer's Lehre von der Augenkr. B. 2, p. 585.*)

In the two cases, which were unaccompanied with fever, the vitreous humour had the appearance of being turbid during the attacks, but regained its natural clearness on each return of vision, the loss of which used to be complete. Here we see another instance, in which a cloudiness behind the pupil in amaurosis did not impede the cure, and went away in the most ready manner. Possibly, the opacity, which in speaking of the prognosis, I said that Langenbeck had not found to prevent the cure of certain cases, might also have had its seat in the vitreous humour, and not depended upon disease of the retina.

Scarpa finds, that the above plan of curing the recent imperfect amaurosis succeeds in the majority of cases, where the disease is only sympathetic, or dependent on the morbid state of the gastric system. But, there are cases, in the formation of which many other causes operate, besides the most frequent one already stated. These demand the employment of particular curative means, in addition to those which have been already described. Such is, for example, the imperfect amaurosis, which occurs suddenly, in consequence of the body being excessively heated, or exposure to the sun, or violent anger, in plethoric subjects. This case requires, in particular, general and topical evacuations of blood, and the appli-

cation of cold washes to the eyes and whole head. An emetic should next be given, and afterwards a purge of potassæ tartras, or small repeated doses of antimonium tartarizatum. Schmucker relates, that by means of bleeding and an emetic, he has often restored the eyesight of soldiers, who had lost it in making forced marches, with very heavy burdens. In amaurosis, suddenly occasioned by violent anger, an emetic is the more strongly indicated after bleeding, as the blindness, thus arising, is always attended with a bitter taste in the mouth, tension of the hypochondria, and continual nausea. Richter gives an account of a clergyman, who became completely blind, after being in a furious passion, and whose eyesight was restored the very next day, by means of an emetic, which was given with a view of relieving some obvious marks of bilious disorder in the stomach.

Scarpa's treatment of the imperfect amaurosis brought on by fevers, deep sorrow, great loss of blood, intense study, and forced exertions of the eyes on very minute or brilliant objects, consists also in removing all irritation from the stomach, and afterwards strengthening the nervous system in general, and the nerves of the eye in particular. In the case originating from fevers, the emetic and opening pills are to be given; then bark, steel medicines, and bitters; while the vapours of the liquor ammonia are applied to the eye itself.

When the disorder has been brought on by grief, or fright, the stomach and intestines are to be emptied by means of antimonium tartarizatum, and the opening pills; and the cure is to be completed by giving bark and valerian; applying the vapour of liquor ammonia to the eyes; ordering nourishing, easily digestible food; diverting the patient's mind, and fixing it on agreeable objects, and recommending moderate exercise. The amaurosis from fright is said to require a longer perseverance in such treatment, than the case from sorrow. (*Scarpa's Osservaz. Cap. 19.*)

The third species of gutta serena, or that which arises from debilitating causes, is of two kinds; in one, the disease is the consequence of a general weakness of the body; in the other, it is the effect of debility, which is confined to the eye itself, and does not extend to the whole constitution.

According to Scarpa, the incomplete amaurosis from general nervous debility, copious hemorrhage, convulsions *ab inanitione*, and long continued intense study, especially by candlelight, is less a case of real amaurosis, than a weakness of sight from a fatigued state of the nerves, especially of those constituting the immediate organ of sight. When this complaint is recent in a young subject, it may be cured, or diminished by emptying the alimentary canal with small repeated doses of rhubarb, and then giving tonic cordial remedies. At the same time, the patient must abstain from every thing that has a tendency to weaken the nervous system, and, consequently, the

eyesight. After emptying the stomach and bowels, it is proper to prescribe the decoction of bark with valerian, or the infusion of quassia with the addition of a few drops of sulphuric ether to each dose, with nourishing, easily digestible food. The aromatic spirituous vapours (mentioned in the article *Ophthalmia*) may then be topically applied; or if these prove ineffectual, the vapour of liquor ammoniac. The patient must take exercise on foot, horseback, or in a carriage, in a wholesome, dry air, in warm weather, and avail himself of sea-bathing. He must avoid all thoughts of care, and refrain from fixing his eyes on minute shining objects. In proportion as the energy of the nervous system returns, and the constitution is strengthened, the sight is restored. In order to preserve and improve this useful sense, the patient must adopt, above all things, every measure calculated to maintain the tone of the stomach, and moderate the impression of light on the retina. This object can easily be fulfilled by always wearing flat green glasses before the eyes, in a vivid light. (*Saggio di Osservaz. Cap. 19.*)

When the weakness is confined to the eye only, Richter thinks the topical employment of corroborant applications alone necessary. Bathing the eye with cold water, says he, is one of the most powerful means of strengthening the eye. The patient should dip in cold water a compress, doubled into eight folds, and sufficiently large to cover the whole face and forehead, and this he should keep applied, as long as it continues cold. Or, else, he should frequently apply cold water to his eyes and face with his hand, on a piece of rag.

The eye may also be strengthened by repeatedly applying blisters of a semi-lunar shape above the eyebrows, just long enough to excite redness. Richter likewise speaks favourably of rubbing the upper eyelid, several times a day, with a mixture of the tinctura lyttæ and spiritus serpilli, great care being taken, that none of the application come into contact with the eye itself. Spirituous and aromatic remedies in general, are also proper. (*Anfangsgr der Wundarz. B. 3, p. 452.*)

When no probable cause whatsoever can be assigned for the disease, the surgeon is justified in employing such remedies, as have been proved by experience to be sometimes capable of relieving the affection, although upon what principle is utterly unknown. The chief means of this kind are emetics, given in small doses, so as to excite nausea, and occasionally in larger ones, in order to produce vomiting; Schmucker's pills, the composition of which has been already described, sometimes assisted with the exhibition of arnica and valerian; preparations of mercury either alone, or in conjunction with sarsaparilla, cicuta, or sulphur auratum antimonii; valerian in powder, either alone, or joined with decoction of bark, containing either subcarbonate of ammonia, or sulphuric ether; pulsatilla, in the form of an

extract or an infusion; the extractum hyoscyami albi, with or without antimonial wine, and various other medicines and applications, which will be considered under the head *Gutta Serena*. To this article, I would refer the reader, before he makes up his mind about any empirical method of treatment, because he will there find many cautions and instructions given by Beer respecting the remedies for amaurosis in general. To his remarks, I have also annexed such others on the same topic, as appeared to me interesting.

In the following view of amaurosis, chiefly taken from the valuable writings of Prof. Beer, the reader will find a more complete history of the different forms of the disease, and their varieties, than has previously been drawn up in our language. The only points, on which Beer perhaps ventures too far, are those relating to the etiology of the several cases; a subject, in which he displays the usual credulity of the continental surgeons. With his observations, I have taken the liberty to blend a few additional remarks, not caring about the length of the article, where the matter seemed new and interesting.

1. OF THE DIFFERENT FORMS OF AMAUROSIS IN GENERAL.

Beer reckons four species of amaurosis.

The first is a genuine uncomplicated amaurosis, the characteristic symptom of which consists peculiarly and entirely in an impairment or loss of vision, without any morbid change in the organic matter of the eye.

Secondly; there is an amaurosis, which, besides being attended with a diminution, or total loss of vision, is also accompanied with appearances of disease in the organic matter of the eye.

Thirdly; there is another amaurosis, in which, together with the above principal symptom, viz. weakness, or loss of sight, there are also morbid phenomena exhibited in the form of the eye in general, or its particular textures, and especially in the action of the irritable parts.

Lastly; Beer says, he can often point out an amaurosis, in which all the characteristic symptoms of the three preceding cases are more or less combined. (See *Lehre von den Augenkr. B. 2, p. 478.*)

Professor Beer's First Species of Amaurosis.

The genuine uncomplicated amaurosis, consisting of a mere diminution or loss of sight, without the appearance of any other defect, is one of the most uncommon forms of complaint, not only because singly operating causes are few, but because they can rarely operate directly upon the optic nerves.

In the true uncomplicated amaurosis, merely the vital qualities of the optic nerve and retina are affected, and after death, no-

thing preternatural can be traced in those parts, either within or on the outside of the eyeball. It is in short, the case, in which the functions of the retina have become imperfect, or destroyed, the eye appearing in other respects sound.

According to Beer, this simple unmixed form of amaurosis is subdivisible into that amaurotic weakness of sight, or blindness, which depends upon the vitality, or rather sensibility of the optic nerve and retina being too highly raised, and into another case, the proximate cause of which is peculiarly and entirely referable to depression of such vitality or sensibility. The first example is much less common than the second.

The general symptoms of the simple uncomplicated species of amaurosis, putting out of consideration the morbid increase, or diminution of the sensibility of the optic nerve, are thus described by Professor Beer. In the first place, all morbid appearances are absent, which might be produced in the amaurotic eye by any one preternatural change in the texture, form, or state of that organ. Hence we are obliged to trust almost exclusively to the patient's assertion, that his sight is bad, or quite gone; and not unfrequently, it is necessary, especially in judicial cases, to employ political artifices, in order to determine whether such assertion be true, particularly when the patient affirms that the blindness is restricted to one eye. Secondly; when the amaurosis is indeed nearly, or quite formed in one eye, a slight degree of strabismus is at most perceptible, arising from the circumstance of the patient's not fixing the eye affected upon any object. This degree of strabismus is noticed by Ackermann and Fischer, as the surest sign of amaurosis. (See *Klinische Annalen von Jena* 1st. p. 144.) And it is particularly pointed out by Richter, as an invariable attendant upon amaurosis. The patient, says he, not only does not turn either eye towards any object, in such a manner, that the object looked at is in the axis of vision; but, he does not turn both his eyes towards the same thing. This was regarded by Richter, as the only symptom, which we can trust, where implicit confidence should not be put in the mere assurance of the patient, that he cannot see, while all the coats and humours of the eyes present their natural appearance. (See *Anfangsgr. der Wundarzn.* B. 3. Kap. 14.) Provided this observation be correct, it must be highly interesting to the military surgeon, amaurosis being a common affliction of soldiers, many of whom, however, endeavour to avoid service by pretending to labour under a disqualification, which they well know does not necessarily produce any very considerable alteration in the natural appearance of the part affected. Thirdly; while the disorder is only in the stage of amblyopia, the patient always complains of continually multiplying *muscæ volitantes*, or of the *visus reticulatus*, or *nebulosus*. Fourthly; luminous forms appear before the eyes, especially in the dark, even when

the patient is entirely blind. Fifthly; the decrease of vision goes on to complete blindness, without any material interruption, or retrogression. Sixthly; when only one eye is quite blind, and the eyesight on the other side is perfectly undisturbed, there is one infallible symptom of this amaurosis, namely, *if the sound eye be very carefully covered, the pupil of the blind one immediately expands, and the iris becomes quite motionless, notwithstanding the diseased eye be exposed to the strongest light possible.* However, this criterion is mostly wanting, because the amaurosis, which is attended with no appearance of defect, except loss of vision, is seldom confined to one eye, but usually affects both. (See *Lehre von den Augenkr.* B. 2. p. 481—82.

1. *Of the genuine uncomplicated Amaurosis, dependent upon what Beer terms preternaturally high Vitality, or rather, as we should say, a Morbid Increase of Sensibility of the Optic Nerve.*

This form of amaurosis is described by Beer as having two stages: in the first, the patient never becomes blind; the eyesight being lost at the end of the second stage. This species of amaurosis always forms with great quickness, so that the limits between the two stages are frequently very indistinct.

The first stage commences with a peculiar sensation of fulness in the eye-ball, conjoined with continually increasing, violent, and annoying luminous appearances, and a remarkable weakness of sight. These symptoms are soon followed by a stupifying constantly increasing headach, during which the power of vision manifestly diminishes, without the slightest defect being perceptible either in the eye itself, or its surrounding parts. The patient, however, is always marked by an athletic constitution, or at all events, by such symptoms of general and local plethora, and of a phlogistic diathesis, as cannot be mistaken.

Upon the advance of the disorder into its second stage, the headach becomes irregular, being less violent at some periods than others; the patient feels as if there were before his eyes, a thick net, or gauze, which, in a bright light, appears quite black, but in the shade, fiery and shining. This net or gauze, when there is any temporary determination of blood to the head and eyes, as in straining at stool, is immediately rendered considerably more dense; and when such determination of blood is often repeated, or long maintained, the density at length remains much greater than before, and consequently, the patient suddenly grows more blind, and is very quickly quite bereft of vision. This complete loss of sight, in the second stage, if efficient assistance be not given, is ultimately produced by the progress of the disease, even without any accidental determination of blood, though never quite suddenly. At last all power of discerning the light is abolished, under in-

cessant stupifying headaches, which are sometimes weaker, sometimes stronger, and are attended with a sensation, as if the dimensions of the eye were increased, and indeed, it really feels harder, than in the healthy state.

All those circumstances, which produce a long and repeated determination of blood to the head and eyes, must be considered as the principal causes of this kind of amaurosis. Beer especially adverts to the habit of sleeping at night with the head low, in individuals who retire early to rest, and with their arms extended above their head. Here also the observations are nearly all applicable, which have been already delivered respecting the effects of immoderately exerting the eyesight and intellects, and concerning the too great irritation of the eye by the light in typhoid fevers. Nor, in the etiology of this species of amaurosis, should what has been stated about idiosyncrasies be forgotten. (*Lehre von den Augenkr.* p. 483—85.)

While the first stage has not yet terminated, and consequently while the power of vision is not obliterated, if the patient can and will put himself without delay into the requisite condition for the cure, a favourable prognosis may invariably be given. But the prognosis is much less promising, when the second stage has already begun, or is threatening to begin, and consequently when the power of seeing is either completely or nearly destroyed, notwithstanding the blindness may not be of more than two days' standing; particularly, if the patient cannot immediately have the best assistance. However, some slight hope of a re-establishment of sight may always be entertained, even though the amaurosis be complete, if it be not of long standing. But when the disorder has existed several months, it is hardly ever practicable to do more than restore a very partial degree of vision. When, in typhus fever, this amaurosis has been brought on altogether by the immoderate irritation of the light, Beer has constantly found the case quite irremediable, the general debility, which often lasts so long after typhus, having no slight share in the prevention of a cure. The prognosis is most favourable, when the amaurosis depends upon some idiosyncrasy which is known, and can be at once removed; and very discouraging is the prospect of relief, when many different causes are concerned in the production of the complaint: while that true sympathetic amaurosis, which arises not merely from over exertion of the eye, but also from great and immoderate mental application, is very serious, both with respect to the fate of the eye itself, and the life of the patient, amaurosis, under these circumstances, being not unfrequently the forerunner of impairment of the intellects, or absolute mania. (*Beer, vol. cit.* p. 486.)

As in this species of amaurosis, a determination of blood to the head and eyes is never altogether absent, and has generally

had a great share in the first production of the complaint, it must be self-evident, that during the whole course of the disease, every thing should be rigorously avoided which can tend to bring on such determination of blood, or disturbance of the circulation; and, when these states already exist, no pains must be spared to lessen and remove them. Hence, when general plethora prevails, venesection, especially in the foot, is the earliest indication; and, if this be not effectual, and the local plethora in the head and eyes still continues, topical bleeding with leeches, &c. must be practised. But, if no signs of universal plethora exist, and there be merely a determination of blood to the head and eyes, local bleeding will be sufficient. At the same time, bathing the feet in lukewarm water, containing salt, or mustard, or applying sinapisms of mustard to the calves, and using gentle opening clysters, aperient medicines, cooling drinks, and a strict vegetable diet, will very much contribute to lessen the determination of blood, and any existing impetuosity of the circulation. These antiphlogistic curative means must be aided by keeping the eyes in a natural, yet complete state of rest, and in particular by keeping the whole body quiet in the recumbent posture, with the irritation of what would otherwise be only an ordinary degree of light, constantly diminished. Nay, in typhoid patients, attacked with this form of amaurosis, the interception of the light by blinds and eyescreens, or a light fine linen bandage, will be of itself effectual to arrest the disorder at once, and prevent blindness, unless the first stage be already too far advanced. When the most careful adoption of the foregoing means is only followed by an imperfect and slow return of vision, the treatment is to be aided by cold bathing of the eye, in practising which care must be taken not to let the patient's head lean forwards. According to Beer, the sympathetic amaurosis, unaccompanied by any appearance of organic disease, and brought on by immoderate exertion of the brain, always demands, in its first stage, not only local, but general antiphlogistic treatment, even though no particular plethora may be present.

When the surgeon meets with this species of amaurosis in the second stage, local fluid stimulants, and tonic remedies, must first be gradually employed. These are to be applied, partly by rubbing them upon the eyebrow, and partly in the form of the vapour of ether directed immediately against the eye. An attempt must also be made to restore the sensibility of the optic nerve, by rubefacients, and, if these be unavailing, by such means as occasion a shock of the vessels and nerves. When, however, it is clear that liniments and vapours of ether are quite ineffectual, these local measures must be combined with suitable general means: a light nutritious diet; an allowance of wine and beer; daily exercise in the open air, particularly in sunbiny meadows, until

the patient be rather fatigued; the slow ascent of hilly places; the exercise of pumping or sawing wood in winter: bathing in mineral steel waters, &c. and the empirical use of antiparalytic and tonic remedies, among which latter, steel medicines are to be employed with the greatest circumspection. (Beer, *Lehre von den Augenkr. b. 2. p. 487—88.*)

2. *Of the genuine uncomplicated amaurosis, which arises from (what Beer denominates) preternatural depression of the vitality (sensitivity) of the optic nerve.*

According to Beer, this amaurosis differs from the preceding, by its formation being scarcely ever quick, but usually very slow, and its not exhibiting any traces of those two very different stages, which are peculiar to the other case. It also invariably commences with the visus reticulatus, or nebulosus, without any alternation with a blinding glare of light; and the eyesight is sometimes considerably better, and sometimes weaker, which always depends upon the accidental operation of internal or external circumstances. Thus, it may be noticed, that, in these cases, immediately after a good repast, the enjoyment of excellent wine and liquor, after unexpected great joy, after the spirits have been raised by the pleasures of a convivial party, or directly after a violent fit of anger, the sight undergoes great amendment. On the other hand, sudden fright, great anxiety, profound grief, loss of sleep, long fasting, &c. constantly produce an immediate aggravation of the blindness; and the difference between these effects is, that the melioration of the eyesight never continues long, while the diminution of it not only remains, but gets worse and worse. It is not at all uncommon for this species of amaurosis, to make its appearance as a nightblindness, because common artificial light is much too feeble to make due impression upon the diminished sensibility of the optic nerve; and consequently these patients always show a partiality to a very strong light. To such weaksighted individuals, the flame of a candle, or the moon, appears as if covered by a dense veil, with an expanded halo round it of various colours. There is no complaint made of pain in the head or eyes; and no sensation of fulness or weight is experienced in the eyeball; much less are there any empirical symptoms of the disease in the structure and form of the eye, or in the action of its irritable textures; but the amaurosis, especially when it has been long complete, is usually conjoined with a debilitated habit.

Every thing, says professor Beer, which tends to produce considerable constitutional weakness, either locally in the eyes, or both locally and constitutionally, must at least be regarded as a more or less obvious cause of this amaurosis; that is to say, when the case is a mere impairment or loss of sight without other morbid appearances;

for, as we shall presently find, there are several kinds of amaurosis, which, though they depend upon direct local debility, or local and general debility together, do not by any means arise in the form of simple diminution or loss of sight, free from every appearance of complication and disease in the eye: here belong especially shocks affecting the optic nerve, the brain, or the whole nervous system, produced rather by moral than physical causes; for a simple physical shock of the nerves, especially when it falls directly upon the eye, commonly produces at once a considerable diminution of cohesion in the nervous texture, as is more or less evinced by the appearances of the eye in general, and by the action of its irritable parts in particular. Secondly must be reckoned every very considerable and long-continued loss of blood or other nutritious fluid. Thirdly, a long residence in a dark place, and the entire nonemployment of the eye. Fourthly, the debility of age, and dulness of the whole nervous system, particularly when the patient's eyesight has been abused in his youth by immoderate exertion, and the eyes are of a dark colour. Fifthly, the present form of amaurosis sometimes comes on as an immediate consequence of typhus, especially when the fever has been attended with severe diarrhoea, and nasal hemorrhage, not of a critical, but of a mere symptomatic kind, hardly admitting of suppression; but, in the latter case, the amaurotic blindness is rarely complete. Beer questions whether, in typhoid patients, the absorption of the fat in the orbit, and the extraordinary retraction of the globe of the eye into that cavity, may not have a share in producing this amaurotic weakness of sight. (*Lehre von den Augenkr. b. 2. p. 491, 92.*)

With respect to the prognosis, this species of uncomplicated amaurosis, unattended with any defect in the structure of the eye, is generally much seldomer curable than the former, because the cause of the disorder usually consists of an assemblage of many concealed and difficultly discoverable circumstances, and because it is rarely possible to put the patient under all the conditions, which are essential to the cure, even when the causes of the disease are understood; as for instance, when the disease has arisen from extreme indigence, or domestic trouble. Even when a cure is effected, it is with the greatest difficulty, and not till after a considerable time. Hence, though circumstances may have a favourable appearance, no promise should be made, and when the amaurosis is already complete and of long standing, great patience must be enjoined during the treatment. In very poor persons, and in hospitals, says Beer, this species of amaurosis may always be regarded as incurable, because, in such examples, the operation of the medicines indicated can never be properly seconded by diet, nutritious food, mental encouragement, and requisite exercise in an open pure air.

At the commencement of the disorder, the depressed vitality (or rather sensibility) of the optic nerve should be raised, if possible, by the gradual use of stimulating liniments, and the vapour of ether. The rest of the treatment, recommended by Beer, resembles that of the second stage of amaurosis from morbid sensibility of the optic nerve. His plan is also to try the use of weak remedies first, and then gradually those which have the most powerful operation. (Beer, vol. cit. p. 493, 94.)

Beer's Second Species of Amaurosis ; Cat-eye Amaurosis.

This species of the disorder, of which Beer has yet met with but one form, rarely increases to complete blindness; it occurs chiefly in very old persons, and it is perhaps this affection to which some oculists have given the unmeaning name of *amblyopia senilis*. Sometimes, however, this kind of amaurosis takes place in young persons and children; and one circumstance, that demands particular notice, in its nosology, is, that it always takes place either in thin, dwindled, old, gray-headed subjects, nearly in the state of *marasmus senilis*, in whom consequently the exchange of organic matter is carried on but tardily, or else in young subjects, who are unhealthy, and disposed to consumption, hectic adults, emaciated children, and as a consequence of severe injuries of the eye. While this amaurosis is not perfectly formed, the iris retains its mobility, and the pupil is neither preternaturally dilated, nor contracted; but when once the patient is quite bereft of vision, the motions of the iris are slow, and the pupil larger than in a healthy eye in an equal degree of light. At the bottom of the eye, very far behind the pupil, a concave pale gray, bright yellowish, or variegated reddish opacity is developed. By this the eyesight is not merely weakened, but rendered quite confused, since all objects, but especially smallish ones, appear to be confounded together, particularly when the patient tries to inspect closely any determinate body. The further the disease advances, the brighter and more visible is the bottom of the eye, the paler is the colour of the iris (a thing very conspicuous in dark-eyed persons,) and when once the amaurosis is complete, so that no susceptibility of the impression of light is left, then, upon an attentive examination of the eye, one can mostly perceive, at the troubled deeper part of the eye, a very slender vascular plexus, which merely consists of the ordinary ramifications of the central artery and vein, which are now visible at the pale-coloured bottom of the eye. In a half-darkened place, such an eye presents a shining yellowish, or reddish appearance, but only in certain positions of the eyeball; and, in this respect, it is somewhat similar to the eye of a cat, whence Beer chooses to term the complaint cat-eye amaurosis. The disorder is also not accompanied with

any other essential morbid appearances, except the decline of vision, or complete blindness. (*Lehre von den Augenkr. b. 2. p. 496.*) Beer, in fig. 1. tab. 4. of his second vol. has given, from nature, an admirable representation of this very remarkable species of amaurosis. The differences in the appearances at the bottom of the eye, in this case, from those presented in the early stage of fungus hæmatodes of that organ, will be best understood by referring to the article *Fungus Hæmatodes*.

Beer observes, that the causes of this species of amaurosis are so obscure, that whatever is offered upon the subject can be received only as conjecture. After what has been said in the foregoing paragraph is considered, about the particular individuals who are liable to be affected, and the change of the iris to a pale colour, as a constant symptom of this case, a suspicion may be entertained, that a deficiency of the pigmentum nigrum, and of the tapetum of the uvea, in consequence of the stoppage of this secretion, may be the cause of the disease. Beer justly remarks, that much might be learned on this point from the dissection of eyes thus affected; but he has never met with the opportunity.

Nothing being known about the etiology, the prognosis cannot but be very unfavourable; for, as the surgeon is ignorant of causes, he cannot know what means ought to be adopted for their removal. It is fortunate, however, that this amaurosis rarely attains its highest degree, but almost constantly remains in the form of a more or less considerable amblyopia.

Just as little is yet known respecting any well-regulated mode of treatment: all that Beer has learnt from his own opportunities of remark is, that, in individuals prone to consumption, or somewhat hectic, but not dangerously so, and especially in emaciated children, whose bellies are not at the same time tense and hard, this amaurotic impairment of sight may sometimes be kept from getting worse, by the careful employment of such general remedies, regimen, and diet, as are calculated to improve the health. But, in the most fortunately managed cases, Beer has never seen a step made towards the removal of the disease. (*Lehre von den Augenkr. b. 2. p. 497, 98.*)

Beer's Third Species of Amaurosis, and its Varieties.

1. *Of the amaurosis which is produced by the abuse of bitters, by coal-smoke, or the effect of lead.*

This amaurosis in its progress presents different stages, to which the utmost attention must be paid in order to avoid treating the case wrongly, or producing complete blindness. The limits between these stages, however, are so faintly marked, that one cannot wonder at their being overlooked by a superficial observer. In the first stage, the complaint never induces entire blind-

ness, but only a more or less considerable diminution of vision.

A manifest turgescence of the blood-vessels, not only in the conjunctiva, but in the sclerotica itself; a disagreeable sensation of fulness in the eye; a perfectly motionless state of the iris; a very considerable dilatation of the pupil; and a peculiar undescribable pale-blackness of that opening, without any appearance that can be called turbidness; a singular pellicle-like cloud, which renders larger objects indistinct, and quite conceals all smaller ones; and, finally, a more or less remarkable trembling of the limbs; are the characteristic symptoms of the first stage.

On the other hand, says Beer, in the second stage, the patient is quite deprived of vision; the pupil is exceedingly large; the iris quite motionless, even when the eyelid is rubbed over the eye; the pupillary edge of the iris is angular, usually only towards the two canthi, so that the breadth of the iris is greatest in the perpendicular direction; nearly every part of the white of the eye exhibits a faint redness; the edges of the eyelids, especially in fair persons with a very delicate irritable skin, are somewhat discoloured; the upper eyelid in consequence of relaxation, hangs farther down over the eye, than natural; the movements of the eye and eyelids are languid; and different muscles are affected with spasm, especially those of the limbs and spine. If, in this stage of the disorder, the power of distinguishing light be completely abolished, then the other external senses, and, at last, the internal ones, but particularly the hearing, speech, and memory, fail. Nay, not unfrequently this form of amaurosis is attended with delirium, and, when produced by the poison of lead, it may be accompanied with lead-colic, ileus, and contractions of the hands and feet.

The abuse of bitters of every kind, whether as articles of food or medicine, especially chicory-coffee, bitter almonds, various high-seasoned dishes, quassia, &c.; likewise of narcotics, especially opium, hyoscyamus, belladonna, thorn-apple, and cynoglossum; lastly, the long-continued and imprudent employment of preparations of lead, paint, &c.; the application of lead cosmetics, and accidental preparations of this mineral, adulterated wine, &c. are the causes of this form of amaurosis, which Beer has often seen, and mostly treated with success.

While the disease is in its first stage, the prognosis is always very favourable, indeed sometimes the blindness now goes off again, without any interference from art. This may happen when it has not yet attained a considerable degree; when the patient avoids every thing conducive to the disease; when he accidentally places himself under such circumstances, as promote the recovery; and when he is not very plethoric; there is no determination of blood to his head and eyes; he has not a phlogistic diathesis; he is not disposed to obstinate constipations; and the amaurotic weakness of

sight has not occurred in the advanced stage of pregnancy. However, Beer is convinced, from repeated observation, that this amaurosis, even though it be not quite in its second stage, and it be skilfully treated, may last a long while, when produced by belladonna, stramonium, and the poison of lead.

When once the disorder reaches its second stage, and the patient is completely blind, the prognosis becomes very serious, though somewhat less so if a glimmering of light can be discerned. But, if all sense of light be lost when the surgeon is first consulted, no promises must be made; or, at most, only a remote and distant hope of the re-establishment of sight must be allowed, notwithstanding all other circumstances may be favourable to the cure. When, however, in a completely amaurotic eye of this kind, any thing wrong is visible in the transparent parts of the organ, or there is a strong tendency to a general varicose affection of its blood-vessels, the complication is always very unpromising, as sooner or later violent pains supervene, and the blindness is irremediable.

When in the first stage of this complaint recourse is at once had to fluid stimulant remedies, useful as they are in the second, it is lucky if the patient do not completely lose his sight. On the contrary, when no complications exist, and the impairment of vision is altogether the effect of the above mentioned causes, a gentle antiphlogistic treatment will preserve him from such a misfortune. Taking away a few ounces of blood, by venesection, when plethora exists; the application of leeches behind the ears, when, after bleeding, a determination of blood to the head and eyes still continues in full habits, or there is any tendency to inflammation. The same topical bleeding, without venesection, and lukewarm pediluvia, containing salt, or mustard, are proper, when no general plethora exists; and merely a determination of blood to the head and eyes, and some acceleration of the circulation prevail. Internally, diluted white wine vinegar, lemon juice, or the liquor ammoniæ acet. have excellent effects; and externally, poultices composed of bread crum and vinegar, or fomentations with oxycrat, are the means which Beer has found most successful in the first stage of this form of amaurosis.

As in the first stage, a moderate antiphlogistic general or local treatment is the only one, which can be adopted, and which in urgent cases may yet save the patient from blindness, so, in the second stage, the internal and external employment of fluid stimulants is of great service; for example, naphtha combined with camphor inwardly; liniments to the eyebrow, and the vapours of ether to the eye. The amaurosis, which is produced altogether by the poison of lead, and is complicated with lead colic and ileus, will require, in addition to the foregoing means, such remedies as are known to be of service in these latter disorders.

(Beer, *Lehre, von den Augenkr.* B. 2. p. 499—503.)

2. *Of the symptomatic amaurosis in individuals affected with hysteria, hypochondriasis, epilepsy, and convulsions.*

This amaurosis is rarely permanent, and usually subsides as soon as the spasmodic, epileptic, or convulsive attack is over. However, the complaint may begin at two periods, viz. either during such an attack, or (what is more uncommon) afterwards, and it never loses its symptomatic character. The pupil always remains perfectly clear, and of a shining blackness, even when the disease has induced entire blindness; but, a slight dull pain in the forehead, especially about the eyebrow, constantly preceding and accompanying the blindness, generally lasts a good while after the amaurosis has completely subsided.

Besides the foregoing general symptoms, the following characteristic appearances present themselves in hysterical and hypochondriacal patients, who suffer frequent attacks of violent spasm. The pupil is much dilated, and the iris, which is immovable, seems evidently to project in a convexity forwards, when the eye is inspected sidewise; consequently, the anterior chamber is lessened. The eye itself does not move freely in its socket, the patient experiencing an annoying, and sometimes a truly painful sensation, as if the eyeball were forcibly compressed; (*Ophthalmodynia*.) Every attempt, which the patient himself makes to move the eye, or the surgeon to push it out of the position, which it has assumed, is unavailing, and excessively painful. The eyelids are either painfully shut, or incapable of being shut at all; the eyesight is very weak, but seldom quite impeded; and, at the termination of each attack, it returns, though every paroxysm leaves it more and more debilitated, until at length, the spasmodic attacks of blindness frequently occurring, and lasting a long while, it is entirely lost. But, when the disorder has acquired its utmost degree, the eye always still retains the power of discerning the light, and it seldom happens, that vision is abolished by the first or second attack. It is different, with respect to the characteristic phenomena of this amaurosis, in hysterical or hypochondriacal patients, especially when often affected with spasms, before, during, or after which the impairment of sight originates: for though the pupil may continue quite clear it cannot escape the notice of an attentive observer, that, together with a pupil of diminished diameter, there exists a peculiar motion of the iris, a constant fluttering of it between expansion and contraction, technically called *hippus pupillæ*. This convulsive state of the iris is mostly accompanied with a similar affection of the eyelids, namely, with an involuntary blinking, *nictitatio*, and not unfrequently with an involuntary pendulum-like rolling of the eyeball, *nistagmus*. In these patients, the amaurotic injury of sight

hardly ever proceeds directly to complete blindness, but more commonly remains as a weakness of vision, characterized during the rest of life by ceaseless oscillations of the eyeball, aversion to light, and frequent sensations, as if there were shining fiery objects before the eyes.

With regard to the symptoms in epileptic patients, in addition to the general effects above enumerated, this case of symptomatic amaurosis is distinguished by an untroubled, but very expanded pupil; considerable diminution of the motion of the iris; a dilated state of the pupil even under the stimulus of the strongest light, and tremulous motions of the eyeball, which continue during life, after the epilepsy and amaurosis are cured; and the case is further characterized by amblyopia, which rarely increases to complete blindness.

The following are described by Beer as the symptoms in patients affected with convulsions.

As a symptomatic effect in convulsions, this amaurosis most frequently happens in children, they being more liable than adults to convulsions, especially during dentition. The first and most prominent symptom of this incomplete or complete amaurosis consists in an extremely violent convulsive rotation of the eyeball, especially upwards, not unfrequently attended with the most violent convulsive motions of the eyelids. The pupil is excessively dilated, and scarcely the least movement of the iris is distinguishable on exposing the eye to the strongest light. When the general twitchings are over, and only an amaurotic weakness of sight is left, strabismus occurs in both eyes in various directions, though the eyes very seldom deviate from the axis of vision in the direction towards the inner canthus. When the general convulsions happen frequently, and are violent and of long duration, the amaurotic weakness of sight usually changes into perfect blindness, in which the pupil, though it be regularly clear, and of a shining blackness, is greatly expanded, and the eyes constantly retain their faulty position and pendulum-like motion.

The causes of this amaurosis are specified, as it were, in the title of this section; for, whatever tends to bring on hysteria, hypochondriasis, epilepsy, or convulsions, in an evidently nervous individual, who either has had from birth weak irritable eyes, or has gradually debilitated them by over exertion, may give rise to this species of amaurosis.

With respect to the prognosis, it is observed by Beer, that even when merely an amaurotic weakness remains, the prognosis is always serious; but, it is naturally still more unfavourable, when the blindness is complete, and when the loss of sight has suddenly recurred after violent spasmodic, epileptic, or convulsive attacks, without such attacks themselves ever returning. Under these circumstances, Beer has not hitherto seen more than two instances of

such blindness partially cured. Generally, some hope of recovery may be entertained, when the amblyopia, or even complete amaurosis, begins with these attacks, but always terminates with them, without leaving any serious impairment of vision. On the contrary, it is a very bad sign, not only in regard to the removal of this symptomatic amaurosis, but likewise to the cure of the original disease, when the amaurosis invariably precedes these attacks, and lasts a considerable time after their cessation. As yet, Beer says he has not known any such patients cured, either of their spasms, epilepsy, or convulsions, much less of their blindness: on the contrary, after three or four attacks, perfect amaurosis remains, and some of the patients die in one of these paroxysms.

As this amaurosis is merely a symptomatic effect of the above general disorders, its removal must entirely depend upon the success with which their treatment is conducted. Were the blindness to continue, however, after the cure of the original disease, the surgeon could do nothing more than try an empirical mode of treatment, and ascertain what good could be effected with antispasmodic and tonic medicines. (*Beer, Lehre von den Augenkr. b. 2. p. 506—10.*)

3. Of the symptomatic amaurosis from infarction, obstruction, and induration of the abdominal viscera.

The following is Beer's account of the complaint. The extremely slow formation of this amaurosis gives it something characteristic; for during ten, twenty, and more years, the patients may have a continually increasing weakness of sight, without becoming completely blind, or rendered quite incapable of following their business. The pupil is invariably found to be dilated, of a pale blackish colour, though very transparent; the somewhat convex iris moves in the varying degrees of light, but very inertly; its pupillary edge is not circular, as in the healthy state, but is drawn into an angle sometimes at one point, sometimes at another; and not only the turgescence of the blood-vessels of the conjunctiva, but a reddish yellowish rather smutty tinge of the whole white of the eye, are evident to the most common observer. As the weakness of sight increases, the patient sees all objects through a thick mist, which, when blindness approaches, seems for a day or two as black as soot, and, for another day or two, of a light gray colour. Hence the patient usually talks of the white and black days. In most patients, those phenomena at length take place, which have been described in speaking of the *visus interruptus*. The purple lips, and wan countenance, correspond to the state of the eyes. A stupefying dull headach, affecting the whole head, and, while any vision is retained, depriving the patient of all inclination to employ his eyes or intellects; a constantly disturbed state of the digestive functions;

and, generally, the whole host of complaints connected with the morbid state of the abdominal viscera, are the never-failing companions of this amaurosis, which, however, does not invariably end in complete blindness.

As for the etiology of this species of amaurosis, every thing that is calculated to induce the above-mentioned morbid state of the abdominal viscera must naturally be taken into calculation; for the affection of the eye is but a symptomatic effect of a general disorder of the chylopoietic organs. Studious persons, and other individuals, who lead sedentary lives, and give immoderate application, or who live upon unwholesome food, are particularly subject to this kind of blindness. However, in duly contemplating its causes, attention must be paid to the almost incessant determination of blood to the head and eyes, prevailing in a greater or lesser degree, and also to the very troublesome hemorrhoidal complaints, as two important circumstances, arising from habitual costiveness, inseparable from the existing state of the abdominal viscera. Further, it is to be understood, that this amaurosis does not attack every individual, who has such disease in the abdomen, but only those whose eyes have been weak, either from birth, or previously to the general complaints, or else, during these complaints, have been immoderately strained.

The surgeon who has learned in practice, and not in the closet, the nature of this chronic disease of the abdominal viscera, and the true nervous connexion between these organs and the affected eyes, and who has also learned from the same source the peculiarity of constitution, habits, &c. of the patient, will know how impossible it is to make any favourable prognosis; for, says Beer, the obstinacy and almost total incurability of the principal complaints, of which the amaurosis is merely a symptom, are known to such a practitioner by the *argumentum crucis*. Even when there is a well-founded hope of cure, Beer argues, that it is difficult to keep the patient under all the requisite conditions for the successful management of the case, on account of his ordinary inflexibility and long-acquired habits. Nay, sometimes, this amaurosis is a very bad omen, in respect to the issue of the case generally; for, according to Beer, when its origin is attended with jaundice, and the affection of the eyes increases with uncommon rapidity to complete blindness, or the jaundice suddenly comes on, during the development of the amaurosis, ascites, or hydrothorax almost always ensues, and, in the latter case, speedy dissolution.

Nothing can be plainer than that, in this alarming case, little can be accomplished by surgery, but that every thing must depend upon judicious medical treatment. Beer remembers with sorrow the time, when, in this kind of amaurosis, such mischief was done by the favourite nauseating plan of treatment, that not a few patients became mournful victims to it. He cannot, there-

fore, too earnestly warn surgeons against that indiscriminate practice, without denying altogether its efficacy, when adopted with the prudence and the cautions laid down in the observations upon various remedies for amaurosis. (See *Gutta Serena*.) Here any employment of external means, even of such as would appear to be of the most innocent nature, always does harm, and if rashly used, or so as chymically to irritate the eye, they may quickly blind the patient. Thus, electricity and galvanism may instantaneously produce complete blindness, attended with severe, obstinate headach; which unfortunate change may be accounted for, when the constant determination of blood to the head and eyes is recollected. If the infarction of the abdominal viscera be successfully removed, the symptomatic amaurosis, depending upon it, is sure to diminish; but when the visceral obstruction and induration are of long standing, the amaurosis is then as incurable as the diseased state of the viscera. (*Beer, Lehre von den Augenkr. B. 2. p. 512—15.*)

4. Of the symptomatic gastric amaurosis.

In no instance has Beer yet seen this amaurosis terminate in complete blindness, excepting when the disease was occasioned by worms in the bowels. The present form of the disorder is always characterized by a considerable dilatation of the pupil, the inner margin of the iris not forming a very regular circle, and the motions of the same organ being exceedingly sluggish, even under the irritation of the strongest light; but the pupil constantly preserves its natural, clear blackness, and there is a frequent involuntary discharge of tears. Besides these pathognomonic symptoms in the eye itself, there are other remote appearances in the constitution, denoting the existence of certain complaints, as the cause of this amaurosis; for when the affection of the eye originates as a sympathetic effect merely, from a redundancy of foul acidity in the stomach, the patient incessantly complains of acid eructations, attended with severe heartburn and epiphora. On the contrary, when the amaurotic weakness proceeds merely from indigestion, the case is accompanied with a tedious, troublesome sense of weight at the scrobiculus cordis; continual eructations, as if occasioned by rotten eggs in the stomach; a yellowish, thickly furred tongue; oppressive thirst; and either an invincible dislike to fish or flesh, and repeated inclination to vomit; or, a swelled belly, and tension of the hypochondria.

On the other hand, when the gastric amaurosis is altogether a sympathetic consequence of worms, it often increases to complete blindness, as Beer has very often remarked, and, in addition to the above described characteristic symptoms, the portion of the sclerotica, surrounding the cornea, has a blue appearance; nay, the eyelids and all the circumference of the eye are said to exhibit quite a peculiar bluish

tinge; while the eye itself is remarkable for its unsteadiness and irregular motions. At the same time children thus affected, as long as they are not blind, usually squint with both eyes, on which account they are not unfrequently reprimanded by their parents and masters, who look upon the deformity as the result of bad habit; a mistake which is the more likely to happen, because these children have a continual irritation and itching in the mucous membrane of the nose, compelling them, as it were, unconsciously, to be frequently picking or wiping their noses. Such children usually have pale countenances; sometimes, also, a true leucophlegmatic habit; an insatiable appetite, and repeated gripings; and, in many cases, considerable swelling and tension of the belly.

As far as Beer's experience reaches, the prognosis in the sympathetic gastric amaurosis is always very favourable, even though the disorder may have attained the degree of complete blindness, provided the complaints, which have been assigned as its cause, are the only ones. But, says Beer, it should be remembered, that, in these cases, children with worms are often scrophulous; and adults, who are troubled with acidities in the stomach, are frequently gouty; while other patients, who complain of dyspeptic symptoms, may labour under hysteria, hypochondriasis, or infarction, obstruction, or actual hardness of one or other of the abdominal viscera, whereby this amaurosis, or even a mere weakness of sight, is often rendered incurable, and made to degenerate into complete blindness.

When the case is uncomplicated, the cure is easy enough; for, with regard to foul acidities in the stomach, Beer has never found it necessary, in the earliest stage, to prescribe any thing but absorbent medicines, which are to be followed by a long careful employment of light, tonic bitters, joined with the spiritus ætheris nitrici. In the second form of the complaint, the frequent drinking of a large quantity of warm water was often found of itself effectual, to remove both the general disorder, and that of the eye, a very gentle vomiting being thus excited, without straining, and the stomach completely freed from what was the source of indisposition. When the saburræ have a tendency to be discharged upwards, as indicated by continual nausea and disposition to vomit, emetics, which never operate without some violence, are to be most carefully avoided in plethoric individuals, or those who have a manifest determination of blood to their heads and eyes, or any acceleration of the circulation. The caution, here given, must be observed, even though emetics may on other accounts seem advisable; and, according to Beer, the determinations of blood and the state of the system here mentioned are commonly attendant upon this species of amaurosis. Indeed (notwithstanding the testimony of Schmucker, Richter, and Scarpa

in favour of emetics in this case) Beer positively affirms, that the violent operation of an emetic frequently converts this sympathetic amaurotic weakness of sight all on a sudden into blindness. Although I apprehend that Beer may here be somewhat prejudiced against emetics, candour obliges me to add, that, in this country, their efficacy in the present disease is by no means equal to the representations of Richter and Scarpa. When there is less tendency to vomiting, but the case is attended with an oppressive sense of weight about the stomach, frequent eructations, as if arising from rotten eggs, an inflated belly, and tense hypochondria, a gentle aperient clyster may be ordered, especially when the bowels have been for some days confined, in which circumstances Beer has found, that tolerably brisk purgatives are always of the greatest service, both in regard to the general complaints, and the amaurotic weakness of sight; the removal of the offensive matter from the alimentary canal being immediately followed by a cessation of the determinations of blood already mentioned. Lastly, when this amaurosis originates altogether from the presence of worms in the bowels, common anthelmintics are to be prescribed. In all these cases, says Beer, mere local treatment is quite inapplicable, and may do mischief. (*Beer, Lehre von den Augenkr. B. 2, p. 517—21*;) yet, as I have already explained in the foregoing pages, Scarpa and Richter here again differ very materially from this experienced oculist.

5. *Of the amaurosis, from the recession of acute cutaneous eruptions, as described by Beer.*

The peculiarity of this amaurosis is, that it comes on very rapidly, and always at that period of scarlatina, the measles, and less frequently the small-pox, when these contagious eruptions do not come out completely, but, from some cause or another, are suddenly repelled. This affection of the eyes, however, does not always induce perfect blindness. The pupil is invariably found preternaturally contracted, but quite transparent; the iris motionless; its pupillary edge however regularly shaped; while no characteristic appearance, like a palpable turgescence of the blood-vessels of the conjunctiva, is present. In a note, Beer remarks, that, although this amaurosis is not characterized by any particularly striking peculiarities of appearance, the diagnosis, especially in such children as can speak and complain of the considerable diminution or entire loss of their sight, is facilitated by the existing general exanthematous disorder; and, the more so as the affection of the sight almost always commences with rapidity in the first stage of the eruption.

In respect to the causes of this amaurosis, Beer remarks, that, if the sudden check of the eruption does not always produce such impairment of sight, but much more

commonly ophthalmia, the explanation is, that, in children, one circumstance, essential to the origin of amaurosis, is frequently wanting, viz. a directly or indirectly formed considerable weakness of the immediate organ of vision, that is to say, of the optic nerve and retina. The production of amaurosis by the recession of eruptions, is a circumstance in which I could never put implicit reliance; and here we find Beer himself compelled to associate with the explanation a previous weakness of the eye. With the above few, but unfavourable appearances in the eye, the prognosis is hopeful, if proper assistance be given without delay, that is to say, before the exanthematous disorder has quite ended. But, when the latter indisposition has terminated, and the amaurotic blindness yet remains, or when the impairment of sight has already existed a long while, an attempt to cure the patient may indeed be made, but, as far as Beer's experience goes, the chance of success is very small.

When the eruptive stage of the general disorder is not past, the indication is to promote, by every possible means, the coming out of the eruption. For this purpose, Beer recommends sudorifics in general, camphor, the warm-bath, &c. And, when the surgeon first sees the patient in a later stage of the exanthema, the same remedies may be tried, though the result will be more uncertain; and in the ultimate period of the general affection, there is a necessity for employing, together with these remedies, various alterative medicines. Local means, applied directly to the eye, are always hurtful, while the constitutional illness lasts, and afterwards are, at the best, only useless. When the eruptive disorder is completely gone, but the amaurosis continues, alteratives may be of service, and in debilitated subjects they should be combined with the calamus aromaticus, (sweet-flag) and camphor, or bark. In this stage, also, the excitement of some counter-irritation is absolutely requisite. On the continent this is sometimes done on the arm with the cortex mezerii; but it is a better practice to rub antimonial ointment alternately behind the ear, and upon the nape of the neck, so as to maintain for a sufficient time an itch-like breaking out upon the integuments. (*Beer, Lehre von den Augenkr. B. 2. p. 523—25.*)

6. *Of the rheumatic amaurosis.*

According to Professor Beer, the rheumatic amaurosis is not very uncommon, and is so plainly denoted by symptoms, to which we shall hereafter advert, that it cannot well be mistaken; namely, a perfectly clear pupil wavers in the midstate between contraction and dilatation, the iris seeming to be nearly motionless; the eyes weep from the slightest causes, and constantly betray more or less aversion to light; the case is invariably attended with wandering, irritating pains, sometimes affecting the eyeball itself, sometimes the vicinity of the eye, and, in other instances, the teeth or

neck. Also, when both eyes are affected together, which is not regularly the case, a cast of the eye, which cannot be called actual squinting, may be remarked, and frequently the motion of the eyeball is chiefly obstructed only in one direction, though sometimes a true obliquity of the organ exists: (*lucitas*.) In nearly every instance, there is considerable weakness of the levator muscle of the upper eyelid, and, not unfrequently, a complete blepharoplegia; but total blindness is seldom produced.

According to Beer, this amaurosis, which is to be considered as chronic rheumatism, often arises from keeping the head long exposed to the air, and is chiefly met with in individuals, who, while sweating profusely from the scalp and brow, in warm weather, have taken off their hats, and remained with their heads a long while uncovered. As, however, in warm weather, the generality of persons expose themselves in this manner, and few are attacked by amaurosis, I infer that something more is requisite for the production of the disease.

Under certain circumstances, the prognosis is by no means unfavourable; and hitherto Beer has mostly succeeded in effecting a perfect cure when the amaurosis was not completely formed; not of very long standing. The patient had no tendency to gout; and when, during the treatment, every thing was avoided that was likely to bring on an attack of that disease. Experience proves, however, (says Beer,) that if the patient be not cautious, the disease be neglected, or the least disposition to gout prevail, this amaurotic impairment of vision may change into a complete gouty amaurosis, just as rheumatic ophthalmia may be converted into gouty inflammation of the eye.

In this amaurotic weakness of sight, the treatment consists not simply of local means, which indeed are always needful, but likewise of general remedies. With regard to the latter, Beer assures us, that manifold experience has convinced him of the preference which ought to be given to the extract of guaiacum, joined with camphor, and given alternately with the compound powder of ipecacuanha; which remedies, as soon as the wandering pains about the eye and eyebrow begin to be milder, and more fixed to one part, are to be succeeded by the extract of aconitum, antimonial preparations, and flowers of sulphur. Externally, the most powerfully operating means are not to be omitted, especially blisters applied successively behind the ears, to the temples, and eyebrows; and as soon as the pain has completely subsided in these last parts, and is perhaps more concentrated in the eye, frictions are to be made on the eyebrow with liniments, containing at first a moderate quantity of opium, and afterwards of the extractum conii. At length, when the pain in and about the eye is nearly subdued, but some degree of amaurotic weakness of sight is left, frictions with naphtha, and a small pro-

portion of tinctura lyttæ and tinctura opii, will be found exceedingly beneficial. Afterwards, when a considerable time has transpired, without the recurrence of the slightest rheumatic pain in the eye, its vicinity, or the head, but the eyesight is not perfectly re-established by perseverance in the above general and local treatment, and especially when the paralytic affection of the levator of one or other of the upper eyelids continues, (as often happens,) galvanism may be tried, with the cautions elsewhere premised (See *Gutta Serena*.) And in the most desperate cases, Beer approves of making an issue in the depression between the angle of the jaw and the mastoid process, and keeping it open for a fortnight after the recovery seems complete. (*Lehre von der Augenkr. B. 2, p. 526—29.*)

7. Of the amaurosis, which proceeds from the stoppage of a catarrh, without any actual collection of mucus in the frontal sinus.

In this instance, as Beer observes, the circumstances of the pupil becoming very much dilated, yet retaining all its wonted transparency, the iris being motionless, and its pupillary edge not regularly circular, but angular, will not form any criterion, because these morbid appearances are common to several forms of amaurosis. But, the constant projection of the margin of the pupil into an angle directed towards the temple, whereby the pupil is also inclined more towards the external, than the internal canthus, is a peculiar mark of the case, and as difficult of explanation as the displacement of the pupil towards the root of the nose in what Beer and others consider as syphilitic iritis. The patient also complains of the eye being unusually dry; of a sensation of particular fulness in it; of a very troublesome dryness of the nose on both sides, even though the amaurosis be restricted to one eye; and his feelings are constantly those of a person who is in a dusty room.

These subjective symptoms (says Beer,) are conjoined with an amazing heaviness about the root of the nose, and a shooting pain in the head, extending from the region of the frontal sinus outwards to the temple, and upwards to the top of the head. This case of amaurosis, however, never terminates in complete blindness, though the impairment of vision may attain a degree which approaches the latter state. The diagnosis will be materially facilitated by an inquiry into the history of the disease, when it will be found, that the affection of the sight followed the sudden stoppage of a violent catarrh.

According to Beer's experience, when an abundant discharge of mucus from the nose can be excited (which mode of treatment, however, requires the greatest caution, lest it do more harm than good,) there are few cases of amaurosis, in which the prognosis is as favourable as in the present example. The indication is to reproduce, as quickly

and as freely as possible, the secretion of mucus from the nose; but this object is not to be at once attempted with the most powerful sternutatories; for (as Beer can affirm from his own experience) such treatment is apt to fail, and do more injury than benefit to the eyesight. This eminent practitioner inculcates, therefore, the propriety of first preparing, as it were, the Schneiderian membrane for the operation of the stronger mechanical, chymical stimulants, which, he says, may be best done, first, by letting the steam of warm water be directed up the nostrils; secondly, by inhaling into the nose warm emollient, mucilaginous decoctions, especially the decoction of mallows; and, lastly, by employing in the same way a warm weak solution of manna in milk. Yet, says Beer, even with these applications, one must proceed with caution; for, when they are made too strong, the headach and weakness of sight are almost instantly augmented. At most, half a scruple of manna canellata is to be dissolved in from four to six ounces of milk; and for children and irritable females, the mixture should be still weaker. When preparation has thus been made, that is, when the mucous membrane of the nose is rendered soft and somewhat tumid, when the dryness of the nose is in some measure lessened, when the patient feels as if his nostrils were constantly filled with thick mucus, which he endeavours to get rid of by blowing his nose; when the sense of heaviness about the root of the nose increases, and the violent headach changes into a dull heavy feel; the precise crisis has arrived when great benefit may be derived from the powder of mild aromatic herbs, blended with a small proportion of calomel. After this has been employed some time, brisk sternutatories may be tried, like those composed of aromatic vegetable powders mixed with black hellebore, or the vapour of strong volatile smelling salts, caustic ammonia, &c. These means frequently bring about a profuse discharge of thick fetid mucus, after which evacuation the disagreeable sensations about the root of the nose, and eyebrow, gradually cease, the nose is left moister than usual, and the eyesight is at length completely restored. The only thing, which it is necessary for the patient most strictly to avoid, during the whole of the treatment, is the cold air, exposure to which (according to Beer's observations) may be the means of frustrating every endeavour to complete the cure. (*Beer, Lehre von der Augenkr. b. 2, p. 530—34.*)

8. Of the genuine paralytic amaurosis.

This is not an unfrequent case: it always originates very suddenly, attended with a manifest contraction of the pupil, which opening has not lost any of its natural clearness; and there is complete immobility of the iris, the pupillary margin of which does not present the slightest irregularity. However, either some muscle of

the globe of the eye, the levator of the upper eyelid, or the orbicularis palpebrarum; nay, several of these muscles, and sometimes all of them together, are affected with paralysis; while the blindness itself is almost always not only complete, but not unfrequently so complete, that every vestige of sensibility to light is lost. The functions of the puncta lachrymalia are also more or less impeded, whence a greater or lesser degree of epiphora usually accompanies the disorder, as a natural effect of the abolished, or diminished absorption and conveyance of the tears into the lachrymal sac; circumstances generally occurring whenever the orbicularis palpebrarum is paralytic. A completely amaurotic eye of this description, says Beer, has the greatest possible resemblance to a dead eye. When all the muscles of the globe are palsied together, the eye can no longer preserve its situation in the orbit, but protrudes, as it were, lifeless (*Ophthalmoptosis paralytica*;) while the whole tunica conjunctiva is commonly oedematous, or very blood-shot; and, it is not unusual to find this amaurosis conjoined either with paralysis of certain muscles of the face, or even with hemiplegia.

The causes of the true paralytic amaurosis comprise violent concussions of the eyeball itself, unaccompanied with any solution of continuity, or any displacement of the internal parts of this organ; concussions of the upper and lower margins of the orbit, especially the eyebrow, and neighbouring part of the forehead, without any laceration of the frontal and infraorbital nerves; and concussions of the whole brain, or spinal marrow: sometimes, however, the disorder is only a symptomatic effect of apoplexy. In the three latter cases, the blindness regularly extends to both eyes.

The prognosis may either be very favourable or unfavourable. When the amaurosis is only the momentary consequence of a simple concussion of the eyeball, without any breach in its internal texture, if the retina be not wounded, and none of the inner parts of the eye displaced, the case always admits of a perfect cure by proper treatment; and, says Beer, it is incredible how much may here be accomplished, by beginning the treatment judiciously, even when the eyesight has been nearly or quite abolished, and the concussion of the eyeball has been so serious, as to produce an effusion of blood in the chambers of the aqueous humour. Beer owns, however, that cures of the latter description, of which the ophthalmic hospital at Vienna has afforded many examples, are only to be considered as extraordinary occurrences, and therefore should not form any general inference for the prognosis. But, when this amaurotic loss of sight is the effect of a severe concussion of the brain or spinal marrow, and the case is unequivocally denoted by its general well-known characteristics, and its history; or when the dis-

order is the symptom of an apoplectic fit; the prognosis is very unfavourable, not merely with respect to the restoration of sight, but the patient's life itself.

In cases of paralytic amaurosis, even where it proceeds from a concussion of the eye itself or its vicinity, a complete cure cannot always be expected from merely local remedies. The treatment, however, should regularly begin in this manner, and the surgeon first try whether it will answer or not. For this purpose, Beer particularly recommends the employment of all those nervous remedies, the cautious gradual use of which in the empirical treatment of amaurosis is particularly praised by that author. (See *Gutta Serena*.) Should local means fail, gradual recourse must be had to antiparalytics and tonics. (*Lehre von der Augenkr. B. 2, p. 535, &c.*)

9. Of the symptomatic amaurosis from hydrocephalus.

According to Beer, this amaurosis may occur, as a symptomatic effect, not merely in internal hydrocephalus and collections of water in the ventricles of the brain, but also in external hydrocephalus and spina bifida. In the two latter cases, the diagnosis is easy; but, in the two first, it is more obscure, though it may generally be made out by attention to the following characteristic symptoms. The perfectly black, clear pupil is very much dilated; the iris is completely motionless, its pupillary edge forming here and there a very small, hardly distinguishable angle; the amaurotic eyes, (for they are constantly both affected,) are either prominent and fixed in a lifeless way, the muscles of these organs evincing little propensity to contract, or they are in a state of continual oscillation in various directions, never, however, in the line of the straight muscles; but the appearance is rather as if there were an incessant struggle between these last and the oblique muscles. In the sclerótica around the cornea, an extraordinary bluish tinge may be noticed. Children never hold their heads up, but incline it to one side or the other; and, if they are old enough to walk, they tread very insecurely, hobble along, and frequently tumble down. Lastly, the os frontis projects in a remarkable degree, and the child, completely bereft of vision, at length dies with convulsive, or apoplectic symptoms.

The cause of this amaurosis, which is merely a symptom, depends upon the principal disease, namely, the hydrocephalus, and it would appear, indeed, that the blindness, which does not accompany every case of internal hydrocephalus, is particularly attendant upon collections of water in the ventricles. And Beer informs us, that, in two cases, in which he saw this amaurosis as a symptomatic effect in spina bifida, he found, after death, a prodigious quantity of water in all the four ventricles.

As hydrocephalus, especially the internal species, and collections of water in the ven-

tricles, are almost always incurable, it is plain enough what expectation can be entertained of a recovery of the eyesight. Yet, when the amaurosis is truly a symptom of water in the ventricles, the stage of the disorder is known, and the practitioner has not been consulted too late, something may yet be done, as Beer has learnt from experience. The surgeon, however, will rarely be able to render any benefit, because his services are usually not required until the last stage, and it only remains for him to foretell the melancholy fate both of the patient's eyesight and life. In the very uncommon case of amaurosis, which is a symptomatic effect of external hydrocephalus, if the health be not too much reduced, there is always more hope.

Medical treatment will sometimes do good, if not administered too late. The period, when the oculist is consulted, says Professor Beer, is never that in which inflammation of the brain exists, and, whatever good can now be done, is generally to be done with calomel and digitalis. (See *Lehre von der Augenkr. B. 2, p. 539—41.*)

Beer's Fourth Species of Amaurosis and its Varieties.

1. Traumatic amaurosis.

Beer applies the epithet *traumatic* to such cases of amaurosis as are the consequence of a considerable wound of the eye itself, its surrounding parts, or the skull. Here consequently is first arranged the amaurosis produced by laceration and stretching of the branches of the frontal nerve from irregular scars about the eyebrow. Secondly, Beer reckons the amaurosis arising from external violence, directed in such a degree against the upper or lower side of the orbit, that the retina is torn, and many of the internal softer textures of the eye forced out of their natural situations. Thirdly, Beer includes every weakness of sight, or perfect amaurosis, which is the result of such injuries of the eyeball itself as extend to the retina, so as either violently to bruise or lacerate it, or cut or pierce it. For the prognosis and treatment of all these cases, he refers to his observations upon ophthalmy. Nor does he choose here to treat of the perfectly complicated amaurosis, which is a direct consequence of a coup-de-soleil, because it never happens unpreceded by a violent general inflammation of the eyeball, and therefore is to be regarded as an effect both of the injury and the inflammation together; but which like the symptomatic amaurosis, which follows common and genuine internal ophthalmy, may be easily known by the total insensibility to light, and the evident changes in the texture and shape of the eye; and is quite as incurable as the other example, to which we have alluded. (*Lehre von den Augenkr. B. 2, p. 542.*)

2. Gouty amaurosis,

Which, according to Beer, is so frequent

at Vienna, that it may be accurately observed in all its stages, plainly assumes two forms, the peculiarities of which probably depend more upon constitutional than external causes.

The first form or degree of the complaint is characterized by a very considerable dilatation and angular displacement of the pupillary edge of the iris towards the canthi; a continually increasing slowness in the movements of the iris, and final immobility of this organ; an actual change of colour at both its circles; a dull, glassy blackness of the pupil, and even a tarnish in the lustre of the cornea; an alternate appearance of the gray and black cloudy substances, described in the account of the general symptoms of amaurosis, which effect lasts while the patient is not totally blind. The disorder is further indicated by a fleeting, wandering, irritating, yet not very severe pain, all about the vicinity of the eye; a manifest tendency to a varicose enlargement of the blood-vessels of the conjunctiva and sclerotica; a very transient melioration of sight after meals, or any accidental excitement or stimulus; a considerable temporary decrease of it after the operation of any causes, which depress the spirits; the excessively slow formation of the disease, for which several years are usually required; and, lastly, by the nature of the patient's constitution. For, in general, this amaurosis (if we are to believe Professor Beer) always attacks both eyes at once, and is confined to fanatic, dark-eyed women, and very irritable, slender, weak, maiden females, who either have suffered from scrophula in their childhood, or from severe acute or chronic diseases at a later period of their lives; who are not yet far advanced in years; and whose menses have never been very irregular, though profuse. This form of amaurosis is restricted to no particular classes of society; it is not, however, so commonly noticed in the higher orders; while it is most frequent in the working middle classes, and scarcely ever remarked in the lowest ranks, especially country people.

It is remarked by Professor Beer, that, although the second form of gouty amaurosis makes its attack upon males, as well as females, the latter, on the whole, are most frequently affected, particularly about the period when the menses cease. This amaurosis, which is seldom formed quickly, that is to say, in a few weeks, or months, but mostly requires years for its production, begins with cloudy, indistinct vision; an appearance of different colours before the eyes; and a peculiar sensation as if insects were crawling over the skin around the eye. The pupil becomes manifestly dilated, and presents a dull greenish-gray colour, which, however, is easily distinguished from the colour seen behind the pupil in the amaurotic cat-eye, and plainly depends upon some defect in the vitreous humour, (*glaucoma*.) Also the iris, the pupillary edge of which is drawn towards both angles of the

eye, as in the first form of the disorder, undergoes an obvious change of colour, first at its lesser circle, which becomes of an uncommon dark hue, and then at its greater circle. The alteration of colour here spoken of, certainly proceeds from a general varicose state of the blood-vessels of the eye, which affection daily augments, and is attended with vehement pain in the organ and surrounding parts, or even in the whole head, or one side of it, whether the blindness attack one or both eyes together. This violent pain, however, which is such as often to distract the patient, is unsteady and irregular, being immediately aggravated by every violent mental emotion, whether of the exalting or depressing kind, every sudden and considerable change of temperature, every quick accession of wet cold weather, or when the patient stays only for a short time near a very heated fireplace, lies on feather pillows, with the affected eye resting in the depression of such a pillow, or covered with flannel, or he has been eating any indigestible food. It is very remarkable, that these attacks of pain subside without any medical assistance, in the dry warm season of the year, and in a mild, not too hot climate, are often kept off for several years. Upon every such attack of gouty pain, the glaucoma becomes more evident, the pupil larger and more angular, and the eyesight perceptibly weaker. At length, during one of these painful exacerbations, vision is completely abolished, not the least sensibility to light remaining; and the pupillary edge of the iris, together with the lesser circle of the same organ, then entirely disappears, being inverted towards the lens. The *cirsophthalmia* also gets so much worse, that the sclerotica acquires a smutty grayish-blue colour; and at length, the bluish windings of vessels may be noticed at various points, particularly about the place where the tendons of the muscles are affixed. Afterwards the green, or what may be more properly called, the glaucomatous cataract, is manifestly developed, and the eye then generally wastes under the most violent attacks of pain. The light, which the patient always thinks he sees, but which, according to Professor Beer, is produced of a reddish or bluish colour in the interior of the eye, like galvanism, keeps up the hope of recovery; but, all consciousness of this luminous appearance ceases as soon as the eye begins to waste. The first degree of gouty amaurosis readily changes to the second, especially in persons who are getting into years, or are near the period of life when menstruation terminates.

That in amaurotic patients of the foregoing kind, a certain morbid tendency to gout exists, may be inferred from what has been already said of the peculiarities of constitution which are noticed. In such individuals, therefore, it is not extraordinary, that the first degree of gouty amaurosis should originate, and almost uninterruptedly augment to complete blindness, while

certain general and local causes are incessantly operating upon the eyes; such as long grief affecting a very sensible mind; excess in wine; sleepless nights, occasioned by care or fear; straining the eyes, either by too much reading, particularly at candle-light, or by any of the fine kinds of work usually done by women; bad, unwholesome sorts of food; and want of good air, and proper exercise.

The causes of the second form of gouty amaurosis, says Beer, are the same as those of gout in general, which, however, are very imperfectly known. Whatever in certain individuals has the effect of promoting, or actually bringing on an attack of gout, may excite this amaurosis, especially, when at the same time hurtful or debilitating circumstances are affecting or have been affecting the eyes. It is to be recollected, however, says Beer, that just in the same manner as few of the individuals, exposed to the influence of these last circumstances, are attacked with gout, so few gouty subjects are afflicted with this amaurosis, and, consequently in both cases, a certain predisposition to such disease, already existing in the eyes, seems essential to its production. According to Beer, such individuals as have been afflicted with scrophula or rickets in their youth, are very liable to gout, when they grow older; and, says he, gouty disease more frequently attacks dark, brown, or black eyes, than eyes of a light colour, especially when they have been much debilitated in the earlier part of life by immoderate exertion.

In the first degree of gouty amaurosis, Beer observes, that the slightest glance at the etiology of the case must show, how unfavourable the prognosis is; for, notwithstanding the disease frequently requires many years to be completely formed, and the causes are by no means so obscure, as in the second degree of the disorder, yet, they are generally such as absolutely cannot be removed, because interwoven, as it were, with the constitution. In fact, the surgeon being hardly ever able to check, much less cure, the blindness, is usually obliged to be an inefficient spectator of its progress. According to Beer, the apothecary's magazines contain no remedies, which are adequate to the cure of this amaurosis. A total change of the whole constitution would be requisite, ere success could be expected, and such change it is not in the power of physic to accomplish. The practitioner may give advice, and make the attempt; but, notwithstanding every exertion, the patient usually falls into a state of complete and irremediable blindness. In one example only Beer has succeeded in checking the disease, by persuading the patient to observe a strict regimen, not a grain of medicine being given; but the patient still remains weak-sighted, though various medicines have latterly been tried.

The following are Beer's observations on the prognosis in the second stage of gouty

amaurosis. If in the first stage, there is scarcely any hope of preserving the sight, where the causes of the disease are apparently known, how little expectation of success can be entertained in the second stage, where the causes are involved in perfect obscurity, and are probably in some measure dependent upon a propensity to gout existing in the constitution from childhood. Indeed, when the patient is living under the influence of such circumstances, as are known to promote gout, certain blindness may be predicted. The same termination may also be foretold, without any chance of error, when glaucoma is evidently present; and, though a weak power of vision be yet left, this will soon be forever lost. It is doing a great deal in these cases to free the patient from intolerable pain, and, by active resistance to gout, perhaps, still preserve the other eye, where this is not yet affected, or not in a serious degree. But if the practitioner find, when he is first consulted, that the green or glaucomatous cataract is already formed, there is then not the slightest chance of obviating the pain, which ordinarily continues, until the eye is completely wasted away, and the fissure of the eyelids has permanently sunk in the orbit and closed.

With respect to the treatment of the second stage of gouty amaurosis, Beer observes, that it should be like that of gouty iritis. In particular, attention must be paid to the attacks of pain, and palliative means adopted. The patient should not lie upon feather beds, nor especially feather pillows, but only employ articles of this kind, which are stuffed with horse hair. Neither must he expose himself to an atmosphere, which is at the same time both cold and damp; and, if he cannot altogether take care of himself in this respect, at all events let him keep his head and feet warm and dry; shun every thing which tends to impede the functions of the skin; and avoid pork-meat, every thing cooked with hog's lard, and very acid salt dishes, like herrings. With what are usually considered as gout-medicines, the practitioner should act very circumspectly; and, as in gouty iritis, he should pay close attention to the state of the constitution, rather seeking to afford relief by means of a well-regulated diet than by the employment of much physic.

With arthritic amaurosis, says Beer, is to be classed an amaurotic, rapidly formed, complete blindness of both eyes, which is the immediate result of a sudden violent fright; but only takes place in such individuals as are excessively nervous and irritable, and more or less prone to or actually affected with gout. The most striking effect, which characterizes this consequence of arthritic amaurosis, is that change, which is instantaneously produced in the structure and form of the eye at the moment when the patient recovers from his fright, and comes to his senses again, of which defects in the interior structure and form of the eyes there was not previously

the smallest vestige, and these organs, if not quite healthy, could only be termed weakish. These changes are indicated by a considerable dilatation of the pupil, which is drawn into an angle upwards and downwards; by the complete immobility, and the projection of the iris towards the cornea; by the manifest appearance of vessels fully distended with blood, on the greater circle of the iris; by all the symptoms of a beginning glaucoma; and by a general varicose affection of the blood-vessels: which two latter effects from this period incessantly continue, attended with violent pain in the head and eyes. (*Lehre von den Augenkr. B. 2. p. 544, &c.*)

3. *Of the amaurosis occasioned by the sudden cure of particular cutaneous diseases, and of old ulcers of the leg.*

Most of the cases, which appertain to this class, are said to have a great resemblance to the second form of gouty amaurosis. According to Beer, when psora, porrigo, old ulcers of the leg, &c. are suddenly healed, a consequence more frequent than amaurosis, is a sympathetic ophthalmia, which indeed may easily be removed by judicious treatment, but, if unskilfully managed, may prove very obstinate and dangerous. This eminent oculist thinks, that, in children, amaurosis is very rarely produced by the indiscreet cure of crusta lactea, and, with one single exception, the blindness has appeared to him to be a symptomatic effect of water in the ventricles of the brain, formed (as he perhaps too credulously supposes) in consequence of the injudicious repulsion of the cutaneous disorder.

When this amaurosis assumes its ordinary form, Beer has not yet been able to remark in it any peculiar characteristic symptoms, by which it can be effectually distinguished from the second form of gouty amaurosis, excepting, first, that it originates and increases very suddenly, while the true arthritic amaurosis is a long time, and for the most part several years, in forming. Secondly; that at its commencement it is never attended with violent pain in the eyes, or head. Hence, the diagnosis will depend very materially upon a correct recollection of circumstances. But, according to Beer, there are some cases, in which, besides the complete blindness, unattended with the slightest power of perceiving light, there is no characteristic symptom, but extraordinary enlargement of the pupil, total immobility of the iris, and an inanimate projection of the eye.

Respecting the causes of this amaurosis, Beer says, that he has nothing important to offer. He owns, that after the sudden cure of certain cutaneous diseases, and of old ulcers of the legs, an amaurotic blindness does not always ensue; and he believes, that the reason why the bad effects take place in other organs, sometimes the brain, the lungs, or the bowels, &c. may probably depend upon this or that organ happening to be most predisposed to disease. Here

the discerning reader will not require me to point out to him, that such a mode of accounting for things is entirely hypothetical, and destitute of proof: it is indeed so convenient a sort of explanation, that it admits of being extended to all diseases, without exception. If we are to believe Beer, the prognosis is very uncertain, and, in many cases, highly unfavourable; first, because an organic part, namely, the optic nerve, is directly affected, which by the operation of external and internal causes, is soon rendered unfit for the performance of its functions. Secondly; because, in the majority of examples, important changes immediately take place in the organization of the whole eye, which are particularly difficult of removal, when the nervous textures are affected. Thirdly; because it is impossible to know, whether morbid changes may not already exist in the retina, or course of the optic nerve.

In the treatment, Beer, who places implicit reliance upon the above statement of causes, is an advocate for reproducing, as quickly as possible, the original disease, and, if that cannot be done, he thinks some artificial disease should be formed in lieu of it. For these purposes, he often employs blisters, and friction with antimonial ointment. What, however, is likely to be ridiculed in this country, his treatment, where amaurosis happens to follow the cure of itch, consists in inoculating the poor patient again with psoric infection, as if it were not more tolerable to remain blind than live perpetually scourged with the other disorder; for the Professor's theory leaves us uninformed of the circumstances, under which the patient whose sight is restored by this expedient, could ever venture to have a sound skin again, without the risk of a fresh attack upon his eyes. But, it seems even from Beer's account, that the patient's subjecting himself to the itch will not always cure his eyes; for, says Beer, when this method fails, friction with antimonial ointment should be tried.

When amaurosis follows the healing of old sores, Beer recommends the formation of them again by applying to the cicatrix strong mustard cataplasms, and the muriate of soda; and, if the new ulcers cannot be made to discharge properly, he praises the application of issues to the calves of the legs, and, in urgent cases, to the thighs. These plans are to be aided by such medicines, as act specifically upon the skin, like antimonials, especially the sulphur auratum antimonii: Beer also speaks favourably of sulphur baths; and, in cases complicated with debility, administers tonics, particularly the calamus aromaticus and bark. (*See Lehre von den Augenkr. B. 2. p. 556—63.*)

4. *Of amaurosis, as the immediate consequence of a violent fit of anger, which has been kept under with difficulty.*

This case, which is described by Professor Beer as one of the most uncommon

forms of amaurosis, begins at once with a very considerable enlargement of the pupil, without any sensible angles in the margin of this opening, but with complete immobility of the iris; a thick plexus of dilated blood-vessels in the conjunctiva; a red yellowish colour of the whole sclerotica; and, usually, a greater or lesser degree of a suddenly formed jaundice; a slight turbidness of the aqueous humour, and complete loss of sight in one, or both eyes, yet without all sensibility to light being abolished. It is not uncommon for the case to be combined with hemiplegia, in which event, only one eye, namely, that on the paralytic side, is entirely blind, while the other is simply weakened; or there are merely signs of paralysis observable in the parts around the eyes, the muscles of the face, or even in organs at a greater distance from the eyes, in which event, vision is impeded in both eyes.

In amaurosis in general, there is often a peculiarity of constitution clearly concerned in the production of the disease, and this seems here to be the case; for, says Beer, "though I have not met with many examples of the present kind, and have had the treatment of still fewer, the patients, whom I have seen, were all very choleric, and bilious, and had dark-brown or almost black eyes. In every case, the amaurosis began, and was formed in a moment, after the patient had been affected with violent anger, which was repressed with great difficulty, to which gusts of passion he was evidently very subject. Yet (adds Beer,) it should be remarked, that all these patients had been immoderately exerting their eyes in various kinds of employment, a little while previously to the attack."

The few opportunities, which Beer has had of seeing this form of amaurosis, incline him to regard the prognosis as very uncertain, especially when professional aid is delayed for some days or weeks, after the commencement of the blindness.

Beer represents the treatment as liable to equal uncertainty: twice he succeeded in effecting an immediate partial restoration of sight, by giving a gentle emetic. In three other cases, where he had not been consulted directly after the beginning of the attack, the emetic plan had no effect. In the two first cases, vision was re-established by long perseverance in the exhibition of arnica, joined with camphor, and in the use of sulphurous baths, by which means the hemiplegia was also removed. The other three patients however continued completely blind; nor could Beer render them any benefit, though he tried the whole catalogue of antiparalytics and antispasmodics. (*Lehre von den Augenkr. B. 2. p. 563—65.*)

5. Of the amaurosis, which follows the stoppage of a catarrh, with collection of mucus and matter in the frontal sinus.

Beer has had as yet the management of

only three cases of this species of amaurosis, which appears to be one of the least frequent forms of the disorder: in each instance, it was indicated by the following characteristic phenomena; though he acknowledges, that, in the first example which occurred, he was very uncertain about the diagnosis. Directly after the sudden stoppage of a violent catarrh, the patient experiences an oppressive, dull, continually increasing pain about the root of the nose and frontal sinuses, and, at the same time, a considerable amaurotic weakness of sight takes place, either in one or both eyes, attended with various luminous appearances; with a contracted, perfectly round, but palish-black pupil; complete immobility of the iris; a deviation of one eye from the axis of sight, when only one is affected; and of both eyes, when the affection extends to both of them. Hence, when the two eyes are open, the patient sees objects double. The case is also attended with weakness of the upper eyelid; great dryness of the nose; a constant sensation as if the nostrils were filled with dust; reiterated fits of sneezing come on, during which ugly transient luminous forms suddenly and rapidly present themselves before the eyes. When the disease is not understood, or it is neglected, the eyeball at length protrudes from the orbit outwards and downwards, in which state the pain in the frontal sinuses becomes irregular, but more severe; the eyesight continues to grow decidedly worse; and, from this period, the patient not only discerns all objects very feebly, but in an imperfect misshapen manner. At length, the front of the sinus not only projects forwards, but forms a swelling, which has the softness of cartilage, in which stage, vision is quite abolished, and all sensibility to light is destroyed.

With respect to an explanation of the manner, in which the alleged cause of this form of amaurosis operates, Beer is more reserved than on some other occasions, and declines offering any hypothesis: he merely states his belief, that actual inflammation within the frontal sinus has a principal share in bringing on the blindness.

As for the prognosis, Beer thinks that some hope of the recovery of sight may be entertained, when vision is not already completely gone, and, in particular, that this benefit may be expected from judicious treatment, when the objects, which the patient is yet capable of discerning, have not a perverted, false, deformed appearance. On the contrary, nearly every hope is past, if all sensibility to light is not only quite annihilated, but the eyeball more or less pushed from its socket by the distension of the frontal sinus.

With regard to local treatment, if the case be not too far advanced, the indications and remedies are here exactly the same as those recommended in speaking of a former case of amaurosis from the sudden stoppage of a catarrh. In the present instance, while the pain is violent and increas-

sant, there is still greater necessity for avoiding all irritating means, on account of the inflamed state of the frontal sinus. Therefore, in the early stage of the disease, when the pain is violent, and when during its prevalence the blindness threatens to augment rapidly, leeches should be applied to the temple, and if there be any symptomatic fever, a moderate general antiphlogistic treatment ought to be adopted.—When the pain about the root of the nose and frontal sinus has considerably declined; when it has become dull and irregular; when the mucous membrane of the nose is moist, soft, and tumid; when the patient feels disposed to blow his nose every moment, and he can do this without at all increasing the pain in the frontal sinus, or eye itself; then the first opportunity has arrived for the use of stimulants, recommended in speaking of the amaurosis from suppressed catarrh. They are to be employed, however, with the utmost caution. Blisters are to be laid on the eyebrow, and afterwards liniments rubbed upon the same part, and about the root of the nose, such as spiritus camphoræ, naphtha, and tincture of opium. Internal alteratives should likewise be ordered, especially arnica, conjoined with guaiacum, and camphor. When by this local and general treatment no discharge of mucus is obtained from the nose, and the symptoms are not materially lessened; but, on the contrary, the eyeball commences to protrude from the orbit; or, should this change already have happened, together with a projection of the anterior parietes of the frontal sinus; then, if this portion of the skull be yet firm and unyielding, there is no other resource left but that of making a perforation into the sinus with a small trephine; or, if the bone be soft enough, the opening may be made with a common perforator. In this manner, an outlet is formed for the mucus and matter collected in the sinus, to which cavity any requisite applications may now be directly made. Beer says, the case is now to be treated as an ill-conditioned ulcer, and he asserts, that it may sometimes be proper to destroy altogether the mucous membrane, which lines the sinus; a proceeding which I have great difficulty in supposing to be correct. If the surgeon defer making an opening too long, Beer says, that the eye is rapidly destroyed, and the mischief of the bones in the orbit extends so quickly from the orbital process of the frontal bone to the os ethmoides, os unguis, &c. that it is now difficult to put a stop to the ravages of the disorder. Beer informs us of one case, which he had under his care, where he trephined the frontal sinus, and every thing went on so favourably after the operation, that, in the end, no deformity was apparent, the eyeball returned into the orbit, and sight was restored. In a second example, also treated by the same author, after the perforation of the sinus, its lower part was found quite softened and carious: the treatment was consequently accommodated to

the diseased state of the bone. In this case Beer simply made and preserved a counter opening in the conjunctiva above the eye, the sight of which was already quite gone. In a third case, the accumulation of mucus and pus in the sinus was obvious; but the patient refused to submit to any operation, and, five weeks after Beer had been first consulted, the front of the sinus gave way, and, in the seventh week, the eye, the greater part of the orbit, and the bones of the nose, were destroyed, and the other eye completely amaurotic. (See *Lehre von den Augenkr. B. 2. p. 566—71.*)

6. *Of the sympathetic amaurosis in lying-in women, from suppression of the secretion of milk.*

This case is set down by Beer as one of the most uncommon varieties of amaurosis. It comes on rapidly, after sudden stoppage of the secretion and excretion of the milk, with violent headach, concentrated about the forehead and eyebrows; troublesome luminous appearances; an inconsiderable dilatation of the pupil; and scarcely any perceptible irregularity in the pupillary edge of the iris, which is quite motionless, somewhat altered in colour, and swollen. The disease is also accompanied with great aversion to light; a palpable turgescence of all the blood-vessels of the conjunctiva; a slight turbidness of the transparent media of the eye; and, at first, with a mere weakness of sight, which, in the end, suddenly changes into complete amaurotic blindness. The breasts, which before the attack were full of milk, are now empty, and hang down like bags, but are quite free from pain.

Beer is of opinion, that this form of amaurosis must be regarded as a true sympathetic effect, the cause depending upon the suppressed secretion of milk. This, says he, is proved, not only by the amaurotic blindness immediately following the stoppage of such secretion, but also by the method of treatment. It is acknowledged, however, that a further investigation of this part of the subject would be attended with great obscurity. As far as this eminent oculist can speak, from the few cases which he has had an opportunity of seeing, the prognosis is always unfavourable when the blindness is complete, and particularly when there is a manifest diseased change in the transparent parts of the eye; for, in the latter case, he has known patients remain perfectly blind, though the secretion of milk had been most successfully and expeditiously re-established. In one instance, the remedies applied to the breast, instead of reproducing the secretion of milk, excited in the part a painful inflammation and abscess, during which the weakness of sight subsided, though it was very considerable.

In considering other analogous cases of amaurosis, enough has already been said concerning the first and most important indication, namely, the re-establishment of the action which is obstructed; and here

the only question is, about the manner in which that object can be most expeditiously and safely effected. For, says Beer, it should be distinctly understood, that the prevention of a complete amaurotic blindness essentially depends not only upon the renewal of the secretion from the breasts, but upon this change being made without delay. The remedies, which Beer has found most effectual for this purpose, are warm poultices applied to the breasts, and at first composed of simple emollients, and afterwards of more stimulating ingredients, such as hemlock, camomile flowers, &c. When the breasts have more of a leucophlegmatic appearance, than that indicative of a fulness of the mammary gland, and disposition to a renewal of the milk-secretion, Beer strengthens these poultices with aromatic herbs, and applies them alternately with well-warmed bags, full of dry aromatic plants, and sprinkled with camphor. These last means are very useful at night, or when the patient is asleep, and fresh warm poultices cannot be put on sufficiently often. In the daytime, the breasts should be frequently and gently rubbed with warm flannels, medicated with olibanum and mastick. This plan is to be followed up until the secretion and excretion of milk are renewed, and the amaurotic amblyopia has subsided. When the secretion either cannot be restored by the foregoing means, or the eyesight does not return with the re-established secretion, internal remedies must be tried, especially arnica, joined with calomel and camphor. Issues or setons should also be formed, and kept open for a considerable time. Such is the treatment by which Beer once succeeded in stopping the increase of this kind of amaurosis, though the result was not indeed what could be named a cure. (*Lehre von den Augenkr. B. 2, p. 572—75.*)

7. *Of the symptomatic amaurosis from morbid changes, either in the optic nerves, and their sheaths, or in the bones of the cranium, or the brain itself.*

Beer says, a very considerable number of cases of this form of amaurosis which have fallen under his notice, have enabled him, as it were, not only to know it at once, but to describe its exact symptoms. However, he does not mean to assert, therefore, that more minute circumstances may not yet exist, which have hitherto escaped his remark, and which may hereafter be detected by other diligent practitioners, so as to facilitate still more the diagnosis, especially in the early stage of the disorder. To an indefatigable observer many pathological examinations of such amaurotic eyes in dead subjects must occur under unfavourable circumstances, which examinations, if properly connected with a minute history of the cases, might lead to important conclusions, with respect to the causes of this very interesting, and not uncommon, species of amaurosis. The title of the present chapter embraces a great diversity of causes,

and the result must necessarily be certain modifications of the disease. Beer then commences with a simple relation of the general appearances which always characterize this amaurosis.—1st, Its formation is constantly very slow, and in all cases the patient is not only completely deprived of vision, but, for more or less time previously to his death, is rendered quite incapable of distinguishing light. 2dly, A second peculiar symptom of this amaurosis consists in morbid changes in the structure of the eye, which changes are at first scarcely perceptible, and increase very slowly. 3dly, The amaurosis either originates during an attack of violent headach, which continues almost uninterruptedly until death, or the headach does not come on until complete blindness has taken place; or the patient may have no pain whatever either in his eyes, or head. 4thly, In the progress of this amaurosis, objects invariably seem to the patient to be perverted, disfigured, &c. which state of the eyesight is termed by oculists *Metamorphosis*.

Symptoms when the disorder proceeds from disease of the optic nerves, or their sheaths.

This case comes on slowly, and rarely attacks both eyes together. It always commences with a black cloud, which grows more and more dense, and with a troublesome, alarming perversion and disfigurement of every object, without the least painful sensation in the eye or head. The patient merely complains of a slight sensation of dull pressure at the bottom of the orbit, as if the eyeball were about to be forced from its socket, of which displacement, however, there is not yet the smallest appearance. In the very beginning of the disease, the pupil is already considerably dilated, and the pupillary edge of the motionless iris presents angles at several points, the pupil sometimes representing an irregular pentagon, or hexagon. By degrees, though very slowly, a glaucomatous change of the vitreous humour ensues, and afterwards of the lens itself, the only species of glaucoma which Beer has ever noticed quite unattended with a varicose affection of the blood-vessels of the eye. At last the globe of the eye becomes perceptibly smaller than natural; but a complete atrophy does not ensue.

Symptoms when the case proceeds from disease of the skull or brain.

In this form of amaurosis, which usually attacks both eyes together, or at least one very soon after the other, the blindness also commences very slowly, with appearances as if every object looked at were perverted or disfigured. However, there is no black cloud, but rather an obscurity or confusion of every object. The disease in this stage is also accompanied with frequent giddiness, ugly luminous spectra, and for the most part, with aversion to light, uncommonly lively motions of the iris, a contracted pupil, angles in the upper and lower portions of the pupillary margin of the

ris; an evident turgescence of the blood-vessels of the eye, gradually augmenting with most violent headach into actual circophthalmia; frequent convulsive motions of the eyes and eyelids, and strabismus of one or both eyes, ending in a true deviation of one or both these organs from their natural positions. Under these symptoms, vision is afterwards entirely abolished; and the headach, though subject to remissions, grows so much worse, extending back to the spine, that the patient is often nearly frantic, and, indeed, after a time, a destruction of the external senses happens followed by that of the intellectual faculties. The first of the external sense which is lost, is always the hearing, which infirmity is next followed by loss of the smell, or taste, or both these senses together; and then the memory, and other intellectual powers decline. In this stage of the disorder, the eyeball not unfrequently protrudes from the orbit; a pathognomonic symptom, to which Beer attaches great importance, because it is an infallible criterion of a diseased state of the bones of the orbit, of the parts which invest this cavity, and of the optic nerve and dura mater, in the sella turcica. In such cases, complete mania now usually follows, and this sometimes in its most violent form, unless the patient happen to be first carried off by paralytic symptoms, life, under these circumstances, never lasting any considerable time.

As far as our external senses can discover, the cause of both these forms of amaurosis, as the title of this section specifies, lies in certain morbid changes in the structure of the optic nerve and its investments, or in diseased alterations of the bones of the cranium, the dura mater, and the brain. But how these changes arise is not so easy of explanation. Beer, therefore, only makes a brief enumeration of his own observations and pathologico-anatomical investigations into this part of the subject. The morbid changes in the structures above mentioned, which Beer has yet ascertained by dissection, consist in a real induration of the optic nerves, and an adhesion of them to their sheaths, while within the skull these ash-coloured gray very much diminished nerves presented no vestige of medullary structure even as far as their origin from the brain. On the contrary, the optic thalamus presented externally its natural appearance. The retina seemed to have lost its pulpy matter, was tough, not easily torn, and appeared to consist but of a vascular membrane. In one example, although both eyes had been completely deprived of sight together, Beer found only the retina and optic nerve of the left side in this state of atrophy as far forwards as the point of union in the sella turcica. On the other hand, the optic nerve of the right eye was hard, without being in the least dwindled, and was closely adherent to its external coverings. Anteriorly to their decussation, nothing at all preternatural in either nerve could be dis-

cerned. But the left corpus striatum was so indurated, that a very sharp strong scalpel was required for its division, though in colour and shape it was perfectly natural. On this side, also, the plexus choroides was entirely wanting. In three amaurotic patients of this kind, Beer found hydatids between the coverings of the optic nerve, and, where such hydatids lay, the medullary matter seemed to have been displaced by their pressure. With the utmost care, he could not trace the ophthalmic ganglion.

Paw also found in the optic nerve a large hydatid, which had produced amaurosis. (*Obs. Anat. Rarior. Obs. 2.*) In Mr. Heavyside's museum, there is a preparation of the optic nerve of an amaurotic eye, where a tumour of considerable bulk has grown from the neurilema. (See *Wardrop's Essays on the Morbid Anatomy of the Human Eye, Vol. 2. p. 157.*) In this work are specified examples of various other morbid changes of the optic nerve, especially calculous concretions within it, the presence of a viscid, muddy, gray fluid, in the thickened neurilema, instead of pulp, a dwindling of the nerve, &c.

To the present description of cases, Beer refers the instance recorded by Haller, (*Opusc. Pathol. Obs. 65, p. 172.*) in which a calcareous mass was found betwixt the membrane of Ruysch, and the vitreous humour. According to Beer, there is preserved in the pathological and anatomical museum of the general hospital at Vienna, an eye distended with a similar osseous mass, without the capsule of the lens being at all affected. Examples, in which the amaurotic blindness arose from abscesses in the brain, are reported by Ballonius (*Paradigmata Hist. 7.*) by Pelargus, (*Med. Jahrg. 3, p. 198.*) Peyronie (*Mém. de l'Acad. Royale de Chir. 1, p. 212.*) Schaarschmid (*Berlin Nachrichte, 1740, No. 26.*) and Langenbeck (*Neue Bibl. 1, p. 61.*) A case occasioned by disease of the thalamus is related by Villeneuve, (*Journ. de Med. continué 1811, Fevr. p. 98.*) another of a tumour of the thalamus on the same side as the blindness, is recorded by Ford, (*Med. Commun. Vol. 1, No. 4.*) and other swellings in various parts of the brain are described in *Ephem. Nat. Cur. Dec. 3, Ann. 9, and 10, Obs. 253.* De Haen's *Ratio Medendi. P. 6, p. 271.* *Journ. des Savans. 1697.* Muzell's *Wahrnehm. 2, No. 13.* Plater, *Obs. lib. 1, p. 108.* Thomann, *Annalen für 1800, p. 400, &c.* On this part of the subject, I beg leave to refer also particularly to my friend Mr. Wardrop's valuable *Essays on the Morbid Anatomy of the Human Eye, Vol. 2, p. 174, &c.*

The morbid alterations of the bones of the cavity of the skull mostly happen at its basis, and not only may caries take place, but still more frequently exostoses of various forms, which are sometimes so small that they are first detected by the bone giving the feel of a rough grater. At the same time they are so sharp, that if the finger be passed rudely over them, it will be

painfully hurt. In these cases, the bones of the cavity of the skull are always found extremely thin; the diploe is almost entirely wanting, and the parietes of the orbit are preternaturally diaphanous, and in some places imperfect. Beer speaks of a lady's skull, who had been completely blind, and for some weeks previously to her death insensible, in which instance scarcely any part of the cavity of the skull could be carelessly touched, without risk of scratching the fingers with spiculæ. Once, in an amaurotic boy, who, for a short time before his death, was so insane, that he used to devour his own excrement, Beer found at the side of the sella turcica a long considerable spicula, which passed directly through the optic nerves at the place of their decussation. A case of amaurosis produced by a spicula of bone, injuring the opposite side of the brain, is related by Anderson. (See *Trans. of the Society of Edinb. Vol. 2.*) Sometimes the ethmoid bone has been found carious, (*Ballonius, Paradigmata, No. 7*;) sometimes other parts of the cranium. (*Mursinna, Beobacht 1, No 6*; *Schmucker, Vermischte Schrift. 2, p. 12.*) Nor is it unfrequent to find the medullary substance of the brain itself as soft as pap, while the cortical substance is full of blood-vessels and unusually firm, the convolutions being hardly distinguishable. It further seems as if only particular individuals were liable to these two forms of amaurosis; for hitherto Beer has not met with these morbid changes of the optic nerves and their coverings, except in emaciated, badly nourished amaurotic patients, in whom some clear signs of scrophula had appeared during youth, especially in the glands of the neck; while the above described changes in the bones of the skull and in the brain itself, Beer has seen only in such amaurotic patients as evidently had suffered in their youth from rachitis throughout their whole osseous system, and who at a later period had had syphilis, or, in their best days, been decidedly gouty. In almost all these cases, a careful inquiry into their history tended to prove, that the affection of the head and eyes had been preceded by a sudden exposure of the head to cold, whence arose rheumatism, particularly affecting the aponeurosis under the scalp, though at first it was apparently inconsiderable.

What degree of accuracy may belong to the foregoing observations, I cannot pretend to say, though it is impossible for me not to suspect, that they are less valuable and correct, than some other remarks made by this experienced writer.

Many of the causes of amaurosis are of such a nature, as to render the disease totally incurable. Of this description is fungus hæmatodes, in which the structure of the retina and optic nerve is changed in a remarkable manner, the whole cavity of the eyeball becoming filled with a substance resembling medullary matter, and the optic nerve changed in its form, colour, and structure. (See *Wardrop's Essays on the*

Morbid Anatomy of the Human Eye, Vol. 2, p. 156, 8vo. Lond. 1818.)

On the authority of Ecker, one case is upon record, where the cause of amaurosis depended upon an aneurism of the central artery of the retina. (*Pinel, Nosographie Philos. Vol. 2, p. 122.*)

In another instance, the macula lutea, which is naturally a yellow spot near the centre of the retina, was found black. (*Mém. de la Société Méd. d'Emulation, an. 1798.*)

Bonetus, in his *Sepulchretum Anatomicum, lib. 1, sect. 18*, describes various cases which were quite incurable. After death, the blindness, in one instance, was found to be occasioned by an encysted tumour, weighing fourteen drams, situated in the substance of the cerebrum, and pressing on the optic nerves near their origin. In a second, the blindness was produced by a cyst, containing water, and lodged on the optic nerves where they unite. In a third, it arose from a caries of the os frontis, and a consequent alteration in the figure of the optic foramina. In a fourth, the cause of the disease was a malformation of the optic nerves themselves. In some of the instances, in which no apparent alteration can be discovered in the optic nerve, Mr. Ware conjectures whether a dilatation of the anterior portion of the circulus arteriosus may not be the cause of the affection. The circulus arteriosus is an arterial circle, surrounding the sella turcica, formed by the carotid arteries on each side, branches passing from them to meet each other before, and other branches passing backwards, to meet branches from the basilar artery behind. The anterior part of the circulus arteriosus lies directly over, crosses, and is in contact, with the optic nerves, and just in the same way as the anterior branches lie over the optic nerves, the posterior ones lie over the nervi motores oculorum. Hence Mr. Ware attempts to refer the amaurosis itself, and the paralytic affection of the eyelids, and muscles of the eye, sometimes attendant on the complaint, to a dilatation of the anterior and posterior branches of the circulus arteriosus. Dr. Baillie has noticed, in his *Morbid Anatomy*, the frequently diseased state of the trunk, or the small branches of the carotid arteries at the side of the sella turcica; and he says the same sort of diseased structure is also found in the basilar artery and its branches. (See *Ware's Chir. Obs. on the Eye.*)

When the diagnosis of these cases is perfectly clear, the prognosis can admit of no doubt; for, in the present state of medical science, what intelligent surgeon can here forbode any thing else, than the gradual formation of complete blindness (if that be not already produced,) and not merely death, but one of a miserable description. Nay, says Beer, even where some specific constitutional disease is manifestly concerned in the production of the amaurosis, like syphilis or gout, none but a fool would hold out any hope of benefit to the patient, be-

cause, in general, when the practitioner is sent for, not only the constitutional complaints have become too deeply rooted and inveterate, but the system has been already too much reduced by anxiety, long suffering, and manifold courses of medicine, for any prospect of a cure of the general disorder to be entertained, much less that of the existing blindness. It is only when this dreadful disease of the head and eyes assuredly proceeds from some known specific disorder that any mode of treatment can be adopted, which is founded on principle. As far as Beer's experience goes, however, the treatment always fails; an event, which, in supposed syphilitic and gouty cases, where the strongest mercurials, antimonials, and other alteratives are useless, he ascribes to the debilitated state of the constitution; but which he might, with more propriety, impute both to our total ignorance of any connexion between the blindness and syphilis, or gout, and to our having no medicine which has the slightest power to check or remove the morbid changes in the optic nerve and its coverings, or in the cranium or brain. Neither, says Beer, can any good be done by scorbutic medicines, where the amaurotic patient has betrayed symptoms of scurvy. The treatment then must be more or less empirical, which is always the most subject to failure, and the least deserving of confidence, especially in these desperate urgent cases. As for local treatment of the eye itself, it is obvious, that nothing need here be said upon the subject. (See *Beer's Lehre von den Augenkr.* B. 2, p. 576. 584.)

Scarpa, Venez. 1802. This book has gone through five editions in Italy. The last, which is much improved, has been well translated by Mr. Briggs. *W. Hey in Practical Observations in Surgery, and Med. Obs. and Inquiries*, Vol. 5. *Schmucker's Wahrnehmungen*, B. 1, p. 273. *Richter's Anfangsgründe der Wundarzneykunst*, B. 3. *Chandler's Treatise on the Diseases of the Eye*, chap. 24. 8vo. Lond. 1780. Some scattered remarks in the posthumous work on the diseases of the eye, of the late J. C. Saunders, &c. *De Wenzel, Manuel de l'Oculiste, ou Dictionnaire Ophthalmologique*, 8vo. Paris, 1808.

Many additional observations connected with the subject of Amaurosis will be found in the articles *Cataract*, *Diplopia*, *Gutta Serena*, *Hemeralopia*, *Hemiopia*, *Nyctalopia*, *Sight Defects of*, &c.

AMBE. (from *αμβη*, the projecting edge of a rock.) An old surgical machine for reducing dislocations of the shoulder, and so called, because its extremity projects, like the prominence of a rock. Its invention is imputed to Hippocrates. The ambe is the most ancient mechanical contrivance for the above purpose; but, it is not at present employed. Indeed, it is scarcely to be met with in the richest cabinets of surgical apparatus. It is composed of a piece of wood, rising vertically from a pedestal. With the vertical piece is articulated, after the manner of a hinge, an horizontal piece, with a gutter formed in it, in which the luxated limb is laid, and secured with straps. The patient places himself on one side of the machine; his arm is extended in the gutter, and secured; the angle, formed by the union of the ascending piece, and by the horizontal branch, is lodged in the armpit, and then the horizontal branch is depressed. In this way extension is made, whilst the vertical part makes counter extension, and its superior part tends to force the head of the humerus into the articular cavity. But, there is nothing to fix the scapula, and the compression made by the superior portion of the vertical piece of the machine tends to force the head of the humerus into the glenoid cavity, before it is well disengaged by the extension. (*Boyer on Diseases of the Bones*, Vol. II.)

AMBLYOPIA. (from *αμβλυς*, dull, and *ὤψ*, the eye.) Hippocrates means by this word, in his Aph. 31. Sect. 3. the dimness of sight, to which old people are subject. Modern writers generally understand by amblyopia, incomplete amaurosis, or the weakness of sight attending certain stages and forms of this disorder. (See *L'Encyclopédie Methodique; Partie Chirurgicale; Art. Amblyopie.*)

AMMONIÆ MURIAS, AMMONIA, MURIATA, or *Sal Ammoniac*. Its chief use in surgery is as an external discutient application. (See *Lotio Ammon. Muriatæ cum Aceto.*)

Mr. Justamond recommends the following application to milk-abscesses: R. *Ammoniae Muriatæ* ℥j. *Spiritus Roris marini* ℔j. *Misce*. Linen rags are to be wet with the

remedy, and kept continually applied to the part affected.

There can be little doubt of the utility of this lotion in dispersing the induration left after mammary abscesses; but, while these cases are accompanied with much pain, tension, and inflammation, emollient fomentations and poultices are to be preferred.

* **AMPUTATION.** (from *amputatio*.) This term signifies the operation of cutting off a limb, or other part of the body, as the breast, penis, &c.

Such an operation frequently becomes indispensably proper, on the principle of sacrificing a branch, as it were, for the sake of taking the only rational chance of saving the trunk itself. Indeed, the suggestion of this measure, in cases of mortification, where there is no chance of the parts recovering, may be said to be derived from nature herself, who by a process, to which I shall advert in speaking of *mortification*, detaches the dead from the living parts; this separation is followed by cicatrization, and the patient recovers.

The necessity for amputation has always existed, and ever will continue, as long as the destructive effects of injuries and diseases of the limbs cannot be obviated in any other manner. As Graefe observes, there was once a period, (I should say, about forty years ago) when the operation was more frequently practised, than at present, and this fact is to be imputed less to the caprice of surgeons, than to the imperfection of the means which used to be employed for the relief of local diseases. For then aneurisms of the limbs, and some other cases, at present treated with success, were always deemed incurable without amputation. Boucher, Gervaise, Faure, and Bilguer inveighed against the frequent performance of amputation on the field of battle; yet their arguments must prove of little value, unless a path were at the same time traced, which would conduct us to the method of remedying the circumstances which form the necessity for the operation. When this condition is fulfilled, and more effectual modes of treatment are devised, as for instance, with respect to the gunshot wounds, specified by Bilguer, then the necessity for amputation in such cases would cease of itself. (*Normen für die Ablösung grösserer Gliedmassen*, p. 13, 4to. Berlin, 1812.)

As the author of another valuable modern work has said, it is an excellent observation, founded on the purest humanity, and justified by the soundest professional principles, that to *save one limb is infinitely more honourable to the surgeon, than to have performed numerous amputations, however successful*; but it is a remark, notwithstanding its quaintness, fully as true, that it is much better for a man to "live with three limbs, than to die with four." (*Hennen on Military Surgery*, p. 251, Ed. 2.)

To this saying should be added the reflection, that some unfortunate beings, influ-

enced by a relish for life, have been known to submit to the loss of all their legs and arms, and yet recover. In the *Hôtel des Invalides* at Paris, mutilated objects are in recollection, who had lost their thighs and arms, so that, unless assisted, they could not stir, and it was necessary to feed and wait upon them, like new-born infants. (*Morand Opusc. de Chir.*, p. 183, and *Graefe Op. cit.* p. 23.)

The amputation of the large limbs was anciently practised under many disadvantages. The best way of making the incisions was unknown; the ignorance of the old surgeons of the right method of stopping hemorrhage was the death of a large proportion of the patients, who had courage to submit to the operation; the mode of healing the wound by the first intention was not understood, or not duly appreciated; and the instruments were as awkward and clumsy, as the dressings were irritating and improper.

Modern practitioners have materially simplified all the chief operations in surgery; an object, which has been accomplished not merely by letting anatomical science be the main guide of their proceedings; not simply by devising more judicious, and less painful methods; not only by diminishing the number, and improving the construction of instruments; but also in a very essential degree by abandoning the use of a multitude of external applications, most of which were useless or hurtful.

The Greek, Roman, and Arabian practitioners amputated limbs with feelings of alarm, and, in general, with the most melancholy results; while modern surgeons proceed to the operation completely fearless, well knowing that it mostly proves successful: hence, as Graefe justly remarks, nothing can be more evident, than that the patient's safety must depend very much upon the kind of practice. (*See Normen für die Ablösung grösserer Gliedmassen* p. 1.) By practice, is here implied the mode in which the operation is performed, the way in which the wound is dressed, and the whole of the after-treatment.

But, much improved as amputation has been, it cannot be dissembled, that it is an operation at once terrible to hear, dreadful to behold, and sometimes severe and fatal in the consequences which it itself produces, while the patient, if saved, is left for ever afterwards in a crippled mutilated state. Hence, it is the surgeon's duty never to have recourse to so serious a proceeding, without a perfect and well-grounded conviction of its necessity. Amputation should be generally regarded as the last expedient to which a surgeon ought to resort; an expedient justifiable, as a late writer says, only when the part is either already gangrenous, or the seat of so much injury, or disease, that the attempt to preserve it any longer, would expose the patient's life to the greatest danger. (*Dict. des Sciences Med. T. 1*, p. 472.)

Although, says a distinguished modern

surgeon, this amounts to a confession, that the cure of some local disorders is not within the limits of our art, yet, on the other hand, it furnishes a proof, that surgery may be the means of saving life under circumstances, which, without its assistance, would infallibly have a fatal termination. The operation is adopted as the safest measure; the cause is removed for the prevention of consequences. (*Græfe, Op. cit. p. 14.*)

Nothing can be more absurd, or more misapplied, than the censures sometimes passed upon amputation, because the body is mutilated by it, &c. Although, as a modern writer remarks, the objection proves the limitation of human knowledge and ability, it must be very unfair on this account to throw blame on surgery, or the practitioner who thus saves the patient's life. For, without dwelling upon the fact, that a humane surgeon would never amputate through a mere love of operating, and without urgent cause, one may simply ask, are all diseases in their nature curable? Does not the surgeon cure such as are curable, without mutilation? And are not cases, which were in the beginning remediable, often first brought to the surgeon, when from neglect they have become totally incurable? Is it not his duty then to employ the only means left for saving the patient? And is not the preservation of a long and healthy life a compensation for the sacrifice? Would it not be just as reasonable to blame an architect, when the irresistible force of lightning or a bomb destroys his building? Indeed, is it not rather a greater honour to surgery, that, even when death has already taken possession, as it were, of a part, and is threatening inevitable destruction to the whole, a means is yet furnished, not only for saving the patient's life, but for bringing him into a state, in which he may recover his former good health? (*Brünnigshausen, Erfahrungen und Bemerkungen über Die Amputation, p. 11, 12mo. Bamberg, 1818.*)

Though amputation is in every respect much better, than in former times, and its right performance is by no means difficult; I would not wish to be thought to say, that it is always or even usually done *secundum artem*, because long opportunities of observation have convinced me of the contrary; and the reason of the knife being yet so badly handled in this part of surgery, may generally be imputed to carelessness, slovenly habits, or, what is as bad, a want of ordinary dexterity. There are several egregious faults in the method of amputating, which even many hospital surgeons in this metropolis are guilty of; but these we shall find, when we criticise them, are, for the most part, easily avoidable, without any particular share of skill being required. A greater difficulty is to ascertain with precision the cases, which demand the operation; those in which it may be dispensed with; and the exact periods at which it should be practised. These are considerations requiring profound attention, and the brightest talents. The most expert opera-

tor (as Mr. O'Halloran observes) may not always be the best surgeon. To do justice to the sick and ourselves, we must, in many cases, rather avoid than perform capital operations; and with respect to amputation, if we consider the many cases, in which it has been unnecessarily undertaken, or done at unreasonable periods, it may be suspected, that this operation, upon the whole, may have done more mischief than good. At all events, it is not enough for a surgeon to know *how* to operate; he must also know *when* to do it. (See *O'Halloran on Gangrene and Sphacelus; preface.*)

For such reasons, I shall first take a view of the circumstances, under which, the best surgeons deem amputation necessary: though it may be proper to observe, that, in each of the articles, relative to the particular diseases and injuries, which ever call for the operation, additional information will be offered.

1. *Compound fractures.*

In a compound fracture, the necessity for amputation is not altogether proportioned to the seriousness of the accident, but also frequently depends in part upon other circumstances. For example, in the field and on board of a crowded ship, it is not constantly in the surgeon's power to pay such attention as the cases demand, nor to procure for the patient the proper degree of rest and good accommodation. In the field, there is often a necessity for transporting the wounded from one place to another. Under these circumstances, it is proper to have immediate recourse to amputation, in numerous cases of bad compound fractures, some of which, perhaps, might not absolutely demand the operation, were the patients so situated, as to be capable of receiving all the advantages of the best and most scientific treatment in a well-ventilated quiet house, or hospital, furnished with every desirable convenience. At the same time, daily experience proves, that there are many other cases, in which it would be improper to have recourse to the knife, even under the most unfavourable circumstances of the above description. So, when a compound fracture occurs, in which the soft parts have not been considerably injured; in which the bones have been broken in such a direction that they can be easily set and kept in their proper position, or in which there is only one bone broken, amputation would be unnecessary and cruel. But, when the soft parts have been more extensively hurt, and the bones have been so badly broken, that perfect quietude and incessant care are required to afford any chance of recovery, it is a good general rule to amputate whenever these advantages cannot be obtained.

The bad air in crowded hospitals and large cities, a circumstance so detrimental to wounds in general, is another consideration which may seriously lessen the chances of saving a badly broken limb, and should be remembered in weighing the reasons for and against amputation.

On this part of the subject, I find the sentiments of Graefe interesting: besides an absolute, says he, there is a relative, necessity for amputation: it is the most mournful, and proceeds altogether from unfavourable external circumstances, though, alas! in many cases nearly unavoidable, when life is to be preserved. In war, every bloody action furnishes proof of what has been stated. The number of the wounded is immense; the number of surgeons for the duty too limited. The supplies most needed are at a distance. In these emergencies, though the military surgeon may from routine and genius be able to suggest the quickest method of obtaining what is wanted, know how to avail himself of every advantage, which circumstances permit, and to contrive tolerable substitutes for such things as are deficient, yet, this will not always do. Were we (says Graefe) here to complain of the Prussian government not providing due assistance for the defenders of our native soil, to many the remonstrance would only appear reasonable. Yet, they who manage the medical affairs of the Prussian army may not constantly have it in their power to avert the inconvenience. The general cannot foretell the number and nature of the wounds, which may happen, so as to enable the medical department to take with them exactly the apparatus required, without encumbering the army with a redundancy of useless articles. The enemy, perhaps, captures the medical stores; or the rapid movements of particular corps cut us off from the principal depôts. Detachments often skirmish at remote points. The hospitals may lie several miles in the rear of the line; and, for want of means, the transport of the imperfectly dressed wounded may continue night and day. Hardly are the sufferers brought into the nearest hospital, in the most pitiful state from pain, anxiety, and cold, when an order is given to break up, and they must be conveyed still further towards their grave; and a thousand other circumstances, as Graefe observes, which deprive the wounded of the requisite attendance, and essential number of surgeons, together with the most necessary stores, make it desirable to simplify every wound as much as possible; which, indeed, is the only means of shunning the reproach, that while we are endeavouring to save one man's limb, we let another die.

Who doubts, says Graefe, that a soldier with a gunshot wound, complicated with a smashed state of the bones, may sometimes be saved, without loss of his limb, by employing all the means, which the resources of surgery offer? But these very resources are often wanting in a campaign; and the business of dressing the patient would occupy the surgeon several hours daily, during which his useful assistance could not be extended to other sufferers. Notwithstanding the utmost care, the removal of patients from one place to another frequently makes their wounds extremely danger-

ous, or fatal; and we now lose many a man, who, had he undergone amputation, would have been able to bear the journey. (See *Normen für die Ablösung grösserer Gliedmassen*, p. 15, 16.)

From what I have seen of the ill effects of moving patients with bad compound fractures of the lower extremity, produced by gunshot violence, I am convinced, that, as a general rule, it is better to perform amputation; but, if this be not done, and an attempt is to be made to save the member, it will be more humane, when the army is retreating, and the enemy are not savages, to leave such wounded behind, than subject them to all the fatal mischief of hastily and roughly transporting them in such a condition. It gives me particular pleasure to find the preceding sentiment confirmed by Dr. Hennen, whose knowledge and experience in military surgery entitle all his opinions to the greatest attention: in noticing what ought to be done with the wounded, when the army is compelled to retreat, he says, "it then becomes the duty of a certain proportion of the hospital staff to devote themselves for their wounded, and become prisoners of war along with them; and it may be an encouragement to the inexperienced, while it is grateful to me, to observe, that I have never witnessed, nor traced, on inquiry, an act of unnecessary severity practised either by the French or English armies on their wounded prisoners."

Compound fractures of the thigh, produced by gunshot violence, too often have an unfavourable termination, especially when the accident has been caused by grape-shot, or even a musket-ball, fired from a moderate distance, and the patient is moved from one place to another after the receipt of the injury. In the military hospital at Oudenbosch, in the spring of 1814, I had charge of about eight bad compound fractures of the thigh, of which cases only one escaped a fatal termination. This was an instance, in which the femur was broken a little way above the knee. Another patient was extricated by amputation from the perils, immediately arising from the splintered displaced state of the bone, the serious injury of the muscles, and enormous abscesses, but was unfortunately lost by secondary hemorrhage. All these patients had not merely been struck by grape-shot, or else by balls fired from a short distance, but they had been moved from Bergen-op-Zoom into my hospital, five or six days after the receipt of the injury, the very worst period possible, on account of the inflammation being then most violent. From the ill success of these cases, many a surgeon, who saw them, might be inclined to think, that immediate amputation ought generally to be performed for all compound fractures of the thigh, as soon after the receipt of the injury as possible. And such is my own sentiment, whenever the accident has been caused in the violent man-

mer above specified, or whenever the patient must be moved any distance in a wagon after the occurrence of the injury. It may be right to state, however, that I have known more than one compound fracture of the thigh cured, where the accident had not been occasioned by gunshot violence, and I have been informed of one or two successful cases, where the bone was broken by a pistol-ball. However, these may only have been lucky escapes, deviations from what is common, and not entitled to any stress with the view of affecting the general excellent rule of amputating, where the thigh-bone is broken by gunshot violence.

As Mr. Guthrie has accurately observed, one circumstance, which increases the danger of fractures of the femur, from gunshot violence, is, that the bone is very often broken obliquely, the fracture extending far above and below the point immediately struck by the ball. (*On Gunshot Wounds*, p. 189, 190.) This disposition of the thigh-bone to be splintered for several inches when hit by a ball, and the increased danger, arising from the occurrence, are also very particularly commented upon by the experienced Schmucker, who was surgeon-general to the Prussian armies in the campaigns of Frederick the Great. (See his *Vermischte Chirurgische Schriften*, B. 1. p. 39. 8vo. Berlin, 1785.) In several of the cases which were under the care of Dr. Cole and myself in Holland, the bone was split longitudinally, to the extent of seven or eight inches.

According to Schmucker, all fractures of the middle or upper part of the femur, are attended with great danger. "But (says he) if the fracture be situated at the lowest part of the bone, the risk is considerably less, the muscles here not being so powerful; in such a case, therefore, amputation should not be performed, before every other means has been fairly tried; and very frequently I have treated fractures of this kind with success, though the limb sometimes continued stiff. But (says Schmucker) if the bone be completely fractured or splintered by a ball at its middle, or above that point, I never wait for the bad symptoms to commence, but amputate ere they originate, and, when the operation has been done early enough, most of my patients have been saved. However, when some days had transpired, and inflammation swelling, and fever had come on, I must candidly confess, that the issue was not always fortunate. Yet the operation should not, on this account, be dispensed with; for, if only a few can thus be saved out of many, some benefit is obtained, as, without this step, such few would also perish." (*Vermischte Chir. Schriften*, B. 1. p. 42.) What I saw of compound fractures of the thigh, after the assault on Bergen-op-Zoom, we may remark, coincides with the results of Schmucker's ample experience; for the only two patients who got over the bad symptoms proceeding directly from the

fracture, were one whose femur was broken near the knee; and another, whose limb I took off, on account of a fracture of the middle of the bone, accompanied with abscesses of surprising extent. The latter was a case, however, in which the limb ought to have been removed earlier. The following remarks by Mr. Guthrie, I consider judicious and correct.

"The danger and difficulty of cure, attendant on fractures of the femur from gunshot wounds, depend much on the part of the bone injured; and, in the consideration of these circumstances, it will be useful to divide it into five parts. Of these, the head and neck included in the capsular ligament, may be considered the first; the body of the bone, which may be divided into three parts, and the spongy portion of the lower end of the bone exterior to the capsular ligament, forming the fifth part. Of these, the fractures of the first kind are, I believe, always ultimately fatal, although life may be prolonged for some time. The upper third of the body of the bone, if badly fractured, generally causes death at the end of six or eight weeks of acute suffering. I have seen few escape, and then not with a useful limb, that had been badly fractured in the middle part. Fractures of the lower or fifth division, are in the next degree dangerous, as they generally affect the joint; and the least dangerous are fractures of the lower third of the body of the bone. Of these even I do not mean to conceal, that when there is much shattered bone, the danger is great, so that a fractured thigh by gunshot, even without particular injury of the soft parts, is one of the most dangerous kinds of wounds that can occur." (See *Guthrie on Gunshot Wounds*, p. 190.)

In compound fractures, as Mr. Pott has correctly pointed out, there are three points of time when amputation may be proper. The first of these is immediately, or as soon as possible after the receipt of the injury. The second is, when the bones continue for a great length of time without any disposition to unite, and the discharge from the wound has been so long, and is so large, that the patient's strength fails, and general symptoms foreboding dissolution come on. The third is, when a mortification has taken such complete possession of the soft parts of the inferior portion of the limb, quite down to the bone, that upon the separation of such parts, the bone or bones shall be left bare in the interspace.

The first and second of these are matters of very serious consideration. The third hardly requires any.

When a compound fracture is caused by the passage of a very heavy body over a limb; such, for instance, as the broad wheel of a wagon or loaded cart, or by the fall of a very ponderous body on it, or by a cannon shot, or by any other means so violent as to break the bones into many fragments, and so to tear, bruise, and wound the soft parts, that there shall be good reason to fear, that there will not be vessels sufficient

to carry on the circulation with the parts below the fracture, it becomes, as Mr. Pott observes, a matter of the most serious consideration, whether an attempt to save such a limb will not occasion loss of life. This consideration must be before any degree of inflammation has seized the part, and therefore must be immediately after the accident. When inflammation, tension, and a disposition to gangrene in the limb have arisen, the period is highly disadvantageous for operating, and the patient's chances of being saved by amputation, under these circumstances, are much smaller than before the changes here spoken of had taken place. At the same time, there are certain examples of mortification from external causes, where, as far as one can judge from the results of later experience than that of Mr. Pott, the surgeon should not defer amputation, even though the disorder be yet in a spreading state, attended with considerable swelling and tension reaching far up the limb. This is a subject, however, which will require more explanation hereafter. (See what is presently said on *Mortification*.) Nor are the cases, to which reference is made, meant to affect the general truth of the observation, delivered by the most experienced surgeons of every age, that when a limb is extensively swelled and inflamed, with a part of it either in a state of spreading mortification, or ready to become gangrenous, the period is so unfavourable for amputation, that very few patients, so circumstanced, ever recover after the operation. Nor is it meant to be insinuated, that in the very cases which form exceptions to the general rule of not amputating before the tendency to gangrene has ceased, the patient might not have had an infinitely better chance of his life, had the operation been done immediately after the first receipt of the injury, before any disposition to gangrene had had time to be produced.

The necessity of immediate or very early decision, in this case, makes this a very delicate part of practice; for, however pressing the case may seem to the surgeon, it will not, in general, appear in the same light to the patient, to the relations, or to bystanders. They will be inclined to regard the proposition as arising from ignorance, or an inclination to save trouble, or a desire to operate; and it will often require more firmness on the part of the practitioner, and more resignation and confidence on the part of the patient, than is generally met with, to submit to such a severe operation, in such a seeming hurry, and upon so little apparent deliberation; and yet it often happens, that the suffering this point of time to pass, decides the patient's fate.

This necessity of early decision arises from the quick tendency to mortification, which ensues in the injured limb, and too often ends in the patient's death. That this is no exaggeration, says Pott, melancholy and frequent experience evinces, even in those whose constitutions, previous to the

accident, were in good order; but much more in those, who have been heated by violent exercise or labour, or liquor, or who have lead very debauched and intemperate lives, or who have habits naturally inflammable and irritable. This is often the case when the fracture happens to the middle part of the bones, but is much more likely to happen when any of the large joints are concerned. In many of these cases, a determination for or against amputation, is really a determination for or against the patient's existence.

That it would have been impossible to have saved some limbs, which have been cut off, no man will pretend to say; but this does not render the practice injudicious. Do not the majority of those who get into the above hazardous condition, and on whom amputation is not performed, perish in consequence of their wounds? Have not many lives been preserved by amputation, which, from the same circumstances, would otherwise most probably have been lost?

Pressing and urgent as the state of a compound fracture may be, at this first point of time, still it will be a matter of choice, whether the limb shall be removed or not; but, at the second period, the operation must be submitted to, or the patient must die.

The most unpromising appearances at first, do not necessarily, or constantly end unfortunately. Sometimes, after the most threatening first symptoms, after considerable length of time, great discharges of matter, and large exfoliations of bone, success shall ultimately be obtained, and the patient shall recover his health and the use of his limb.

But sometimes, after the most judicious treatment through every stage of the disease; after the united efforts of physic and surgery, the sore, instead of granulating kindly, and contracting daily to a smaller size, shall remain as large as at first, with a tawny, spongy surface, discharging a small quantity of thin sanies, instead of a large one of good matter; the fractured ends of the bones, instead of tending to exfoliate, or to unite, will remain as perfectly loose and disunited as at first, while the patient shall lose his sleep, his appetite, and his strength; a hectic fever, with a quick, small, hard pulse, profuse sweats, and colliquative purging, contributing at the same time to bring him to the brink of the grave, notwithstanding every kind of assistance: in these circumstances, if amputation be not performed, Mr. Pott asks, what else can rescue the patient from destruction?

The third and last period is a matter which does not require much consideration. Too often the inflammation consequent upon the injury, instead of producing abscess and suppuration, tends to gangrene and mortification, the progress of which is often so rapid, as to destroy the patient in a very short space of time, constituting that very sort of case in which amputation should

have been immediately performed. But sometimes even this dreadful malady is, by the help of art, put a stop to, but not until it has totally destroyed all the surrounding muscles, tendons, and membranes quite down to the bone, which, upon the separation of the mortified parts, is left quite bare, and all circulation between the parts above and those below, is by this totally cut off. In this instance, whether the surgeon saw through the bare bone, or leave the separation to be effected by nature, the patient must lose his limb. (See *Pott's Remarks on the Necessity, &c. of Amputation in certain Cases, &c. Chir. Works, vol. 3.*)

For the consideration of a variety of complicated cases, which affect the question of amputation in compound fractures, I must refer to the article *Gunshot Wounds*.

2. Extensive contused and lacerated wounds.

These form the second class of general cases requiring amputation. Wounds without fracture are not often so bad as to require this operation. When a limb, however, is extensively contused and lacerated, and its principal blood-vessels are injured, so that there is no hope of a continuance of the circulation, the immediate removal of the member should be recommended, whether the bones be injured or not. Also, since no effort on the part of the surgeon can preserve a limb so injured, and such wounds are more likely to mortify than any others, the sooner the operation is undertaken the better.

In these cases, as in those of compound fractures, though amputation may not always be necessary at first, it may become so afterwards. The foregoing observations, relative to the second period of compound fractures, are equally applicable to badly lacerated wounds, unattended with injury of the bones. Sometimes a rapid mortification comes on; or a profuse suppuration, which the system can no longer endure. (*Encyclopédie Méthodique; Partie Chir. t. 1. p. 80.*)

3. Cases in which part of a limb has been carried away by a cannon ball.

When part of a limb has been torn off by a cannon ball, or any other cause, capable of producing a similar effect, the formation of a good and serviceable stump, the greater facility of healing the clean, regular wound of amputation, and the benefit of a far more expeditious as well as of a sounder cure, are the principal reasons which here make the operation advisable.

This was an instance, in which some former surgeons disputed the necessity of amputation. They urged as a reason for their opinion, that the limb being already removed, it is better to endeavour to cure the wound as speedily as possible, than increase the patient's sufferings and danger, by making him submit to amputation. It must be remembered, however, that the bones are generally shattered, and reduced into

numerous fragments; the muscles and tendons are unequally divided, and their ends torn and contused. Now, none of the old surgeons questioned the absolute necessity of extracting the splinters of bone, and cutting away the irregular extremities of the tendons and muscles, which operations would require a longer time than amputation itself. Besides, we should recollect, that, by making the incision above the injured part, so as to be enabled to cover the bone with flesh and integuments, perfectly free from injury, the extent of the wound is so diminished, that the healing can be accomplished in one third of the time which would otherwise be requisite, and a much firmer cicatrix is also obtained. Such reflections must convince us, that amputation here holds forth very great advantages. It cannot increase the patient's danger, and, as for the momentary augmentation of pain, which he suffers, he is amply compensated by all the benefits resulting from the operation. See *Gunshot Wounds*.

4. Mortification.

Mortification is another cause, which, when advanced to a certain degree, renders amputation indispensably proper. We have noticed, that bad compound fractures, and wounds, often terminate in the death of the injured limb. Such surgeons as have been determined, at all events, to oppose the performance of amputation, have pretended, that the operation is here totally useless. They assert, that when the mortification is only in a slight degree, it may be cured, and that when it has spread to a considerable extent, the patient will perish, whether amputation be performed or not. But this way of viewing things is so contrary to facts, and the experience of every impartial practitioner, that I shall make no attempt to refute the assertion. While it is allowed that it would be very bad practice, to amputate on every slight appearance of gangrene, it is equally a fact, that when the disorder affects the substance of a member, the operation is generally the safest and most advantageous measure. Nay, there are, as we shall presently see, certain forms of mortification, in which the early performance of amputation is the only chance of saving the patient.

Practitioners have entertained very opposite opinions, concerning the period when one should operate in cases of mortification. Some pretend, that whenever the disorder presents itself, and especially when it is the effect of external violence, we should amputate immediately the mortification has decidedly begun to form, and while the mischief is in a spreading state. Others believe, that the operation should never be undertaken, before the progress of the disorder has stopped, even not till the dead parts have begun to separate from the living ones.

The advocates for the speedy performance of amputation declare, that the further progress of the mortification may be stop-

ped, and the life of the patient preserved, by cutting above the parts affected. However, according to the reports of the greater number of eminent surgical writers, this practice is highly dangerous, and undeserving of confidence. Whatever pains may be taken in the operation, only to divide sound parts, there is no certainty of succeeding in this object, and the most skilful practitioner may be deceived. The skin may appear to be perfectly sound and free from inflammation, while the muscles which it covers, and the parts immediately surrounding the bone, may actually be in a gangrenous state. But even when the soft parts are found free from apparent distemper, on making the incision, still, if the operator should not have waited till the mortification has ceased to spread, the stump will almost always be attacked by gangrene. Surgeons, who have had opportunities of frequently seeing wounds which have a tendency to mortify, entertain the latter opinion. Such was the sentiment of Pott, who says, that he has often seen the experiment made, of amputating a limb in which gangrene had begun to show itself, but never saw it succeed, and it invariably hastened the patient's death.

The operation may be postponed, however, too long. Mr. S. Sharp, in particular, recommended too much delay, advising the operation never to be done till the natural separation of the mortified parts had considerably advanced. Mr. Sharp was a surgeon of immense experience; and his authority carries with it the greatest weight. But perhaps he was too zealous in his opposition to a practice, the peril of which he had so often beheld. When the mortification has ceased spreading, there is no occasion for further delay. We now obtain, just as certainly, all the benefits of the operation, and get rid of a mass of putridity, the exhalations from which poison the atmosphere which the patient breathes, and are highly detrimental to his health. Nay, according to the reports of writers, patients in these circumstances may actually fall victims to the absorption of the putrid matter which is suffered to remain too long. However, this danger would not be so considerable as that which would arise from too precipitate an operation; and it is better to defer amputation a little more than is absolutely requisite, than run any risk of doing the operation before it is certain that the parts have lost their tendency to gangrene.

In the article *Mortification*, we have noticed particular cases of gangrene, where, according to the experience of M. Larrey, the surgeon is not to wait for the line of separation being formed, but have recourse to the immediate performance of amputation. The experience of Mr. Lawrence tends also to confirm the propriety of such practice. (See *Medico-Chir. Trans.* vol. 6, p. 156, &c.)

In an example, where a large part of the arm was deeply affected with gangrene

from external violence, and the disorder was yet making rapid progress, I once recommended the performance of amputation at the shoulder joint. On the whole, this instance was favourable to the practice; for, though the patient died at the end of a fortnight, probably he would not have lived twenty-four hours, had the operation not been done; nor was the stump attacked with mortification, a circumstance worthy of attention, because it is a danger particularly insisted upon by the opponents of amputation, under the preceding circumstances; and, had it not been for a large abscess, which formed in the back, as was supposed, from a violent blow received in the fall, which produced the original injury, there were well-grounded hopes of recovery. The patient, here spoken of, was attended by Dr. Blicke.

There is likewise a species of gangrene, which is pointed out by Mr. Guthrie, as requiring early amputation. "A soldier (says he) shall receive a flesh-wound from a musket ball in the middle of the thigh, which passed through the limb apparently, on a superficial inspection, without injuring the main artery; or it shall pass close behind the femur, where the artery turns to the back part of the bone; or it may go through the middle of the bone, from behind forwards, between the condyles of the femur into the knee joint; and the patient shall walk to the surgeon with little assistance, be superficially dressed, and, in many cases, considered slightly wounded; yet, the femoral artery, and vein of the whole of these cases, and, indeed, in many others, shall be wounded, or cut across, and the local inflammation be so slight as to obtain little attention. On the third, or fourth day, the patient shows his toes discoloured, and complains of pain and coldness in the limb below the wound, the constitution begins to sympathize with the injury, and the surgeon probably thinks the case extraordinary. Perhaps, he suspects the real state of the injury; but is surprised that a wound of the femoral, or popliteal artery, with so little attendant injury, could cause mortification, &c. He is anxious to do something; but, mortification, or at least gangrene having commenced, he must, according to general rule, await the formation of the line of separation. The temperature of the leg, a little above the gangrene, is good, perhaps higher than natural; he hopes it will not extend farther, and it probably does remain stationary for a little time. At last, the parts originally affected, the toes, become sphacelated, and gangrene quickly spreads up the leg as far as the wounded artery, by which time the patient dies."

For the purpose of preventing such a disaster, where the artery, or artery and vein have been divided, Mr. Guthrie recommends the performance of amputation, as soon as the gangrene is perceived to extend beyond the toes; and the swelling and slight attendant inflammation, which is marked more by the tumefaction, than the

redness of the part, has passed higher up, than the ankle. (See *Guthrie on Gunshot Wounds*, p. 60, 61.

5. *White-swellings.*

Scrofulous joints, with diseased bones, and distempered ligaments, and cartilages, is another case, in which amputation may become absolutely necessary. As Mr. Pott remarks, there is one circumstance attending this complaint, often rendering it particularly unpleasant, which is, that the subjects are most frequently young children, so as to be incapable of determining for themselves, which inflicts a very distressing task on their nearest relations. All the efforts of physic and surgery often prove absolutely ineffectual, not only to cure, but even to retard the disease in question. Notwithstanding many cases admit of cure, there are numerous others which do not so. The disease often begins in the very inmost recesses of the cellular texture of the heads of the bones, forming the large articulations, such as the hip, knee, ankle, and elbow; the bones become diseased in a manner, which we shall explain in the article (*Joints*), sometimes with great pain and symptomatic fever; sometimes with very little of either, at least in the beginning. The cartilages covering the ends of these bones, and designed for the mobility of the joints, are totally destroyed; the epiphyses in young subjects are either partially or totally separated from the said bones; the ligaments of the joints are so thickened, and spoiled by the distemper, as to lose all natural appearance, and become quite unfit for all the purposes for which they were intended: the parts appointed for the secretion of the synovia, become distempered in like manner; all these together furnish a large quantity of stinking sanious matter, which is discharged either through artificial openings made for the purpose, or through small ulcerated ones. These openings commonly lead to bones which are diseased through their whole texture. When the disease has got into this state, the constant pain, irritation, and discharge, bring on hectic symptoms of the most destructive kind, such as total loss of appetite, rest, and strength, profuse night sweats, and as profuse purgings, which foil all the efforts of medicine, and bring the patient to the brink of destruction.

It is an incontestable truth, that, unless amputation be performed, a patient thus situated must perish; and it is equally true, that numbers, in the same circumstances, by submitting to the operation, have recovered vigorous health. (See *Pott on Amputation*.)

It is a fact, highly important to be known, that, in these cases, amputation is attended with more success when performed late than when undertaken at an early period before the disease has made great advances. This is particularly fortunate, as it affords me for giving a fair trial to such remedies as are best calculated to check the progress

of the disorder, and obviate all necessity for the operation. (*Encyclopédie Méthodique*, Tom. 1, p. 83.) See *Joints—White-swelling*.

6. *Exostoses.*

Here it will be sufficient merely to mention, that this disease may render amputation necessary, when the tumour becomes hurtful to the health, or insupportable, on account of its weight, or other circumstances, and cannot be removed by any of the plans specified in the article *Exostoses*.

7. *Necrosis.*

Another distemper, sometimes producing a necessity for amputation, is necrosis, or the death of the whole, or of a very considerable part of the bones of the extremities, accompanied with such extensive abscesses, such disease of the soft parts, such disorder of the constitution, and prostration of strength, that every hope of a cure being effected by a natural process must be renounced. By necrosis, is here meant, not merely some disease, which destroys the surface of a bone, but one which extends its depredations to the whole of the internal substance, and that from end to end. Portions of the bones die from a variety of causes, such as struma; lues venerea, deep-seated abscesses, pressure, &c.; and bones in this state, when properly treated, often exfoliate, and cast off their dead parts. But, when the whole substance of a bone becomes diseased, from end to end, frequently no means will avail. In the words of Mr. Pott, the use of the scalper, the raspatory, and the rugine, for the removal of the diseased surface of bones; of the trephine, for perforating into the internal texture of the diseased bone, and of exfoliating applications, (if there be any such which merit the name,) will prove in many instances unavailing, and, unless the whole bone be removed by amputation, the patient will die. Mr. Pott's refutation of Bilguer, who asserts that amputation is not requisite in these instances, is a masterly and most convincing production; but I would not exactly do as the former of these writers has done, and positively affirm, that every extensive necrosis, affecting a bone, nearly its whole length, must inevitably require amputation. The power of nature in restoring the bones is sometimes wonderful, as will be hereafter explained. (See *Necrosis*.)

The very late period, at which an extensive necrosis may follow the injury of a bone, and make amputation necessary, is sometimes almost incredible. Schmucker details the case of a captain, who received a musket-ball through the left arm, four or five inches above the elbow. The bone was violently struck, but not broken; several exfoliations followed, and, after more than a year's treatment, the patient appeared perfectly cured. For nine years this officer remained well; but, at the end of this time, being on a journey, he was af-

tacked with pain and inflammation in the wounded part, and febrile symptoms. He hastened to Berlin, and put himself under the care of Theden and Schmucker, who found an abscess in the situation of the former wound, and, as an opening had been already made, the bone could be felt stripped of its periosteum. At length, a piece of bone exfoliated, and became loose, precisely under the brachial artery, which interfered with its removal. Notwithstanding the discharge, the elbow-joint continued swelled, and there were red points observable, not only above that joint, but also over the heads of the ulna and radius, indicating disease of those bones. Amputation was therefore performed by Theden, and the patient got quite well. On examining the os brachii, a splinter was found three inches in length, and one in breadth, its edges being thin and sharp, while its centre was more than three lines thick. The bone, every where about the place, where it had been struck by the ball, seemed to consist of callus, without any medullary cavity, and the whole of it down to the elbow had no periosteum. The cartilage appeared also disposed to separate, and the periosteum was detached from the radius and ulna, which were likewise affected with necrosis. (See *Schmucker's Vermischte Chir. Schriften*. B. 1, p. 23. Ed. 2.)

8. Cancerous and other inveterate diseases, such as fungus hæmatodes.

Cancerous, inveterate diseases, and malignant incurable ulcers on the limbs, sometimes render amputation a matter of necessity. In treating of cancer, we shall remark that little or no confidence can be placed either in internal or any kind of topical remedies, and that there is nothing, except the total separation of the part affected, upon which any rational hopes of cure can be built. Cancer is not frequently seen on the extremities. Every man of experience, however, must occasionally have seen, in this situation, if not actually cancer, diseases quite as intractable, and which cannot be cured, except by removing the affected part. This may often be accomplished, without cutting off the whole limb. But, when the disease has spread beyond certain bounds, amputation, above the part affected, is the only thing to which recourse can be had with any hope of success. Sometimes when the operation has been delayed too long, even amputation itself will not effect a cure. In a few cases of fungus hæmatodes, the operation has succeeded, however, when the disease had reappeared after a cure had been seemingly achieved by the excision of the diseased parts. Yet, from what I have seen of fungus hæmatodes, I should much doubt, whether the benefit obtained by amputation would be lasting, as when this disease shows itself only externally, internal organs are mostly at the same time similarly affected. (See *Fungus Hæmatodes*.)

Besides cancerous, there are other ulcers,

which may render amputation indispensable. Thus, when an extensive ulcer, of any sort whatsoever, is evidently impairing the health; when, instead of yielding to remedies, it becomes larger and more inveterate; when, in short, it puts life in imminent danger; amputation should be advised.

9. Various tumours.

That there are numerous swellings, which destroy the texture of the limbs, rendering them useless; causing dreadful sufferings, and bringing the patients into the most debilitated state, no man of observation can fail to have seen. When such tumours can neither be dispersed, nor cut out with safety, amputation of the limb is the only resource.

Mr. Pott has particularly described a tumour affecting the leg, for which the operation is sometimes requisite. It has its seat in the middle of the calf of the leg, or rather more towards its upper part, under the gastrocnemius and soleus muscles. It begins by a small, hard, deep-seated swelling, sometimes very painful, sometimes but little so, and only hindering the patient's exercises. It does not alter the natural colour of the skin, at least until it has attained a considerable size. It enlarges gradually, does not soften as it enlarges, but continues through the greatest part of it incompressibly hard, and, when it is got to a large size, it seems to contain a fluid, which may be felt towards the bottom, or resting, as it were, on the back part of the bones. If an opening be made for the discharge of this fluid, it must be made very deep, and through a strangely distempered mass. This fluid is generally small in quantity, and consists of a sanies mixed with grumous blood: the discharge of it produces very little diminution of the tumour, and very high symptoms of irritation and inflammation* come on, and advancing with great rapidity, and most exquisite pain, very soon destroy the patient, either by the fever, which is high, and unremitting, or by a mortification of the whole leg. If amputation has not been performed, and the patient dies, after the tumour has been freely opened, the mortified and putrid state of the parts, prevents all satisfactory examination; but, if the limb was removed, without any previous operation, (and which Mr. Pott, in his experience, found to be the only way of preserving the patient's life) the posterior tibial artery will be found to be enlarged, distempered, and burst; the muscles of the calf to have been converted into a strangely morbid mass; and the posterior part of both the tibia and fibula more or less carious. (*Pott on Amputation*.)

It seems only necessary to subjoin another species of tumour to illustrate the necessity of amputation. The following case is related by Mr. Abernethy. A woman was admitted into St. Bartholomew's Hospital with a hard tumour in the ham. It was about four inches in length, and three in breadth. She had also a tumour in front

of the thigh, a little above the patella, of lesser size and hardness. The tumour in the ham, by its pressure on the nerves and vessels, had greatly benumbed the sensibility, and obstructed the circulation of the leg, so that the limb was very œdematous. As it appeared impossible to remove this tumour, and its origin and connexions were unknown, amputation was performed. On examining the amputated limb, the tumour in the ham could only be divided with a saw. Several slices were taken out of it by this means, and appeared to consist of a coagulable and vascular substance, in the interstices of which, a great deal of bony matter was deposited. The remainder of the tumour was macerated and dried, and it appeared to be formed of an irregular and compact deposition of the earth of bone. The tumour on the front of the thigh was of the same nature as that of the ham, but contained so little lime, that it could be cut with a knife. The thigh bone was not at all diseased, which is mentioned, because when bony matter is deposited in a limb, it generally arises from the disease of a bone. (*Surgical Observations*, 1804.)

Before the late facts and improvements, relative to the treatment of aneurisms, these cases, on the extremities, were generally set down as requiring amputation. Even Mr. Pott, and J. L. Petit, wrote in recommendation of such practice, and their observations on this subject are among the few parts of their writings, which the enlargement of surgical knowledge, since their time, has rendered objectionable. The surgeon to whom the honour of first correcting this erroneous doctrine belongs, is A. N. Guenault, who opposed the advice delivered on this subject by Petit. (*Haller, Disp. Chir. vol. 5. p. 155.*)

I shall conclude these remarks on the cases requiring amputation, with advising surgeons never to undertake this serious operation, without consulting the opinions of other professional men, whenever their advice can be obtained. The best operators are often deficient in that invaluable kind of judgment, by which the cases, absolutely demanding amputation, are discriminated from others, in which the operation may be wisely postponed, and a chance taken of preserving the limb.

Historical Remarks on Amputation.

The history of amputation evinces, that the steps of surgery to perfection are slow, and that they even sometimes deviate from the straight path, though upon all essential points no retrogradation has ever taken place. Here nature has acted as the guide, and the surgeon's chief merit has consisted in obeying the hints which she herself has thrown out. As already mentioned, the following natural occurrence, no doubt, was one of the circumstances, which first led to the old practice of amputation; in consequence of disease, and grievous local injuries, whole limbs were sometimes seized with mortification. In the majority of ca-

ses, this was attended with so much constitutional disturbance, that the patients died; but, in other less numerous instances, the mortification was confined to the part; suppuration was established between the dead and living parts; the whole of the mortified limb fell off; the suppurating surfaces healed up; and thus, by the powers of nature, the patients were restored to health. Here was clearly proved the possibility of recovery, notwithstanding the loss of a limb. The surgeon, as Brunninghausen remarks, viewed with surprise this course of nature, and hardly ventured to promote it by the feeble means formerly employed, which, however, were not really needed. But, as the mortified parts, previously to their detachment, caused great annoyance by their fetor, a surgical attempt was at length made to get rid of them; in doing which, the knife was always kept from touching the living flesh, on account of a well-grounded fear of bleeding, for the suppression of which no effectual methods were known. Such was the practice that prevailed from Hippocrates down to Celsus. (*Erfahr., &c. über die Amp. p. 14.*) "*Partes autem corporis, quæ infra terminos emigrationis fuerint, ubi jam prorsus emortuæ fuerint et dolorem non senserint, ad articulos auferendæ ea cautione ut ne vulnus inferatur,*" &c. (*De Articulis, sect. 6.*) Here we find, that the earliest mode of amputation was that done at the joints.

A. C. Celsus, who lived in the reign of Tiberius, and whose book, *de Re Medicâ*, should be read by every surgeon, has left us a short description of the mode of amputating the gangrenous limbs. (*Lib. 7. c. 33.*) It has been often remarked, that Celsus has left no instructions for securing the divided blood-vessels; but it has not been commonly noticed, that, in his chapter on wounds, he directs us to stop hemorrhage by taking hold of the vessels, then tying them in two places, and dividing the intermediate portion. If this measure cannot be adopted, he advises the use of a cauterizing iron. Several hints are to be met with in the writings of Celsus, from which it may be inferred, that the ligature of bleeding vessels was sometimes practised at the early age in which he lived; and this supposition is strengthened, by a fragment of Archigenes, preserved by Cœchius, on the subject of amputation, where he speaks of tying, or sewing, the blood-vessels. We are not, however, in possession of all the writings of medical authors, prior to the time of Galen, and must therefore remain in doubt upon this point. (*Rees's Cyclopædia, Art. Amputation.*)

This anonymous writer argues, therefore, with some appearance of reason, that if amputation often proved fatal in the days of Celsus, "*sæpe in ipso opere,*" as the expression is, it was owing to the want of some efficacious method of compressing the blood-vessels, during the operation itself; for, whether the use of the ligature were known to the ancients or not, no

doubt exists about their ignorance of the tourniquet.

But, admitting that the ancients were not altogether uninformed of the plan of tying arteries, it cannot be credited, that they adopted the practice to any extent; for, if they had, they would not have continued so partial to the cautery, boiling oils, and a farrago of astringent applications. They would also never have had recourse to the barbarous method of cutting the flesh with a red-hot knife, with the view of stopping the hemorrhage by converting the whole surface of the stump into an eschar. Painful in its execution, and horrid in its consequence, as this burning operation was, it seldom proved a lasting antidote to the bleeding, which generally came on in a fatal manner, as soon as the sloughs were loose. On this part of the subject, my own ideas fully agree with those of a distinguished foreign surgeon, who says, that although the document left us may prove that the ligature was known to the ancients, and employed in cases of aneurisms and wounded blood-vessels, nay, that the arteries were secured with a needle and ligature; yet the practice could not have been extended to the operation of amputation, since with the custom of making the incisions in the dead parts, the method scarcely admitted of being put in execution. (*Brünninghausen, Erfahr. über die, Amput. p. 29.*) Ambrose Paré, therefore, seems to me to deserve as much praise for the introduction of the ligature into common use, as if no allusion to this method whatsoever had existed in the writings of Celsus and other ancients.

The different parts of the operation, meriting particular attention, are, the choice of the part of the limb where the incisions are to begin; the measures for guarding against bleeding during the operation; the division of the integuments, muscles, and bones, which is to be accomplished in such a manner, that the whole surface of the stump will afterwards be covered with skin; tying the arteries, which should be done without including the nerves, or any other adjacent part; placing the integuments in a proper position after the operation; and, finally, the subsequent treatment of the wound.

At the period of making the incision, the ancients contented themselves with having the skin forcibly drawn upward by an assistant; they next divided, with one sweep of the knife, the integuments and flesh down to the bone, and, afterwards, sawed the bone on a level with the soft parts, which were drawn upward. Celsus considered it better to let the incision encroach upon the living flesh, than leave any of the diseased parts behind. "*Et potius ex sana parte aliquid excidatur, quam ex agra relinquatur.*" (*De Medicina, Lib. 7. c. 33.*)

It appears, however, that his views extended further than those of most of his contemporaries, and even his followers, almost down to modern times. After cutting

the muscles down to the bone, he says, that the flesh should be reflected, and detached underneath with a scalpel, in order to denude a portion of the bone, which is then to be sawn as near as possible to the healthy flesh, which remains adherent. He states that, when this plan is pursued, the skin around the wound will be so loose, that it can almost be made to cover the extremity of the bone. It is to be lamented, that this advice, inculcated by Celsus, should not have been comprehended, or that it should have been so neglected, as to stand in need, as it were, of a new discoverer, and that a suggestion of such importance should have remained so long useless. But, the fact is, hemorrhage formerly rendered amputation so dangerous, that the ancient surgeons could not devote much attention to any thing else in the operation, and practitioners amputated so seldom, that we read in Albucasis, that he positively refused to cut off a person's hand, lest a fatal hemorrhage should ensue, and the patient did it himself and recovered. Over that part of the stump, which the small quantity of preserved skin would not cover, Celsus recommended compresses, and a sponge dipped in vinegar to be laid. (*De Re Medica, Lib. 7. c. 33.*)

Archigenes, who was born at Apamia, in Syria, was the disciple of Agathinus, and physician to Philip, king of that country. He repaired to Rome, where he practised physic and surgery, in the reign of the emperor Trajan, about 108 years after the birth of Christ. (*Portal, Hist. de l'Anatomie et de la Chirurgie, Vol. 1, p. 61.*) In the history of amputation, the name of Archigenes is conspicuous, not only because he is supposed to have been acquainted with the use of the needle and ligature for the stoppage of bleeding, but because his description of the operation is in some respects more minute than that of Celsus. For the hinderance of loss of blood in the operation, says Sprengel, (*Geschichte der Chir. B. 1, p. 404, Halle, 1805.*) he first of all tied up the vessels, and often the whole limb over which he also sprinkled cold water. The integuments were then drawn upwards from the wound, and confined there with a band; and after the limb was off, he cauterized the stump, and applied folded compresses. The band was now loosened, and a mixture of leeks and salt laid on the stump, to which were also applied oil and cerate. (*Nicet. Coll. Chir. p. 155.*) Such was likewise the practice of Heliodorus, who thus early made objections to the plan of cutting off a limb by a single stroke, a proposal that was renewed in far later days. The same author has also spoken of amputating at the joints; a method, of which he disapproves. (*Nicet. Coll. Chir. p. 155.*) However, Galen entertained a favourable opinion of it, on account of its safety and expedition. (*Comm. 4, in lib. de artic. p. 650.*) Galen's precepts concerning amputation are, upon the whole, very like those given by Hippocrates; for he directs only dead parts to be cut, and the stump to be

cauterized. (*De Arte Curativa ad Gloucomem*, lib. 2.) By all the old writers, amputation was entirely restricted to cases of mortification; further they were afraid to go; and this precept, and all the other doctrines of Galen, may be said to have been the guide of the whole surgical profession for full fourteen centuries.

The timid Arabians were not partial to amputation, and even in cases of mortification, generally preferred a farrago of useless applications, like Armenian bole, &c. Paulus Aegineta, like Galen, deviated from Celsus's good rule of making the incisions in the healthy parts, and only approved of making the requisite division near them. (*Lib. 4, c. 19, p. 140.*) Avicenna, however, repeated the directions left by the Greek writers, (*Can. lib. 4. Fen. 3, tr. 1, p. 454.*) and Abu'l Kasem proposed doing the operation with a red-hot knife. (*Chirurg. lib. 1. Sect. 52, p. 99.*) In the middle ages, little was done for the improvement of amputation. In the 14th century, gunpowder was invented, and soon applied to the purposes of war, so that an abundance of cases must have presented themselves, in which the wise maxim of not deferring amputation, until mortification had come on, but of preventing the mischief by the operation, ought to have struck an intelligent surgeon. One might also expect that practitioners would now have been led to make the incisions in the sound flesh. Unfortunately, the invention of gunpowder, and its immediate consequences in surgery, happened at a period when practitioners were ill qualified to profit by the new lessons of experience set before them. The writings of their predecessors furnished them with no directions how they ought to act, and they were themselves too much confounded at the sight of the mischief, for which they were consulted, to be able to form any correct opinion about causes and effects. Their first idea was, that the terrible symptoms proceeded from the parts being actually burned, and they afterwards inclined to the belief, that gun-shot wounds were poisoned. Hence, the most absurd modes of treatment were instituted, and as Brünninghausen expresses himself, human nature groaned under a new evil, for which there were for some time no true plans of relief. (*Erfahr. &c. über die Amp. c. 19.*) This deplorable state was the natural result of the depression of science in general, and of the healing art in particular, in the days to which I now refer. In these middle ages, as they are called, the population of all Europe was plunged in the deepest ignorance; and whatever little knowledge remained, either of the arts, or languages, was monopolized by the priesthood, the physicians of those times, who, instead of studying the volume of nature, wasted most of their time in discussing the doctrines of Galen. Surgery itself sunk to the lowest ebb, as may be well conceived from the decrees issued at Rheims, by pope Boniface the eighth, forbidding any of the

clergy to do any thing themselves, which drew blood, and, of course, all the operative part of surgery, that which required most skill and science, was transferred to a set of illiterate, low-bred mechanics, far inferior to the worst country-farriers of modern times. Yet, the clergy, who were here scrupulously averse to soiling their own hands with blood, or hurting their own tender feelings by viewing the agony of their fellow-creatures submitted to operations, had no hesitation in taking the chief emoluments and honours of the profession, or in turning over these poor sufferers to men more qualified to torture and murder, than give relief; and what nearly staggers all credulity, the same professors of christianity, who shuddered to spill a drop of blood themselves, on a proper occasion, as Haller observes, eagerly had a hand, and acted an important part in every sanguinary war, where it was possible for them to interfere. In these dismal days for surgery, the advice delivered by Celsus was renewed by Theodoricus, who used to administer opium and hemlock previously to the operation, for the purpose of rendering the patient less sensible of pain, and afterwards vinegar and fennel were given, with the view of dispersing the intoxicating effects of the preceding medicines. (*Chirurg. lib. 3, c. 10.*)

The renowned Guido di Cauliaco was the inventor of the plan of taking off limbs, without any bloodshed. It is better, says he, for the limb to drop off, than be cut off, as in the latter circumstance, the conduct of the surgeon is viewed with spite, because it is supposed, that the part might have been saved. Guido's practice consisted in covering the whole membrane with pitch-plaster, and applying round one of the joints so tight a band, that the parts below the constriction ultimately dropped off. (*Chirurg. tr. 6, Doctr. 1. Cap. 8.*) As Sprengel next observes, the method of amputating, suggested by Celsus, was again revived by Gersdorf, who after the operation, not only drew down over the stump the skin which had been retracted, but applied a hog's or bullock's bladder over the stump, so as to render all burning and stitching of the parts needless. (*Feldbuch der Wundarzn. fol. 63.*) Bartholomew Maggi also endeavoured to preserve a considerable flap of integuments for covering the stump. (*De Vulner. bombard. et sclopet. 4to. Bonon. 1552; see Sprengel's Geschichte der Chirurgie, p. 404, 406, 8vo. Halle, 1805.*)

At length, in the 15th century, the revival of learning occurred first in Italy. Men now began to think for themselves again, and physicians turned from compilations and scholastic nonsense, to the consideration of nature. Anatomy was cultivated with great ardour, and made brilliant progress under the eminent characters of the time: De la Torre, Berengarius Carpi, Vesalius, Fallopius, Eustachius, and others, who were also for the most part very dis-

distinguished surgeons. "In Italia scientiarum matre medici se nunquam chirurgia abdicarunt. Seculo 15 et 16, professores medici academice Bononiensis, Palavinae, et aliarum in Italia illustrium scholarum et manu curaverunt, et consilio, et inter istos viros summi chirurgi extiterunt." (Haller, Bibl. Chir. p. 1. p. 161.) Practitioners now ventured to amputate limbs in the sound part for other incurable diseases, besides mortification; but, the art of stopping hemorrhage after the operation continued imperfect. Though the method of applying the ligature in cases of wounded arteries and aneurisms was understood, yet, from some unaccountable causes, the practice was never thought of in amputations. Even Fallopius knew of no other means for stopping the bleeding, but the cautery. (*De Tum. prætern. p. 665.*) On the whole, the stoppage of bleeding was not attended with a degree of success proportionate to the advances of the healing art in general. Straps, bands, and compresses were indeed put round the member; but, as the circulation of the blood was not yet correctly known, they were not applied in the proper places; being arranged either close to the wound, or several of them put at random round the limb. The effects of such immoderately tight, long-continued constriction, could be nothing less than gangrene, and hence, the actual cautery was still chiefly employed. The other means for suppressing hemorrhage scarcely merit the name. Terrified at the insecurity and ill consequences of such expedients, J. de Vigo, (*Practica in Chirurgia Copiosa*, 491, Romæ, 1514,) and Fabricius ab Aquapendente, (*Op. Chir. Venet.* 1619,) disapproved of amputating in the sound flesh, and returned to the principle, inculcated by the ancients, of making the incision in the mortified parts. Others endeavoured to lessen the peril of the bleeding by the rapidity with which the limb was removed, and the instantaneous application of the cautery. For this purpose, L. Botalli invented a sort of guillotine, by means of which a member was severed from the body in an instant, (*De Curandis vulneribus sclopetorum*, Lugd. 1560;) while others laid a sharp axe upon the limb, and effected the dismemberment by the blow of a wooden mallet. An example of this barbarous practice is recorded by Fabricius Hildanus, called by his countrymen the patriarch and ornament of the German surgery. In consequence of this fear of bleeding, before he knew of the use of the ligature, he was himself accustomed to amputate with a red-hot knife, the representation of which is given in his work. (*De Gangrana et Sphacelo*, Op.) Hildanus became a better surgeon, however, as he grew older, and, in the end, partly contributed to the improvement of amputation, inasmuch as he made the incisions completely in the sound parts, and adopted the method of tying the arteries, as then recently proposed by Paré, but unfortunately, in weak persons he still pre-

ferred the actual cautery to the ligature, (*Op. p. 814.*) One of his inventions was a linen bag, or cap for the stump; and a sort of retractor for holding back the muscles. According to Sprengel, (*Geschichte der Chir. B. 1, p. 407.*) his observations on the pain following the operation, are interesting. (*Op. p. 807, 814.*)

Ambrose Paré, a French surgeon, who flourished in the 16th century, (*Opera, Parisiis 1582.*) and to whom I have already alluded, made some beneficial innovations, with regard to the operation of amputation. It is to his industry, good sense, and skill, that we are chiefly indebted for the abolition of cauterising instruments, and the general use of a needle and ligature for the suppression of the bleeding. (*Lib. 6, c. 28, p. 224.*)

An anonymous writer has given the following account of the practice and opinions of this distinguished surgeon, in relation to amputation. "Paré recommended to cut off the whole of the gangrenous part, if the limb be mortified; but, to encroach as little as possible upon the living flesh. At the same time, he laid it down as a rule, not to leave a very long stump to an amputated leg; because the patient could more conveniently make use of a wooden leg, with the stump only five finger-breadths long, below the knee, than if much more of the flesh were to be preserved. In the arm, however, he left the whole of the living and healthy portion of the member, only separating the diseased part from the sound.

"In preparing for amputation, he directs the skin and muscles to be drawn upwards, and bound tight with a broad bandage, a little above the part, where the incision is to be made. This fillet was intended to answer a threefold purpose: 1st, to afford a quantity of flesh for covering the bone, and facilitating the cure. 2dly, To close the extremities of the divided blood-vessels. 3dly, To dull the patient's feelings, by pressure on the subjacent nerves. When this firm ligature has been applied, Paré directs an incision to be made down to the bone, either with a common large scalpel, or a curved knife. Then, with a smaller curved knife, we are carefully to divide the muscle, or ligament, remaining between the bones of the fore-arm, or leg; after which, we may proceed to saw off the bone as high as possible, and to remove the asperities, occasioned by the saw.

"With the assistance of a curved pair of forceps, he drew out the extremities of the bleeding arteries, either by themselves alone, or with some portion of the surrounding flesh, to be firmly tied with a strong double thread. He now loosened his bandage, brought together the lips of the wound over the face of the stump, and kept them as close as he could, without actual stretching, by means of four stiches, or sutures. If the larger tied vessels should accidentally become loose, he desires the ligature, or bandage, to be again passed round the

limb; or, else, what is better, to let an assistant gripe the limb firm with both hands, and press with his fingers over the course of the bleeding vessel, so as to stop the hemorrhage; then, with a square-edged needle, about four inches long, and a thread, four times doubled, the surgeon must secure the artery in the following manner. Thrust the armed needle into the outside of the flesh, half a finger's breadth from the vessel which bleeds, and bring it out at the same distance from the bleeding orifice; then surround the vessel with the ligature, pass it back again to within one finger's breadth of the place, where it first entered, and tie a fast knot upon a folded slip of linen rag, to prevent its hurting the flesh. By this means, says Paré, the orifice of the artery will be agglutinated to the adjoining flesh so firmly, as not to yield one drop of blood: but, if the hemorrhage were not considerable, he contented himself with the application of astringent powders, &c.

"Thus did this famous surgeon endeavour, by his single example and precepts, to exclude the barbarous use of hot irons in amputation. He says, he knew not of any such practice among the old surgeons; except that Galen recommended us to tie bleeding vessels, towards their origin, in accidental wounds: and he thought proper to do the same in cases of amputation. But, in an apology, at the end of his book, Paré has quoted, in his own defence, a dozen authors, who employed or recommended the ligature before him; and he might have cited many more.

"From the statement we have here given, it may be seen how far the best writers of almost every country have erred in ascribing the original invention of tying arteries to Ambrose Paré. Great merit, indeed, was due to him, for the part he took in extending, and even reviving this incomparable practice: nay, it is not certain, whether any one before him had ever applied the needle and ligature in similar cases, i. e. after amputation; but how very wide of the truth Mr. John Bell's recent account of this matter is, will appear to every person, who will inquire into the facts themselves; for not only were ligatures and needles in use among the ancients, but likewise the tuniculum, or hook to lay hold of the bleeding vessels when they had buried themselves in the muscles. We refer our inquisitive readers to Avicenna, Aëtius Albucacis, Brunus, Theodoric, Guido di Cauliaco, John de Vigo, L. Bertapaelia, Tagaultius, Petrus Argillata, Andreas a Cruce, &c. &c. where they will find enough to satisfy them on this head." (*Rees's Cyclopædia*, art. *Amputation*.)

I shall not here expatiate upon the ill-treatment, which Paré experienced from the base and ignorant Gourmelin; nor upon the slowness and reluctance, with which the generality of surgeons renounced the cautery for the ligature. These circumstances may be conceived from what has been already stated. Suffice to add, upon the authority of Dio-

nis, that, almost 100 years after Paré, a button of vitriol was ordinarily employed in the Hôtel Dieu at Paris for the stoppage of hemorrhage in amputation. And Dionis was the first Frenchman, who openly taught and recommended Paré's method. This however happened towards the close of the 17th century, while Paré lived towards the end of the 16th. (*Dionis Cours d'Opérat. Paris 1707.*)

As Paré, like the rest of the old surgeons, used to cut directly down to the bone, many of the stumps, which he made, must have been badly covered with flesh, and ill-fitted for bearing pressure. But, all that I have read on the subject of amputation impresses me with a strong conviction, that, in former times, the projection of the end of the bone, the sugar-loaf form of the stump, the frequent exfoliations, and the difficulty in healing the part, and keeping it healed, were as much owing to the mischief done with the cautery, the rude way of dressing the stump, and ignorance of the right method of promoting union by the first intention, as to the mode of operating, or any other circumstance.

By many surgeons, however, the tying of arteries continued to be deemed too troublesome, and hence, they persisted in the barbarous use of the actual cautery: of this number were Pigras, (*Epitome des Préceptes de Med. et de Chir. 8vo. Rouen, 1642.*) F. Plazzone, (*De Vuln. Sclopet. 4to. Venet. 1618.*) and P. M. Rossi, (*Consult. et Observ. 8vo. Francof. 1616.*) Nay, so difficult was it to eradicate the blind attachment to the ancients, that Theodorus Baronius, a professor at Cremona, publicly declared in 1609, that he would rather err with Galen, than follow the advice of any other person; and Van Hoorne seems even to have countenanced the detestable machine of Botalli. (*Muzgorixm*, p. 75.)

What, asks Brünninghausen, was the reason why the ligature of the arteries, which is now regarded by the surgeons of all civilized nations, as the best, easiest, and safest method of stopping hemorrhage after amputation, should so long have remained undepicted? Besides the prejudice for the opinions of the ancients, already mentioned, another cause was undoubtedly the imperfect knowledge of the circulation of the blood, a correct description of which was first delivered by the immortal Harvey early in the 17th century. (*Exercitatio Anat. de Mortu Cordis et Sanguinis in Animalibus. Francof. 1628.*) For some time, this grand discovery met with violent opposition; but, after it had been acknowledged as an eternal truth, a happy application of it was made to surgery by a French surgeon, named Morell, who at the siege of Besancon in 1674, invented the field-tourniquet, by means of which more certain pressure was made on the trunk of the artery. By this simple invention, founded however on a knowledge of the circulation, the surgeon could at option let the blood of

the stump spirt out, or stop its jet entirely ; and now, both during and after the operation, he was first enabled to command the hemorrhage, and coolly and judiciously employ whatever measures were indicated ; for the most powerful bandages and pressure, previously in use, either stopped the circulation in the whole limb, or could not be made to have the right effect with sufficient quickness. (*Brunninghausen Erfahrung. &c. über die Amp p. 36.*) Morell's tourniquet, however, was very imperfect, and it was not till the year 1718, that J. L. Petit, whose name shines so brightly in the history of surgery, invented the kind of tourniquet now employed.

Richard Wiseman, who is justly considered as the father of good English surgery, saw the necessity of making the incision in the sound parts, because gangrene does not always spread evenly, but frequently extends much higher up one side of the limb, than the other. He deemed the actual cautery objectionable, as the sloughs were so long in being thrown off. He applied a ligature round the limb, two inches above the limits of the mortification, and drawing up the muscles, made the incision with a large curved knife, with the back of which he scraped off the periosteum. The bag, or sort of retractor, employed by Fabricius Hildanus, Wiseman thought unnecessary, as the muscles spontaneously drew themselves up as soon as divided. He tied the blood-vessels after the manner of Paré, and deprecated all burning of the stump. After the operation, he drew the flaps over the bone, and either fastened them in this position with stiches, or a tight bandage, though he generally preferred the former, as the surest means of keeping the end of the bone from protruding. Across the stump, he laid a pledget of wax-cerate, and over this a thick layer of Armenian bole and other styptics, and the whole was covered with a bullock's bladder, and a roller applied spirally from the upper part of the remaining portion of the limb, down to the extremity of the stump. On the third day, the dressings were taken off, and a digestive ointment applied. (*Chirurg. Treatises, vol. 2, p. 220, 8vo. Lond. 1690.*)

From this time, amputation may be considered as being an infinitely safer proceeding, than what it used to be ; for, as we have explained, the ligature of the arteries was now practised and commended in Germany by F. Hildanus, in England by Wiseman, and in France by Dionis. Much however remained to be done. The wound was large, and suppurated long and profusely ; the healing was slow ; the ends of the bones perished, and projecting far beyond the soft parts, retarded the cure so long, that the patient was not unfrequently worn out. Hence the best surgeons began seriously to consider what further could be done, with the view of lessening the exposed surface of the wound, and making a

better covering of flesh for the ends of the bones.

According to Sprengel, most of the old surgeons preserved a flap of flesh, and he is therefore by no means disposed to regard our countryman Lowdham, as the inventor of this method, though it is acknowledged, that the latter surgeon's practice was novel, inasmuch as the flap was formed by making an oblique incision through the integuments from below upwards. (See *James Yonge's Currus Triumphalis e Terebintho, 8vo. Lond. 1679, and Sprengel's Geschichte der Chirurgie, B. 1. p. 408.*) Here, if Sprengel means, that many of the old surgeons endeavoured to preserve a partial covering of flesh for the bone, there can be no doubt of his correctness, because we find, that they drew back the flesh before they divided it, and Celsus and some others even did more, for, after cutting down to the bone, they detached the flesh further from it upwards, previously to taking the saw ; but, on the contrary, if Sprengel wish us to believe, that there were practitioners, who previously to Lowdham, in the operation of amputation, formed what in England is usually understood by a flap, that is, a portion of flesh, generally of a semilunar shape, and saved particularly from one side of the member for covering the bone, I cannot see any reason for coinciding with Sprengel's observation. Upon the merit of Lowdham's suggestions, and the practice and principles inculcated by J. Yonge, some reflections lately sent me by Mr. Carwardine, I insert with great pleasure, as perhaps he is right in thinking, that the last edition of this work did not do justice to the memory of the latter writer.

"At the time Yonge wrote (1679) says Mr. Carwardine, it was supposed impossible to heal a stump before the bone had exfoliated, and therefore, no surgeon would venture upon an attempt at uniting the surface by the first intention. Now this union by the first intention, was the chief object of Mr. Yonge in proposing the flap operation, and it is to him, and not to Mr. Alanson, who wrote precisely 100 years after him, that we must attribute the honour of this improvement. It is related in a letter addressed to his friend Thomas Hobs, surgeon in London, dated Plymouth, August 3, 1678, and published 1679, at the end of his *Currus Triumphalis e Terebintho*. It begins thus :—

"Sir, I find by yours that you are surprised with the intimation I gave you, of a way of amputating large members, so as to be able to cure them *per symphysin* in three weeks ; and without fouling or scaling the bone. It is a paradox which I will now evince to you to be a truth, after I have first taken notice of what you affirm, that there is a necessity of scaling the ends of those bones left bare after the usual manner of dismembering before the stump can be soundly cured ; that you never yet found it otherwise, but that where it hath been attempted, the stumps have apos-

tumated, and the caries come off thereby.

"Yonge then acknowledges, that it was from an ingenious brother, Mr. C. Lowdham of Exeter, that he had the first hint thereof. He then describes the operation—the laying down the flap over the face of the stump, and sewing it by four or five stitches, &c. After this Yonge proceeds with a methodical enumeration of the advantages of this mode of operating over all others then in use, viz. that it is more speedy—the cure not occupying a fourth of the usual time—no suppuration—no exfoliation—less danger of hemorrhage—not liable to break open again from slight injury—and lastly, much better adapted to the pressure from an artificial leg, &c.

"The foregoing abstract will show, (says Mr. Carwardine,) how far Mr. O'Halloran's method, presently to be described, in which he dresses the flap and the stump as distinct surfaces, can be regarded as a revival of Lowdham's operation, or whether it has been superseded or improved upon by the mechanical ingenuity of the Dutch and French surgeons. The apparatus of M. de la Faye and Verduin appear to have been merely clumsy and unscientific contrivances for the suppression of hemorrhage. Garengeot's operation had also for its object to supersede the use of the ligature, which, however, after twelve years practice, he was obliged to give up, and tie the vessel before he laid down the flap: (the particulars of all these methods the reader will presently meet with.) Opinions therefore founded upon the practice of these gentlemen, I conceive cannot fairly be admitted as evidence against the flap operation of Lowdham, which nevertheless appears sinking in the estimation of the best modern surgeons: perhaps no material advantage is gained by it over the common mode of operating in the lower extremities, as now practised; but, even here, cases may occur where we are glad to resort to it. A few years since, I attended a patient, in consultation with a friend at Dunmow, in Essex, where we thought it necessary to remove a man's leg for a caries of the tibia. An ulceration in front extended so high, that no integument could be saved; and the limb would have been removed above the knee, if I had not suggested the propriety of making a flap from the calf of the leg. The tibia was obliged to be sawn as high as possible, but the flap was left sufficiently long to cover the surface, and that most important object, the bend of the knee, was preserved to bear the pressure of a wooden leg. In the removal of the arm at the shoulder joint, doubtless the advantages of making a flap from the deltoid, &c. are sufficiently established; but, in the mode of dressing, I presume, that no English surgeon will admit, that the practice of M. Larrey (perhaps the most eminent surgeon that has been formed by the wars of Bonaparte, and whose practice will be hereafter noticed,) can supersede the method of Yonge (or

Lowdham,) who wrote 140 years before him! Larrey introduces charpie beneath the flap to prevent union by the first intention! Lowdham's object is simply to lay the flap over the wound to prevent exfoliation, and to heal the surface '*per symphisin*' in three weeks." To the correctness of these sentiments of Mr. Carwardine, I believe, that every impartial surgeon will bear witness; and it merely remains for me to thank him for his obliging communication, and say, that I have recently looked over the copy of the *Currus Triumphalis e Terebintho*, preserved in the valuable library of the Medical and Chirurgical Society, and find, that what he has stated is fully confirmed by the contents of that ancient work. At the same time, I retain the belief, that the example set by Mr. Alanson, with respect to the proper method of dressing stumps, and obtaining a speedy union of the wound, is entitled to the praise of posterity, because his advice was so well enforced that it soon produced a revolution in practice; while the correct suggestions of Lowdham and Yonge, like the hint in Celsus, of the double incision, had sunk into oblivion, or were only known to a few admirers of surgical antiquities.

As Sprengel remarks, Purmann, Dionis, (*Cours d'Oper. de Chir. p. 611.*) De la Vauguyon, (*Traité Compl. des Opér. de Chir. p. 531.*) and most other surgeons of the seventeenth century, continued the method of first drawing up the integuments, and then applying a band round the member. Dionis also took particular pains to recommend the ligature of the vessels, and expresses a strong aversion to the actual cautery. Neither did he approve of amputation at the knee joint, because he thought that the patella, which must be left behind, would impede the healing of the stump, and he was apprehensive of the articular surface of the femur becoming diseased. De la Vauguyon relied upon the styptic properties of vitriol, and he praised drawing back the muscles by means of the kind of bag invented by Fabricius Hildanus.

Taking off the limbs at the joints was first commended again in modern times by J. Munnicks, who was more partial to styptics, than the ligature; and for dressing the wound employed compresses and sticking plaster. (*Chirurgia, p. 101.*)

Marquest de la Mothe adopted the plan of operating recommended by Dionis; he was also one of the first who made common use of the tourniquet in amputations, afterwards drawing out the vessels with the forceps and tying them. (*Traité Compl. de Chir. Vol. 3. p. 171.*) Lowdham's original suggestion of amputating with a flap has been briefly noticed. About eighteen years after Yonge's publication, Peter Verduin, an eminent surgeon at Amsterdam, submitted to the judgment of the profession a new kind of flap amputation, which he had put in practice. (See *Dis. Epistolica de Nova Artium decurtandorum ratione, Svo.*

Amst. 1696.) The following are the chief particulars of Verduin's flap operation.

Two compresses were applied, one under the ham, and the other on the course of the large vessels. The thigh was wrapped in a fine linen cloth, which was sustained by some turns of a roller. This apparatus was covered with a piece of leather, six inches broad, furnished with three straps with buckles, to secure it round the part. The tourniquet was placed in the usual manner. The part, above the place intended to be amputated, was surrounded with a leather strap. The point of a crooked knife, which was made to pass as near to the back part of the bones as possible, was thrust in on one side of the leg, and made to come out on the other. The knife was then carried down nearly to the tendo achillis, and thus it separated almost the whole calf of the leg. The flap being formed, the operation was finished in the ordinary manner. The wound was then washed with a wet sponge, in order to clear it from the fragments of sawn bone. The leather strap, which served to secure the flesh, was next loosened, and the flap laid over the stump. The wound was dressed with lycoperdon, lint, and tow, over which was put a bladder, sustained by strips of sticking-plaster. Upon this bladder was placed an instrument, called a *retinaculum*, consisting of a compress, and a concave plate, which were made to press upon the stump, by means of two straps, that crossed each other, and were attached to the broad leather strap surrounding the thigh.

In 1702, Sabourin, an able surgeon at Geneva, gave an account of Verduin's practice to the Royal Academy of Sciences, which, however, declined to pronounce any judgment about it, without further experience.

Though this method of amputation was objected to by Konerding, in a tract published at Amsterdam in 1705, it was afterwards highly extolled by P. Massuet, on account of the quickness with which the stump healed, the safety with which the flap served for the stoppage of the hemorrhage, and the avoidance of exfoliation by the non-exposure of the bone. He also dwelt upon the excellency of the stump for the application of an artificial foot. (*De l'Amputation à lambeau*, 8vo. Paris, 1756.) Heister disapproved of the flap amputation, because it appeared to him, that the irritation of the flesh by the projecting bones was apt to cause pain and inflammation: he operated himself after the manner of Dionis, and was strongly in favour of the use of ligatures.

Some excellent precepts were delivered by J. L. Petit concerning amputation. He improved the tourniquet; and, instead of the large crooked amputating knife, formerly employed, first brought into use the straight more moderate-sized knives with sharp backs, now seen in the hands of the best surgeons, because much better calculated than crooked knives, for dividing the

flesh by a sawing movement, which is the only right and surgical way of attempting to cut any part of the human body. He proved that making the division in the mortified parts was frequently followed by hemorrhage; and for the suppression of bleeding he thought it the best principle to promote the formation of a coagulum. (*Mém. de l'Acad. des Sciences*, an. 1732, p. 285. See Hemorrhage.) For compressing the vessels, he employed an instrument, which covered the stump, like Verduin's retinaculum, and made pressure by means of a screw. His only objection to Verduin's method was, that the extension of gangrene up the limb frequently hindered the formation of so large a flap. He laid down the valuable general maxim of always removing as much bone, and as little flesh, as possible; for which purpose, he invented what is termed the *double incision*, or dividing the business of cutting through the soft parts into two stages. About an inch higher than the place where he meant to saw through the bones, he first made the circular cut through the integuments down to the muscles; the skin was then pulled up so as to leave the flesh uncovered to the extent of an inch, and the muscles were now divided at the highest point of their exposure. Lastly, the flesh was held out of the way with a retractor, and the bone was sawn through high enough up to allow of its extremity being well covered with flesh and integuments. The greatest defect in the doctrines of Petit, relative to amputation, was the confidence he put in pressure, instead of the ligature. (*Traité des Malad. Chir.* vol. 3, p. 126.) The first performance of amputation at the shoulder-joint, by Le Dran, and the improvements and alterations of that operation suggested by Garengot, De la Faye, Desault, &c. I shall notice in a future section.

In chronological order, the next event claiming notice, in the history of amputation, was the promulgation of an opinion by T. R. Gagnier, that Verduin's flap-amputation might be traced back to times of great antiquity, the method described by Celsus being very similar. (*Haller, Dis. Chir.* vol. 5, p. 161.) On this point, with reference to Lowdham, the true inventor of the flap-operation, I have already delivered my own sentiments.

The flap-amputation of the leg, after Verduin's manner, was tried by De la Faye, who found that the pressure of the flap was not enough to check bleeding from all the vessels, as it only operated on the anterior tibial artery, and, by pressing the flesh more firmly against the end of the bones, he thought the risk of mortification would be occasioned.

Verduin, and Sabourin, as we have seen, made only one flap. Two French surgeons, Ravaton and Vermale, afterwards thought, that it would be better to save a flap from each side of the limb. They were also advocates for tying the vessels, and bringing the two flaps into contact, so as to

procure their speedy union, and prevent exfoliations and profuse suppuration.

However, there is some difference in their methods of forming the flaps. Ravaton, who submitted his plan to the French Academy in 1739, made three deep incisions down to the bone; first, a circular one, with a crooked knife, within four finger-breadths of the bone intended to be sawn; and then with a somewhat larger knife; the two others perpendicularly to the first, one at the forepart, and the other at the back of the limb; and, taking care not to touch the principal vessels, he detached the two flaps from the bone.

Vermale formed the separate flaps by two incisions. After applying the tourniquet, he surrounded the part with two red threads, at the distance of four finger-breadths from each other; one at the place where the bone was to be sawn; the other at the place where the incision of the flaps was to terminate. He afterwards thrust a long bistoury down to the bone, at the forepart of the limb; turned it round the circumference, so that it might come out at the opposite part; then directing the edge of the knife along the bone, he cut down to the inferior thread, where he separated the first flap, which, as the author says, was of a round or conical figure at its extremity. The second flap was made in a similar way on the interior side of the member. (*Traité des Playes d'Armes à feu, par Ravaton, 8vo. Paris, 1750; De la Faye, in Mém. de l'Acad. de Chir. T. 5, ed. 12mo. Vermale, Obs. de Chir. 8vo. Manheim 1767.*)

In presence of M. Quesnay, Garengot performed the flap amputation according to the method of Verduin and Sabourin. We know, that they made no ligature on the vessels, and that their intention was, that the flap, when applied to the stump, and sustained by a particular apparatus, should reunite, and stop all bleeding.

Garengot's patient died on the third day after the operation; and hemorrhage was allowed to have had a considerable share in producing death.

The multiplicity of machines described by Verduin, La Faye, &c. had no other end, but that of keeping the flap near the orifices of the vessels, so as to compress and close them. Garengot reflected that, to obtain a just degree of this compression was very difficult, as the most considerable vessels were situated between the two bones, and, in general, when cut, withdrew themselves. Hence, he determined in future to employ ligatures.

With these views, twelve years after the foregoing case, Garengot performed a flap amputation of the arm, preserving two flaps, according to the method communicated to the Academy by Ravaton. The brachial artery was tied, and the patient got well, without any exfoliations.

Garengot made a third trial of this operation on a soldier dangerously wounded

in the right foot by the bursting of a bomb, which fractured the interior part of the two bones of the leg, and several of the foot: the patient got well in twenty-seven days.

In this operation, one single flap was made. Garengot was fearful, however, that the quick union might create some difficulty of withdrawing the ligatures, and he therefore took a means of hindering adhesion where they were situated; but, of this objectionable plan, I shall not speak. He rightly preferred dressing and bandaging the stump to the use of the compressing machines invented by Verduin and La Faye; and his choice of a straight knife, instead of a crooked one, was equally judicious.

The preceding case dictated a truth, which will last as long as surgery itself,—viz. *that it is advantageous to apply the ligatures in such manner as to embrace no more than the vessel, so that they may fall off the sooner, and the parts more quickly unite.* (*M. de Garengot, in Mémoires de l'Acad. de Chirurgie, Tom. 5, in 12mo.*)

At one time, a frequent objection, urged against the foregoing methods, was, that, when the fresh-cut flap was immediately laid over the stump, inflammation and abscesses were apt to ensue. Hence, in 1765, Sylvester O'Halloran, a surgeon at Limerick, was led to make the experiment of deferring laying down the flap till the end of the first eight, or twelve days after the operation, when it was conjectured that the risk of inflammation and abscesses might be abated. The tenor of Mr. O'Halloran's book is apparently corroborated by the facts brought forward. Here we see one of the grand points, insisted upon by our worthy countryman James Yonge, viz. the chance of an immediate union of the wound from laying down the flap without delay, suddenly given up, and because the wound could not always be healed without suppuration, it was determined that it never should do so. However, it is consolatory to find, that O'Halloran's suggestion only now exists in the history, and not in the practice of surgery. Alexander Monro, senior, was a great opposer of certain methods, which originated among the French surgeons, and, in particular, he disapproved of the tourniquet: he secured the vessels with needles and ligatures; and was the inventor of a bandage, which has been extensively approved of under the name of Monro's roller. (*Medical Essays of Edinb. Vol. 4, p. 257.*)

Bromfield, like Le Dran, restricted amputation to a few cases; and he did not acknowledge its necessity, as a matter of course, in every case of gangrene, much less in every instance of white-swelling, or caries. From a passage, which I have cited from Dr. Rees's Cyclopædia, it would seem that the tenaculum was known to the ancients; yet, according to general opinion, (and I cannot affirm that it is incorrect from any passage in my recollection,)

Bromfield is allowed to be the first surgeon who employed this very useful instrument. (*Chir. Cases and Obs. Vol. 1, p. 41, Sec. Lond. 1773.*)

About the year 1742, the removal of thighs without bloodshed, was a subject a good deal broached. A single case, recorded by Schaarschmid, where a mortified thigh separated without hemorrhage, was the foundation of the scheme. The arteries were completely blocked up, and the parts insensible. (*Haller, Dis. Chir. Vol. 5, p. 155.*) A similar occurrence was related by Acrel (*Chir. handels. p. 557*); and Lalouette professed himself a believer in the security from hemorrhage, on account of the vessels being filled with coagula, and approved therefore of letting dead parts be removed, or rather fall off, without bloodshed. (*Haller, Diss. Chir. Vol. 5, p. 273.*)

Bagieu, an experienced French military surgeon, in cases where the projecting bone of the stump was affected with necrosis, ventured to amputate a second time, and urged a variety of arguments in defence of the practice. (*Mem. de l'Acad. de Chir. T. 2, p. 274.*) He coincided with Le Dran and Bromfield, however, about the propriety of restricting amputation to few cases, and has related numerous examples of limbs being saved, which, according to the doctrines then in vogue, ought to have been cut off. (*Deux Lettres d'un Chir. de l'Armée, 12mo. Paris, 1750.*)

M. Louis, a French surgeon of extraordinary talents, introduced the plan of dividing the loose muscles first, and lastly those which are closely connected with the bone. This eminent man took notice, that the muscles of the thigh became retracted in an unequal degree, after being divided. Those which are superficial, and extend along the limb, more or less obliquely, without being attached to the bone, were drawn up with greater force, and in a greater degree, than others, which are deeply situated, in some measure, parallel to the axis of the femur, and fixed to this bone throughout their whole length. The retraction begins the very instant when the muscles are cut, and is not completed till a short time has elapsed. Hence, the effect should be promoted, and be as perfect as possible, before the bone is sawn. In the amputation of the thigh, M. Louis was always desirous of letting the muscles contract as far as they could, and, for this reason, he was rather averse to using the tourniquet, as the circular pressure of this instrument rather counteracted what he wished to take place, and hence he at one time preferred letting an assistant make pressure on the artery, though he subsequently expressed his approbation of the tourniquet proposed by M. Pipelet for compressing the femoral artery. (*Mém. de l'Acad. de Chir. Vol. 4, p. 60, 4to.*)

Actuated by such principles, M. Louis practised a kind of double incision different

from that of Cheselden and Petit, and different also from Alanson's method, which I shall hereafter notice. By the first stroke, he cut, at the same time, both the integuments and the loose superficial muscles; by the second, he divided those muscles, which are deep, and closely adherent to the femur. On the first, deep, circular cut being completed, M. Louis used to remove a band, which was placed round the limb, above the track of the knife. This was taken off, in order to allow the divided muscles to become retracted without any impediment. He next cut the deep adherent muscles, on a level with the surfaces of those loose ones, which had been divided in the first incision, and which had now attained their utmost state of retraction. In this way, he could evidently saw the bone very high up, and the painful dissection of the skin from the muscles was avoided. M. Louis was conscious, that there was more necessity for saving muscle than skin; and he knew, that, when an incision is made at once down to the bone, the retraction of the divided muscles always left the edge of the skin projecting a considerable way beyond them. Hence he deemed the plan of first saving a portion of skin, by dissecting it from the muscles, and turning it up, quite unnecessary. As the bone should always be sawn rather higher than the division of the soft parts, Louis, like J. L. Petit, and most other judicious surgeons, highly approved of the employment of a retractor. He was likewise the author of some valuable instructions for preventing the protrusion of the bone after the operation. (*See Mém. de l'Acad. de Chir. T. 2, p. 268—410, &c. 4to.*) The impartial reader, who takes the trouble to read the remarks on amputation, published by this greatest of all the French surgeons of the last century, with the exception perhaps of J. L. Petit, and Desault, will at once be impressed with the force and perspicuity of his matter, and with the evident propriety of a good deal of the practice inculcated.

In England, Cheselden, and not J. L. Petit, is regarded as the surgeon who revived Celsus's method, in proposing to divide the soft parts by a double incision; that is, by cutting the skin and cellular substance first, and then, by dividing the muscles, down to the bone, on a level with the edge of the skin, so that the bone might be sawn higher up, and its end be more completely covered with skin. Whether Cheselden had the priority in this improvement, I cannot presume to say; but, he gave an account of it in Gataker's translation of Le Dran's treatise on the operations, as early as 1749, which was long prior to the appearance of Petit's posthumous writings; and Mr. Cheselden further mentions, that, during his apprenticeship to Mr. Fern, he had communicated to that gentleman his sentiments about the double incision.

In order to hinder the stump from assuming a pyramidal, or sugar-loaf shape

which sometimes happened notwithstanding every improvement hitherto mentioned, a circular bandage was employed, which acted by supporting the skin and muscles, and preventing their retraction. This bandage, when properly applied, from the upper part of the limb downward, fulfilled, in a certain measure, the end proposed, though many stumps yet turned out very badly. Mr. Sharp was induced therefore to revive the very ancient plan of bringing the edges of the skin together with sutures; but, the pain and other inconveniences of this method were such, that it was never extensively adopted; and Mr. Sharp himself ultimately abandoned it. The cross bandage, however, which he used to put over the end of the stump, remains in fashion even at the present day. (*Treatise on the Oper.* p. 216; *Critical Inquiry*, p. 268.) It is to be regretted, that an excellent modern surgeon, the late Mr. Hey, should have commended so much as he has done the use of sutures, in bringing together the edges of the wound after amputation. (*Practical Observations in Surgery*, p. 534. Edit. 2.)

In opposition to Louis, the inefficiency of his method for hindering the protrusion of the bone was asserted by Valentin, who thought the object might be better attained by dividing the parts while they were in a state of tension; for which purpose, he recommended changing the posture of the limb, according to the parts which he was about to cut. (*Recherches Critiques sur la Chirurgie moderne*, Soc. Amst. 1772.) Valentin's proposal seems never to have made much impression on the profession; whether on account of its inconvenience, or inefficacy, I know not: certain it is, many cases present themselves, in which the posture of a limb absolutely could not be changed during the operation, owing to the nature of the disease, or could not be altered without extreme agony to the patient.

At this period arose the celebrated controversy about the propriety of amputation in general. As Sprengel remarks, several French surgeons now began to be convinced, with Le Dran and Bagieu, that the operation was undertaken on too light grounds, and, in particular, that bad complicated fractures might be healed very well without amputation. Such was the doctrine of Boucher (*Mém. de l'Acad. de Chir.* T. 2, p. 304,) Gervaise (*Anfangsgr. der Wundarzn.* Soc. Strasb. 1755,) and Faure (*Mém. qui ont concouru pour le prix de l'Ac. de Chir.* Vol. 1, p. 100.) The latter especially urged the prudence of delay, in gun-shot wounds, and comminuted injuries of the bones. But, the writer, who at this time made most noise in the world, by his general condemnation of amputation, was Bilguer, (*Diss. de Membrorum Amputatione*, Soc. Hal. 1761,) whose sentiments have received so complete a refutation from his own contemporaries, Pott, (*Chir. Works*, Vol. 2,) Morand, (*Opusc. de Chir.* T. 1, p. 232,) and de La Martinière (*Mém. de l'Acad.*

de Chir. Vol. 4, p. 1,) and also from later writers, to whom reference will be made in speaking of *Gun-shot Wounds*. Even Bilguer himself was compelled to admit the necessity of amputation in cases of gangrene. (*Anweis für die Feldwundärzte*, S. 170.)

Bilguer's colleague, the celebrated Schmucker, inclined to the same doctrines, and has detailed several cases, where limbs were not only shattered, but actually carried away by balls, yet where a cure followed without amputation. One of his maxims was, that it was better for the member to be taken off by gun-shot, than by the surgeon's knife, as the ball operated on a healthy subject, the knife on a person debilitated by an hospital. (*Chir. Wahrn.* Th. 2. S. 493.) In a later valuable essay on this subject, he restricts amputation to shattered limbs, affected with gangrene. His mode of operating was that of M. Louis. He sanctioned joint-operations at the hip and shoulder; but condemned those of the knee and elbow, as never answering. (*Verm. Schrift.* Th. 1. S. 3.)

Soon after the middle of the last century, the practice of amputating at the joints began to excite increased attention; but, as this is a topic, to which I must presently return, it is unnecessary now to dwell upon it. The writings of Puthod, Wohler, Brasdor, Barbet, Sabatier, Park, Moreau, and Vermandois, in relation to this subject deserve particular notice.

I now come to Mr. Alanson, whose name cuts as great a figure in the history of amputation, as that of any surgeon yet mentioned. His chief objects were to hinder a protrusion of the bone, and promote union by the first intention. He rejected the band, which used formerly to be put round the limb for the guidance of the knife, as altogether useless, and an impediment to the quick performance or the circular incision through the skin. When the tourniquet had been applied, an assistant grasped the integuments with both hands, and drew them and the muscles firmly upwards. The operator then fixed his eye upon the proper part, where he was to begin the incision, which was made with considerable facility and despatch, the knife passing with greater quickness in consequence of the tense state of the integuments.

After the incision through the integuments, the assistant still continued a steady support of the parts, while Mr. Alanson separated the cellular and ligamentous attachments with the point of his knife, till as much skin had been drawn up as would, with the united assistance of the particular division of the muscles hereafter recommended, fully cover the whole surface of the wound. Then, instead of applying the knife close to the edge of the integuments, and dividing the muscles in a circular perpendicular manner down to the bone, Mr. Alanson proceeded as follows: when operating upon the thigh, and standing on the outside of the limb, he applied the edge of his

knife, under the edge of the supported integuments, upon the inner margin of the vastus internus muscle, and cut obliquely through that and the adjacent muscles, upwards as to the limb, and down to the bone, so as to lay it bare, about three or four finger-breadths higher than is usually done, by the common perpendicular circular incision. He now drew the knife towards himself, then keeping its point upon the bone, and the edge in the same oblique line already pointed out for the former incision, he divided the rest of the muscles in that direction all round the limb; the point of the knife being in contact with, and revolving round the bone through the whole of the division.

According to Mr. Alanson, the speedy execution of the above directed incision, will be much expedited, by one assistant continuing a firm and steady elevation of the parts, and another attending to preserve the skin from being wounded, as the knife goes through the muscles, at the under part of the limb. Mr. Alanson censures the old method of depriving the bone of its periosteum to a considerable extent, above and below the part, where he saw was to pass, not only as creating unnecessary delay, but since the periosteum serves to support the vessels in their passage to the bone, as apt to produce exfoliations, above the part where the bone is to be divided with the saw. Instead of this practice, he advises first the application of the retractor, as advised by Gooch and Bromfield; and then denuding the bone at the part, where the saw is to pass, whereby the bone may be sawn off higher than is usually practised; a material object in preventing a projection of the bone, and forming a small circatrix.

If the flesh of a stump, formed in the thigh, agreeably to the foregoing plan, be gently brought forward after the operation, and the surface of the wound be then viewed, it may be said to resemble in some degree, a conical cavity, the apex of which is the extremity of the bone; and the parts thus divided, are obviously the best calculated to prevent a sugar-loaf stump.

The part where the bone is to be laid bare, whether two, three, or four finger-breadths higher than the edge of the retracted integuments; or, in other words, the quantity of muscular substance to be taken out, in making the double incision, must be regulated by considering the length of the limb, and the quantity of skin that has been previously saved by dividing the membranous attachments. The quantity of skin saved, and muscular substance taken out, must be in such exact proportion to each other, that the whole surface of the wound will afterwards be easily covered, and the limb not more shortened, than is necessary to obtain this end.

After the removal of the limb, Mr. Alanson drew each bleeding artery gently out with the tenaculum, and tied it as nakedly as possible, with a common slender ligature. When the large vessels had been tied, the tourniquet was immediately slackened, and

the wound well cleaned, in order to detect any vessel, that might otherwise have remained concealed with its orifice blocked up with coagulated blood; and before the wound was dressed, its whole surface was examined with the greatest accuracy, by which means Mr. Alanson frequently observed a pulsation, where no hemorrhage previously appeared, and turned out a small clot of blood from within the orifice of a considerable artery. He urges bestowing particular attention in making every vessel secure which is likely to bleed on the attack of the symptomatic fever; for besides the fatigue and pain, to which such an accident immediately exposes the patient, it seriously interrupts the desired union of the wound. He used always to clean the whole surface of the wound well with a sponge and warm water, as he thought, that the lodgment of any coagulated blood would be a considerable obstruction to a quick union of the parts.

The skin and muscles were now gently brought forwards; a flannel roller was put round the body, and carried two or three times rather tightly round the upper part of the thigh, as at this point, it was intended to form what Mr. Alanson called a sufficient basis, which materially added to the support of the skin and muscles. The roller was then carried down in a circular direction to the extremity of the stump, not so tight as to press rudely or forcibly, but so as to give an easy support to the parts.

The skin and muscles were now placed over the bone, in such a direction, that the wound appeared only as a line across the face of the stump, with the angles at each side, from which points, the ligatures were left out, as their vicinity to either angle might direct. The skin was easily secured in this posture by long slips of linen, or flax of the breadth of about two fingers, spread with cerate, or any cooling ointment. If the skin did not easily meet, strips of sticking plaster were preferred. These were applied from below upwards, across the face of the stump, and over them a soft tow-pledget and compress of linen; the whole being retained with the many-tailed bandage, and two tails placed perpendicularly, in order to retain the dressings upon the face of the stump.

Mr. Alanson censured the plan of raising the end of the stump far from the surface of the bed with pillows, as the posterior muscles were retracted by it; and he considered it best to raise the stump about half a hands breadth from the surface of the bed, by which means the muscles were put in an easy relaxed position. The many-tailed bandage Mr. Alanson found much more convenient than the woollen cap, frequently used in former times to support the dressings and he observes, that though this seems well calculated to answer that purpose, if not put on with particular care, the skin is liable to be drawn backwards from the face of the stump; nor can the wound be dressed, without first lifting up

the stump to remove the cap. (See *Alanson's Practical Obs. on Amputation*, 8vo. Lond. 1779.)

The chief peculiarity of Alanson's method of operating, namely, the mode in which he recommends the oblique division of the muscles to be performed, did not, however, meet with universal approbation, and his extensive dissection of the skin from the muscles was complained of as excessively painful. The formation of a conical wound, by following Alanson's directions, was regarded by several as impracticable. (See *Marten's Paradoxiën*, B. 1. S. 88; *Loeffler, Beytrage* 1. No. 7; *Wardenburgh, Briefe Eines Arztes* 2. B. p. 20; *Richter, Anfangsgr.* vol. 7; *Graefe, Normen, &c.* p. 8; *Hey, Pract. Obs.*) In my opinion, there can be no doubt of the truth of some of the criticisms made by these, and some other writers, on the impossibility of making a wound, with a regular conical cavity, by observing the directions given by Alanson; for, if the knife be carried round the member with its edge turned obliquely upwards towards the bone, it will pass spirally, and, of course, the end of the incision will be considerably higher, than the beginning. But, although Alanson probably never did himself exactly what he has stated, I am sure, that his proposition of making an oblique division of the muscles all round the member, has been the source of great improvement in amputations in general, and is what is usually aimed at by all the best modern surgeons. It is true, they do not actually perform the oblique incision all round the limb, by one stroke, or revolution of the knife round the bone, as Alanson says that he did; but, they accomplish their purpose by repeated, distinct, and suitable applications of the edge of the instrument, turned obliquely upwards towards the bone, or bones.

Among others, Mynors found fault with some of Alanson's instructions, and thought every desideratum might be more certainly attained by saving skin enough, and then cutting through the muscles. The first incision, however, he directs obliquely upwards through the integuments, while they were drawn up by an assistant, and he then cut down to the bone. (*Pract. Thoughts on Amputation*, 8vo. Birmingham. 1783.) Sprengel considers Mynors's plan merely as a revival of Celsus's method, as it had in view only the preservation of skin, and not the formation of a fleshy cushion. (*Geschichte der Chir.* B. 1. p. 426.)

Kirkland endeavoured to improve Mynors's plan, by cutting off a piece of skin at each angle of the stump, so as to keep the integuments from being thrown into folds; and, in opposition to Pott, he defended the sentiments of Bilguer concerning the successful management of desperate cases, without amputation. (*On the present State of Surgery*, p. 273, and *Thoughts on Amputation*, 8vo. Lond. 1780.)

B. Bell used to operate very much in the same way as Mynors; and, when it seemed

advantageous to make a flap, he did not disapprove of the plans suggested by Ravaton, Verduin, and Alanson. (*Syst. of Surgery.*)

An interesting paper on amputation was some years ago published by Loder; its chief purport was to defend Alanson's method, with some slight modifications. (*Chir. und Medic. Beobacht.* B. 1. p. 20. 8vo. 1794.) However, the alterations suggested by Loder, do not seem to Graefe at all adequate to the removal of the difficulties, with which the mode of cutting the flesh exactly after Alanson's directions is complicated. (*Normen für die Abl. grosserer Gliedmassen*, p. 8, 4to. Berlin 1812.)

The removal of limbs without bloodshed, proposed by Guido di Cauliaco in the 14th century, has met with modern defenders in J. Wrabetz and W. G. Plouquet. J. Wrabetz, with a ligature which was daily made tighter, took off an arm above the elbow. In the fissure, he sprinkled a styptic powder. On the fourth day, the flesh was severed down to the bone, which was sawn through. (*Geschichte eines ohne Messer abgesetzten Oberarms*. 8vo. Freyb. 1782.) Plouquet thought the plan suited to emaciated timid subjects; but not well adapted to the leg, or forearm. (*Von der unblutigen Abnehmung der Glieder*, 8vo. Tub. 1786.)

Some other modes of doing flap-amputations, and in particular, the suggestions and improvements, made by Hey, Chopart, Dupuytren, Larrey, and other modern practitioners, will be noticed in the description of the amputation of particular members. In the mean time, I shall conclude this section with mentioning the laudable attempts made at different periods, to render the patient less sensible of the agony produced by the removal of a limb. Theodoricus, as we have said, administered for this purpose opium and hemlock, and though he was imitated by many of the ancient surgeons, few moderns have deemed the practice worthy of being continued. Guido made the experiment of benumbing the parts with a tight ligature; but a machine, devised a few years ago in England, expressly for the object of stupifying the nerves of a limb previously to amputation, is perhaps not undeserving of further consideration. (See *J. Moore's Method of preventing, or diminishing Pain in several Operations of Surgery*, 8vo. Lond. 1784.) The great reason of the latter plan being given up, is, that some patients have made more complaint of the sufferings occasioned by the process of dulling the sensibility of the nerves, than of the agony of amputation itself, without any such expedient. Yet, daily experience proves, that the pressure caused on the sciatic nerve by sitting with the pelvis in a certain position, will completely benumb the foot and leg, and this with such an absence of pain, that the person so affected is actually unaware of his foot being asleep, as it is termed, until he tries to walk. On the little good done by warming and oiling the cutting instruments,

a method recently much commended, (*Faust und Hunold über die Anwendung des Oehls und der Wärme*, p. 3-23, Leipzig, 1806,) I am sure it is unnecessary for me to comment.

AMPUTATION OF THE THIGH.

The thigh ought always to be amputated as low as the disease will allow, so that as little of the limb may be cut off as possible, the pain may not be greater than necessary, and the surface of the wound have less extent than would otherwise happen. (*Sabatier, Méd. Op.* p. 350. t. 3. Ed. 2.) The patient is to be placed on a firm table, with his back properly supported by pillows, and assistants, who are also to hold his hands, and keep him from moving too much during the operation. The ankle of the sound limb is to be fastened, by means of a strong band, or garter, to the nearest leg of the table.

Here, however, through an imprudent solicitude to obtain the above advantages, let not the surgeon ever be unmindful of the great axiom in surgical operations, that all the diseased parts should be removed; but, let him be assured of the truth of what Graefe inculcates, that it is more pardonable to cut away too much, than too little. (*Normen für die Ablosung grosserer Gliedm.* p. 60.) At the same time I do not agree with some modern writers, who deem it necessary to amputate beyond the limits of every abscess and sinus, which may extend very far above a diseased joint, or compound fracture. Many of these suppurations are only like ordinary abscesses, and finally get well, after the main disease or injury is removed, as I have often seen. Were it an invariable rule to cut off a limb, above every collection of matter, sometimes five, or six inches more of the thigh would be sacrificed, than circumstances absolutely demanded, and the greater danger of a high, than a low operation, would be encountered. However, in all cases, where the bone is suspected to be unsound, or the muscles are affected with the morbid changes, peculiar to fungus hæmatodes, or other incurable diseases, the operation should be practised sufficiently high to take away all the distempered parts. In secondary amputations, where there has been much suppuration in the limb, and a sinus runs up, Mr. Guthrie says, that if the sinus extend only a short way between the muscles, the membrane lining it may be dissected out; but, if the matter has lain upon the bone, this will have become diseased, and amputation should be done high enough to remove the affected part of it. (*On Gunshot Wounds*, p. 87.)

Many writers disapprove of amputating too close to the knee (*Graefe, Op. cit.* p. 60;) and Langenbeck urges one objection to it, not specified by any other author, viz. that, if the operation be done lower down than two hand-breadths above the knee, the femoral artery shrinks into the

aponeurotic sheath, which it here receives from the vastus internus and triceps, and cannot be drawn out with the forceps, so as to be separately tied, without first slitting up that sheath. Hence, he recommends cutting through the muscles at the distance above the knee already mentioned. (*Bibl. für die Chir.* B. 1, p. 571, 12mo. Gott. 1806.) But when I come to look at the breadth of two adult hands, and see how much of the limb would be sacrificed, at all events, only to save a little trouble, I cannot bring my mind to concur with Langenbeck, the remedy being worse than the evil alleged.

The next thing is the application of the tourniquet. (See *Tourniquet*.) The pad should be placed exactly over the femoral artery, in as high a situation as can be conveniently done. When the thigh is to be amputated high up, it is better to let an assistant compress the femoral artery in the groin, with any commodious instrument, furnished with a round blunt end, calculated for making direct pressure on the vessel without injuring the integuments.—Some authors indeed give a general preference to this method, whether the thigh be amputated high up, or low down, except where skilful assistants are not at hand. (*Paroisse, Opuscules de Chir.* p. 188. *Brunninghausen, Erfahr. über die Amp.* p. 273. *Langenbeck, Bibl. Chir.* p. 564.) Were the patient, however, in a debilitated state, and unable to bear loss of blood, as there might, in this way, be some considerable bleeding, by reason of the anastomoses with the branches of the internal iliac artery, I should feel disposed to employ the tourniquet whenever circumstances would admit of its application. In amputations of the thigh, the great objection to the use of this instrument, is, that it impedes the free and immediate retraction of the loose muscles after they have been cut, the consequence of which is, that the surgeon cannot divide so high, as he otherwise could do, those deeper muscles which are more fixed and attached to the bone. Yet, in order to have the bone well covered with flesh, and no danger of a sugar-loaf stump, the latter object is one of infinite importance. Perhaps the best general rule is, to abandon the application of the tourniquet in amputations, done as high as the middle of the thigh, except where the patient is remarkably weak, so that he cannot bear the smallest loss of blood, and there is no steady intelligent assistant at hand, to whom the compression of the artery in the groin can be prudently confided. When, however, the operation is to be done much higher up, of course the employment of a tourniquet is wholly inadmissible.

Whether the right or left thigh is to be removed, it is customary for the operator to stand on the patient's right side. The great advantage of this situation seems to be, that the surgeon's left hand can be thus more conveniently, and quickly brought into use, than if he were always to stand

on the same side, as the limb he is about to amputate. This seems to be the only assignable reason for this habit: for, when the left thigh is to be amputated, it is certainly some inconvenience to have the right limb, between the operator, and the one that is to be removed. But this is found less inconvenient, than not having the left hand next the wound.

Mr. Guthrie, in speaking of amputations on the two lower thirds of the thigh, observes, that "in these cases the tourniquet should be used;" but in operations high up the thigh, he joins all other surgeons in recommending the inguinal artery to be compressed against the os pubis. (*On Gunshot Wounds*, p. 202.) The utility of slackening the tourniquet completely, however, as soon as the principal vessels are secured, a piece of advice delivered by this excellent surgeon, I presume, cannot be right on the ground, which he specifies, viz. the impediment made by the strap of the instrument to the retraction of the muscles, and the consequent difficulty in high operations of sawing the bone, *because in common practice, the bone is always sawn before any of the vessels are secured*; and loosening the tourniquet entirely, while any arterial branches still require the ligature, must generally be objectionable, if loss of blood be a disadvantage. In flap-amputations, high up the limb, indeed, where the arteries are sometimes tied, before the division of the bone, the employment of a tourniquet at all is quite out of the question.

We know that it was an opinion of the late Mr. J. Bell, that the flow of blood through a large artery could not be completely stopped by pressure; and Mr. Hey of Leeds adopted a similar notion, in consequence of seeing a case, in which the application of two tourniquets to the thigh did not restrain the hemorrhage from a fungus hæmatodes of the limb. He says; the pressure of the tourniquet does not completely obstruct the passage of blood in the arteries; it only diminishes so much of the force of the current, as to enable the vessels, in a sound state, to exert their natural contractile power so effectually as to prevent hemorrhage. (*See Hey's Pract. Ob.* p. 257, 258, Ed. 2.) Of the inaccuracy of this doctrine, no man can doubt, who sees the femoral artery with its open mouth on the face of a stump not bleeding, while the tourniquet is tight, or skilful pressure is kept up, but throwing out its blood to a great distance, the instant the pressure is discontinued. Nor, I apprehend, can any surgeon, who has amputated at the shoulder, and seen how completely pressure commands the flow of blood through the open-mouthed axillary artery, join in the sentiment of John Bell and Hey upon this particular point. Here I can speak with confidence, because I have myself amputated at the shoulder, and assisted at this operation several times, and found the statements of the preceding writers perfectly and clearly contradicted. Were any

further testimony required, I might cite that of Dr. Hennen, who mentions, among other facts, that in a shoulder joint case operated upon by Mr. Dease, the amount of blood, lost from the principal artery, was no more than the quantity contained between the point of pressure, and the point of incision through the vessels. (*Principles of Military Surgery*, p. 257, Ed. 2.) The same fact presented itself in the example, where I recently assisted Dr. Blicke, in private practice.

How then are we to explain the occasional continuance of bleeding, notwithstanding the pressure of one, or even two tourniquets? Without doubt, by the fact, that the pads of these instruments, when not duly arranged, do more harm than good, by raising the band off the vessel, and, perhaps also in Mr. Hey's example, by the additional consideration, that tumours of the fungus hæmatodes kind, include a large quantity of blood, and will bleed profusely, and for a considerable time after the main supply of blood to them is cut off. The same thing happens in the disease, called aneurism by anastomosis, as I have had several opportunities of witnessing, but in no instance more strikingly, than in one, where, some time after Mr. Hodgson had tied the radial and ulnar arteries, Mr. Lawrence divided every part of the finger, excepting the tendons and bone, and yet a considerable bleeding went on from the further side of the wound. (*See Med. Chir. Trans.* vol. 9, p. 216.)

The application of the tourniquet is generally left too much to assistants; but, as far as my judgment extends, no operator is justified in commencing his incisions, before he has examined and fully satisfied himself, that the instrument is correctly applied. Mr. Guthrie candidly tells us, that he once lost an officer, in consequence of hemorrhage during the operation, although the tourniquet was in the charge of a surgeon of ability; and the advice with which he follows this statement, is worth recollecting: "In a case of this kind, where it (the tourniquet) is found of little benefit, the surgeon should not continue twisting and turning it, whilst his patient is bleeding, but quit it altogether, and compress the artery against the pubis." This maxim, I think, cannot be too highly commended.

The shape and size of the pad of the tourniquet are deemed by surgeons matters of importance. At St. Bartholomew's, the pads employed are very firm, being composed of wood, or cork covered with leather, and rather thicker than the thumb, the upper surface being flat, and the lower, which is put against the thigh, being convex. They are about an inch and a half in length. Such pads answer extremely well, as I can affirm from the observation of some hundreds of amputations in that hospital. A common fault formerly was the employment of pads which were too large, and soft, and not judiciously shaped. As Mr.

C. Hutchinson remarks, the principal objection to a large pad is, that the band of the tourniquet is so much raised by it, that a considerable space is left on each side of it, where no compression is made on the limb, however closely the instrument may be screwed, and thus there will be a risk of hemorrhage from such vessels as happen to be in these situations. The same gentleman uses a pad, which is not thicker than a finger, and places it obliquely over the artery, so as to preclude the possibility of displacement. (*Pract. Obs. in Surgery*, p. 21-23.) Mr. Guthrie says, "the pad should be firm and rather narrow, and carefully held directly over the artery, while the ends of the bandage, in which it is contained, are pinned on the thigh. The strap of the tourniquet is then to be put round the limb, the instrument itself being directly over the pad, with the screw entirely free. The strap is then to be drawn tight, and buckled on the outside, so as to prevent its slipping, and not interfere with the screw, which is to be turned until the pressure is sufficiently strong to stop the circulation. If the screw require to be turned, for more than half its number of turns to effect this, the strap is not sufficiently tight, or the pad has not been well applied; and they must be replaced." (*On Gunshot Wounds*, p. 204.)

In two amputations at St. Bartholomew's Hospital, I saw the tourniquet break after the soft parts had been divided, and, as in one of these cases a good deal of blood was lost, because another tourniquet happened not to be in the room, and pressure on the artery in the groin was not immediately adopted, I coincide with such writers, as recommend the rule of always having two tourniquets ready. Graefe even goes so far as to advise putting both of them round the limb before the operation commences. (*Normen für die Ablosung grosserer Gliedmassen*, p. 48;) but, the frequency of a tourniquet breaking is not so great, I believe, as to demand such precaution, and the plan would be very objectionable in thigh amputations, where it is a material advantage to have plenty of room between the place of the incision and the band which goes round the limb.

An assistant, firmly grasping the thigh with both hands, is to draw upward the skin and muscles, while the surgeon, beginning with that part of the edge of the knife, which is towards the handle, makes a circular incision, as quickly as possible through the integuments down to the fascia, or, as Mr. Guthrie and Dr. Hennen recommend, even completely through it. According to Mr. Guthrie, the skin cannot be sufficiently retracted, unless the fascia be divided, which he appears to think ought rather to be drawn up with the integuments, than dissected from them. (*On Gunshot Wounds*, p. 205. Also *Hennen's Military Surgery*, p. 263.) On the contrary, Professor Langenbeck is very particular in enjoining surgeons to avoid cutting through

the fascia by the first sweep of the knife, because he finds the muscles are better held together, and can be more regularly divided, by cutting them and the fascia at the same time. (*Bibl. für die Chir. l. 1. p. 564.*) Nor does M. Roux divide the fascia by the first incision. (*Mem. sur la Reunion immediate de la Plaie apres l'Amputation circulaire*, p. 9. *Svo. Paris*, 1814.) At St. Bartholomew's, the surgeons rarely, or never cut through the fascia with the integuments, but aim at carrying the knife perfectly down to it all round the limb. This at least ought to be done, without fear of doing rather more; for, as Graefe observes, if the outer layers of the muscles be here and there a little touched, this occasions less pain, than the additional strokes of the knife for dividing any portion of the skin and cellular substance, not completely cut through in the first instance. Graefe also dissents from Mynors and others, who are advocates for cutting the skin obliquely instead of perpendicularly, because he finds the thin edge of the integuments, thus separated from the subjacent cellular membrane, very apt to slough. (*Normen für die Abl. grosserer Gliedmassen*, p. 102.) In a thigh of ordinary dimensions, the first incision should be made four inches below where it is intended to saw the bone. When the thigh is bulky, the large amputation knife will be found the best. Before beginning this first cut, the arm is to be carried under the limb, till the knife reaches almost round to the side on which the operator stands. With one sweep, penetrating at least to the fascia, the knife is then to be brought round to the point, where it first touched the skin. Thus, the wound is more likely to be regularly made, than by cutting first on one side, and then on the other, while the patient is saved some degree of pain, in consequence of the uninterrupted quickness, with which the incision is made. At the same time I ought to confess, that the late Sir C. Blicke, and some other surgeons, whom I have seen operate, used to complete the circle by two strokes of the knife so well and expeditiously that their capricious attachment to this plan could hardly be found fault with.

The next object is the preservation of as much skin as will afterwards conjointly with the muscles, cut in an oblique direction, cover the end of the stump with the utmost facility. It is rather difficult to lay down any other general principles, for the guidance of the surgeon in saving integuments. I am disposed to agree with several modern writers, that the painful dissection of the skin from the muscles has been recommended and practised to a very unnecessary extent; that is to say, unnecessarily, if the division of the muscles be performed in the most advantageous manner. Graefe, one of the best surgeons at Berlin, does not dissect the skin from the muscles at all in amputating the thigh, but takes care, after making the cutaneous incision, to have the integuments, and subjacent

flesh very firmly drawn up before commencing the oblique division of the muscles. This retraction he also strongly advises to be done uniformly and smoothly all round the member, lest, in dividing the muscles, any irregular projection of the skin interfere with the requisite movements of the knife. (*Normen für die Alb. grosserer Gliedmassen.* p. 103.) However, Langenbeck, another of the most skilful operators on the continent, prefers detaching the integuments from the fascia for about two finger-breadths. (*Bibl. für die Chir. b. 1. p. 567.*) as is perhaps the most common practice in the London hospitals. Brünninghausen thinks skin a better and more durable covering for the end of the bone, than muscular fibres, which after a time dwindle away, and hence he computes the quantity of integuments which ought to be saved, by the measure of the circumference and diameter of the member. Thus, when the limb is nine inches in its circumference, the diameter is about three: therefore, one inch and a half of skin on each side is to be saved. (*Erfahr. &c. über die Amp. p. 75.*) But this author cuts the muscles perpendicularly, so that he is obliged to separate much more skin from the flesh than is necessary, when the incision through the muscles is carried obliquely upward. Mr. Hay's method of calculation, which I shall presently notice, appears more adapted to ordinary practice; and he says, "the division of the posterior muscles may be begun at half an inch, and that of the anterior, at three quarters, above the place where the integuments were divided." (*Pract. Obs. in Surgery, p. 528, Ed. 2.*) With a view of preventing the necessity of dissecting the skin from the fascia, Mr. Guthrie, as already noticed, commends the plan of cutting through the fascia, together with the integuments by the first stroke of the knife, and retracting these parts at the same time, instead of detaching them from each other. If this method be found perfectly efficient, and it be not objectionable, as exposing the muscles to be cut unnecessarily. I think the reason specified against it by Langenbeck, and explained in a preceding page, not weighty enough to form a just ground for rejecting a practice, which comes with the alleged advantage of superseding the necessity for all painful dissection of the skin from the muscles. However, in secondary amputations of the thigh, if the integuments be unsound, and will not retract, Mr. Guthrie approves of their being dissected back to an equal distance all round. (*On Gunshot Wounds, p. 205—208.*) Dr. Hennen, by giving an oblique direction to all the incisions through the muscles, obviates the necessity for much dissection of the integuments, and, he says, that, in a small limb, he has repeatedly performed the operation with one sweep of the knife, cutting obliquely inwards and upwards at once to the bone. (*Principles of Military Surgery, p. 265, Ed. 2.*) This author, like Mr. Guthrie, also recommends carrying the knife through

the fascia in the first circular incision; and so does Mr. C. Hutchinson, who makes no mention of dissecting back the skin, but simply states, that the "integuments and fascia being divided by a circular incision, and retracted upwards, as high as is judged necessary, the superficial muscles should next be divided, &c." (*Pract. Obs. in Surgery, p. 23, 8vo. Lond. 1816.*) We are therefore to conclude, that he joins Graefe and others in thinking the separation of the skin from the fascia unnecessary. My own observations in practice, lead me to believe, that the dissection of the integuments from the subjacent parts used formerly to be carried to an extent beyond all moderation and necessity, and that as it is a most painful proceeding, and hurtful by forming a large loose pouch for the lodgment of matter, it ought to be abandoned by every surgeon, who follows the method of sawing the bone considerably higher, than the first cut through the superficial muscles. I am not, however, prepared to assert, that no dissection at all is generally requisite, but am rather disposed to believe the moderate adoption of it, as recommended by Mr. Hey, the most prudent. This gentleman, like Desault, (*Œuvres Chir. T. 21, p. 545.*) is an advocate for amputating with a triple incision, and for preserving such a quantity of muscular flesh and integuments, as are proportionate to the diameter of the limb. By a triple incision, he means first an incision through the integuments alone; secondly, an incision through all the muscles, made somewhat higher, than that through the integuments; and thirdly, another incision through that part of the muscular flesh, which adheres to the bone, made round that point of the bone, where the saw is to be applied. The proper distance of these incisions from each other, he says, must be determined by the thickness of the limb, upon which the operation is to be performed; making allowance for the retraction of the integuments, and of those muscles which are not adherent to the bone. Supposing the circumference of the limb to be twelve inches, where the bone is to be divided, the diameter is about four inches, and, if no retraction of the integuments were to take place, a sufficient covering of the stump would be afforded by making the first incision at the distance of two inches from the place where the bone is to be sawn, that is, at the distance of the semidiameter of the limb on each side. But, as the integuments, when in a sound state, always recede after they are divided, it is useful to make some allowance for this recession; and to make the first incision, in this case at least two inches and a half, or three inches, below the place where the bone is to be sawn. As the posterior muscles of the thigh retract a great deal in the process of healing, Mr. Hey advises their division to be begun half an inch above the place where the integuments were cut, and the anterior muscles three quarters of an inch. The integuments, says he, will

retract a little both above and below the place, where they were divided; but, the distance from that place must be computed from the mark left upon the surface of the muscles in dividing the integuments. Thus, in fact, in a common thigh amputation, Mr. Hey deemed it necessary to detach the skin from the muscles merely to the extent of half an inch at the back part of the limb, and of three quarters in front: a very different practice from the old custom of making quite a bag of integuments, and turning them back, like the upper piece of a glove is turned down, or rather as the sleeves of a coat are turned up.

In common amputations of the thigh, Roux strongly disapproves of separating the skin far from the muscles, as a circumstance highly unfavourable to the healing of the wound by adhesion; he divides only a few of the cellular bonds between the integuments and fascia; and occasionally he has imitated M. Louis in cutting through the skin, and superficial muscles together. (*Mem. sur la Reunion de la plaie après l'Amputation, &c. p. 9.*)

I believe the generality of the best modern operators are now convinced of the impropriety of dividing the muscles exactly in the manner directed by Mr. Alanson, viz. by letting the knife revolve uninterruptedly all round the bone with its edge turned obliquely upwards, towards the point where it is intended to apply the saw. It is a topic, indeed, to which I have already called the reader's attention in the foregoing columns. Langenbeck says, that he is perfectly convinced of the impossibility of forming a conical wound with one stroke of a large amputating knife, and joins Mr. Hey in approving of the triple incision. (*Bibl. für die Chir. b. 1, p. 564.*) The objections first urged by Wardenburgh against Alanson's method, are mathematically correct, inasmuch as the course of the edge of the knife, in this gentleman's method, must be spiral, and the end of the incision be considerably higher, than the beginning of it. Such must be the result of performing the division of the muscles all round the limb by one continued stroke of the knife, with its edge directed obliquely, upwards; for the idea of making the knife revolve in this manner, while its point is confined to an imaginary, regular, determinate circle on the bone, I believe is now abandoned, as not really practicable. Yet, with the exception of Desault, who confined himself to the triple incision, conducted on the principles of M. Louis, (*Œuvres Chir. T. 2, p. 547.*) few experienced surgeons refuse to acknowledge, that, in this operation, immense advantage does proceed from the oblique division of the muscles, the honour of bringing which method into practice, Mr. Alanson still unquestionably merits, however he may have erred in recommending the conical wound to be made with one sweep of the knife. Nor are there many living surgeons, who entertain a doubt of the excellence of the

principle, inculcated by M. Louis, respecting the utility of dividing the loose superficial muscles first, and then such as are deeper and adherent to the bone. In fact, a combination of this last method, with the oblique division of the muscles, not exactly by one, but several strokes of the knife, constitutes the mode of amputating at present most extensively adopted, and sometimes termed, as already mentioned, amputation by a triple incision. Thus, after the skin is cut, and as much of it retracted and saved as is deemed necessary, the operator next cuts through the loose muscles of the thigh, at the edge of the retracted skin, first those on the forepart of the limb, and then such as are situated behind. For this purpose, he makes two, or more sweeps of the knife as may be found necessary, carefully directing them obliquely upwards toward the point, where he means to saw the bone. The oblique division of the muscles does not merely enable the operator to saw the bone higher up than he could otherwise do, and leaves at the same time more muscle covering its extremity, but it is a preservation of sound undetached integuments, which assuredly form the most efficient and durable covering for the stump. I say this, without precisely coinciding with Brunninghausen, who trusting entirely to skin for covering his stumps, makes an extensive detachment of it from the muscles, and then cuts straight down to the bone. The loose muscles, actually cut through, now retract considerably, leaving those which are deeper and attached to the bone, in a condition to be cut higher up, than could have been previously done. Lastly, these are also to be divided by the edge of the knife directed obliquely upwards toward the place, where the saw is to be applied. Some operators do more than this, for after cutting down to the bone, they follow the plan of Celsus, and detach the flesh from its whole circumference upwards with a scalpel, to the extent of about another inch, in order to be enabled to saw the bone still higher up. "*Inter sanam vitalemque partem incidenda scalpello, caro usque ad os, reducenda ab eo sana caro, et circa os subsecanda est, ut eâ quoque parte aliquid ossis nudetur.*" This method, I think, deserves commendation, because it may have considerable effect in hindering a protrusion of the bone, if it does not, in conjunction with the foregoing method of operating, and judicious dressings, render this disagreeable event quite impossible. As long as I live, however, I shall never forget a poor soldier, whose thigh had been amputated in Bergen-op-Zoom, and who was brought about ten days after the operation into the military hospital at Oudenbosch under my care. Not the slightest union of any part of the wound had taken place; abscesses had formed under the fascia on every side of the stump; the loose skin was literally a large bag of purulent matter; the muscles were wasted to almost nothing, and their remains retracted,

and shrinking still further away from the extremity of the bone, which protruded at least three inches beyond the soft parts. This unfortunate man had been attacked with chronic tetanus soon after the operation, and, probably, it was to the disturbance of the stump by the effects of that disease, and to the strong and continual tendency of the muscles to retract themselves, induced by this state of the system, the deplorable state of the stump was to be attributed. He lingered nearly a fortnight in the hospital before he died, previously to which event large abscesses, communicating with the hollow of the stump, surrounded the greater part of the pelvis. As I had every reason to believe that the operation had been skilfully done, perhaps when I say that the above mode of amputating will make a protrusion of the bone impossible, it is not exactly correct, as the occurrence may sometimes originate from causes, which are quite independent of the particular way, in which the operation has been executed.

The practice of detaching the bone from the circumjacent flesh to the extent of about an inch, after the other principal incisions are completed, as advised by Celsus and Louis, I have sometimes seen done at St. Bartholomew's Hospital, and have practised myself on other occasions, with the decided advantage of letting the bone be sawn higher up, than could otherwise have been effected. Mr. Guthrie, after the incisions are carried down to the bone, even recommends dissecting back the muscles from it "for the space of two, or three inches, as the size of the limb, or other circumstances may require;" but, I should be reluctant myself to imitate the practice to this extent, though inclined to think most favourably of it within more moderate limits. If we reckon that three inches of the member lie between the first circular cut in the skin and the place, where the knife arrives at the bone, and then take away two or three inches more of the femur, it is clear that, in many examples, we should be getting very high up the limb, and, if a detachment of the muscles from the bone to the extent of two or three inches were thus made, it would at all events be of no service, unless the bone would admit of being sawn at this great distance from the termination of the oblique division of the muscles. However, if this were truly practicable (a point, which I leave for others to discuss) it would certainly be consonant to the excellent general maxim, laid down by J. L. Petit, that in amputation as much of the bone, and as little of the flesh, should be taken away as possible. (See *Traité des Mal. Chir.* T. 3. p. 150.) When this final detachment of the deep muscles from the bone is adopted, particular care, as Roux observes, should be taken always to divide the thick aponeurosis, connecting the triceps to the linea aspera. (*Mem. sur la réunion de la Plaie après l'Amputation*, p. 10.)

With respect to Desault's method of amputating the thigh by a circular incision, already mentioned, he considered turning the knife obliquely upwards quite unnecessary: his plan was to cut through the muscles, layer after layer, with the precaution of retracting the first stratum before he divided the second: the latter was then cut through on a level with the flesh that had been previously divided and retracted; and so on down to the bone. This, says he, is the right way of forming a true hollow cone, of which the integuments, which were drawn up before the muscles were cut, form the base, from which are gradually continued the various layers of muscles, and the highest point of which is the bone itself. Desault owns, that this method is somewhat tedious and painful: but, in his opinion, these disadvantages are more than counterbalanced by the benefits procured for the patient. (*Œuvres Chir. de Desault par Bichat*, T. 2. p. 547.)

Having cut all the muscular fibres on every side, down to the bone, a piece of linen, somewhat broader than the diameter of the wound, should be torn at one end, along its middle part, to the extent of about eight or ten inches. This is called a retractor, and is applied by placing the exposed part of the bone in the slit, and drawing the ends of the linen upward on each side of the stump. In this manner, the retractor will obviously keep every part of the surface of the wound out of the way of the saw. Graefe thinks, that, in amputations of parts, where there is only one bone, the unsplit portion of the linen should always be applied over the anterior muscles, as these ought constantly to be most evenly kept back, so that no projection of them may interfere with the action of the saw. (*Normen für die Ablosung grösserer Gliedm.* p. 105.) This is a preference, however, which may not be of great importance, though I confess, that there appears some reason in what Graefe has stated. That meritorious surgeon, J. L. Petit, whose name I always mention with pleasure, strongly commends the use of the retractor, the ends of which he drew over the anterior muscles: he says, that he has employed this simple and natural means, but, that it did not suit the taste of every body, especially of those who consider all the merit of an operation to consist in the quickness of its performance, or who think it satisfactory reasoning to say, this is not their way. (*Traité des Mal. Chir.* T. 3, p. 152.) I have seen the saw do so much mischief, in consequence of the operator neglecting to use the retractor, that my conscience obliges me to censure such surgeons as neglect to defend the soft parts by this simple contrivance. There are some who have rejected the use of the retractor, because they have seen it get under the teeth of the saw, and obstruct the action of the instrument; but, this very circumstance adduced against the retractor, is, when considered, the strongest one that could possi-

bly be brought forward in its favour, as the surface of the wound itself, and particularly the edges of the skin, would, in all probability, suffer the same fate as the linen, by getting under the teeth of the saw, if no retractor were employed, in attempting to saw the bone high up, as closely as possible to the soft parts. I think no one can urge any, but the most frivolous objections to the use of the retractor; and I know, that many who have been with myself eye-witnesses of the mischief frequently done by the saw in amputations, are deeply impressed with an aversion to the neglect of this bandage. I have often seen the soft parts skilfully divided, and I have, in these same instances, seen the operators, directly afterwards, lose all the praise, which every one was ready to bestow, by their actually sawing through one half of the ends of the muscles together with the bone. Men who have had fortitude not to utter a sigh, nor to let a groan be heard, in the previous sufferings, have now had their involuntary cries extorted from them by unnecessary, unjustifiable torture. But, besides defending the surface of the stump from the teeth of the saw, the retractor will undoubtedly enable the operator to saw the bone higher up, than he could otherwise do.

Another proceeding, which seems fit for reprobation, and which, indeed, Mr. Alanson very properly condemned, is the practice of scraping up the periosteum with the knife, as far as the muscles will allow. Nothing seems more probable, than that this may be the cause of the exfoliations which occasionally happen after amputations. At all events, it is a superfluous, useless measure, as a sharp saw, such as ought to be employed, will never be impeded by so slender a membrane as the periosteum. All that the operator ought to do, is to take care to cut completely down to the bone, all round its circumference. Thus a circular division of the periosteum will be made, and upon this precise situation the saw should be placed. This is the method which was approved of by J. L. Petit. (*Traité des Mal. Chir. T. 3, p. 159.*) It is what I have always done and recommended; yet, it must be confessed, that differences of opinion prevail about the necessity, and modes of dividing the periosteum. Graefe, in common with several others, entertains considerable apprehension of the effects of the periosteum being torn and lacerated by the saw, exfoliations of the bone and abscesses up to the joint being possible consequences of the rude separation and inflammation of this membrane. Hence, he is an advocate for making a circular cut through at the place where the saw is to be applied, and then scraping away all below this point in the direction downwards. (*Normen für die Abl. grosserer Gliedm. p. 165, and 105.*) Perhaps, no very great objection may lie against this mode, which is not uncommonly followed, though I have some doubts of its real utility, as it scarcely seems practicable, in the midst of the ooz-

ing of blood, to hit with the saw the precise line at which the remains of the periosteum terminate; and, in confirmation of the safety of Petit's practice, Mr. Guthrie's experience may be adduced, who says, "I have often sawn through the bone, without previously touching the periosteum, and the stumps have been as soon healed, and with as little inconvenience, as any others." (*On Gun-shot Wounds, p. 88.*) A very modern author, impressed, like many others, with the fear of tearing the periosteum with the saw, differs from them in thinking it best to scrape the periosteum upwards, by which means, he says, that at least half an inch of this membrane, and a proportionate quantity of muscular fibres, may be preserved for covering the end of the bone, inasmuch as the muscular fibres, adherent to the periosteum, will remain connected with it; an advantage, which this author deems very important while the edges of the bone are sharp. In amputation below the knee, he considers the method highly useful, as the sharp edge of the tibia may be not merely covered with skin, but periosteum, and the cellular membrane connected with it. Since his adoption of this practice, he assures us, that he has not for a very long time seen any exfoliation of the tibia, and never any protrusion of the bone of a stump. (*Brunninghausen Erfahr. &c. über die Amp. p. 65. 66. 8vo. Hamb. 1818.*) Such are the sentiments of a gentleman who has published a valuable tract on amputation, as well as some other works of deserved reputation. His opinion is unquestionably the reverse of what is mostly prevalent in England; and I think his practice liable to the objection, that the disadvantages of scraping the bone at all, and denuding it, may exceed the benefit supposed to proceed from afterwards bringing down the detached membrane over its sharp margin, even admitting this to be always practicable.

But, in no part of the operation of amputation do operators in general display more awkwardness, than in sawing the bone, though, if we except directing the saw against the flesh, the faults are here less pernicious in their consequences than the errors already noticed. At the time of sawing the bone, much depends upon the assistant who holds the limb. If he elevate the lower portion of the thigh bone too much, the saw becomes so pinched that it cannot work. On the other hand, if he allow the weight of the leg to operate too much, the thigh bone breaks before it is nearly sawn through, and its extremity is splintered. It is one of the most common remarks of such persons, as are in the habit of frequently seeing amputations, that the part of these operations, which a plain carpenter would do well, foils the skill of a consummate surgeon, and few operators acquit themselves well in the management of the saw. Many of them begin the action of this instrument, by moving it in a direction contrary to the inclination of its teeth.

Many, seemingly through confusion, endeavour to shorten this part of the operation, by making short, very rapid, and most convulsive strokes, with the saw. Almost all operators fall into the error of bearing too heavily on the instrument. That operator will saw best, who makes the first stroke of the saw, by applying its heel to the bone, and drawing the instrument across the part, towards himself, so as to make a slight groove in the bone, which serves very materially to steady the future operations of the instrument; and who makes long, regular sweeps with the saw, rather slowly than quickly, rather lightly than heavily. But, there is often a fault in the construction of the saw itself, which impedes its action, quite independently of any fault on the part of the surgeon. I allude to not having the edge of the instrument a little broader, than its blade. When the saw is well made, the teeth always make plenty of space for the movement of the rest of the instrument. The instrument, as Mr. Guthrie recommends, should cut with both edges, backwards and forwards, which expedites the operation, and (what is of more consequence) helps to prevent splintering when the bone is nearly divided, because the division can be finished by the backward motions, which are the most gentle. (*On Gunshot Wounds*, p. 89.)

Graefe commends the plan of oiling the saw, for the purpose of facilitating its action; (*Normen für die Abl. grösserer Gliedmassen*, p. 65.) and though the method is innocent enough, the best operators in this metropolis do not consider it sufficiently important for adoption.

If the bone should happen to break before the sawing is finished, the sharp pointed, projecting spiculæ, thus occasioned, must be removed by means of a strong, cutting sort of forceps, termed *bone nippers*. The perpendicular division of the bone leaves a sharp edge at the extremity of its circumference: it is not the common practice to take any measures for the removal of such sharpness; yet, Graefe recommends filing it away, (*Op. cit.* p. 66.) and Mr. C. Hutchinson makes it an invariable rule, whether there be any occasion to use the bone nippers or not, "to take off the asperities, and scrape, or endeavour somewhat to round, the sharp cut edge of the bone, with a strong blunt scalpel, in order to prevent the soft parts from being injured when brought over the end of the bone in forming the stump." (*Pract. Obs. in Surgery*, p. 24.) Though I have not followed this practice, or rather the part of it, which relates to cutting off the edge of the bone, nor seen it adopted in London in amputation of the thigh, I know of no objection to it, unless it be on the score of its inutility, and the delay, which it occasions. All projecting points of bone, it is the ordinary custom to remove.

After the removal of the limb, the femoral artery is to be immediately taken hold of with a pair of forceps, and tied with a

firm round small ligature, the best being that kind which is recommended and used by my friend Mr. Lawrence, (See *Ligature*) care being taken to leave the accompanying branches of the anterior crural nerve out of the noose. None of the surrounding flesh ought to be tied, though the ligature should undoubtedly be placed round the artery, just where this vessel emerges from its lateral connexions. Mr. Hey has been accustomed to tie the femoral artery twice, leaving a small space between the ligatures, and this method has been constantly used in the Leeds Infirmary. Some reasons against this plan will be found in the article (*Hæmorrhage*.) The other arteries are usually taken up with a tenaculum. After tying as many vessels as require it, one half of each ligature is to be cut off, near the knot on the surface of the stump. One portion is quite sufficient for withdrawing the ligature when this becomes loose, and the other being only an extraneous body, and productive of irritation and suppuration, should never be allowed to remain.

My friend, Dr. Hennen, in his excellent publication, ascribes the improvement of removing one half of the ligature, to Mr. James Veitch, a naval surgeon, who, in April, 1806, published some valuable precepts relative to the mode of tying the arteries in amputation. (See *Edinb. Med. and Surgical Journal*, Vol. 2. p. 176.) But highly as I approve of the tenor of the anonymous paper here referred to, it is impossible for me to suppose Mr. Veitch could be the first, who suggested such improvement. When I went as an apprentice to St. Bartholomew's hospital, in 1797, no surgeon of that hospital ever followed any other mode, and the practice was then so far from being new there, that gentlemen, who were at the hospital seven years before myself, saw one half of each ligature regularly cut off the first time they went into the operating theatre of that munificent institution. The use of very broad ligatures, and the inclusion of a considerable quantity of flesh in the noose together with the vessel, were also practices quite exploded at St. Bartholomew's at the very beginning of my apprenticeship. Mr. Veitch, however, seems to merit the honour of having been perhaps the first to set the example of *tying every vessel, the femoral, as well as the smaller arteries, with a single silk thread*, taking care to include, as far as possible, nothing but the artery; and when this had been done, he took off one half of each ligature, as near as possible to the knot, "so that the foreign matter introduced was a mere trifle, compared with what I had been accustomed to see." (*Edinb. Med. and Surg. Journ.* Vol. 2. p. 178.) The use of a *single silk thread* was then the part of these improvements, probably originating with Mr. Veitch, though the principles which led to this innovation, were unquestionably first established by Dr. Jones.

Mr. Alanson directs the ends of the ligatures to be left hanging out at the two ex-

tremities of the wound, according as their nearness may point out as best. But when a ligature is situated in the centre of the wound, it is best to bring it out between the strips of adhesive plaster, at the nearest part of the surface; otherwise its running across one half the wound to get at either angle, would create a great deal of unnecessary irritation and suppuration. The advantages of this method of placing the ends of the ligatures were well explained by Mr. Veitch, but, his practice, like the innovation of cutting off the half of each ligature, as been common in the London hospitals, and at St. Bartholomew's in particular, many years earlier. I presume, than the case referred to by this gentleman, since it has been familiarly adopted in those institutions ever since 1797, as I can testify from my own personal observation. These remarks are offered, without the slightest intention of detracting from the merits of the above-mentioned paper, which is replete with valuable advice; nor am I influenced by any design of throwing honour on the memory or character of any other individual at the expense of Mr. Veitch, being at this time unacquainted with the exact periods, when either this improvement, or that of removing the half of each ligature commenced. M. Roux is one of the few remaining modern surgeons, who declare their preference to the method of bringing out all the ligatures at the lower angle of the wound, the benefit of having them brought out thus down, so as to keep up a drain for any pus that may form, being in his opinion greater, than that of arranging them at the points of the wound nearest to them. *Mém. sur la Reunion de la Plaie après l'Amp. p. 12.*)

As Dr. Hennen observes, the reducing the immoderate size of ligatures; the separating the threads of which they were composed, and placing them at convenient points along the face of the stump, or wound; and the actual removal of one half of each ligature, were amendments very slowly made; but, (says he,) "an improvement, which appears to me of great consequence, was the last of introduction, and is now the slowest of adoption, although the artery once secured, and the value of adhesion duly acknowledged, it is the most obvious of all. I allude to the plan of removing the ends of the ligature altogether, and thus leaving to an extensive wound the greatest possible chance of immediate union." The first printed mention of this practice, as far as Dr. Hennen's investigations have discovered, was in a letter written by Mr. Haire, dated Southminster, Essex, Nov. 1786. "The ligatures," says this gentleman, "sometimes became troublesome and retarded the cure. An intimate friend of mine, a surgeon of great abilities, proposed to cut the ends of them off close to the knot, and thus leave them to themselves. By following this plan, we have seen stumps healed in the course of ten days. The short ligature thus left in, commonly made its

way out by a small opening in a short time, without any trouble, or the patient being sensible of pain." (See *Lond. Med. Journ. Vol. 7.*) Certainly, considering the thickness of the ligatures in use at the above period, this testimony of the success of the method, as Dr. Hennen remarks, is very satisfactory. (*Principles of Military Surgery, p. 181, Ed. 2.*) In a letter received by me from Mr. Dunn, surgeon at Scarborough, and dated June 3, 1819, he tells me, "My predecessor Mr. J. Wilson, the late partner of Mr. Travis, amputated a limb in 1792, or 93, and cut off the ligatures close to the arteries, and no trouble ensued. He did this from the recommendation of Dr. Balcombe, of York, who had seen the method practised on the continent." In September, 1813, Dr. Hennen, who was serving with the army in Spain, began the adoption of this plan, which, he expected, would not only prove useful in promoting immediate union, but in obviating any accidental violence to the ligatures, and the wrong interference of the younger dressers in trying to pull them away. Between September and January, thirty-four cases were treated in this way, without any inconvenience following, or the small particles of silk left behind giving rise to any apparent irritation. Dr. Hennen also presented to Sir J. M'Grigor, some of the small circles of silk, a part of which had come away with the dressings, while others had floated out on opening the little pustules, which formed over the face of the stump at the points, where the arteries had been tied. Some few of the ligatures never made their appearance, and the patients complained of no uneasiness whatever. Convinced of the utility of the method, Dr. Hennen, afterwards published an account of it. (See *Lond. Med. Repository, Vol. 3. p. 177. and Vol. 5. p. 221.*) This gentleman subsequently found that Dr. Maxwell of Dumfries had adopted the plan as far back as 1798; and Dr. Ferguson, who was at Stockholm during the peace of Amiens, saw it also then followed by some of the surgeons of that city, without any ill effects. (*Hennen's Military Surgery, p. 175,—178, Ed. 2.*) In July, 1814, Mr. Lawrence communicated to the Medical and Chirurgical Society of London, some cases and observations highly in favour of the practice; and the particularity, which he laid much stress upon, is using for the purpose minute firm ligatures composed of what is called dentist's silk. (See *Med. Chir. Trans. Vol. 6. p. 156.*) And, in a paper of later date, he says, his further experience had confirmed the usefulness of the method, "that this plan, by diminishing irritation and inflammation, and simplifying the process of dressing, very materially promotes the comfort of the patient, and the convenience of the surgeon, while it has not produced ill consequences, or any unpleasant effect, in the cases which have come under his own observation." According to Mr. Lawrence, the small knots of silk generally separate early, and come away with the dis-

charge; that where the integuments have united by the first intention, the ligatures often come out rather later, with very trifling suppuration, and that, in some instances, they remain quietly in the part. (*Obs. cit. Vol. 8, p. 490.*)

After the battle of Waterloo, it was tried in many cases both by Mr. Collier, and myself, though our ligatures were certainly not so minute and eligible as those employed by my friend Mr. Lawrence. As I joined the army in the field after nine days, and was therefore obliged to leave my patients at Brussels to the care of others, I lost the opportunity of witnessing the effects of this method. But, from Mr. Collier, I afterwards learned, that the new plan and the common one appeared in his judgment to answer about equally well; which report, considering that we did not use the smallest ligatures, must be regarded as favourable. When the plan is tried, single strong threads and silks, or rather the kind of ligature, which will be described in another place, (*See Ligature,*) should be employed; for, otherwise the knots would be large, and likely to create suppuration and future trouble. The practice has likewise been tried by M. Delpech at Montpellier; but, it is not explained, whether he used single threads, or silks, or whether any inconveniences resulted from the method. (*See Relation d'un Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise by P. J. Roux, 8vo. 1815.*) Yet candour requires me to state, that the method is not universally adopted, and that one well informed writer, as I shall hereafter notice, (*See Hemorrhage,*) has recited a case and some experiments, which are unfavourable to the practice. (*Cross, in Lond. Med. Repository, Vol. 7, p. 355.*) Mr. Guthrie has also in two or three instances seen some ill looking abscesses arise from the presence of the bits of ligature, though he approves of the plan where the wound will not unite by the first intention, which, however, can rarely be known beforehand. (*On Gun-shot Wounds, p. 941.*)

My friend, Mr. Downing, deputy inspector of military hospitals, formerly saw this practice tried; but he informs me, it did not answer, as repeated suppurations and discharges of bits of ligatures followed from time to time, after the patients conceived themselves cured. But, probably, the large thick ligatures in common use some years ago, were here employed, and if this were the case, the experiments cannot be compared to that made with a minute ligature of dentist's silk.

Sometimes, the sawn surface of the bone itself bleeds rather profusely. When this happens, it is an excellent plan, which I have often seen my late master, Mr. Ramsden, and others, adopt with the greatest success, to hold a compress of lint over the end of the bone, during the time requisite for securing the rest of the vessels. At the end of this period, the compress may gene-

rally be taken away, the bleeding from the bone having entirely ceased. As Monro remarks, the surgeon ought not to content himself with tying only such vessels, as he observes throwing out blood, while the patient is faint with pain: he should endeavour to rouse him from that faintish state by a cordial; and then wiping off the coagulated blood with a sponge, wet in warm water, he should examine narrowly all the surface of the stump; for, otherwise, he may expect to be obliged by a fresh hemorrhage to undo all the dressings. (*On Amputation of the Larger Extremities, p. 475, Monro's Works.*)

When there is merely an oozing from small vessels, Bromfield's advice to loosen the tourniquet completely, is highly proper, as this measure, and washing the stump with a little cold water, will put an entire stop to such bleeding, without any occasion for more ligatures. A good deal of blood is sometimes lost from the mouths of the larger veins, and where they bleed much in debilitated subjects, I think Dr. Hennen is right in recommending them to be tied. (*On Military Surgery, p. 264.*) There is no necessity for doing so, however, in ordinary cases; nor should I be disposed to imitate Mr. Hey, who, in consequence of having seen a few instances of bleeding from the femoral vein, generally enclosed that vessel in the ligature along with the artery. (*Practical Obs. in Surgery, p. 530. Ed. 2.*) This method, however, was sanctioned by Desault, who says, that if the vein be left open, and the bandage at the upper part of the limb be too tight, the flood regurgitates downwards, and hemorrhage takes place, as this surgeon assures us, he has often seen. When the vein and artery lie close together, as often happens, one branch of the forceps is to be introduced into the artery, and the other into the vein, which being done, the two vessels are to be drawn out together, and included in one ligature, but, if they are not so near together, they must be tied separately. (*Euvres Chir. de Desault par Bichat, T. 2, p. 550. 8vo. Paris, 1801.*) At St. Bartholomew's, it is not the usual practice to tie the femoral vein, though it has been occasionally done; and, except in particular cases, I consider the custom wrong, because a ligature on a large vein sometimes excites a dangerous and fatal inflammation within the vessel, while the intervention of the vein between the one side of the circle of the ligature and the artery, must rather tend to hinder the thread from operating in the most desirable manner upon the latter vessel.

The wound is now to be evenly closed with strips of sticking plaster, so that the edges of the cut skin may form only a straight line across the face of the stump. This was the mode commended by Alanson, and is what is preferred by the generality of the best surgeons in this country. It is also advised by Graefe. (*Normen für die Abl. grösserer Gliedm. p. 106. Guthrie on Gunshot Wounds, p. 208.*) Over these

plasters, and the ends of the ligatures, it is best to place some pieces of lint, spread with the unguentum spermatis ceti, in order to keep such lint from sticking, which becomes an exceedingly troublesome circumstance, when the dressings are to be removed. I am decidedly averse to the general plan of loading the stump with a large mass of plasters, pledgets, compresses, flannels, &c.; and I see no reason, why the strips of adhesive plaster, and a pledget of simple ointment, should not suffice, when supported by two cross bandages, and a common linen roller, applied spirally round the limb, from above downward. The first turn of the roller, indeed, should be fixed round the pelvis, while the lower circles secure the cross bandages, often called the Malta-cross, over the end of the stump. It is also an excellent method to leave some little interspaces between the plasters, and in summer to keep the linen bandages constantly wet with cold water. In this way any discharge will readily escape, and the parts, being kept cool, will be less disposed to hemorrhage and inflammation.

I am completely of opinion with Mr. Alanson, that the elastic woollen cap, commonly placed over all the bandages and dressings, if not put on with a great deal of care, has a tendency to push the skin backward from the extremities of the stump, and as it must also heat the part, its employment ought apparently to be discontinued.

If possible, the dressings should never be removed before the fourth day, not reckoning the one on which the amputation is performed. Monro set down the fifth, sixth, or seventh day, as generally soon enough for this purpose. He allows, however, that, if the smell of the wound should become offensive, the outer dressings may be removed sooner. Even when the dressings are to be taken away, it will frequently be found useful not to remove one strip of plaster; but the stump must be made clean, and any discharge washed away. These and other valuable precepts, derived from the eminent Dr. A. Monro senior, are worthy their great source, and the correctness of them promises to be acknowledged for ever.

The manner of renewing the dressings of stumps, is indeed a very important business, which should never be intrusted to mere novices; for in taking off the straps of sticking plaster, if great care be not taken, the slight and newly formed adhesions may be torn asunder. Thus, as Mr. A. C. Hutchinson has remarked, if the strap be pulled off by holding one end of it at nearly a right angle with the adhering part, the flap will be raised up with it, and thus a separation of the newly united parts will be produced. "My plan (says he) is to reflect the raised end of the strap close down upon the adhering part, and to bring it gently forward with one hand, while the removing part of the strap is followed by two fingers of the other placed upon the skin, &c.; and when one end is detached from its ad-

hesion, as far as the line of incision on the face of the stump, in like manner the other end is brought down and wholly removed." (*Pract. Obs.* p. 46.)

In order to facilitate the removal of the plasters, and save the patient a great deal of pain, I have always followed the plan of letting warmish water drop over them from a sponge for a few minutes previously to the attempt to remove them. In the early part of the treatment, it is also a valuable rule never to have every strap of plaster off at once, so as to leave the flesh quite unsupported. Some skill and care are also invariably necessary, in order to avoid pulling away the ligatures at the same time with the other dressings.

At the end of five or six days, the surgeon may begin to try, in a very gentle manner, whether any of the ligatures are loose; observing rather to twist, than suddenly pull them directly outward. However, he should not use the smallest force, nor persist if the trial create pain. One would hardly try, whether the ligature on the main artery were loose, before the eighth or ninth day. If minute ligatures made of dentists silk be employed, and both their ends cut off close to the knot, of course, this delicate business of trying to get rid of the irritation of those foreign bodies is entirely superseded.

Though, in the above account, I have directed the edges of the wound, after the amputation of the thigh, to be brought together in such a way, that the wound shall appear as a line across the face of the stump, yet there are instances in which the bone seems most easily and conveniently covered, by making the line of the wound in a perpendicular direction.

Mr. B. Bell, indeed, generally approved of it, as affording a ready outlet for matter; it is likewise directed by Mr. C. Bell, (*Op. Surgery, Vol. 1.*) by Roux (*Mém. sur la Réunion immédiate de la Plaie après l'Amput.* p. 11;) and by Dr. Hennen (*On Military Surgery, p. 165. Ed. 2.*)

On the other hand, Mr. C. Hutchinson objects to it, because it seems to him, that when a stump, thus put up, is laid on a pillow, the pressure tends to separate and open the lower part of the wound. (*Pract. Obs. on Surgery, p. 37.*)

It is curious to remark, however, that the thing which leads this gentleman to disapprove of the plan, is one which would be urged in its favour by Roux, and some other surgeons, who actually take the precaution of never closing the lower angle of the wound, in order that whatever discharge occurs may find a ready outlet. (*Mém. cit. p. 14.*)

Mr. Alanson objected to this method, asserting that the cicatrix afterwards became situated immediately over the end of the bone, the pressure of which was very likely to make the part ulcerate. However, in St. Bartholomew's Hospital, a thigh was sometime ago amputated by Sir L. Harvey, and the edges of the stump were brought

together in the perpendicular direction; yet, according to all accounts, a better stump could not have been made. In a case, in which I assisted Mr. Ramsden at Christ's Hospital, when an attempt was made to put up the wound in the common manner, the bone seemed to make considerable pressure against the skin, which did not happen when the line of the wound was made in the other direction, which of course was immediately adopted. Mr. Hey has noticed this subject as follows: the integuments and muscles may be brought into contact by pressing either the anterior and posterior parts, or the sides of the thigh, together. The former method, by the gradual retraction of the posterior muscles, causes the integuments of the anterior part of the stump to cover more completely the extremity of the bone. The latter method causes the integuments and muscles to meet each other the more readily, and, therefore, is to be preferred when the quantity of soft parts preserved is somewhat deficient. (*Practical Observations on Surgery*, p. 533. Edit. 2.)

From the observations of another modern writer, who disapproves of making the line of the stump perpendicular, the difficulty of covering the end of the bone sometimes arises from not duly relaxing the posterior muscles of the thigh, and therefore he condemns laying the stump on pillows, which are too high. (*A. C. Hutchinson Pract. Obs.* p. 41.)

The plan of bringing the edges of the wound together, after amputation, so that they may unite by the first intention, has received, for many years past, the universal approbation of British surgeons. It is the general practice in the treatment of all incised wounds. It may be said to be the pride of English surgery; for, in nothing does she display more convincingly her superiority. Baron Larrey, however, in cases of amputation, disapproves of the attempt to unite the wound by the first intention, and merely brings forwards its edges somewhat towards each other with a piece of linen, which covers the whole of the wound, and has small holes cut in it for the passage of the discharge. (*Mém. de Chir. Mil.* T. 3, p. 379.) This piece of linen is supported with a moderately tight roller.

M. Roux, on his arrival in this country, wondered to see British surgeons so prejudiced in favour of union by the first intention, as to adopt it after all amputations. "*C'est pareillement abuser de la réunion immédiate que d'appliquer en toute circonstance à la plaie qui résulte de l'amputation des membres. J'entends parler de l'amputation dans la continuité des membres et plus particulièrement encore de l'amputation circulaire.*" (P. 128. *Parallèle de la Chirurgie Anglaise avec la Chirurgie Française*, 8vo. Paris, 1815.) M. Roux, however, has curiously omitted to explain in his book, what are the advantages of not bringing the edges of the wound together, and why he calls prejudice the partiality to a method, the superior efficacy of which is continually de-

monstrated in every hospital of London. He does not indeed presume to condemn the practice altogether; on the contrary, he allows it to be proper in certain cases; yet he contends that it ought to be confined within particular limits. (P. 130. See, also, *Mem. et Obs. sur la Réunion immédiate de la Plaie après l'Amputation*, &c. 8vo. Paris, 1814.)

In this tract, which is well drawn up, Roux proves most convincingly the benefits of union by the first intention, after amputation of the thigh by the circular incision; but, strangely enough, his prejudices hinder him from advising the practice to be extended to other amputations. He does not positively condemn it in the arm, though he thinks the method less necessary, because amputation there is less dangerous than in the thigh, &c. (P. 45.) To such futile reasoning is this author reduced by the unsoundness of his doctrine. He also deems the attempt at union by the first intention counterindicated, where limbs are amputated for injuries, which violently contuse and crush the parts (P. 48,) and where the limb is much wasted. (P. 50.) In the latter condition, however, he thinks Desault's flap amputation may be done, and an effort made to heal the wound by adhesion. In one case, he did this with success. (P. 51.)

Richerand informs us, that Dubois at Paris follows the plan with a success equal to that of the London surgeons. For some years past, he has himself also constantly endeavoured to accomplish union by the first intention, after all the amputations which he has had occasion to practise, and he succeeds at least in three out of four. "The method is preferable (says he) to the old one, in whatever point of view it is considered. This union is more expeditious, a few days being sufficient for its completion. A woman, whose thigh I took off in 1810, was very well in a week, &c. Besides the advantage of a quick cure, and such quickness is especially of great importance, where the patient has been much reduced, so that he would hardly be able to bear a long suppuration, union by the first intention has the recommendation of saving the patient from a great deal of pain, the flap of integuments, with which the bleeding surface of the stump is covered, being much less irritating to the flesh, than the softest charpie would be, &c. Three years have elapsed since the publication of the third edition of this book. During this interval, I have performed more than a hundred and fifty amputations, and the utility of immediate union has been more and more proved to me." (*Nosographie Chirurg.* p. 475, 477. Edit. 4.)

But, notwithstanding these and other encomiums on the practice, Richerand, like other French surgeons, is not an advocate for it in certain cases, as, for instance, limbs shattered by gunshot wounds, or affected with hospital gangrene. Here, he maintains, that it hardly ever succeeds. (P. 478.) But, though it be true that ampu-

tations after gunshot-wounds do not generally heal so well, as many other cases, it cannot be denied that they do sometimes unite more or less by the first intention, and why should not the chance be taken? It is productive of no danger; there is nothing better to be tried; and, if it fail, what is the harm? Why, the wound will then heal by suppuration, and the granulating process, just as soon, as if the hollow of the stump had been filled with charpie, or left open; it will in fact heal in a way, which is less advantageous, than union by the first intention, but which is the best which can now happen.

From what has been said, it appears, that the practice of healing the wound by the first intention after amputation is less general in France, than it is in England; a circumstance which may perhaps be explained by the fact of its being much newer to the French than to us. Every improvement must encounter for a time the opposition of prejudice; but, one so important as that which we are considering, must at length prevail, and meet with universal adoption. Our extraordinary partiality to union by the first intention arises from a conviction of its superior efficacy, and is a decisive proof of the goodness of English surgery in respect to wounds. The observations of Roux and Richerand tend to prove, that they are not altogether unaware of its advantages, and they therefore recommend it for certain cases; but, their backwardness to extend it to all amputations, without exception, is little in favour of the parallel, which they are so fond of advancing between French and English surgery.

However, that stumps may fall into a state, in which the pressure of all plasters and bandages whatever should be most carefully avoided, and emollient poultices used, is a truth of which every surgeon of experience must be fully convinced. This happens whenever the parts are affected with considerable tension, inflammation, and swelling, or painful acute abscesses. There is also no utility in keeping the edges of the wound very closely compressed together, when all chance of adhesion is past, and the parts must heal by the granulating process. My friend, Mr. Guthrie, after amputations, performed from necessity in parts not in a healthy state, as in most secondary amputations after compound fractures of the thigh, does not insist upon the edges of the wound being brought into close contact by sticking plaster, compress, and bandage. In these cases, he also recommends the bone to be sawn an inch shorter than usual, or than would be necessary under other circumstances, in order to prevent its protrusion, and the ligatures to be cut off close to the knots, so as to lessen irritation. The integuments and muscles are to be brought forward, and retained so by a moderately tight roller, but not laid down against the bone. Some fine lint, smeared with cerate or oil, is to be put between the edges of the wound; and a piece of linen and a Malta-cross over it, supported by a few light

turns of the roller. "In some cases (says Mr. Guthrie,) I have put one, and even two straps of plaster over the stump to keep the edges approximated, without being in contact; and, where the parts are but little diseased, this may be attempted; but, if the stump becomes uneasy, they should be cut, and a poultice applied. When only a part of the stump has appeared to slough, I have found the spiritus camphoræ alone, or diluted with a watery solution of opium, applied with the lint, very useful." (*On Gunshot Wounds*, p. 104.)

The reasons, which induced Mr. Guthrie to incline to the plan of not bringing together the edges of the wound, in cases of this description, must be learned by reference to his own valuable work. His cases and arguments are entitled to serious consideration; and though they, as well as the observations of Roux, (*Mém. sur la Réunion immédiate de la Plaie après l'Amputation*, 8vo. Paris, 1814,) leave me unconvinced of the usefulness of not bringing the edges of the wound together, immediately after the amputation of bad compound fractures, there are some of his observations respecting the injurious effects of too much pressure in certain conditions of the stump, perfectly agreeing with my own sentiments. At present, I have never seen any case of amputation, in which I should not have thought the surgeon wrong, had he not brought the sides of the wound together directly after the operation, so as to afford the chance of union by the first intention.

HEMORRHAGE AFTER AMPUTATION.

Bleeding, after the operation, is of two kinds, in regard to the time, when it occurs. The first takes place within twenty-four hours after the operation. Hence, an assistant should always be left with the patient, with directions carefully and repeatedly to look at the stump, and if any bleeding should arise, to apply the tourniquet, until further aid be obtained. In case no assistance can be spared for this purpose, as must frequently happen in country practice, the tourniquet should always be left slackly round the limb, and the nurse, or patient, himself, directed to turn the screw of the instrument, in order to tighten it in case of need. A slack tourniquet left round the limb, after amputation, cannot do harm, and its not having been ready in this way, has cost many patients their lives, as I have known instances of.

This kind of hemorrhage has often been known to arise from the pressure of a tight bandage round the stump. As Monro observes, the circular turns of the bandage, when tight, must stop the return of blood in the cutaneous veins, and thus by making a greater resistance to the blood in the arteries, which anastomose with them, occasion the contracting power of the heart and arteries to dilate, and force more blood into their other branches; but, these being cut in the amputation, will pour out their blood, and so hemorrhage is brought on. Making

much pressure round the stump is highly deserving of reprobation; and whenever there is an universal oozing of blood, I would recommend the operator to be sure, that the circulation in the superficial veins is not impeded by the tightness of any bandage or tourniquet.

If the bleeding should not be from an artery of consequence, the application of linen, dipped in the cold water, will sometimes check it, and the disagreeable necessity for removing the dressings and opening the wound, may thus be avoided.

But, it often happens, that the wound must be opened, and the bleeding vessel tied. This is a very painful proceeding to the patient, and when the dressings have been applied some hours, so that the stump has had time to inflame, nothing can exceed the suffering to which the patient is now subjected. Here we see the prudence of being particularly careful at first to tie every suspicious vessel.

The second sort of hemorrhage, after amputation, arises from ulceration of the large arteries, and may occur a month after the operation, when the ligatures are all away, and the patient seems nearly well.

Two such cases are related by Mr. Bromfield (Vol. I. p. 307.) This kind of bleeding is less common than formerly, now the plan of covering the stump with sound skin is adopted. When the bleeding vessel is large, there is no chance of putting the patient out of danger, except by cutting down to the vessel, and tying it. The trunk of the vessel, however, may sometimes be more conveniently tied, than the bleeding branch itself.

Mr. Hey makes mention of a particular sort of hemorrhage, after the operation: "I have seen (says he,) a few instances of the integuments becoming so contracted after the operation, as to compress the veins just above the extremity of the stump, and bring on after some hours a copious hemorrhage. When it has appeared clear to me, that the hemorrhage was venous, I have made a division of the integuments, on one side of the thigh, sufficient to remove the stricture, and this method has immediately suppressed the hemorrhage." (P. 530. Edit. 2.)

I have never yet met with a case, in which a hemorrhage was unequivocally produced by a contraction of the integuments. Dr. Hennen says, that he has seen only one example, and it was successfully treated by loosening the bandage, and moistening the dressings with cold water. (*On Military Surgery*, p. 264. Ed. 2.) Doubts may therefore be entertained, whether the cause was the pressure of the integuments, or of the roller, on the veins.

In Mr. Guthrie's truly practical work, there are some excellent remarks on the hemorrhages, which, in the irritable and sloughing state of a stump, frequently take place from the small branches, or from the main trunks of the arteries, in consequence of ulceration. It is (says he) not always

easy to discover the bleeding vessel, or when discovered, to secure it on the face of the stump; for, as the ulcerative process has not ceased, and the end of the artery, which is to be secured, is not sound, no healthy action takes place. The ligature very soon cuts its way through, or is thrown off, and the hemorrhage returns; or, some other branch is opened, and another ligature is required, which is equally uncertain; and under this succession of ligatures and hemorrhages, the patient dies. Here, cutting down to the principal artery, in preference to another amputation, has often succeeded; but, under certain circumstances, it fails, and amputation becomes ultimately necessary. At the same time, it is allowed, that this operation may also fail. On the whole, Mr. Guthrie professes himself to be an advocate in most cases for tying the artery in the first instance; and if this proceeding should not answer, he would then amputate. However, the practice of taking up the artery in these cases, he thinks, should not be adopted indiscriminately, the doctrines of aneurism not being here applicable, because there is a wounded vessel, with an external opening. "In the thigh, the operation is less certain, than in the arm, and especially, if it is not the main artery that bleeds; for, the branch, from which the hemorrhage proceeds may come from the profunda, and tying the artery in the groin on such opinion would be doing a serious operation, and one, which probably would not succeed; for, the anastomosing branches would restore the circulation in the stump in a short time, and again establish the bleeding. If it is the femoral artery that bleeds, and the ligature is applied high, it is very liable to a return of hemorrhage. To obviate these difficulties, the part, from which the bleeding comes should be well studied, and the shortest distance from the stump carefully noted, at which compression on the artery commands the bleeding; and, at this spot, the ligature should be applied, provided it is not within the sphere of the inflammation of the stump." (*On Gun-shot Wounds*, p. 105-106.) Thus far the advice seems to me correct and valuable; but, where the hemorrhage could be restrained by taking up the artery in the groin, though not lower down, I doubt the propriety of preferring amputation to this other far less severe operation, admitting that the efficiency of a ligature above the profunda, has been proved in the manner judiciously recommended by Mr. Guthrie, viz. by means of pressure.

The following is the council offered by Mr. Hey in a case of this nature.

"When we are under the necessity of amputating a limb, that has suffered great contusion, though the operation is performed upon a part apparently sound, the wound sometimes becomes sloughy and ill conditioned. No good granulations arise to cover the extremities of the arteries; but the ligatures cut through these vessels, or becoming loose, cease to make a sufficient pressure

upon them, and hence repeated hemorrhages ensue. This is a dangerous state for a patient; for, if the vessels are taken up afresh with the needle, the hemorrhage will now and then return in the course of two, or three days. In such cases, the application of dry sponge, cut transversely, as directed by Mr. White (*Cases in Surgery*), has been found singularly useful, and has saved the life of the patient. But, a constant pressure must be kept upon the pieces of sponge, by the fingers of a succession of assistants, till granulations begin to arise upon the stump, and the prospect of future hemorrhage disappears. This method is of the greatest importance after amputation on the thigh, or leg, where the great vessels are deeply seated. In the arm, above the elbow, where the vessels are more superficial, the great artery may be taken up, with a portion of muscular flesh, above the surface of the stump, by making first an incision through the integuments. My colleague, Mr. Logan, has done this twice within the last year, with complete success, when repeated ligatures, applied in the usual way, had failed.

"In the morbid sloughy state of the stump, above-mentioned, the application of lint, soaked in a liquid, composed of equal quantities of lemon-juice and rectified spirit of wine, has been found very advantageous, and has caused it to put on soon a healthy aspect." (*P. 536, 537, edit. 2.*)

ON PROTRUSION OF THE BONE.

It is clearly proved by the observations of M. Louis, that this disagreeable consequence may be generally prevented by taking care to divide the loose muscles first, and (after their complete retraction, which will be favoured by no band, nor tourniquet being applied round the limb,) by observing to divide with a bistoury the muscles which are adherent to the bone; for instance, the crural muscle, and the point of adhesion of the vasti and triceps at the posterior spine of the femur. By this method, the bone may be very easily sawn three finger-breadths higher than it can be, if no attention be paid to beginning with the division of the loose muscles, and concluding with that of such as are more attached to the bone.

The protrusion of the bones will never take place, so long as they are immediately encompassed with the fleshy substance of the muscles: this proposition is incontestable. The state of the skin, whether longer or shorter, conduces nothing to this protrusion; nor will the inconvenience be prevented by drawing the skin upward, and preserving as much of it as possible. (*See Mém. sur la Saillie de l'Os après l'amputation in Mém. de l'Acad. de Chirurgie, tom. 5. p. 273, edit. in 12mo.*)

As Mr. Guthrie has correctly observed, a protrusion of the bone, after sloughing of the stump, or other accidental circumstances, will sometimes happen, without any

fault on the part of the operator; but, he thinks, it may almost always be prevented by attention to the following rules: 1. To leave the integuments attached to the muscles, instead of turning them back. 2. When the muscles are cut through in a slanting direction, upwards and inwards, or even directly downwards, to separate them from the bone, so that it may appear at the bottom of the cone as a depressed point; 3. To cut the bone short, and to keep the thigh constantly bandaged from the trunk during the cure, so as to prevent the retraction of the muscles. If, says Mr. Guthrie, a surgeon find directly after the operation, that the bone cannot be well covered, he should immediately saw off as much more of it, as will reduce it to its proper length. The error may be remedied at this moment with very little inconvenience in comparison with what must afterwards be encountered, if the opportunity be neglected. (*On Gun-shot Wounds, p. 109.*) For some very useful directions how to bandage and support the soft parts with adhesive plasters, with the view of counteracting the tendency of the bone to protrude, I refer to some observations by Mr. Wright. (*See Bromfield's Chir. Cases, &c. Vol. 1, p. 177.*)

Having explained, that the surest way of preventing the evil is to save a sufficiency of muscle, especially of that muscular substance which is naturally most near and adherent to the bone, we shall next speak of the mode of relief.

When the end of the thigh-bone protrudes, it of course hinders cicatrization, and becomes itself affected with necrosis. By the process of exfoliation, the dead portion of bone is sometimes thrown off, and a cure follows. But, in general, this desirable change is extremely tedious, and uncertain as to the result, because it frequently happens, that after the piece of bone has separated, the rest yet projects too much, and the stump still continues too conical to heal firmly enough to be capable of bearing the pressure of a wooden leg. When, however, the end of the bone forms only a slight projection, and the stump is not too conical, it is always best to leave it to nature to throw off the redundant exfoliating portion. In the opposite circumstances, the operation of removing all such part of it as cannot be covered by the integuments, is the best thing which can be attempted, and, if well executed, will effect a cure.

This second operation is exceedingly unpleasant to the surgeon, because patients are apt to suspect, with reason, that the first was not properly managed. Let me therefore repeat, that the surest way of avoiding the evil, is to cut the deep muscles rather higher than the superficial ones, as inculcated by M. Louis, by which means the bone will certainly lie within the level of the surface of the divided flesh. The advice delivered by my friend, Mr. Guthrie, I also consider valuable.

The second performance of amputation is a still more severe and unpleasant opera-

tion; yet, as Dr. Hennen has explained, it sometimes becomes necessary from osteosarcoma, extensive necrosis, abscesses of the medulla, unsuspected fissure, phagedena, or great protrusion of bone, with an extensively diseased periosteum, where the powers of nature are inadequate to the cure. "If the general health is not impaired, and the flesh does not peel off from the bone, as if it were boiled, the efforts of nature may be trusted to, aided by proper bandaging, and, in some cases, by the employment of the saw; but, when restless nights, intense pain, flushings, and irregular bowels, with great tumefaction and hardness of the stump, take place, indicating approaching hectic, and there is evidence of an irregular action of the parts, osseous matter becoming deposited, and forming a distinct tumour around the stump, our best plan will be to operate again near the trunk." (*Principles of Military Surgery*, p. 226, Ed. 2.) The following works are particularly recommended by this gentleman for information on diseases of the bones of stumps: *Bonn, Thesaurus Ossium Morborum*, Amst. 1788; *Weidmann de Necrosi Ossium*, Francof. 1798; *Macdonald, De Necrosi ac Callo*, Edinb. 1799; the abovementioned *Essays of M. Louis*; *Léveillé sur les Mal. des Os après l'Amputation*, *Mém. de la Société d'Emulation*, T. 1. p. 148; *Von Hoorn De iis, quæ in partibus membri, præsertim osseis amputatione vulneratis, notanda sunt*; Lugd. 1803. *Roux, de la resection des Os Malades*, Paris 1812; and *Mém. de Physiologie, &c. par Scarpa et Léveillé*, Paris, 1804.

SPASMS OF THE STUMP.

Spasmodic contractions of the muscles of the stump is another very afflicting occurrence. Such spasms put the patient to the greatest agony, tend to cause a protrusion of the bone, or sugar-loaf stump, and, in some cases, increase, affect the whole body, and ultimately occasion death. But, this unfortunate affection, which was rather frequent after amputations performed in the ancient manner, is infinitely less so, after the modern improved plans of operating, tying the vessels, and dressing the wound. When, however, it does occur, the stump must be kept from starting, by fastening it to the pillow and bedding, on which it lies, the flesh is to be properly supported with a bandage, applied from the pelvis downwards, and opium, and camphorated medicines are to be liberally exhibited (*Encyclopédie Méthodique, Partie Chirurgicale*, Tom. 1. p. 93. *Latta's Surgery*, Vol. III. &c.)

FLAP-AMPUTATION OF THE THIGH.

Although I concur with the majority of surgeons in regarding the operation by a circular incision the most eligible under ordinary circumstances, no doubt can exist about the preference, which should be given to amputating with a flap, in particular examples. This method, I believe, has the important advantage of being least exposed

to the danger of a protrusion of the bone, and hence, I think, it may be advisable, whenever any reasons exist in the state of the parts, or the constitution, for apprehending that disagreeable occurrence. An experienced modern military surgeon informs us, that, in the first years of his practice, he performed several amputations by the double incision, strictly according to the precepts of Sabatier, Desault, Pelletan, and Pott, but had the mortification to have three cases, in which the bone protruded, though the greatest circumspection was used in the operation and after-treatment. Hence he was induced to make trial of the flap-amputation, and although he imitates O'Halloran in not attempting to bring the flaps close together for the first eight days, he reports that the stump is generally healed in from twenty to thirty days, and exfoliations rarely happen, on account of the bone being so well covered. In short, he says, that this method is to be preferred to all others. (*J. B. Paroisse Opusc. de Chir.* p. 185-203, Paris 1806.)

A description of Desault's, or rather Vermale's mode of operating, being given in the 4th Ed. of the First Lines of the Practice of Surgery, Vol. 2, I need not here repeat it, nor say, by how many respectable names the practice is sanctioned. Of late, the operation has been done by my friend Mr. Vincent in St. Bartholomew's Hospital, who showed me a few weeks ago a capital stump, which he had made in this manner, and which had healed with great expedition.

By Mr. Guthrie, the flap-operation is considered preferable to the circular incision at the upper part of the thigh, "as it permits the head of the bone to be removed, if found necessary, allows it to be examined and cut shorter with greater ease, and makes a much better covering afterwards." (*On Gunshot Wounds*, p. 200.)

In military surgery, flap-amputation of the thigh is often advantageous, because all the flesh on one side of the limb is frequently torn away, or left in so terribly a mangled state, as to be unfit for making a covering for the end of the bone. Here a flap, sufficient to cover the whole face of the stump, should be saved from the sound flesh on the other side of the limb. When the surgeon chooses the flap-amputation, not from necessity, as under these last circumstances, and the flesh is sound all round the member, the best way is to save a flap on each side of the limb, by making two semi-circular cuts, the convexities of which extend in a parallel manner forwards, and the terminations of which meet at the upper and lower surfaces of the limb. The skin is not to be at all dissected from the muscles, which are to be obliquely divided as high as the base of the flap on each side. However, though this is the best plan, particular cases may require a flap to be made from the anterior, or even the posterior side of the thigh. The latter method should never be followed, but from necessity.

(See Hey's *Pract. Obs. in Surgery*, p. 531, Ed. 2.)

According to Mr. Guthrie, the difference between the flap-operation, at the upper part of the thigh, and that at the hip, consists in its being done lower down, and in the flaps being saved more immediately from the external and internal sides of the thigh, the inner flap being the largest, in order to prevent the inconvenience, which might arise from the external one being tightly stretched over the end of the bone. For the same reason, Mr. Guthrie also recommends the bone to be sawn off close to the lesser trochanter, even when the nature of the injury would allow of its being left an inch longer. (*On Gunshot Wounds*, p. 200.)

Flap-amputation of the thigh, after the manner of Vermeil, is now preferred to the common mode by Klein, one of the best operating surgeons in Germany. Of seven cases, in which he adopted this method, the greater number were healed in ten days, and the rest in three weeks; and this success determined him in future always to practise it. After this mode, he finds there is no danger of the muscles retracting themselves, and leaving the end of the bone protruding, even though the patient be transported from one place to another. With respect to the occasional difficulty of taking up the obliquely cut vessels, Klein admits this objection, but thinks that it equally applies to Alanson's method. He lays great stress on the utility of giving due support to the flaps with compresses and a roller. (*See Practische Ansichten der bedeutendsten chirurgischen Operationen*, p. 35—38, 4to. Stuttgart, 1816.)

In one instance, where a ball had broken the upper third of the femur, and mortification had spread so far towards the great trochanter and buttock, that it was impossible to operate, except by the flap-operation, or by taking the head of the bone out of the joint, Klein made a broad flap six inches long at the inner and upper part of the thigh, and then he cut the soft parts straight across just below the great trochanter, so as to make this wound meet the termination of the incision, by which the inner flap was formed. This patient got perfectly well in three weeks; (*Op. cit.* p. 39.) and so did another very similar case operated upon by the same gentleman. (p. 43. Where the bleeding is considerable, the femoral artery and profunda should be tied previously to sawing the bone; but, if the vessels are well commanded by the pressure, the sawing ought to be first completed.

AMPUTATION BELOW THE KNEE.

In treating of amputation of the thigh, I have remarked, that as much of the limb as possible should be preserved. The longer it is after the operation, the stronger and more useful will it be found. But when the leg is to be amputated, authors have set it down, as almost an invariable rule, that the

operation is to be performed a little way below the knee, even though the disease, for which the limb is removed, may be situated in the foot, or ankle, and would allow the operation to be done much further down. The common practice is to make the incision through the integuments, just low enough to enable the operator to saw the bones, about four inches below the lowest part of the patella. This degree of lowness is usually deemed necessary, in order not to deprive the stump of that power of motion, which arises from the flexor tendons of the leg continuing undivided. It is alleged also, as a reason for this mode of proceeding, that it is quite sufficient to preserve a few inches of the leg, in order to afford the body a proper surface of support, in walking with a wooden leg, whereas if a larger portion were saved, the superfluous part would be a great inconvenience, both in walking, and sitting down, without being of the smallest utility, in any respect whatever. However, as I shall presently notice, experience proves, that, where according to these maxims, an injury, or disease would dictate the performance of amputation above the knee, the practice of amputating below this joint, but much higher than is generally sanctioned, may be followed with advantage.

The tourniquet should be applied to the femoral artery, about two-thirds of the way down the thigh, just before the vessel perforates the tendon of the triceps muscle. This place is much more convenient than the ham, where it is very difficult to compress the vessel against the bone. The patient is to be placed upon a firm table, as in the amputation of the thigh, and the leg being properly held by one assistant, while the integuments are drawn upward by another, the surgeon, with one quick stroke of the knife, is to make a circular incision through the integuments all round the limb. Some recommend the operator to stand on the inside of the leg, in order that he may be able to saw both bones at once. No reflections could ever make me perceive, that any real advantage ought strictly to be imputed to this plan. Many suppose this method diminishes the chance of the fibula being splintered, this bone being completely divided rather sooner than the tibia. But splintering the bones generally arises from the assistant depressing the limb too much, or else not supporting it enough. If the assistant were to be guilty of this mismanagement, it would be difficult to explain, why, the tibia should not be splintered instead of the fibula, when a certain thickness of it had been sawn through. At the same time, it must be admitted, that if the surgeon prefer standing on the inside of the limb, there is no objection to it at the time of using the saw; but, before this period, in amputating the right leg, there is great convenience in having the left hand next to the wound, as is the case, when the surgeon stands on the outside of the right limb. Hence I have seen many hospital surgeons,

in amputating the right leg, cut the soft parts, while they stood on the outside of the limb, and having done this part of the operation, they proceeded to the other side of the member for the purpose of applying the saw. I have only to repeat, that, I do not think any particular reason exists against sawing the two bones together, yet, in such manner, as to let the fibula be divided entirely through first; and, the advantage of fixing this bone against the tibia by the pressure of the hands of the assistants, while the surgeon is sawing it, is another circumstance, which influences a great many writers to commend the latter plan. Graefe, who, as already mentioned, prefers the true flap-operation, does not think it advisable for the surgeon to stand on the inside of the limb in his method of operating, because when the knife is introduced through the muscles of the calf, its point would be apt to go between the two bones. (*Normen für die Abl. grösserer Gliedm.* p. 130.) The following are the precepts, given by him respecting the sawing of the bones. They should, he says, be divided as high as possible; and, during this part of the operation, the fibula is to be firmly pressed by the assistant against the tibia, above and below the wound, so as not to be shaken too much in consequence of the weakness of its upper articular connexion. Graefe then directs the surgeon, as he stands on the outside of the limb, to apply the saw, as high as possible, close to the periosteum, with the handle downwards, and to saw both the bones together, until a groove deep enough for the guidance of the saw is made in each of them. The foot is now to be turned very much inwards, and the fibula completely divided, the handle of the saw being depressed as far as practicable. The foot is then to be inclined outwards, and the tibia cut through, the saw, with its handle elevated, being placed in the furrow already prepared for it. By beginning with making a groove in both bones, we are sure, says Graefe, of sawing them through exactly at the same height. The plan of beginning the division of the bones with the handle of the saw depressed, however, must certainly be inconvenient.

A circular cut having been made through the integuments, about two inches below the place where it is intended to saw the bones, the next object is to preserve skin enough to cover the front of the tibia, and the part of the stump, corresponding to the situation of the tibialis anticus, extensor longus pollicis pedis, and other muscles, between the tibia and fibula, and those covering the latter bone. Throughout this extent, there are no bulky muscles which can be made very serviceable in covering the end of the stump, and consequently the operator must take care to preserve sufficient skin in this situation, by dissecting it from the parts beneath, and turning it up.

On the back part of the leg, on the contrary, the skin should never be uselessly detached to a great extent from the large gastrocnemius muscle, which, with the soleus,

will here form a sufficient mass for covering the stump. However, the experience which I had in the army, taught me the truth of a remark made by Graefe, that, in forming the posterior flap of muscle, it is a matter of the highest importance to let the integuments be somewhat longer than it; for, otherwise, when it is turned forward, as it must be for the purpose of covering the ends of the bones, its front edge will be left uncovered by integuments, which being the outermost describe a greater circumference than the deeper muscular flap. (*Normen für die Abl. grösserer Gliedm.* p. 131.) I was fully convinced of the truth of this observation, by two amputations which were done by myself, one in the neighbourhood of Antwerp, in 1814, and the other at Brussels, the day after the battle of Waterloo. Yet Graefe, who performs the flap-amputation, strictly so called, (that is to say, the operation in which a flap of skin, corresponding in shape to the flap of muscle, is preserved) does not himself detach the skin from the muscles of the calf at all, but, at the time of making the incision in that situation, directs one assistant to pull up the integuments, while another bends the foot as much as possible, which manœuvres have the effect of letting the muscles be cut rather shorter than the skin. Unfortunately, however, in many cases, the very nature of the disease, or injury, for which the operation is performed, would not admit of these proceedings. Nor in a very muscular limb, would they be likely to suffice, as Graefe himself confesses, since, in such cases, he recommends the use of a knife bent laterally, for the purpose of excavating, as it were, as the incision is made, the thick muscular flap. (*Op. cit.* p. 134.) In the common method, with the circular incision, I am disposed to think it best, therefore, to let a small quantity of skin be detached and saved at the back part of the leg, so that there may be a certainty of having enough to cover well the extremity of the divided muscles of the calf. As soon as the skin has been separated in front, and on the outside of the leg, the surgeon is to detach the skin from the calf for about an inch, and having reflected or drawn this preserved portion out of the way, he is to place the edge of the knife close to the edge of the retracted or reflected skin at the back of the limb, and cut obliquely upwards through the muscles of the calf, from the inner edge of the tibia quite across the fibula, supposing the operator to be on the outside of the right leg, and that it is this member, which is undergoing removal. In performing this last incision, as M. Louis well observes, it is essential to incline the edge of the knife obliquely upwards. In this manner the skin will be longer than the muscles, and the cure will be considerably accelerated. (*Mém. de l'Acad. de Chirurgie*, tom. 5. edit. in 12mo.)

In the leg, the necessity of dissecting the skin from the subjacent parts, is acknowledged to be greater than in the thigh; thus,

Mr. Guthrie says, "as the attachment of the skin to the bone will not readily allow of its retraction, it must be dissected back all round, and separated from the fascia, the division of which in the first incision would avail nothing, from its strong attachment to the parts beneath." (*On Gunshot Wounds*, p. 220.) In dissecting the skin, however, a much greater detachment of it should be made at the front and outer part of the limb, than at the opposite points, as already explained.

The flap formed by the integuments, and muscles of the calf, is then to be held back by one of the assistants, while the surgeon completes the division of the rest of the muscles, together with that of the interosseous ligament, by means of the catling, a kind of long, narrow, double-edged knife.

In amputating below the knee, very particular care must be taken to cut every fasciculus of muscular fibres, before using the saw. Every part, except the bones, being divided, the soft parts are next to be protected from the teeth of the saw by a linen retractor, made with two slits to receive the two bones, care being taken to let the unsplit part be applied to the muscles of the calf, as particularly advised by Graefe. (*Op. cit.* p. 136.)

In the leg, there are only three principal arteries, requiring ligatures, viz. the anterior and posterior tibial, and the peroneal or fibular arteries. In addition to these, however, there are sometimes large muscular branches, which require to be taken up. The anterior tibial artery will be found in front of the interosseous membrane, and between the extremities of the bones; the fibular artery behind the fibula; and the posterior tibial, situated more inwardly than the last among the first of the soleus, near the tibia. (*C. Bell, Oper. Surgery*, vol. 1. p. 385.)

When the soft parts have been cut in the preceding way, the bones sawn, and the arteries tied, the wound is to be closed by bringing the flap of skin over the front and external part of the stump, so as to meet the flap composed of the gastrocnemius, soleus, and integuments on the opposite side. This should be done without letting any tight strap of plaster press the skin against the sharp edge of the tibia, a serious and hurtful practice, which has often occasioned ulceration and sloughing of the integuments, and protrusion and necrosis of the bone. It is this danger which leads Mr. Guthrie to prefer closing the wound vertically, or nearly so, and applying the adhesive straps from side to side. (*On Gunshot Wounds*, p. 221.) I think, however, the above mode of operating almost necessarily requires the wound to be closed, so as to form a line, extending in a direction from the tibia to the fibula. But, where a great deal of skin is saved all round the limb, and the muscles of the calf are not chiefly calculated upon for covering the bones, the perpendicular line of the wound will answer very well.

Many surgeons, however, operate differently. They first make the circular incision through the skin, two inches below where they mean to saw the bones. They next detach the skin from the muscles and bones equally all round the limb to the extent of about a couple of inches. The integuments are then turned up, and a division of the muscles made all round down to the bones, on a level with a line where the detachment of the skin has terminated. The parts between the bones are afterwards cut through, &c. The hemorrhage having been stopped, the integuments are drawn down over the stump. Here, I think, the wound might be closed so as to let the cicatrix be perpendicular; yet Richerand recommends it to be united from before backward, because (says he) the greatest diameter of the stump is from without inward. (*Nomographie Chirurg. t. 4. p. 485—486. edit. 4.*)

In the army, the practice has sometimes been adopted of sawing off the sharp upper ridge of the tibia; but I can offer no exact judgment on the merits of the innovation, which is making only slow progress. It has been done a few times at St. Bartholomew's, and I should have no objection to giving it a fair trial, especially as it has the sanction of Mr. Guthrie, who says, that, in thin persons, where the spine of the tibia is very sharp, this part should be removed with the saw. (*p. 222.*)

Occasionally, surgeons have also removed the small remnant of the fibula, and such was sometimes the practice of Larrey, when he amputated nearer the knee than common. (*Mém. de Chir. Mil. T. 3. p. 389.*)

Whether the above plan of amputating the leg so high up, when the foot or ankle is the part diseased or injured, be on the whole most advantageous, I cannot presume to determine. There are certainly many clever men who condemn the practice, and though we see it pursued by the best surgeons in this metropolis, we may safely assert, that the matter requires further consideration. If it were a decided point, that the common custom of bending the knee, for the sake of bearing the weight of the body on its anterior part, were the only one admissible, after amputation of the leg, there could be no doubt of the propriety of performing the operation a little way below the knee, in preference to any other situation. But, since there have been numerous instances of persons walking very securely with machines, which allow them to make use of the knee, and are more pleasing to the eye, on account of their perfect resemblance to a natural limb; and since also, the operation at the lower part of the leg is more easy of performance, and safer, than when done high up; some very eminent surgeons have thought that it ought always to be done near the ankle, when possible, instead of near the knee.

Mr. White of Manchester, in a paper dated 1769 (*Med. Obs. and Inq. vol. 4.*) informs us, that he took the hint to amputate a little

above the ankle, from seeing a case, in which this had been done by a simple incision, with such success, that the patient could walk extremely well, though with a machine that was very badly constructed. After this, Mr. White began to operate above the ankle with the double incision: and he invented a machine much better calculated for the patient to walk upon.

In 1773, Mr. Bromfield published his *Chirurgical Cases and Observations*, wherein he mentions his having begun about the year 1740 to amputate above the ankle, in a case of gangrene of this part of the leg. The patient walked so well, with the aid of a very simple machine, both along a level surface, and in going up and down stairs, that it was difficult to perceive he had lost his foot. Mr. Bromfield was persuaded, however, to give up this practice, until he learned that, in 1754, a Mr. Wright had thrice amputated in this way with success, when he again had recourse to it, without the least unpleasant consequences. (See *Chir. Cases and Obs. vol. 1. p. 189, &c.*)

The advantage of amputating a little below the knee is, that pressure in walking with a wooden leg is entirely confined to the front of the limb, and the cicatrix itself is not subjected to irritation. After amputating at the ankle, the pressure in walking operates directly on the cicatrix; but if the mechanical contrivances for walking are now brought to such perfection, that this pressure does no harm, the operation, perhaps, ought not to be entirely abandoned. According to Sabatier, however, the plan has been extensively tried in France, and not found to answer, the stump being incapable of bearing pressure, and not continuing healed. (*Médecine Opératoire, T. 3. p. 377. edit. 2.*) Baron Larrey also speaks of it as an objectionable operation, not merely because some patients, as for instance, soldiers, have not the means of providing themselves with artificial legs, of the above description, but because it is almost always followed by bad symptoms, owing to the small quantity of cellular substance and flesh, and the thickness of the bone at this part of the leg, whereby cicatrization is impeded. A nervous irritation is more apt to be produced by this, than the common mode of operating, and the suppuration, which is always sanious, takes place with difficulty. "I have (says Larrey,) seen many amputations done at this part, but nearly all the patients died of nervous fever, or tetanus." (*Mém. de Chir. Mil. t. 3. p. 394.*)

In the foregoing columns, I have given some account of the flap-amputation of the leg, as done by Lowdham, Verduin, Garengeot, Vermale, and others, and, in particular, the practice of O'Halloran has been touched upon, whose chief peculiarity, viz. that of not laying down the flap until ten or twelve days had elapsed, was unquestionably his greatest error, though the idea may have been admired and followed by a few speculators in modern times. (See

Paroisse, Opusc. de Chir. p. 196, &c. Paris, 1806.) This last author, who is a general approver of flap-amputations, leaves the stump unclosed for some days after the removal of the limb; but what surprises me is, to hear, that, in one of the finest hospitals in this metropolis, three or four trials have been made, in the course of the last year, of a modification of this absurd practice, after amputation by the circular incision. Instead of bringing the sides of the wound together, the stumps were only partially closed, and kept for a day or two covered with wet linen. The last patient whom I heard of as having been treated in this manner, died a few days after the operation; and it gives me pleasure to hear, that all further intention of subjecting more patients to the experiment, in the hospital alluded to, is given up.

In flap-amputations below the knee, Alanson and Lucas conjectured, that the cure might be rendered more safe, easy, and expeditious, by applying the flap, with the view of uniting it by the first intention.

The following case explains Mr. Alanson's flap-operation. The disease was in the left leg, the patient, therefore, lay on his right side, upon a table of convenient height, so as to turn the part to be first cut fully into view. The intended line where the knife was to pass in forming the flap, had been previously marked out with ink. A longitudinal incision was made with a common scalpel, about the middle of the side of the leg; first on the outside, then on the inside, and across the tendo Achillis: hence, the intended flap was formed, first by incisions through the skin and adipose membrane, and then completed by pushing a catling through the muscular parts in the upper incised point, and afterwards carrying it out below, in the direction of the line already mentioned. The flap was thick, containing the whole substance of the tendo Achillis. The usual double incision was made; the retractor applied to defend the soft parts; and the bone divided, as high as possible with the saw.

The flap was placed in contact with the naked stump, and retained there, at first, by three superficial stitches, between which adhesive plasters were used. Notwithstanding the patient caught an infectious fever a few days afterwards, the stump healed in three weeks, except half an inch at the inner angle, where the principal vent had been. In another week, the wound was reduced to a spongy substance, about the size of a split-pea. This, being touched with caustic, healed in a few days. The man was soon able to use an artificial leg, with which he walked remarkably well. He went several voyages to sea, and did his business with great activity. He bore the pressure of the machine totally upon the end of the stump, and was not troubled with the least excoriation or soreness.

In the next instance, in which Mr. Alau-

son operated, he formed the flap by pushing a double-edged knife through the leg, and passing it downwards and then outwards, in a line, first marked out for the direction of the knife. In this way, the flap was more quickly made. (*Alanson on Amputation.*)

The leg should be completely extended during the operation; and kept in that posture till the wound is perfectly healed.

We shall next notice Mr. Hey's method. This gentleman is satisfied, that very near the ankle is not the most proper place for this kind of amputation.

Some cases occurring, in which, from a scrophulous habit, the wound at the stump would not heal completely, nor remain healed, Mr. Hey determined to try whether amputation, in a more muscular part, would not secure a complete healing, and give the patient an opportunity of resting his knee on the common wooden leg, or using a socket, as he might find most convenient. Mr. Hey now prefers this method, and has reduced it to certain measures.

It had been customary, at the Leeds Infirmary, to make the length of the flap equal to one-third of the circumference of the leg. This was determined by the eye of the operator, who usually pushed the catling through the leg, near the posterior part of the fibula. Mr. Hey, finding the flap was not always of the proper breadth, began to determine this by measure, and now operates as follows: to ascertain the place where the bones are to be sawn, together with the length and breadth of the flap, he draws upon the limb five lines, three circular, and two longitudinal ones. He first measures the length of the leg from the highest part of the tibia to the middle of the inferior protuberance of the fibula. At the mid-point, between the knee and ankle, he makes the first or highest circular mark upon the leg. Here the bones are to be sawn. Here Mr. Hey also measures the circumference of the leg, and thence determines the length and breadth of the flap, each of which is to be equal to one-third of the circumference. In measuring the circumference of the limb, Mr. Hey employs a piece of marked tape, or riband, and places one end of it on the front edge of the tibia. Supposing the circumference to be twelve inches, he makes a dot in the circular mark on each side of the leg, four inches from the anterior edge of the tibia. These dots must, of course, be four inches apart behind. From each of these dots, Mr. Hey draws a straight line downwards, four inches in length, and parallel to the front edge of the tibia. These lines show the direction which the catling is to take in making the flap. At the termination of these lines, Mr. Hey makes a second mark round the limb, to show the place where the flap is to end. Lastly, a third circular mark is to be made, an inch below the upper one, first made for the purpose of directing the circular cut through the integuments, in front of the limb. The catling,

for making the flap, should be longer than those commonly employed in amputations. Mr. Hey uses one which is seven inches long in the blade, and blunt at the back, to avoid making any longitudinal wound of the arteries, which is very difficult to close with a ligature; and, for the same reason, he pushes the catling through the leg a little below the place where such muscles are to be divided, as are not included in the flap. The limb being nearly horizontal, and the fibula upward, he pushes the catling through the leg, where the dot was made, and carries it downward along the longitudinal mark, till it approaches the lowest circular mark, a little below which the instrument is brought out. The flap being held back, Mr. Hey divides the integuments on the front of the limb along the course of the second circular mark. The muscles not included in the flap, are then divided a little below the place where the bones are to be sawn. No great quantity of these muscles can be saved, nor is it necessary, as the flap contains a sufficient portion of the gastrocnemius and soleus muscles, to make a cushion for the ends of the bones. After sawing the bones, Mr. Hey advises a little of the end of the tendon of the gastrocnemius to be cut off, as it is apt to project beyond the skin, when the flap is put down; and he recommends the large crural nerve, when found on the inner surface of the flap, to be dissected out, lest it should suffer compression.

As strips of adhesive plaster cause great pressure on the end of the stump, Mr. Hey prefers using sutures for keeping the flap applied; small strips of court-plaster being put between the ligatures. The sutures may be cut out on the eighth or ninth day, and the flap supported by plasters.

Mr. C. Bell describes another sort of flap-amputation. The operation is not to be done so low, as there will not be a sufficiency of muscle to cover the end of the bones. An oblique cut is to be made, with the large amputating knife, upward, through the skin of the back part of the leg. The assistant is to draw up the skin, and the knife is to be again applied to the upper margin of the wound, and carried obliquely upward till it reaches the bones. The knife, without being withdrawn, is next to be carried, in a circular direction, over the tibia and fascia, covering the tibialis anticus, until it meets the angle of the first incision on the outside of the limb. The surgeon is then to pierce the interosseous membrane, &c. The sawing being completed, and the arteries secured, the flap is to be laid down, and the integuments of the two sides of the wound will be found to meet. (*Operative Surgery. vol. 1.*) Langenbeck disapproves of the plan of pushing the knife through the calf of the leg, as practised by Alanson, Hey, Graefe, &c. because an inexperienced surgeon may run the point between the two bones, and in this way the wound is never made evenly. His manner of forming the flap is very similar to Mr. C.

Bell's, except that he makes first three cuts in the integuments, two longitudinal and one transverse, by which the shape of the flap of skin is determined. (*Bibl. fur dei Chir. B. 1. p. 571.*)

The regular flap-amputation of the leg, I mean that operation in which the circular incision is abandoned, and a semi-circular flap both of skin and muscle preserved, is often considered more painful than the common method, because it cannot be done with equal celerity. Yet when we come to see what respectable names are recorded in its favour, how soon the stump generally heals, how well the ends of the bones are covered, and how all dissection of the integuments from the fascia is avoided in this mode of operating, at least as far as the flap extends, the method must be allowed to possess weighty recommendations. Indeed in its present improved state, and with the peculiar fitness of such a stump for adhesion, this operation, I think, is again rather rising in the estimation of the profession. In 1816, Klein had performed flap-amputation of the leg, about twenty times. If the flap should happen to be made too large, he particularly dwells on the propriety of removing part of it at once; and, when it is too short, he enjoins carrying the incision a little further upwards without delay. He confesses that the plan is attended with some little trouble in securing the interosseous arteries, which are apt to retract considerably, but, such has been the success of his practice, that out of twenty cases, seventeen got well, and most of them very soon, without the least exfoliation; and the other three died of typhus. (*Practische Ansichten der bedeutendsten Chir. Op. 1tes. Heft. p. 47.*) In the same work, this experienced surgeon, convinced how much more quickly and certainly the wound heals after amputations with two flaps, than those with one, has suggested a plan of amputating below the knee, so as to form two lateral flaps. I regret that my limits prevent me from entering into a description of it.

I have already specified the principal reasons, which have established the common custom of amputating the leg, about four inches below the patella, and, if the disease or injury will not admit of the operation being done thus low, of removing the limb above the knee joint. In the Egyptian campaign, however, Baron Larrey performed two amputations very near the knee joint, almost on a level with the head of the fibula, which he judged proper to extirpate. The successful result of these operations dispelled the fear, which this experienced surgeon previously entertained about amputating in the thick part of the upper head of the tibia; for, no caries of his spongy portion of the bone, no bad effects on the knee-joint, and no anchylosis of the stump ensued; and, with the difference of a few days, the wound healed as easily, as that made in the common place of election, viz. three or four finger breadths below the tuberosity of the tibia. Since

the above-mentioned campaign, Larrey has adopted this practice in many cases, where it was impossible to have operated at the usual place, and he assures us, the success fully equalled what attends operations done at the ordinary distance from the knee. In 1806, another French military surgeon, who had tried this method himself, published a dissertation, in which he commended operating, where circumstances required it, much higher than the point allowed by generally received rules. Larrey differs, however, from Garrigues, in forbidding amputation higher than the level of the tuberosity of the tibia, the thick portion of which may be sawn, but not above the insertion of the tendon of the patella. A transverse line, drawn from this point, usually passes below the articulation of the fibula, and over the lower portion of the uppermost part of the condyles of the tibia: but as the relative positions of the heads of the two bones to each other differ somewhat in different individuals, Larrey makes the tuberosity of the tibia the point, above which the bone should never be sawn. By cutting higher, the ligament of the patella is separated from its insertion: the bursa mucosa, situated underneath it, is wounded; and the ligaments at the sides of the joint are injured; whence arise retraction of the patella, effusion of the synovia, and such disease of the knee-joint, as may render another amputation indispensable. By making the division on a level with the tuberosity of the tibia, the attachment of the ligament of the patella is preserved, as well as that of the flexor tendons of the leg, which are requisite for the motion of the stump. The bursa mucosa is left untouched; and the head of the bone is sawn low enough to avoid creating a risk of caries. But, says Larrey, if this mode of amputating below the knee be compared with amputation of the thigh, as recommended by authors for the cases in which the new method is proposed, the advantages of the latter are considerable. In the first place, life is less endangered, because a smaller portion of the body is removed. The operation is as easy in one situation as the other. The stumps heal with equal facility. Larrey has never seen the spongy part of the tibia become carious, nor perceptibly exfoliate. When the remaining portion of the fibula is very short, as usually happens, it ought to be taken away, as it is an useless body, inconvenient for the employment of a wooden leg. Larrey directs as much skin as possible to be preserved, and making a perpendicular incision through that part of it, which covers the tibia, in order to hinder the bone from making its way through it by ulceration.

With a stump, thus formed, comprising the knee and one or two finger breadths of the leg, the patient has a firm point of support, on which he can securely walk without a stick. The stump admits also of an artificial leg of the natural shape being worn, the knee being always bent, provided the

length of the stump do not exceed the diameter of the call of the artificial limb. (*Mem. de Chir. militaire*, T. 3. p. 386—394.) From a passage, quoted from Mr. Bromfield, (*Chir. Obs. & Cases*, vol. 1. p. 185.) by Mr. Guthrie, it would seem, that the first of these gentlemen advised amputating as near to the knee as could be done without risk of cutting the ligament of the patella, so that the stump might not extend beyond the wooden leg. On the whole, Mr. Guthrie's own observations are very favourable to this practice; but he candidly acknowledges his belief, that "it would not succeed when indiscriminately done in the hospitals of large cities," though it may frequently be practised in the army with advantage, provided the surgeon saw through the tibia below its tuberosity. (*On Gunshot Wounds*, p. 223, and 227.) Upon looking over the details of the cases recorded by Larrey in confirmation of the above statement, I was struck with one important fact, which does not justify a part of his commendations; viz. most of the stumps were above four months in healing; and that which healed most quickly was not well before the sixty-eighth day. (*See Mem. de Chir. Mil.* T. 3. p. 57, 397, 398, &c.) Hence, unless it be supposed, that the wounds produced by amputation below the knee in the ordinary manner, are generally thus long in healing, as treated by the French surgeons, the inference is rather unfavourable to the method so highly commended by Larrey, though I am far from wishing to assert that, even if the stumps cannot usually be healed in less time, more than a full compensation for this disadvantage is not obtained by some of the benefits above enumerated. However, in order to be able to pronounce any positive judgment on the merits of this mode of operating, it would be requisite not only to see two or three successful cases just after their cure, but to examine the state of a tolerable number of stumps, sometime after they had been subjected to the pressure of an artificial leg.

AMPUTATION OF THE ARM.

The structure of the arm is very analogous to that of the thigh: like the latter it contains only one bone, round which the muscles are arranged. The interior muscles are attached to the os brachii, while the more superficial ones extend along the limb, without being at all adherent. The first consist of the brachialis internus, and the two short heads of the triceps: the second, of the biceps, and long head of the triceps. Hence, amputation is here to be done in the same way as in the thigh, unless when we are necessitated to amputate very high up, above the insertion of the deltoid muscle. In the arm, says Graefe, the incisions through the muscles should even be made more obliquely upwards than in the thigh, where the muscles are more bulky, by which means two inches of muscle may be saved, besides the retracted integuments; an abundance for covering the

stump, were the arm full ten inches in circumference. (*Normen für die Abl. grosserer Gliedm.* p. 109.)

The patient being properly seated, the arm is to be raised from the side, and, if the disease will allow it, into a horizontal position. As I have seen some inconveniences produced by the patient's fainting in the midst of the operation, I join Graefe and some other practitioners in thinking that the patient, if circumstances will allow, should be placed upon a table in the recumbent position. (*Normen für die Ablösung grösserer Gliedm.* p. 108.) The surgeon is to stand on the outside of the limb, apply the tourniquet as high as possible, and to have the skin and muscles which he is about to divide, made tense by the hands of an assistant. The soft parts are next to be divided, as much of this limb being preserved as possible. The retractor to be applied, the bone sawn with the usual precautions, and the bleeding stopped in the ordinary way, care being taken to leave the radial nerve out of the ligature, which is put round the brachial artery. The wound is then to be closed so as to form a transverse line, the dressings are to be applied, and the patient put to bed, with the wound a little elevated from the surface of the bedding.

In taking off the arm, I entirely coincide with Mr. Guthrie, with regard to the uselessness of dissecting back the integuments, their effectual retraction by an assistant, after their complete division, being quite enough; (*On Gunshot Wounds*, p. 354.) but, as I have invariably imitated Graefe and others, in making the incisions through the muscles with the edge of the knife turned very obliquely upwards, it has not appeared to me necessary, after cutting down to the bone in this manner, to clear away the muscles from it to the extent of an inch and a half, or two inches higher. Instead also of attempting to perform the circular oblique incision through the muscles with one stroke of the knife, the objections to which have been noticed in the description of amputation of the thigh, I have made it a rule to divide the loose biceps muscle, as soon as the integuments had been cut and retracted, and of letting it fully recede, before the division of the rest of the soft parts was begun.

If the disease should require the arm to be taken off at its upper part, there would be no room for the application of the tourniquet. Here, instead of putting a compress in the axilla, and having it held firmly upon the artery by a by-stander, as advised by Sabatier, it is more eligible to make pressure on the artery as it passes over the first rib, of which method I shall speak in treating of amputation at the shoulder-joint. With a straight bistoury, the surgeon is now to make a transverse incision down to the bone, a little above the lower extremity of the deltoid muscle. Two other longitudinal incisions made along the front and back edge of this muscle, now form a flap, which must be detached, and reflected. Lastly, the rest of the soft parts of the limb are to

be divided by a circular cut, made on a level with the base of the flap, and the operation finished like a common amputation. (*Sabatier, Médecine Opératoire, t. 3, p. 375, &c. ed. 2.*)

As a matter of choice, and not at all of necessity, the arm may be amputated with two flaps; one anterior; the other posterior. The first should be formed of the skin and biceps, and be three or four inches in length; the other is to be of the same size, and composed of the triceps and integuments. The muscular flesh, close to the bone, is now to be divided all round, and the saw used. Klein of late has preferred this to the common method, having adopted it in nine cases. So well is the end of the bone always covered, that a protrusion of it is impossible. (*Practische Ansichten der Chirurgischen Operationen, p. 44.*)

When the arm is injured very high up, Baron Larrey differs from Sabatier, and prefers amputation at the shoulder joint to preserving a short stump, containing the upper end of the humerus; for, says he, if this bone cannot be divided at least on a level with the tendinous insertion of the deltoid, the stump is retracted towards the arm-pit by the pectoralis major and latissimus dorsi; the ligatures on the vessels irritate the brachial plexus of nerves; great pain, and nervous twitchings, often ending in tetanus, are produced; the stump continues swelled; and, in the end, the humerus is fixed by ankylosis to the shoulder, so that this portion of the arm remains altogether useless, and renders the patient liable to accidents. "I have seen (says Larrey) many officers and soldiers, who, on these accounts, were sorry that they had not undergone amputation at the shoulder." (*Mem de Chir. Mil. T. 3. p. 53, 400.*)

Mr. Guthrie also states, that when amputation by the circular incision is attempted at the insertion of the pectoralis major, the bone will generally protrude after a few dressings. However, he entirely dissents from Larrey, respecting the necessity of taking off the limb at the shoulder, and prefers doing it from half an inch to an inch and a half below the tuberosities of the humerus, as the state of the injury may require. Two incisions are to commence, one or two finger-breadths below the acromion; and the inner one is to be extended directly across the under side of the limb, till it meets the lower point of the outer wound. Thus the under part of the arm is cut by a circular incision; the upper in the same manner as it sometimes is in removing the limb at the shoulder joint. Without detaching the skin from the muscles, these are cut through; the soft parts are held out of the way of the saw; the bone is sawn; the vessels secured; and the flaps brought together, so as to form a line from the acromion downwards. (*Gunshot Wounds, p. 337, &c.*) I am decidedly of opinion, that in the description of cases referred to, either this method, or Sabatier's operation, should be

preferred to the removal of the whole limb at the shoulder joint.

AMPUTATION OF THE FOREARM.

The wisest maxim, with respect to the place for making the incision, is to cut off as little of the limb as possible. This fact is perfectly established, though it is true that Larrey, in consequence of his mode of dressing the stump, has not experienced success in his amputations done in the tendinous part of the forearm. The forearm is to be held by two assistants, one of whom is to take hold of the elbow, the other of the wrist. The tourniquet is to be applied to the lower part of the arm, and the assistant holding the elbow, should draw up the integuments, so as to make them tense. The circular incision is then to be made down to the fascia; from this as much skin is to be detached, reflected and saved, as is necessary for covering the ends of the bones, and the muscles are to be cut on a level with the reflected skin, the knife being at the same time directed obliquely upward. As many of the muscles are deeply situated between the two bones of the forearm, too much attention cannot be paid to dividing all of them, with a double-edged knife introduced between the radius and ulna.

The soft parts are to be protected from the saw by a linen retractor. It is generally recommended to saw the two bones together, for which purpose the forearm should be placed in the utmost state of pronation. In any other position, the ulna is situated almost directly under the radius.

The ulnar, radial, and two interosseous arteries, are those, which usually require a ligature.

Graefe removes the forearm by making a flap from the flesh in front of the limb, and then extending the wound quite round the member. (*Normen für die Ablösung grösserer Gliedm. p. 138, &c. 4to. Berlin, 1812.*) Mr. Guthrie makes two flaps, one in front, the other on the back of the forearm; but, above the middle of this part of the limb, he prefers the circular incision. (*On Gunshot Wounds, p. 373—374.*) Dr. Hennen also expresses his approbation of amputating the forearm, so as to make two semilunar flaps: (*Principles of Military Surgery, p. 265, edit. 2;*) which is the method recommended and practised by Klein. (*Practische Ansichten bedeutendsten operationem Heft, p. 45.*) These flap-operations of the forearm are rather proceedings of choice, than of necessity; for, I have seen this part of the limb removed in numberless instances by the circular incision, and can hardly remember a case, in which the stump turned out badly. In making the inner flap, the radial and ulnar arteries must obviously be in danger of being wounded higher up, than the point where they are quite cut through, as Mr. Guthrie candidly acknowledges; an accident which I think might give rise to a great deal of trouble.

With respect to Larrey's preference to amputating in the fleshy part of the fore-

arm, though the case would admit of the operation being done much lower, I need only say, he would find no reason for this choice, were he to practise union by the first intention, at every opportunity, as is the custom in England.

The hand may be amputated at the joint of the wrist, whenever the disease does not extend too high, and a flap can be made of the integuments of the back of the hand. Richerand thinks such an operation sometimes preferable to amputation above the joint. (*Nosogr. Chirurg. T. 4, p. 506, edit. 4.*)

AMPUTATION AT THE HIP-JOINT.

The very idea of this formidable operation, for a long while, checked the hand even of the most ready advocate for the use of the amputating knife, and every mind shuddered at so extensive a mutilation. Still, it could not be denied that the chance of saving life occasionally depended upon a submission to the greatest temporary suffering, and that without the most cruel of sacrifices, the preservation of the patient was totally impossible. Dreadful as the amputation at the hip appeared, both in respect to the magnitude of the part of the body to be removed, and the extent of the wound caused by such removal, the desperate nature of some cases at length began to incline surgeons to view more dispassionately a scheme, at which the mind at first must naturally have revolted. Morand is the earliest practitioner, who made this severe operation the subject of considerable attention, (*Opusculs de Chir. T. 1. p. 176, 8vo. 1768.*) and in the year 1739, two essays on the same topic were communicated to the Royal Academy of Surgery at Paris, by two of his pupils, Volner and Pethod. In 1743, Ravaton wished to have performed amputation at the hip-joint in a case of gunshot fracture of the trochanter major, and neck of the thigh bone, but was prevented by the opposition of other surgeons. (*Chir. d'Arm. p. 323, &c.*) In 1748, the propriety of attempting the operation was urged by l'Alouette. (*Disp. Chir. Halleri, t. 5, p. 265.*) At length, the Royal Academy of Surgery at Paris thought the subject highly deserving of further investigation, as it appeared to several of its members, that there were circumstances under which its performance might be advisable. In the year 1756, they therefore proposed the following question, as the grand prize subject; *In the case, in which amputation of the hip-joint should appear to be the only resource for saving the patient's life, to determine whether this operation ought to be practised, and what would be the best way of performing it?* No satisfactory memoirs having been presented, the same subject was proposed in 1759. The approbation of the Academy was now conferred on a paper written by Barbet, in which the propriety of amputating at the hip-joint was defended, and some of the cases demanding the operation specified. If, for instance, a cannon ball, or any other violently contusing cause,

had carried off or crushed the thigh, so as to leave only a few parts to be cut to make the separation complete, he thought a surgeon ought not to hesitate about doing it. The same author conceived that a sphacelus, extending to the circumference of the joint, and destroying the greatest part of the surrounding flesh, might also render the operation equally necessary and easy. (*See Sabatier, Med Opératoire, t. 3, p. 271, &c.*) Cases were also adduced, where the surgeon completed the separation of the dead parts with a knife. However, this cannot be considered as amputation at the hip-joint. Dividing a few dead fibres was a thing of no importance, in regard to the likelihood of its creating any bad symptoms. The proceeding, in fact, seems to me to have no analogy at all to the bloody operation of taking the thigh bone out of the socket. It is quite a different thing, when the operator has to cut through parts, which bleed profusely, and are endued with life and sensibility.

In addition to the memoir by Barbet, thirty-three other essays were offered to the academy, the majority of which were filled with arguments in favour of the operation; and, besides these productions, two other memoirs were published at Paris, one by Goursand in 1758, explaining a new method of operating, and another by Moublet, (*See Journ. de Médéc. an. 1759.*) in which, says Professor Thomson, the operation is very ably considered in all its different relations. (*Obs. made in the Mil. Hospitals in Belgium, p. 260, 63.*)

Some of the first modern surgeons condemn the proceeding. The following are Mr. Pott's sentiments: "M. Bilguer, and M. Tissot, are the only people whom I have met with, or heard of, in the profession, who speak of an amputation in the joint of the hip, as an advisable thing, or as being preferable to the same operation in the thigh." After a quotation or two, he continues; "that amputation in the joint of the hip is not an impracticable operation (although it be a dreadful one) I very well know. I cannot say, that I have ever done it, but I have seen it done, and am now very sure I shall never do it, unless it be on a dead body. The parallel, which is drawn between this operation and that in the shoulder will not hold. In the latter it sometimes happens, that the caries is confined to the head of the os humeri, and that the scapula is perfectly sound and unaffected. In the case of a carious hip-joint, this never is the fact; the acetabulum ischii, and parts about, are always, more or less, in the same state, or at least in a distempered one, and so indeed most frequently are the parts within the pelvis," &c. (*Pott on Amputation.*) Callisen has difficulty in supposing any circumstances, in which the amputation could be undertaken with hopes of success. (*Syst. Chir. Hod. p. 418. Tom. 2. edit. 1800.*) And Richerand thinks, that, unless the limb be nearly separated by the disease, or accident, a prudent surgeon should decline making

the attempt. (*Nosogr. Chir. Tom. 4. p. 519. edit. 4.*)

As Professor Thomson has justly observed, it is a remarkable fact in the history of surgery, that an operation, which had been invented in France, and concerning which so much had been written in that country, should have been first actually put in practice in England. "I have been informed, (says he) that the operation was performed in London by the late Mr. H. Thomson. Surgeon to the London Hospital, and imagine that it must have been his operation, to which Mr. Pott alludes." (*Obs. made in the Mil. Hospitals in Belgium, p. 264.*) At all events, whether this was the identical case which Mr. Pott saw, or not, the example referred to by this distinguished surgeon is the earliest instance of the operation being actually performed. It was even repeated in this country before it was ever practised on the continent, as far as can be made out from the records of the profession; for, it was performed by Mr. Kerr, of Northampton, on a girl, between eleven and twelve years of age, in a case of diseased hip; a case, in which I am now completely satisfied that it ought never to be attempted, for the reason laid down by Mr. Pott. In fact, Mr. Kerr, after removing the limb, found the acetabulum, and all the adjacent parts of the ossa innominata, carious. But, the experiment was here rendered still more hopeless, by the patient being consumptive. Yet with all these disadvantages, the girl lived till the eighteenth day from the operation, and, after death, her lungs were found to be a complete mass of disease, one of them being totally reduced to matter. (*See Duncan's Med. Commentaries, vol. 6, p. 337, 8vo. Lond. 1779.*) M. Larrey performed this operation twice in Egypt; and once, while he was a surgeon to the French army on the Rhine. He was encouraged to make these attempts to save his patients by the consideration, that he had already preserved some lives by amputating either both thighs, both legs, or both arms, or removing the humerus at the shoulder joint. Larrey has also the true merit of having first done the operation in the only description of cases, in which perhaps it ought ever to be performed; viz. gunshot injuries of head, neck, and upper part of the femur, with, or without injury of the femoral artery, or where the limb had been carried away by a shell, or cannon-ball, too high up to admit of amputation in the ordinary manner. However, he also regards as fit occasions for amputation at the hip-joint, circumstances in which, from gunshot violence, the limb is seized, or threatened with gangrene, nearly up to the hip. (*Mém. de Chir. Mil. t. 2. p. 185.*)

Severe as the operation is, Larrey contends, that it is an act of humanity, if it ever is the means of saving lives, which are in danger, and, he argues, that it is justifiable by the old maxim of Hippocrates, "Ad extremos morbos extrema remedia." To the chief objections, which have been made to

it, he replies, 1st, That the wound is more alarming than dangerous. The Cæsarean operation, (says he) has been successfully performed on the living female, and is still recommended by many practitioners. L'Aumonier, principal surgeon of the Rouen Hospital, has successfully removed a scirrhus ovary of considerable size. Examples are recorded of the arm and scapula being torn away, and the patients soon recovering. Besides, the surgeon has it in his power to lessen the wound, produced by the operation. 2dly. The dangers of hemorrhage may be obviated by the assistants temporarily placing their fingers on the mouths of the cut vessels, until ligatures can be applied.

In confirmation of his sentiments, concerning the propriety of the operation, Larrey adverts to a fact reported by Morand, where a soldier had both his legs amputated very high up, and also both his arms so near the shoulders, that he could hold nothing in his armpits. Yet, mutilated as he was, he enjoyed good health. (*Opusculs de Chir. p. 183.*) And Larrey, in his own work, has recorded several instances, in which the whole of a limb was removed, or more than the halves of both the upper or lower extremities of the same subject, without any fatal constitutional disturbance. (*Mém. de Chir. Mil. t. 2. p. 182-184.*) One of his patients above alluded to, survived the operation a week, at the end of which he was carried off by the plague; and the others died, after being conveyed, in a very uneasy manner, during the precipitate march of the army. (*See Relation de l'Expedition de l'Armée d'Orient en Egypt, &c. p. 319, 8vo. Paris, 1803.*) At the battle of Wagram, Larrey operated at the hip-joint on two soldiers of the imperial guard, under very unfavourable circumstances; and the events were fatal in a few hours. (*Mém. de Chir. Mil. T. 3, p. 349.*)

Larrey used to operate as follows: he began with making an incision in the track of the inguinal artery in the bend of the groin, and, after carefully excluding the nerve, which is more externally situated, he tied this vessel, with the aid of a semicircular curved needle, as closely as possible to Poupart's ligament, in order that the ligature, which was placed above the origin of the circumflex arteries and the profunda, might obviate all inconvenience from the bleeding, which might otherwise happen from their numerous branches. This being done, a straight knife was perpendicularly plunged between the tendons of the muscles attached to the trochanter minor and the base of the neck of the femur, so as to bring out its point at the back part of the limb, or in a diametrically opposite situation to its first entrance; and now by directing the knife obliquely inwards and downwards, a flap, which was not to be too large, was made of the soft parts at the inner and upper portion of the limb. This flap was now drawn towards the scrotum by an assistant, and the articulation was brought into view.

The obturator artery, and some branches of the pudental, wounded by making the flap, were immediately tied. The thigh was now put into the state of abduction; the inner part of the orbicular ligament, made tense by this position, was divided, and the joint opened. The ligamentum teres was then to be cut, and the bone dislocated. The knife was next to be brought to the outside of the great trochanter, and an external flap formed of the soft parts, calculated to meet that which had been made at the inside of the limb. In proceeding through the operation, Larrey secured, as soon as they were divided, the obturator arteries, and several branches of the pudental, gluteal, and ischiatic arteries. The two flaps were brought together, and kept in this position, with strips of adhesive plaster, and a woollen spica bandage. (See *Mém. de Chir. Mil.* t. 2. p. 186, 188.)

In the Russian Campaign, Larrey had two more opportunities of amputating at the hip-joint. In the first instance, he operated upon a Russian at Witepsk, whose thigh bone was broken to pieces up to the trochanter, and the soft parts of two-thirds of the thickness of the limb destroyed. This man went on as favourably as possible until the 25th day from the operation, the parts being healed except at two points, where the ligatures had been brought out; but, unfortunately a scarcity of provisions now occurred from some neglect, or another; and the patient on the 29th or 30th day, fell a victim. The second operation was done on a French dragoon after the battle of Mozaïsk, who was afterwards seen perfectly cured by the surgeon-major, at Orcha, who received him there, and made a report of the fact to Larrey by letter. (See *Mém. de Chir. Mil.* T. 4, p. 26-50-51, 8vo. Paris, 1817.)

In 1812, M. Baffos, surgeon to the Hôpital des Enfants Malades at Paris, amputated at the hip nearly in the manner of Larrey, except that he only compressed the artery in the groin, and did not begin with tying it, a method to which Larrey himself now gives the preference. (See *Mém. de Chir. Mil.* T. 4. p. 434.) The patient was a child, seven years old, and the case a diseased hip. The patient got well of the wound; but died of a scrofula, three months afterwards. The cotyloid cavity was found full of fungous flesh, and the os innominatum carious. As the latter state always exists in the diseased hip-joint, the whole of the disease does not admit of removal by amputation, and consequently the attempt ought never to be made. (See *Joints, Diseases of.*)

The plan of operating, adopted by Baffos, is considered, I believe, by all surgeons of the present day, better than that formerly advised by Larrey, inasmuch as the objectionable and unnecessary preliminary measure of taking up the artery in the groin, instead of simply compressing it against the os pubis, was rejected. Cutting down to the artery as a precaution against hemorrhage, is doing a double operation, and put-

ting the patient to needless suffering: it was the earliest method, having been proposed by Volther and Puthod. Who was the first proposer to press the artery against the os pubis, instead of cutting down to the vessel, I am not at present aware; but I know that it has been publicly recommended by Mr. Abernethy, in his anatomical lectures for the last thirty years: it is twenty-three years since I began to attend his courses, and, in the exhibition of this operation, by the circular incision upon the dead subject, compression of the artery in the groin was then advised, and, as I have stated, not for the first time. Larrey's practice also of running a long narrow knife through the limb, in order to form the inner flap, is highly objectionable, as the parts can never be divided in this vague manner without considerable irregularity. I am glad to find Mr. Guthrie has entered his protest against it, and recommended making the incisions for both flaps from without inwards; (*On Gunshot Wounds*, p. 178.) an improvement, which would have been right in advising for other flap-amputations.

When serving with the army in Holland in 1814, I assisted Dr. Cole in the performance of this operation. The plan adopted by him, is the same as has been taught by Mr. Abernethy, in his lectures for the last thirty years. The flow of blood through the femoral artery was stopped by compressing the vessel in the groin with the handle of a key covered with lint. The thigh was then amputated as high as possible, close below the trochanters. The femoral artery was immediately secured, and afterwards every other vessel requiring ligature. An incision was now made directly on the acetabulum, and the head of the bone removed with the utmost facility and expedition. The patient lost even less blood, than in an ordinary amputation, and the wound admitted of being brought together with adhesive plaster in the best manner possible, so as to represent a transverse line. I am sorry to add, that the patient lived only till the following day. In one dreadful case of fracture of the upper part of the femur by a grape shot, when the operation had been delayed too long, the whole limb being inundated with matter, and the upper end of the lower portion of the bone projecting through the flesh backward, I ventured to perform the same operation at Oudenbosch in Holland, a few days after the assault on Bergen-op-Zoon; and, here happened, what must often occur; instantly after the division of the soft parts, the bone being broken to pieces, the limb came off, leaving the head of the bone, the trochanters, and a small piece below them projecting. Had not the man appeared in a very bad way by the time the vessels had been secured, I should now have removed the head of the bone; but the shock of the operation was such, that he survived it but a few minutes, though scarcely any blood was lost. The mode of operating, by the circular incision is preferred by Graefe, who unknowingly appears to consider it as a new method.

thod. (*Normen für die Abl. grosserer Gliedm.* p. 118.) It has also been proposed by Mr. Veitch, with the modification of leaving an inch or two of the bone projecting, which is done, without giving any additional pain, by dissecting off the soft parts below the first incisions down to the bone. This projecting piece is intended to serve as a lever, with which the head of the bone is to be got out of the acetabulum. (*Edinb. Med. and Surg. Journ.* vol. 3, p. 129.) Ingenious as this suggestion may be, I do not regard it as an important practical improvement; 1st, because in almost all cases, where the operation is necessary, the bone is so fractured, that its division is already made by the injury: 2dly, because the scheme is unnecessary; for in Dr. Cole's case, where I assisted, the head of the femur was removed from the acetabulum with the utmost facility, by merely making an incision over that cavity, cutting the ligaments, and availing ourselves of the small piece of bone accidentally projecting. In fact, in all gunshot injuries, requiring this operation, excepting a few instances of spreading gangrene from wounds, the bone is usually broken too high for Mr. Veitch's method to be practicable. With the same view of facilitating the exit of the head of the bone from the acetabulum, Graefe (p. 123.) recommends dividing the transverse ligament completing the brim of the anterior and inferior side of the socket. From my having once seen one of the first anatomists in London, with a powerful young assistant, and the whole length of the unbroken femur for a lever, baffled for nearly half an hour before he could dislocate the head of the bone, I supposed Graefe's maxim worth collecting.

I am acquainted with only three cases, in which amputation at the hip-joint proved successful. The first operation was that done by Mr. Brownrigg, surgeon to the forces, on the 12th of December, 1812. The upper part of the thigh bone had been broken by a gunshot, near Merida, in Spain, the 29th of December, 1811. The man was some time ago living at Spalding, in Lincolnshire, in perfect health.

The second successful operation was that performed by Larrey, at Witepsk.

The third was done by Mr. Guthrie, in the Netherlands, on a French prisoner of war, who completely recovered.

On the other hand, the examples which have failed are numerous, though undertaken by surgeons of reputation and ability. Mr. Guthrie, Dr. Emery, Mr. Brownrigg, Larrey, Mr. Brodie, Drs. Blick and Cole, and many other military practitioners, have had opportunities of amputating at the hip without success.

No one can expect, however, this operation not to fail in a large proportion of the cases, in which it is attempted: this must always happen, let it be done in the most skilful manner possible. Yet, as there are unquestionably some descriptions of injury, where life must inevitably be lost, if this proceeding be rejected; and experience

proves, that it sometimes answers: an important consideration is, what cases are most proper for it? Here I am decidedly of opinion, with Professor Thomson, that the examples, in which it is particularly called for, and where no delay should be suffered, are those in which the head or neck of the thigh bone has been fractured by a musket-ball, grape-shot, or small piece of shell. Eight or ten such cases, where amputation ought to have been done in the first instance, were brought in wagons, several days after the assault on Bergen-op-Zoom, into the hospital, superintended by myself, at Oudenbosch, and not one of these patients lived ten days after their removal. In the whole course of my professional life, I have never elsewhere witnessed so much suffering, or suppuration in such profusion. From each limb, I should guess, that at least three, or four pints of matter were discharged daily. Had amputation at the hip been performed at first, some of these patients might possibly have been saved; at all events, I am certain, that it was their only chance.

Larrey, as I have stated, thinks the operation proper, where the thigh has been shot off high up, or where the femur and soft parts near the hip have been broken, and extensively lacerated by a cannon-ball, or pieces of shell. Here the operation (though perhaps the only chance) must almost always fail, because, as Professor Thomson observes, these injuries occasion a shock to the constitution, of which the patient mostly sinks either immediately, or in a few hours. (*Obs. made in the Mil. Hosp. in Belgium*, p. 274.) The truth of this observation I saw exemplified at Merxham, near Antwerp, at the bombardment of the French fleet in that port. A shell burst between the thighs of one of the guards; tore and lacerated two-thirds of the thickness of the upper part of the right thigh; broke the ascending ramus of the ischium; lacerated the perineum and scrotum; and fractured the higher part of the femur. There was no hemorrhage of consequence: but the exposed lacerated surface of the soft parts was immense; and the unfortunate patient, who lay with his hairs standing erect, and bereft of his intellectual faculties, sunk in the course of a quarter of an hour into a state of insensibility, and was quite dead in twenty minutes. However, there are numerous cases, in which the patients, after dreadful injuries of the upper part of the thigh, are less depressed and overcome, and live several weeks; facts clearly proving that the operation ought to be attempted. Many instances of this kind are related by Mr. Guthrie. (*On Gunshot Wounds*, p. 134, &c.) This last work, and Baron Larrey's *Mémoire de Chir. Mil.*, contain the most valuable information respecting this operation. The propriety of the operation in desperate cases is now perfectly established; and beginning to be acknowledged by the best surgeons in Europe; Walther (*Abh. aus dem*

Gebiete der Practischen Med. &c.) Paroisse (*Opusc. de Chir. p. 208*;) Graefe (*Normen, &c. 4to. Berlin, 1812.*) The sentiments of these three surgeons, however, are not founded upon any cases of their own, in which the operation was performed; yet as being men of considerable experience and talents, their sanction may be proper, as a counterbalance to the opinions of some other men of eminence, who, without any personal experience of their own, have condemned the proceeding, as unfit to be attempted.

AMPUTATION AT THE SHOULDER JOINT.

H. F. Le Dran performed the first operation of this kind, of which the particulars are recorded. It was in a case of caries and exostosis, reaching from the middle to the neck of the humerus. Le Dran began with rendering himself master of the bleeding; for which purpose, he introduced a straight needle, and a strong ligature under the artery. This was passed from the front to the back part of the arm, as closely to the axilla and bone as possible. The ligature, then including the vessels, the flesh surrounding them, and the skin covering them, was tightened over a compress. Le Dran, with a straight narrow knife, then made a transverse incision through the skin and deltoid muscle down to the joint, and through the ligament surrounding the head of the humerus. An assistant now raised the arm, and dislocated the head of the bone from the cavity of the scapula. This allowed the knife to be passed with ease between the bone and the flesh. Le Dran then carried the knife downward, keeping its edge always somewhat inclined towards the bone. In this manner, he gradually cut through all the parts, as far as a little below the ligature. As there was a large flap, Le Dran made a second ligature with a curved needle, which ligature included a great deal of flesh, the redundant portion of which was cut off together with the first ligature, which had become useless. The cure was completed in about ten weeks. (*Obs. de Chir. T. 1, p. 315, Paris 1731; and Traité de Opér. p. 365.*) Le Dran (the son) who published this memorable case, does not state, that the operation was a new one, and it appears, from the *Recherches Critiques sur l'origine, &c. de la Chirurgie en France*, and from La Faye's notes on Dionis, that it had been previously practised by Morand, the father.

Garengot thought that the ligature might be applied by means of a curved needle, with sharp edges, and, in order to lessen the wound, he directs the incision to begin two or three finger-breadths below the acromion, across the deltoid muscle, so as to form one flap, then a lower one was made in the axilla; and after the second ligature had been applied, the two flaps were brought into contact. (*Traité des Opér. de Chir. t. 3. p. 350, Mém. de Acad. de Chir. T. 2, p. 261.*)

La Faye extended the improvements further. After placing the patient in a chair, and bringing the arm into a horizontal position, he made, with a common bistoury, a transverse incision into the deltoid muscle down to the bone, four finger-breadths below the acromion. Two other incisions, one in front, the other behind, descended perpendicularly to this first, and made a large flap of the figure of a trapezium, which was detached and turned up towards the top of the shoulder. The two heads of the biceps, the tendons of the supra-spinatus, infra-spinatus, teres minor and subscapularis, and the capsular ligament, were next divided. Now, when the assistant, who held the lower part of the limb, made the bone describe the motion of a lever upward, the head of the bone was easily dislocated. La Faye next carried his incision downward, along the inner part of the arm, until he was able to feel the vessels, which he tied as near the axilla as possible. The separation of the limb was then completed a finger's breadth below the ligature. The flap was then brought down over the glenoid cavity, and the wound was dressed. (*See Nouvelle Méthode pour faire l'Opération de l'Amputation dans l'articulation du Bras avec l'Omoplate, par M. La Faye, in Mém. de l'Acad. de Chirurgie, Tom. 5, p. 195, Edit. in 12mo.*) With respect to La Faye, it is curious to remark a coincidence between him and Larrey: the latter, though generally averse to attempt to unite stumps by the first intention, is an advocate for this practice after hip-joint amputations; so La Faye, who was fearful of laying down the flap, after amputation of the leg, had no such apprehension at the shoulder.

La Faye's method is yet regarded as one of the most approved, where the state of the soft parts will admit of it. But, it is absurd to think of applying any one plan to all the various states, in which the injured or diseased limb may present itself.

It is advised by Larrey himself, when a wound extends through the upper part of the arm, breaking the bone, and injuring the soft parts. Here, says he, it would be impossible to form an anterior and a posterior flap, for the soft parts in these situations have been destroyed. On the contrary, when the deltoid is shot away, La Faye's plan is inadmissible. (*Mém. de Chir. Mém. T. 2. p. 167*)

The advantages of La Faye's plan are obvious. As only one ligature was applied, the patient was saved a great deal of pain: the flap connected with the acromion was capable of covering the whole surface of the wound, and was more easily applied and kept on the stump, than the lowermost of the two flaps which Garengot recommended; and the discharge found a ready outlet downwards.

Mr. S. Sharp recommended the following plan. "The patient's arm being held horizontally, make an incision through the membrana adiposa, from the upper part of

the shoulder across the pectoral muscle, down to the arm-pit, then turning the knife with its edge upwards, divide that muscle and part of the deltoid, all which may be done without danger of wounding the great vessels, which will become exposed by these openings. If they be not, cut still more of the deltoid muscle, and carry the arm backward. Then with a strong ligature, having tied the artery and vein, pursue the circular incision through the joint, and carefully divide the vessels at a considerable distance below the ligature; the other small vessels are to be stopped, as in other cases.

"In doing this operation, regard should be had to the saving as much skin as possible, and to the situation of the processus acromion, which, projecting considerably beyond the joint, an unwary operator would be apt to cut upon." (*Operations of Surgery.*)

Bromfield used to have pressure made on the artery above the clavicle. His incision began on the inside of the arm, by the edge of the deltoid muscle, as high up as where the pectoralis goes over the axilla, to its insertion into the humerus. Cutting through the integuments and muscles, he continued his incision obliquely downwards, and outwards, as far as a little below the termination of the deltoid muscle. Then carrying on the incision transversely for a small space in a semicircular direction, the wound was next extended to the external part of the arm, as high up as the fold of the integuments in the axilla. The flap, thus shaped, when raised from the humerus, was intended to fill up the axilla, after the removal of the limb. Bromfield's next incision began at the acromion, and, being carried through the skin and deltoid down to the bone, terminated in the semicircular incision above described, and it was so guided, that it left the outer portion of the divided flap larger than the inner one. Bromfield then passed his knife under the lower edge of the internal half-flap, and dissected it up as high as possible. The tendon of the pectoral muscle was thus exposed, under which he now passed his left forefinger, which served as a conductor to a probe-pointed curved bistoury. With this, he now divided the attachment of that muscle to the humerus. If the vessels were not now sufficiently brought into view, he cut through the outer head of the biceps, and tied them (artery and vein) each with two strong ligatures about half an inch apart. The vessels were then cut through in the interspace, and the nerve was divided much higher than the artery. The external flap was now raised sufficiently to expose the joint; and the muscles and capsular ligament having been cut through in the superior and lateral parts, the humerus slipped out of the glenoid cavity, immediately the arm was carried a little backward. Lastly, the ligatures and vessels being held out of the way, the soft parts towards the axilla were divided in a

semicircular direction. (*Chir. Obs. and Cases, vol. 1. p. 249—252. 8vo. London, 1773.*) The unnecessary tediousness, and, I may add, severity of Bromfield's method, have long withdrawn from it the approbation of modern operators. The division of the flap into two portions; its extraordinary length; and the painful dissection practised to get at the artery; were serious faults in the operation.

In 1774, Alanson amputated at the shoulder-joint, as follows: the subclavian artery was compressed by the fingers of an assistant. An incision was made about a hand's breadth below the acromion, and carried through the integuments all round the limb. The deltoid and posterior muscles were then obliquely divided up to the capsular ligament. The tendon of the biceps, and the capsular ligament upon the anterior and posterior part of the joint, were now cut through. One of the circumflex arteries, which bleed a good deal, was next tied. The great pectoral muscle, the rest of the capsule, and all the other parts, except the vessels and nerves, were then divided, but previously to cutting the vessels, a temporary ligature was put round them. Thus the separation of the limb was completed. The mouths of the vessels were drawn out, and tied, and the temporary ligature taken away. Lastly, the sides of the wound were brought together, so as to make a transverse line. Graefe, seeming not to recollect that amputation by the circular incision directed obliquely upwards, had been practised by Alanson, mentions it as a new proposition. In one case, after operating in this manner, his patient was quite well in three weeks; and, with the particular sort of knife which he uses, and which is broadest towards its point, he pretends to be able to make the oblique incision through the muscles all round the limb with one sweep. Of course, he is very careful to make pressure on the artery, both with Mohrenheim's compressor applied under the clavicle, and the fingers of an assistant above it. (*See Normen für die Abl. grosserer Gliedm. p. 110, &c.*) In proof of the possibility of making the oblique incision quite evenly with one stroke of his particular knife, he injected a female subject, did the operation, and caused the stump to be drawn from nature. (*See Plate 2, of his Work.*)

In 1760, P. H. Dahl published at Göttingen a Latin dissertation on amputation at the shoulder. In this tract a tourniquet was proposed, the pad of which was calculated to press upon the subclavian artery under the clavicle, and enabled the operator to dispense with tying the vessels in the first instance. Camper had observed, that if the scapula were pushed backward, and the axillary artery pressed with the finger between the clavicle, coracoid process, and great pectoral muscle, the pulse at the wrist might be instantly stopped.

Dahl's tourniquet was obviously constructed, in consequence of what Camper

had observed. It is made of a curved, elastic plate of steel, to the shortest end of which a pad is attached, capable of projecting further by means of a screw. The instrument embraces the shoulder from behind forward, while the pad presses on the hollow under the clavicle, between the margins of the deltoid and pectoral muscles. The long extremity of the steel plate, which descends behind the shoulder, is fixed to the body by a sort of belt. The pad is depressed, until the pulsation of the axillary artery is stopped.

Further experiments have proved, however, that this tourniquet may be dispensed with, and the flow of blood in the axillary commanded, by properly compressing this vessel with a pad, or even the fingers alone, as some operators prefer, at the place where it emerges from between the scaleni muscles, above the middle part of the clavicle. Thus the artery is pressed between the pad or fingers and the first rib, across which it runs. In some plans of operation, hereafter to be described, all compression of the artery, either above or below the clavicle, is dispensed with.

Some practitioners, forgetful of the horizontal posture in which the patient is usually placed after the operation, have feared that, in La Faye's method, the lower flap may sometimes confine the discharge. In order to avoid this inconvenience, Desault recommended the formation of two flaps, one of which was anterior, the other posterior. The axillary artery was compressed from above the clavicle, at its coming out from between the scaleni muscles, while the integuments and flesh of the upper and internal part of the arm were pushed away from the humerus. A knife was plunged between these and the other soft parts behind, to make the anterior flap. The arm being inclined backward and outward, the humeral artery was tied, the articulation opened, and the head of the bone dislocated. The knife was then carried downward and backward, so as to form the posterior flap; the incisions meeting in the axilla. (See *Sabatier's Médecine Opératoire*, t. 3. p. 393—399, edit. 2.)

Larrey, who has had frequent opportunities of amputating at the shoulder-joint, has aimed at the same object which Desault did, but, in his earlier operations, he was in the habit of beginning with the formation of the external, or posterior flap, for the following reason: by proceeding in this way, the surgeon can tie the humeral artery more safely, because the ligature is applied after the operation is entirely finished, and consequently at a time when there is nothing to be attended to but the hemorrhage. Thus, the patient being placed on a stool, and well supported, the arm is to be raised from the side, and the axillary artery compressed from above the clavicle. The integuments and other soft parts of the upper and outer parts of the arm are then to be pushed away from the humerus, and the external flap formed. It is now very easy

to cut the tendons of the infra-scapular, and teres minor, and open the outside of the joint. The limb is to be carried inward, and luxated backward. The tendons of the supra-scapular and biceps are to be divided, and as soon as the head of the bone is out of the glenoid cavity, the knife is to be carried along the internal part of the head and neck of the humerus, with its edge close to the bone. An internal flap, equal to the external one, is to be formed, consisting of a portion of the deltoid, great pectoral, biceps, and coraco-brachialis, muscles, and including the brachial vessels and nerves. The artery is to be taken hold of with a pair of forceps, and tied. Any other vessels, which require a ligature, are also now to be secured. Larrey puts some charpie betwixt the flaps, and brings them towards each other by the usual means. (See *Mém. de Chir. Militaire*, t. 2. p. 170.) Of this method of putting charpie to prevent union by the first intention, I entertain the most unfavourable opinion.

When Larrey published his campaign in Egypt, he had operated in this way on nineteen patients, thirteen of whom recovered. But, at a subsequent period, he and his colleagues had amputated at the shoulder, in the above manner, in upwards of a hundred cases, more than ninety of which recovered. (*Mém. de Chir. Mil.* t. 4. p. 432. 8vo. Paris, 1817.)

In his later operations, he has adopted the innovation of first making a longitudinal incision from the acromion to about an inch below the neck of the humerus, down to the bone, so as to divide the fleshy part of the deltoid into two even parts. This cut, he says, facilitates and renders more exact the rest of the operation. From this wound, the incisions for the flaps are continued. Having made the foregoing incision, "I direct an assistant to draw up the skin of the arm towards the shoulder, and I form the anterior and posterior flaps by two oblique strokes of the knife made from within outwards and downwards, so as to cut through the tendons of the pectoralis major and latissimus dorsi. There is no risk of injuring the axillary vessels, as they are out of the reach of the point of the knife. The cellular connexions of these two flaps are to be divided, and the flaps themselves raised by an assistant, who, at the same time, is to compress the two divided circumflex arteries. The whole joint is now exposed. By a third sweep of the knife, carried circularly over the head of the humerus, the capsule and tendons running near the articulation are cut; and the head of the bone being inclined a little outwards, the knife is to be carried along its posterior part, in order to finish the section of the tendinous and ligamentous attachments in that direction. The assistant now applies his forefingers over the brachial plexus, for the purpose of compressing the artery, and commanding the current of blood through it. Lastly, the edge of the knife is turned backwards, and the whole

fasciculus of axillary vessels are cut through, on a level with the lower angles of the two flaps, and in front of the assistant's fingers. The patient does not lose a drop of blood; and ere the compression is remitted, the extremity of the axillary artery is readily seen, taken up with a pair of forceps, and tied. The circumflex arteries are next secured, which completes the operation." (*Mém. de Chir. Mil. t. 4. p. 428. Paris, 1817.*) In addition to these important deviations from his earlier method, he now brings the flaps together with two or three straps of adhesive plaster, and interposes no charpie. (P. 429.) It should be observed, also, that he lays no stress on first making the outer flap; though, from the description, it does not exactly appear which flap he now begins with. He has changed, likewise, on another point of importance; viz. instead of preferring La Faye's plan, in certain examples already specified, he affirms, that the above described way of operating is applicable to almost every case met with in military practice. First, because all gunshot wounds, generally, which mutilate the arm, so as to create the necessity for the operation, partly or entirely destroy the centre of the deltoid, while there is always enough flesh left at the sides for making the two flaps. Secondly, because, in the very rare instances, where the lateral parts of the shoulder are destroyed, and the middle untouched, no advantage would be gained by operating in La Faye's manner, as Larrey conceives that the detached flap would slough or become, as he terms it, disorganized. Here Larrey now prefers dividing the middle piece of flesh, and giving the flaps the same shape as if they were uninjured. He even asserts, that the operation, done without any flaps at all, answers better, than any method, in which the surgeon preserves flaps not naturally intended for the part. Thus, when all the flesh of the shoulder has been shot away, he has seen surgeons cover the glenoid cavity with a flap, saved from the soft parts of the axilla; but such flaps invariably sloughed, hemorrhages ensued, and the patients died. (P. 430, 431.) Some of these latter observations are, clearly enough, the result of great partiality to a particular method of operating; because who can doubt, when the lateral parts of the shoulder are injured, as they frequently are (and not very rarely, as Larrey asserts,) by the passage of a musket-ball through the shoulder, from before backwards, that the right method is that of La Faye; or the same operation, with the slight difference of making the flap of a semicircular shape? It was for cases of this description that Mr. Collier and I operated after La Faye's plan, with perfect success, after the battle of Waterloo; and a poor fellow of the rifle brigade, who was brought in too late for operation, and died of sloughing, had his shoulder injured in the same way, the middle of the deltoid being untouched, and shot-holes behind, and in front of, the

articulation. But, if it require any further arguments to prove, that Larrey is wrong in wishing to extend his, or rather Desault's method, to all cases, I might criticise his assertions about the sloughing of the flap, when it is not cut into two portions, and its preservation by the singular expedient of making a division of it, and of course, injuring it still more, than it may have been injured underneath by the bullet. The cases, however, which have fallen under my own personal observation, and numerous others on record, furnish an adequate proof, that, excellent as Larrey's method is for many cases, La Faye's answers very well in others. Thus, in an example where a Prussian hussar had had his arm amputated, and a projection of the bone took place, to the extent of three inches, with hospital gangrene commencing in the stump, Klein felt obliged to remove the limb at the shoulder. He operated in La Faye's manner; the separation was finished in one minute; and, on the eighteenth day, the stump was perfectly healed. (*See Practische Ansichte Chir. op. h. 1. p. 1—10. 4to. Stuttgart, 1816.*) The same practitioner had five other secondary amputations of the same kind; but one patient was afterwards carried off by the hemorrhage, and another by hospital gangrene. Klein, however, in common with the majority of army surgeons, considers the idea of applying any one plan of operating, to different cases, totally absurd. (P. 12.) After the storming of St. Sebastian's, nine shoulder-joint amputations were done with success: seven of them by raising the deltoid as a flap. (*See Guthrie on Gunshot Wounds, p. 106.*)

After the battle of Waterloo, I adopted La Faye's plan; but with this difference, that I did not cut the brachial artery till I made the last stroke of the knife, which separated the limb, and consequently I did not tie the vessel till the time when I had nothing but the hemorrhage to occupy my attention. The circumflex arteries however, I tied as soon as the external flap was made. The modification of thrusting a knife under the deltoid, quite across the shoulder, and making the flap by cutting downwards, until the instrument comes out again through the skin, as practised by some surgeons of eminence (*Klein, &c.*;) but this is a method which I should never choose to follow, as the flesh may be more smoothly and accurately cut from without inwards. This is a principle which, in my opinion, ought to apply to every flap-amputation.

When the state of the integuments will permit the choice, Mr. Guthrie thinks their preservation best effected by Larrey's first method; but he particularly insists upon the advantage of raising the shattered arm, or stump, to nearly a right angle with the body, before the operation begins, and even before the assistant makes pressure on the subclavian artery, as some change in the mode of accomplishing the latter object might be rendered necessary by elevating the limb during the operation itself. Mr.

Guthrie commences the first incision immediately below the acromion, and with a gentle curve, extends it downwards and inwards, through the integuments only, a little below the anterior fold of the armpit. The second incision outwards is made after the same manner, but is carried rather further down, so as to expose the long head of the triceps at the under edge of the deltoid. The third incision, commencing at the same spot as the first, but following the margin of the retracted skin, divides the deltoid on that side down to the bone, and exposes the insertion of the pectoralis major, which must be cut through. This flap is now to be raised, so as to expose the head of the bone. The fourth incision outwards divides the deltoid muscle down to the bone, when the posterior flap is to be well turned back, so as to bring into view the teres minor and infra-spinatus passing from the scapula to the great tuberosity of the humerus. The outer and inner flap being now raised, the head of the bone may be rolled a little outwards, the teres minor and infra-spinatus cut, and an opening made into the joint. The capsular ligament, supra-spinatus, and long head of the biceps are then divided. The inner side of the capsule is now cut through, together with the subscapularis muscle, as it approaches its insertion, into the lesser tuberosity of the humerus. The long head of the triceps is next divided, and, lastly, with one sweep of the knife, the rest of the soft parts are cut, together with the axillary artery, veins, and nerve. (*On Gun-shot Wounds*, p. 274-276.) The doubtful part of this method seems to be, that of cutting the circumflex arteries twice, which, when they bleed much, ought to be secured without any delay, more especially in secondary operations, where every drop of blood is of consequence. The principle laid down by Desault, that in operative surgery in general, all important vessels should be tied, if possible, ere other things are done, is one of the most valuable maxims which can be inculcated. On this point I should more strongly differ from Larrey, who, in his latest method, takes no measures in the first stage of the operation for commanding the flow of blood, as the assistant merely presses the axillary artery between his fingers just before it is divided.

Some of the modern French surgeons were earlier, than Larrey, in dispensing with the compression of the axillary artery, and following a method which renders it unnecessary. Richerand, for instance, describes nearly the same plan as was advised by La Faye; but after making the deltoid flap, cutting the tendons, and dislocating the bone, he dissects down close to the inside of the humerus, so as to enable an intelligent assistant to put his thumb on the cut surface behind the artery, which, with the aid of the four fingers, applied to the skin of the axilla, can then be grasped and compressed, so as to command the flow of blood through the vessel. The operator no *x*. fearless of hemorrhage, com-

pletes the incision of the internal or inferior flap.—(*Richerand, Nosographie Chirurgicale*, t. 4. p. 509-511 edit. 4.)

Dupuytren, surgeon to the Hotel-Dieu, at Paris, amputated at the shoulder, in a manner which seems principally commendable on account of its celerity. The arm being raised and held at a right angle with the trunk, Dupuytren stands at the inside of the limb, with one hand grasps and elevates the mass of the deltoid muscle, and plunges under a two-edged knife, from before backward, on a level with the end of the acromion. Cutting in this way, close to the head of the humerus, he continues the incision downward between this bone and the deltoid, and at length bringing out the knife, completes the external or superior flap. The rest of the operation does not essentially differ from Richerand's, except that M. Dupuytren takes hold of the lower flap itself, before dividing it, and compresses the artery, until he has cut through it, and tied it.

Dupuytren's plan would be difficult on the left side, unless the surgeon were an ambidexter; but in other respects, it cannot be found much fault with. This surgeon has also proposed making one flap in front, and the other behind, in order to prevent the lodgment of matter. Richerand justly observes, however, that frequently a good deal of the wound unites by the first intention, and that as the patient after the operation lies in the recumbent posture on an oblique plane, he cannot see what advantage one way of making the flaps has over another, in regard to affording a ready issue to the discharge. (*Op. cit.* p. 515.)

For the sake of celerity, of which the French are rightly admirers in all capital operations, another plan of amputating at the shoulder has been proposed by Chopesme and Lysfranc. In front of the fleshy part of the shoulder, and the scapular end of the clavicle, there is a slight triangular depression. Into the middle of this a narrow double edged bistoury is introduced. The instrument enters the joint, the head of the humerus not being in contact with the surface of the glenoid cavity of the scapula, when the arm is left to its own weight, and allowed to hang down by the side of the body. The incision is then carried round to make the external flap; and the head of the bone, which becomes more and more distant from the scapula, is easily dislocated, the tendons of the supra and infra-spinatus muscles having been cut in the beginning of the operation. Lastly, the internal flap is made in the way practised by Dupuytren, Richerand, &c.

Speaking of this mode of operating, Richerand remarks: "en l'employant, on parvient à désarticuler l'humérus, et à séparer le bras en aussi peu de temps qu'en met un habile découpeur à détacher l'aile d'un perdrix." (*P* 514.)

When the scapula is shattered, of course the loose fragments should be taken away, and, if the acromion be broken, and the remnant of it pointed and irregular, the

sharp rough portion should be sawn off, as was practised long ago by M. Faure. (See *Mém. de l'Acad. de Chir.* t. 6. p. 114.) In one case, indeed, Larrey found it necessary to take away more than two-thirds of the scapula, and the humeral end of the clavicle. (*Mém. de Chir. Mil.* t. 4. p. 432.) Sawing off, part of the acromion, and coracoid process, as a general rule, seems to me quite unnecessary (See *Frazer on the Shoulder-joint Operation*. See *Lond.* 1813.) and improper, not only as producing delay, but by wounding other parts which should not be at all disturbed. (See *Guthrie on Gunshot Wounds*, p. 285, 286, &c.) The practice of scraping away the cartilage of the glenoid cavity, except when it is diseased, is not of greater value.

Amputation at the shoulder has been partly superseded by a preferable operation, even in cases in which it would formerly have been deemed quite indispensable, such as considerable gunshot fractures of the head of the humerus; a caries of the substance of this part, &c. Boucher in 1753, proved, that considerable wounds, extending into the shoulder-joint, might be successfully treated, by extracting the fragments and splinters of bone. (*Mém. de l'Acad. de Chir.* t. 2, p. 287 et 461.) Instances are also recorded, in which when the head and neck of the humerus in children had been totally disunited from the body of that bone, a cure was accomplished by making such incisions as allowed the portions of bone, now become extraneous bodies, to be taken away. The earliest case of this kind on record is that in which M. Thomas, a surgeon at Pezenas in Languedoc, removed the separated head of the humerus in 1740, which, in a child four years of age, presented itself loose in an incision, which had been previously made for the extraction of some sequestra. The particulars may be read in Guthrie's valuable work. (*On Gunshot Wounds*, p. 215, &c.) Mr. White, of Manchester, proceeded further, for he made a deep incision at the upper part of the arm, dislocated the head of the humerus, which he knew was carious, and, pushing it through the wound, took it off with a saw. He began an incision at the orifice of a sinus situated just below the processus acromion, and extended the wound down to the middle of the humerus by which all the subjacent bone was brought into view. He then took hold of the patient's elbow, and easily forcing the upper head of the humerus out of its socket, he brought it so entirely out of the wound, that he readily grasped it in his left hand, and held it there till he had sawn it off with a common amputation saw, having first applied a pasteboard card betwixt the bone and the skin. The patient did not lose more than two ounces of blood, only a small artery, which partly surrounded the joint, being wounded, which was easily secured.

In about five or six weeks, the part from which the bone had been taken, had acquired a considerable degree of firmness, and

the boy was able to lift a pretty heavy weight. At the end of two months, a large piece of the whole substance of the humerus was ready to separate from the sound bone, and with a pair of forceps it was easily removed. After this exfoliation the wound healed very fast; and, in four months after the operation, the boy was discharged perfectly cured. On comparing this arm with the other, it was not quite an inch shorter; the boy had the perfect use of it, and could not only elevate his arm to any height, but perform the rotary motion as well as ever. The figure of the arm was not at all altered. Mr. White did not make use of any splints, machine, or bandage, during the cure, in order to confine the limb strictly in one certain situation, nor was the patient's arm ever dressed in bed, but while he was sitting in a chair, and as soon as he could bear it standing up. To this method, Mr. White attributed the preservation of the motion of the joint.

"As this is the first operation of the kind that has been performed, or at least made public, (says Mr. White) I thought the relation of it might possibly conduce to the improvement of the art. That ingenious surgeon, Mr. Gooch, has indeed related three instances of the heads of bones being sawn off in compound luxations. In one of these cases, the lower heads of the tibia and fibula were sawn off, in another, that of the radius; and, in the third, that of the second bone of the thumb; but these were in many respects different from the present case. I believe it will seldom happen, that this operation will not be greatly preferable to amputation of the arm of the scapula, as this last is generally performed for a caries of the upper head of the os humeri, and as the preservation of a limb is always of the utmost consequence, and what every surgeon of the least humanity would at all times wish for, but particularly where, as in this case, the whole limb, and its actions, are preserved entire, the cure no ways protracted, and the danger of the operation most undoubtedly less. For though amputation is often indispensably necessary, and frequently attended with little danger or inconvenience when only part of a limb is removed, yet when the whole is lost, the danger is greatly increased, and the loss irreparable." Mr. White concludes, with suggesting an analogous operation for removing the head of the femur, in lieu of amputation at the hip. Something of this kind is indeed reported to have been actually done on a girl with success. (See *Joannis Mulder Oratio de Meritis P. Camperi*, &c. p. 81. *Cases in Surgery*, by C. White, p. 57. or *Phil. Trans.* Vol. 59. for 1769.)

Here, however, the acetabulum and ossa innominata being always, or generally, more diseased than the head of the femur, neither of these operations, I think, ought to be attempted. Long after the publication of White's case, viz. in 1767, an example, in which Vigaroux adopted the same practice, in 1788, was communicated to the profes-

sion: the result, however, was unfortunate, the patient, a lad seventeen years of age, having died soon after the experiment. (See *Œuvres de Chir. Prat. par J. M. I. Vigaroux (fils.) Montp. 1812.*)

Bent, of Newcastle, has inserted a similar case to Mr. White's in the 64th vol. of the *Philosophical Transactions*. White made only one incision, from the vicinity of the acromion down to the middle of the arm. Bent, not being able to get at the head of the bone through the wound which he had made, from the clavicle to the attachment of the pectoral muscle, detached a portion of the deltoid, where it is connected with the clavicle, and another part, where it is adherent to the humerus. A third successful case is also reported in the 69th vol. of the same work, p. 6. Afterwards, Bromfield published some directions for the guidance of the surgeon in the execution of such operations. (*Chir. Obs. and Cases.*) Sabatier has proposed making two cuts at the upper part of the arm, which meet below like the letter V, extirpating the flap, dividing the inner head of the biceps, and capsular ligament; dislocating the head of the bone, and sawing it off. (*Médecine Opératoire, t. 3.*)

I think the cases recorded by White and Bent are truly important, inasmuch as they appear to have been the earliest models of a practice, which may sometimes supersede all occasion for one of the most formidable and mutilating operations of surgery. To military and naval surgeons, these cases cannot fail to be highly interesting, as they must have frequent opportunities of availing themselves of the instruction which they afford. Larrey, who was surgeon general to the French army in Egypt, employed the practice, with the greatest success, in cases of gunshot wounds. He thereby saved limbs, which, according to ordinary precepts and opinions, would have been a just ground for amputating at the shoulder; and, when it is considered, not only that a most dangerous operation is avoided, but that an upper extremity is saved, for which no substitute can be applied, we must allow that the plan, first suggested and practised by Mr. White, cannot be too highly appreciated. When the arm was fractured near its upper extremity by a musket-ball, most surgeons formerly deemed it necessary to amputate the limb. Here, says Larrey, it would be useless to dilate the entrance and exit of the ball, because a sufficient opening could not be prudently made in this way for the extraction of the head of the bone. Yet this body is now an extraneous substance, having lost its connexion with the body of the humerus, and its presence exciting irritation and inflammation of the joint, abscesses, necrosis, &c. Here Larrey seems to imply, that the detached head of the bone cannot unite again; an assertion which, I have no doubt, is quite incorrect, as I have attended several cases in which the humerus was broken very high up, yet united without difficulty. The bad symptoms, which he so emphatically attributes to the detachment of

the head from the body of the bone, are in reality the effects of the gunshot violence itself. If, therefore, the head of the bone were merely broken off, and it and the neighbouring part of the bone not splintered, nor the flesh not more extensively injured than would arise from the passage of a musket-ball, and the joint itself not involved, I should question the propriety of having recourse, at once, either to the extraction of the head of the bone, or amputation at the shoulder. When the bone is shattered, the case is often very different, and Larrey's practice is then commendable. In confirmation of these sentiments, I may mention Mr. Guthrie's opinion, who, in reference to the extraction of the head of the bone, says, he does not consider a perfect fracture of the humerus, an inch below its head (although there be evident separation,) as demanding even this operation, as he has known such cases do well, when treated as other compound fractures, except that the motion of the joint was nearly lost. (*On Gunshot Wounds, p. 329.*) However, it is fair to mention, that Mr. Guthrie inclines to amputation at the shoulder when the body of the bone is splintered, or has long fissures in it, in which sentiment he is probably right. The other operation seems principally calculated for cases, in which the damage is restricted to the head and uppermost portion of the bone.

According to Mr. Guthrie, when the ball passes out with little injury to the bone, and the openings already made are not sufficient to admit of a moderate examination with the point of the finger, the wound should be enlarged. However, others might argue, that such dilatation should be made only when the bone is felt to be seriously broken, and the fragments will probably require immediate removal. But whatever course be adopted, the most rigorous antiphlogistic treatment will be proper; and, if abscesses form, depending openings should be made for the discharge.

Larrey says, "I have had the good fortune, on ten different occasions, to supersede the necessity for amputation at the shoulder, by the complete and immediate extraction of the head of the humerus, or its splinters, without delay. I perform the operation in the following manner: I make an incision in the centre of the deltoid muscle, and parallel to its fibres, carrying the incision as low down as possible. I get the edges of the wound drawn asunder, in order to lay bare the articulation, of which the capsule is generally opened by the first incision, and by means of a probe-pointed bistoury, I detach with the greatest ease from their insertions the tendons of the supra and infra spinati, of the teres minor, of the subscapularis, and of the long head of the biceps; then I disengage the head of the humerus, and remove it through the wound in the deltoid by means of my fingers, or of an elevator. I bring the humerus up to the shoulder, and fix it in a proper position with the aid of a sling and a bandage. Such is the operation."

ration, which I performed on ten patients, in extirpating the head of the humerus; one of these died of the hospital fever, two of the scurvy, at Alexandria, and the fourth, after he was cured, died of the plague on our return to Syria. The rest returned to France in good health. In some the arm became ankylosed to the shoulder, and in others, an artificial joint, allowing of motion, was formed." (*See Mém. de Chir. Militaire, t. 2, p. 175.*) Another successful case, of the same kind, has been more recently published by Mr. Morel. (*See Medico-Chirurg. Trans. vol. 7, p. 161.*)

Mr. Guthrie thinks it not sufficient to make a simple incision through the deltoid muscle into the capsular ligament, and take away the fragments of bone, but urges the removal at the same time of a considerable part of the capsular ligament, lest disease still go on in the joint. Also, as it is impossible to know, beforehand, in what state the bone may be below the fracture (that is, with respect to fissures running more or less down it,) he advises the incision, designed for the extraction of the splintered head of the bone, to be made in a situation where, if amputation at the joint be found indispensable, it will be of advantage. Mr. Guthrie likewise describes the manner of turning out the head of the bone in these cases, and sawing it off; the necessity of which, however, I do not clearly comprehend, unless the taking away of any sharp spicula of the upper end of the body of the bone be implied, which may be right. (*On Gunshot Wounds, p. 333—335.*) My ideas, however, chiefly extend to the removal of loose fragments, and splinters, and, with respect to sawing off the head of the bone, this is a proceeding, I suppose, necessarily limited to the kind of case reported by Mr. White.

AMPUTATION OF THE HEADS OF BONES.

In a letter, dated 1782, and addressed to Mr. Pott, Mr. Park, surgeon of the Liverpool Hospital, made the proposal of totally extirpating many diseased joints, by which the limbs might be preserved, with such a share of motion as to be of considerable use.

Mr. Park's scheme, in short, was to remove entirely the extremities of all the bones, which from the diseased joint, with the whole, or as much as possible, of the capsular ligament; and to obtain a cure by means of callus, or by uniting the femur to the tibia, when the operation was done on the knee; and the humerus to the radius and ulna, when it was done on the elbow; so as to have no moveable articulation in those situations.

To determine whether the popliteal vessels could be avoided, without much difficulty, in the excision of the knee, Mr. Park made an experiment on the dead subject. An incision was made, beginning about two inches above the upper end of the patella, and

extending about as far below its lower part. Another one was made across this at right angles, immediately above the patella down to the bone, and nearly half round the limb, the leg being in an extended state. The lower angles formed by these incisions were raised, so as to lay bare the capsular ligament; the patella was then taken out; the upper angles were raised, so as fairly to denude the head of the femur, and to allow a small calling to be passed across the posterior flat part of the bone, immediately above the condyles, care being taken to keep one of the flat sides of the point of the instrument quite close to the bone all the way. The calling being withdrawn, an elastic spatula was introduced in its place, to guard the soft parts, while the femur was sawn. The head of the bone thus separated, was carefully dissected out; the head of the tibia was then with ease turned out, and sawn off, and as much as possible of the capsular ligament dissected away, leaving only the posterior part covering the vessels, which, on examination, had been in very little danger of being wounded.

The next attempt was on the elbow; a simple longitudinal incision was made from about two inches above, to the same distance below, the point of the olecranon. The integuments having been raised, an attempt was made to divide the lateral ligaments, and dislocate the joint; but this being found difficult, the olecranon was sawn off, after which the joint could be easily dislocated, without any transverse incision, the lower extremity of the os humeri sawn off, and afterwards the heads of the radius and ulna. This appeared an easy work; but Mr. Park conceives the case will be difficult in a diseased state of the parts, and that a crucial incision would be requisite, as well as dividing the humerus above the condyles, in the way done with respect to the thigh bone.

Mr. Park first operated, July 2, 1781, on a strong, robust sailor, aged 33, who had a diseased knee, of ten years standing. The man's sufferings were daily increasing, and his health declining. Mr. Park, in the operation, wished to avoid making the transverse incision, thinking that after removing the patella, he could effect his object by the longitudinal one; but it was found that the difference between a healthy and diseased state of parts, deceived him in this expectation. Hence the idea was relinquished, and the transverse incision made. The operation was finished exactly as the one on the dead subject related above. The quantity of bone removed was very little more than two inches of the femur, and rather more than one inch of the tibia. The only artery divided was one on the front of the knee, and it ceased to bleed before the operation was concluded, but the ends of the bones bled very freely. In order to keep the redundant integuments from falling inwards, and the edges of the wounds in tolerable contact, a few sutures were used. The

dressings were light and superficial, and the limb was put in a tin case, sufficiently long to receive the whole of it, from the ankle to the insertion of the gluteus muscle.

I shall not follow Mr. Park throughout the treatment. Suffice it to remark, that the case gave him a great deal of trouble, and that it was attended with many embarrassing circumstances, arising chiefly from the difficulty of keeping the limb in a fixed position, the great depth of the wound, and the abscesses and sinuses, which formed in the part. On the other hand, however, the first symptoms were not at all dangerous. But, the patient was obliged to keep his bed nine or ten weeks, and it was many months more before the cure was complete. The man afterwards went to sea, and did his duty very well, so useful was his limb to him.

Subsequently to the publication of the letter to Mr. Pott, another excision of the knee was done by Mr. Park, on the 22d of June, but the event was unsuccessful, as the patient lingered till the 13th of October, and then died.

About the same time that Mr. Park made his proposal, P. F. Moreau, a French surgeon, wrote in favour of a similar method. It only seems necessary to notice here the difference in Moreau's plan of operating from that adopted by our countryman. Moreau, the son, who has published the account, observes, that the multiplicity of flaps is unnecessary, as two answer every purpose; and he deems Mr. Park's direction to remove the olecranon, if this be free from caries, at least useless. Moreau, junior, operated on the elbow as follows: with a dissecting scalpel he cut down to the sharp edge, or spine of the inner condyle of the os humeri, about two inches above its tuberosity; and directed by the spine, he carried the incision down to the joint. He did the same on the other side, and then connected the two wounds by a transverse incision, which divided the skin and the tendon of the triceps, immediately above the olecranon. The flap was dissected from the bone, and held up out of the way, by an assistant.

The flesh which adhered to the front of the bone, above the condyles, was now separated, care being taken to guide the point of the instrument with the fore-finger of the left-hand, and, when the handle of the scalpel could be passed through between the flesh and the bone, M. Moreau allowed it to remain there, and sawed the bone through upon it. The removal of the piece of bone was next finished, by detaching it from all its adhesions. The removal of the heads of the radius and ulna, remaining to be done, was more difficult, and the first flap being insufficient, it became necessary to make another. The lateral incision, at the outer side of the arm, was extended downwards, along the external border of the upper part of the radius. The head of the radius was separated from the surrounding parts; its connexion with the ulna des-

troyed, and a strap of linen was introduced between the bones, in order to keep the flesh out of the way of the saw. The radius was sawn through, near the insertion of the biceps, which was fortunately preserved. Some remaining medullary cells, filled with pus, were removed with a gouge. The ulna was now exposed, by extending the lateral incision on the inner side of the arm. Thus another flap was made, and detached from the back part of the fore-arm, and that portion of the bone which it was wished to remove. The bone, being separated from every thing that adhered to it, and a strap of linen put round it to protect the flesh, about an inch and a half of it was sawn off, measuring from the tip of the olecranon downwards. A few diseased medullary cells were taken away with the gouge. Two or three vessels were tied, and the flaps were brought together with sutures. In a fortnight this man became so well, that he was allowed to go wherever he pleased, with his arm supported in a case. The arm was at first powerless, but it slowly regained its strength, and the man could ultimately thrash corn and hold the plough with it &c.

Seven months after, another operation, performed in the same way as the preceding one, by Moreau the father, the patient was completely cured, and two years after this period, the flexion of the fore-arm on the arm, was very distinct. In another case, only one longitudinal incision, and a transverse one, were made, the flap being of course triangular. The patient got well in six weeks, and in three months more joined his regiment.

In all Moreau's cases, the flexion and extension of the fore-arm were preserved, which circumstance no doubt depended very much on the insertion of the biceps not being destroyed. After the excision of the knee, however, the bones grew together.

Moreau, junior's, method of operating differed from his father's, inasmuch as the patient was in a recumbent, instead of a sitting, posture, and the os humeri sawn before it was dislocated.

In a knee case, Moreau the father operated as follows:—He made a longitudinal incision on each side of the thigh, between the vasti and the flexors of the leg, down to the bone. These incisions began about two inches above the condyles of the femur, and were carried down along the sides of the joint, till they reached the tibia. They were united by a transverse cut, which passed below the patella, down to the bone.

The flap was raised; but the patella attached to it, being diseased, was dissected out. The limb was then bent so as to bring the condyles of the femur into view. As it was desired to cut them from the body of the bone, before dislocating them, every thing adhering to them behind, where they joined the body of the bone, was separated, and, at that place the fore-finger of the left-hand was passed through, in order to press back the flesh from the bone, while the saw was used. The knee having been

bent, Moreau drew the cut piece towards him, and easily detached it from the flesh and ligaments.

The head of the tibia was laid bare by an incision, nearly eighteen lines long, made on the spine of that bone. The first lateral incision on the outer side of the knee, was extended nearly as far down on the head of the fibula. Thus were obtained one flap, which adhered to the flesh filling up the interosseous space, and another triangular flap, formed of the skin, covering the inner surface of the tibia, which bone was of necessity exposed, before the saw could be applied.

Upon raising the outer flap, the head of the fibula came into view, and, after being separated from its attachments, was cut off with a small saw. The inner flap was then raised, and the head of the tibia, having been separated from the muscles behind, was sawn off.

It does not appear necessary to insert in this work the account of cutting out the ankle joint; an operation which will never be extensively adopted, nor shall I add any thing more concerning the mode of removing, in a similar way, the shoulder joint. In treating of amputation in this situation, I have already said enough, and whoever wishes for further information, respecting this practice, must refer to Dr. Jeffray's Work, entitled "*Cases of Excision of Curious Joints.*" This publication contains all that is known on the subject. Dr. Jeffray has recommended a particular, and, indeed, a very ingenious, saw, for facilitating the above operation. The saw alluded to is constructed with joints, like the chain of a watch, so as to allow itself to be drawn through behind a bone, by means of a crooked needle, like a thread, and to cut the bone from behind forward, without injuring the soft parts. An instrument of this kind was executed in London, by Mr. Richards, who was assisted in making it by his nephew, the present Mr. Richards of Bricklane. In placing the saw under a bone, its cutting edge is to be turned away from the flesh. Handles are afterwards hooked on the instrument.

According to my notions of the treatment of diseased joints, as long as the patient's strength is not subdued by the irritation of the local disease, humanity dictates the propriety of persevering in an attempt to save the affected limb, &c. Will a patient, greatly reduced by hectic symptoms, be able to recover from so bold and bloody an operation, as the dissection of the whole of the knee-joint out of the limb? If some few should escape, with life and limb preserved, would the bulk of persons, treated in this manner, have the same good fortune? I cannot admit, that the extirpation of the whole of so large an articulation as the knee, can be compared with the operation of amputation, in point of simplicity and safety. However, it is not on the difficulty of practising the former, that I would found my objections; for, I believe, that any man

possessing a tolerable knowledge of the anatomy of the leg, might contrive to achieve the business. The grounds, on which I withhold my approbation from the attempt to cut out large joints, are the following:—1. The great length of time which the healing of the wound requires. Whoever peruses the case of Hector McCaghan, will find that the operation was performed on the 2d of July, 1781, and that it was February 28th of the following year, before all the subsequent abscesses and sores were perfectly healed. This space of time is very nearly eight months! Mr. Park describes the patient as a strong, robust sailor, and gives no further particulars concerning the state of his constitution, than that his health was declining. I entertain little doubt, that if the excision of the knee had been performed in that state of the health, in which amputation becomes truly indispensable, this man would not have survived the illness arising from the operation. The only other case, in which Mr. Park extirpated the knee, ended fatally. In the instance related by Moreau, there seemed, indeed, to be considerable debility. This patient escaped the first dangers consequent to so severe an operation; and, after three months confinement, the patient was in such a state, that Moreau expected he would be able to walk upon crutches in another month or six weeks! The young man in the mean time was attacked by an epidemic dysentery, and died. On the 21st of October, 1809, Mulder extirpated the knee-joint of a pregnant woman in the hospital at Groningen; but she died of tetanus on the 8th of the following February. He conceives, the operation is much facilitated by removing the ends of the femur and tibia in their connected state. (See *Diss. de Articulis extirpandis auctore G. H. Wachter.*) 2. Even supposing the excision of the knee to be followed by all possible success, is the advantage of having a mutilated, shortened, stiff limb, in lieu of a wooden leg, sufficiently great to induce any man to submit to an operation, beyond a doubt infinitely more dangerous than amputation? I think not. The practice is at present nearly exploded in this country; but, at Paris, I hear every now and then of its being attempted. Many interesting observations on the extirpation of various diseased joints, may be found in the above-mentioned dissertation by Wachter, and in the analysis of it by Langenbeck (*Bibl. für die Chir. B. 3, Göttingen, 1811.*)

In quitting this part of the subject, I may just notice, that an extraordinary case was communicated to me about two years ago by Mr. Dunn, of Scarborough, who cut out several of the tarsal bones, including the diseased surface of the astragalus, and also some of the metatarsal bones, from a boy's foot, with complete final success. The hemorrhage however was profuse, and great difficulty experienced in stopping it. Whether this bold experiment merits imitation, I am not at present prepared to say; but, be this as it may, the fact is interesting

AMPUTATION OF THE FINGERS AND TOES,
AND PART OF THE FOOT.

The best surgeons all agree with Mr. Sharp, that the amputation of the fingers and toes is most conveniently performed in their articulations. With a common scalpel, the skin is to be cut through circularly, not exactly upon the joint, but a little towards the extremity of the fingers, in order that a sufficient flap may be preserved for covering the end of the bone. On taking away a finger from a metacarpal bone, Mr. Sharp recommends making two small longitudinal incisions on each side of the joint, as a means of facilitating the separation.

In amputating the fingers and toes, the operation is greatly facilitated by cutting into the joint when it is bent. Having made an opening in the back part of the capsule, one of the lateral ligaments may easily be cut, after which nothing keeps the head of the bone from being turned out, and the surgeon has only to cut through the rest of the exposed ligamentous and tendinous parts.

Some recommend making a small semicircular flap of skin to cover the bone; but this is quite unnecessary, if care be taken to draw the skin a little up, and to cut where Mr. Sharpe directs. However, as making a small flap gives little pain, I have generally followed this method, though it appears to me nearly a matter of indifference which plan is adopted. In operating at the joints between the phalanges and metacarpal bones, a flap should always be made, either on the upper, or under part of the fingers to be removed.

Although it is generally best to remove the fingers at the joints, it is sometimes thought right, where the injury just includes the joint, and no more, to saw through the bone, instead of operating at the next articulation. (See *Guthrie on Gunshot Wounds*, p. 384.)

It may happen, that the bones of the toes, and only part of the metatarsal bones, are carious, in which case, the leg need not be cut off, but only so much of the foot as is disordered. A small spring saw is here the most convenient. When this operation is performed, the heel and the remainder of the foot will be of great service, and the wound heal up safely, of which Mr. S. Sharp says, he had in his time seen one example. (*Op. of Surgery*, Chap. 37, Ed. 3.) Mr. Hey confirms this statement of Sharp's concerning the impropriety of removing the whole foot, when the metatarsal bones are carious, and every other part of the leg is sound, as the remainder of the foot is of immense service in walking, the use of the ankle not being destroyed.

Mr. Hey describes a new mode of removing the metatarsal bones, which on repeated trial has answered his expectations. By the term *new*, I here mean a particular method, which had not been previously described, though it may have been performed by others before Mr. Hey himself; for the

merit of having first done it is imputed to the late Mr. Turner of North Yarmouth, who did it with success about the year 1787. (See *Hutchinson's Pract. Obs.* p. 70.) Mr. Hey makes a mark across the upper part of the foot, to denote where the metatarsal bones are joined to those of the tarsus. About half an inch from this mark, nearer the toes, he makes a transverse incision, through the integuments and muscles covering the metatarsal bones. From each extremity of this cut, he makes an incision along the inner and outer side of the foot to the toes: he removes all the toes from the metatarsal bones, and then separates the integuments and muscles, forming the sole of the foot, from the inferior part of the metatarsal bones, keeping the edge of the knife as near the bones as possible, in order to expedite the operation, and preserve as much muscular flesh in the flap as can be saved. He then separates the four smaller metatarsal bones, at their junction with the tarsus, and divides, with a saw, the projecting part of the first cuneiform bone, which supports the great toe. The arteries being tied, Mr. Hey applies the flap, which had formed the sole of the foot, to the integuments, which remain at the upper part, and keeps them in contact with sutures. The cicatrix being situated at the top of the foot, is in no danger of being hurt, while the place where the toes were situated, is covered with such strong skin, viz. what previously formed the sole of the foot, that it cannot be injured by any moderate violence. (See *Practical Observations in Surgery*, p. 535, &c.)

When the metatarsal bone of the great toe is alone diseased, Mr. Hey recommends dissecting it out from the cuneiform bone, instead of sawing it. The latter plan cannot be easily accomplished, without removing part of the integuments and muscles, and making a transverse, as well as a longitudinal, incision. These disagreeable things may be avoided by following the method of Mr. Hey, or of Mr. C. Bell. For removing the metatarsal bone, either of the little, or great toe, the latter gentleman directs us to carry a scalpel round the root of the toe, and then along the side of the foot. The flaps are then to be dissected back, the metatarsal bone is to be separated from the next; and its square head is to be detached from the tarsus. (*Operative Surgery*, Vol. 1. p. 390.)

The removal of the central metatarsal, and metacarpal bones, is an operation of much difficulty, and, the sawing of them is hardly practicable, without injuring the soft parts. Hence I am decidedly of opinion, with Mr. C. Bell, that, instead of a formal amputation, it is better to extract the diseased bones from the foot, or hand, as, indeed, Mr. Hey was in the habit of doing.

That skilful surgeon, Langenbeck, however, has devised a ready mode of taking away the middle finger, with its metacarpal bone, from the *os magnum*, or the ring finger, with its metacarpal bone, from the *ar-*

tication of the latter with the os magnum and os cuneiforme. In order to find out these articulations, he draws a line from the upper head of the metacarpal bone of the thumb straight across to the metacarpal bone of the finger to be extirpated, and, at this place, he begins his first incision, which runs towards each side of the finger, like an inverted V. The bone is then separated all round from the soft parts, and dislocated from the carpus, when nothing remains to be done but to cut the parts towards the palm, where the wound is also made to resemble an inverted V, but does not extend any farther than is necessary to complete the separation. (See *Langenbeck's Bibl. B. 1, p. 575. and Plate 3, F. 1.*) This is unquestionably a simple and excellent method of operating, which Langenbeck also recommends as the best way of removing such bones of the metatarsus, as are not situated at the sides of the foot; care being taken to save a flap from the sole. It is often difficult, however, to know with certainty, whether the disease is confined to the metacarpal, or metatarsal bones; and, if it be not, and the carpus, or tarsus be affected, the operation will not answer, and amputation be indispensable. This happened in one of Langenbeck's cases, in which he had removed one of the metacarpal bones.

Modern surgeons never amputate the whole of the foot, or hand, when there is a reasonable chance of preserving any useful portion of it, though the rest may be most severely shattered. Thus, where a soldier had been struck by a grape shot, which shattered the metacarpal bones of the little and ring fingers, grazed the middle finger, and tore up the integuments on the palm and back of the hand, Mr. Guthrie succeeded in saving the two fingers and thumb, although, in the removal of the other parts, no regular flaps could be made for covering the wound. (*On Gunshot Wounds, p. 382.*) In winter campaigns, the toes, and more or less of the foot, are often attacked with mortification from cold. In this circumstance, when the disorder does not extend beyond the middle of the foot, or the toes, it is only necessary to cut away the gangrenous part. On the first entrance of the French army into Holland after the revolution, Paroisse met with many of these cases, in which it was necessary merely to take away the metatarsal bones, or sometimes those of the tarsus. All the patients, operated upon in this manner for the effects of cold, were cured; walking afterwards with more or less difficulty, according as the portion of the foot taken away had been greater or smaller. (*Opusculum de Chir. p. 218.*)

M. Roux, in his late publication, finds fault with our ignorance of Chopart's method of removing a part of the foot. He says, "I am certain, the principal surgeons in England, have never practised, and are even totally unacquainted with the amputation of the foot at the junction of the two

halves of the tarsus, or Chopart's operation." (*Voyage fait à Londres en 1814, on Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, p. 338.*) As it is an operation of considerable merit, I think it will be useful to introduce a description of it in the present work. It is performed in the nearly parallel articulations of the os calcis with the os cuboides, and of the astragalus with the os naviculare. Thus the heel is preserved, on which the patient can afterwards walk. The performance of it is simple. The tourniquet having been applied, the surgeon is to make a transverse incision through the skin, which covers the instep, two inches from the ankle joint. He is to divide the skin, and the extensor tendons, and muscles, in that situation, so as to expose the convexity of the tarsus. He is next to make on each side a small longitudinal incision, which is to begin below and a little in front of the malleolus, and is to end at one of the extremities of the first incision. After having formed in this way a flap of integuments, he is to let it be drawn upward by the assistant who holds the leg. There is no occasion to dissect and reflect the flap; for the cellular substance connecting the skin with the subjacent aponeurosis is so loose, that it can easily be drawn up above the place, where the joint of the calcaneum with the cuboides, and of that between the astragalus and scaphoides ought to be opened. The surgeon will penetrate the last the most easily, particularly by taking for his guidance, the eminence, which indicates the attachment of the tibialis anticus muscle to the inside of the os naviculare. The joint of the os cuboides and os calcis lies pretty nearly in the same transverse line, but rather obliquely forward. The ligaments having been cut, the foot falls back. The bistoury is then to be put down, and the straight knife used, with which a flap of the soft parts is to be formed under the tarsus and metatarsus, long enough to admit of being applied to the naked bones so as entirely to cover them. It is to be maintained in this position with three or four strips of adhesive plaster, which are to extend from the heel, over the flap, to the inferior and anterior part of the leg.

Chopart used to tie every artery as soon as it was divided. On the instep, the continuation of the anterior tibial artery will require a ligature; and, in the sole, the internal and external plantar arteries, in the thickness of the flap of soft parts, must generally be taken up. One half of each ligature is to be cut away, and the other one is to be left hanging out between the plasters, at the nearest and most convenient point.

Walther and Graefe have given some very precise directions for the performance of this operation. A cut is first made, beginning half an inch below the outer ankle, and extending forwards along the side of the foot two inches. Another similar incision is then made from one inch below the inner ankle. The foot is now to be bent up-

wards, and the two first cuts united by a transverse incision, two finger-breadths from the front of the tibia. A flap is then dissected up, as far back as the commencement of the lateral incisions, or a line corresponding to the articulation of the astragalus with the os naviculare, and of the os calcis with the os cuboides. An assistant now checks the bleeding by applying the points of his fingers on the mouths of such vessels as bleed profusely, and holds up the flap. The extremity of the foot is now to be firmly inclined downwards, so as to stretch the ligaments connecting the tarsal bones together. The ligaments between the astragalus and os naviculare are to be first cut, when the foot may be twisted somewhat outwards, and the ligaments between the os calcis and os cuboides divided. The division is lastly completed by cutting through the soft parts regularly from above downwards, with the precaution of directing the amputating knife so as to leave a flap composed of part of the sole of the foot. (See *Abhandl. aus dem Gebiete der Pract. Med. &c. Landshut*, 1810, B. 1, p. 152, & *Graefe Normen für die Abl. grosserer Gliedm.* p. 142.)

Sometimes, in consequence of the soft parts of the instep being all gangrenous or otherwise destroyed, it is necessary to make the flap entirely from the sole of the foot, as Klein was obliged to do in one of his cases. (*Practische Ansichten bedeutendsten Chir. Operationen.* H. 1. p. 28.) Indeed, Richerand thinks this mode generally advantageous, as the line of the cicatrix is not placed at the lower end of the stump, where it would be most exposed to injury. (*Nosogr. Chir.* T. 2, p. 502, &c. Ed. 4.) Langenbeck and Klein also condemn the painful and unnecessary measure of dissecting up a flap from the instep, as advised by Walther and Graefe. Chopart himself, as we have seen, merely drew back the integuments of the instep, without making any detachment of them from the subjacent parts. When the ends of the flexor tendons of the toes project too much from the inner surface of the lower flap, they are to be cut shorter, as Klein particularly directs; and I consider his advice not to use sutures for keeping the flap applied, but merely strips of sticking plaster, perfectly judicious. (*Op. cit.* p. 33-34.)

AMY-LUM. Starch. Powdered starch is sometimes used as an external application to erysipelas; but, chiefly, in clysters, when the neck of the bladder is affected with spasm. The following is the formula used at St. Bartholomew's Hospital. R. Mucilaginis Amyli, Aquæ distillatæ: sing. ℥ij Tinct. Opii guttas quadraginta: Misce.

* ANASTOMOSIS, (from *ανα*, through, and *στομα*, a mouth.) Anatomists and surgeons imply by this term, the communications of the blood-vessels with each other, or their running and opening into each other, by which the continuance of a free circulation of the blood is greatly ensured, and the danger of mortification lessened. The immense importance of this part of our structure, in all cases in which the main artery, or veins of a limb are obliterated, is

particularly conspicuous in the disease called aneurism. (See *Aneurism*.)

Nay, such has been the providence of nature in this respect, that, even where the thoracic aorta has been completely obstructed, the channels for the conveyance of the blood to the lower extremities have yet been found adequate to that purpose. This was proved in an example where the obstruction had been gradually produced by disease, and the anastomosing vessels of course had had time for enlargement; for, this is a very different case, from that in which a ligature is suddenly applied to the aorta; though, as far as can be deduced from the particulars of some experiments made on dogs by Mr. A. Cooper, and of one operation in which this gentleman tied the human abdominal aorta, (*Surgical Essays*, Part 1, p. 101,) blood will still pass to the lower extremities in sufficient quantity for their nutrition. At least, this inference is safely deducible from the very memorable operation to which I have referred, subject to one important condition, viz. that there be no additional cause of impediment to the passage of blood, to the lower extremities, besides the ligature above the bifurcation of the aorta. When Mr. A. Cooper tied the human aorta in the abdomen, the experiment was made as the only possible means of hindering a man from bleeding to death, who had a large aneurism of the external iliac artery actually beginning to bleed, and extending too high to admit of any thing else being done. Now, although the unfortunate patient was not saved, and it must be acknowledged that the chances of any other result were very small, the case furnished the important proof, that, if the abdominal aorta be suddenly and completely obstructed, the blood may yet pass in adequate quantity to the lower extremities, provided there exist no other cause of impediment to the passage of the blood into those members; for, on the side, occupied by the aneurism, the circulation in the limb was stopped, while, in the opposite limb, the circulation and natural warmth were preserved. To this subject, I shall hereafter return. (See *Aorta*.)

The changes which take place in the arterial system of the limb, when the main artery is rendered impervious by the application of a ligature, are well described by Mr. Hodgson: "The blood, meeting with an obstacle to its progress through the accustomed channel, is thrown in greater quantity, and with greater force, into those branches, which arise above the seat of the obstruction. The ramifications of these branches, in consequence of the unusual influx of blood, undergo a remarkable dilatation; the more minute vessels also, by which they anastomose with corresponding ramifications, arising from branches given off below the obstruction, are from the same cause sufficiently enlarged to allow a free passage of the blood into the inferior trunks of the limb. At first, the circulation

is in this manner carried on through a congeries of minute anastomosing arteries: in a short time, a few of these channels become more enlarged than the rest: as these increase in size, the smaller vessels gradually collapse, and ultimately a few large communications constitute permanent channels through which the blood is transmitted to the parts, that it is destined to supply. This is one mode by which a collateral circulation is established.

"But, in some situations, more direct and ostensible inosculation is provided; so that when one channel is obstructed the blood passes at once through the other in a sufficient stream for the nourishment of the part, which it is destined to supply. Under these circumstances, no dilatation of the collateral branches is necessary: the circulation in such instances, may be said to be constantly carried on through inosculating trunks. These great communications principally exist in the extremities of the body, where the dilating impulse, which the blood receives from the heart, is of course diminished. Thus, the radial artery inosculates freely with the ulnar; the anterior with the posterior tibial; and the internal carotid with the vertebral arteries. Two modes therefore exist, by which arteries communicate with each other—the anastomoses of minute ramifications, and the direct inosculations of trunks." (See *Hodgson on the Diseases of Arteries and Veins*, p. 234.) Refer also to *Inosculation*. The best general account of the inosculations, in relation to aneurism, is contained in Scarpa's *Treatise on Aneurism*; more especially, the Italian edition, which is embellished with beautiful engravings.

ANCHYLOPS, (from *αγγι*, near, and *ὤψ*, the eye.) Same as *Ægylops*.

ANCHYLOSIS, (from *αγκυλος*, crooked.) This denotes an intimate union of two bones, which were naturally connected by a moveable kind of joint. All joints originally designed for motion, may become ankylosed, that is, the heads of the bones, forming them, may become so consolidated together, that no degree of motion whatever can take place. Bernard Conner (*De stupendo ossium coalitu*) describes an instance of a general ankylosis of all the bones of the human body. A still more curious fact is mentioned in the *Hist. of the Acad. of Sciences*, 1716, of a child 23 months old, affected with an universal ankylosis. In the advanced periods of life, ankylosis more readily occurs, than in the earlier parts of it. The author of the article *Ankylosis* in the *Encyclopédie Méthodique*, mentions his having preserved a specimen, in which the femur is so ankylosed with the tibia and patella, that both the compact and spongy substances of these bones appear to be common to them all, without the least perceptible line of separation between them. In old subjects, the same kind of union is commonly observable between the vertebrae, and between these and the heads of the ribs.

The greater, or lesser degree of immobility, has caused ankylosis to be distinguished into the *true* and *false*. In the true ankylosis, the bones have grown together so completely, that not the smallest degree of motion can take place, and the case is positively incurable. The position, in which the joint has become thus inalterably fixed, makes a material difference in the inconvenience resulting from the occurrence. The false ankylosis is that, in which the bones have not completely grown together, so that their motion is only diminished, not destroyed. The true ankylosis is sometimes termed *complete*; the false, *incomplete*.

In young subjects in particular, ankylosis is seldom an original affection, but generally the consequence of some other disease. It very often occurs after fractures, in the vicinity of joints; after sprains and dislocations attended with a great deal of contusion; and after white swellings and abscesses in joints. Aneurisms, and swellings and abscesses on the outside of a joint, may also induce ankylosis. In short, every thing which keeps a joint long motionless may give rise to the affection, which is generally the more complete the longer such causes have operated.

When a bone is fractured near a joint, the limb is kept motionless by the apparatus, during the whole time requisite for uniting the bones. The subsequent inflammation also extends to the articulation, and attacks the ligaments and surrounding parts. Sometimes, these only become more thickened and rigid: on other occasions, the inflammation produces a mutual adhesion of the articular surfaces. Hence fractures so situated, are more serious, than when they occur at the middle part of a bone. Though common fractures leave, after their cure, a certain degree of stiffness in the adjacent joints, this is different from true ankylosis; it merely arises from the inactivity, in which the muscles and articular surfaces have been kept for a time, and may generally be cured by gradually exercising, and increasing the motion of the limb.

The position of an ankylosed limb is a thing of great importance. When abscesses form near the joints of the fingers, and the tendons mortify, the fingers should be bent, that they may ankylose in that position, which renders the hand much more useful, than if the fingers were permanently extended. On the contrary, when there is danger of ankylosis, the knee should always be kept as straight as possible. The same plan is to be pursued, when the head of the thigh bone is dislocated in consequence of a diseased hip. When the elbow cannot be prevented from becoming ankylosed, the joint should always be kept bent. No attempt should ever be made to cure, though every possible exertion should often be made to prevent, a true ankylosis. The attempt to prevent, however, is not always proper, for many diseases of joints

may be said to terminate, when ankylosis occurs.

When the false, or incomplete ankylosis is apprehended, measures should be taken to avert it. The limb is to be moved as much as the state of the soft parts will allow. Boyer remarks, that this precaution is much more necessary in affections of the ginglymoid articulations, than of the orbicular ones, on account of the tendency of the former to become ankylosed, by reason of the great extent of their surfaces, the number of their ligaments, and the naturally limited degree of their motion.

The exercise of the joint promotes the secretion of the synovia, and the grating first perceived in consequence of the deficiency of this fluid soon ceases. A certain caution is necessary in moving the limb: too violent motion might create pain, swelling, and inflammation, and even caries of the heads of the bones. It is by proportioning it to the state of the limb, and increasing its extent daily, as the soft parts yield and grow supple, that good effects may be derived from it. (See *Boyer Mal. des Os*, Tom. 2.) The use of embrocations, and pumping cold water on the joint, every morning, have great power in removing the stiffness of a limb remaining after the cure of fractures, dislocations, &c.

Unreduced dislocations are not always followed by ankylosis. Nature often forms a new joint, especially in persons of the lower order, who are obliged to move their limbs a great deal, in order to obtain a livelihood. The surrounding cellular substance becomes condensed, so as to form, around the head of the luxated bone, a membrane serving the purpose of a capsular ligament. The muscles, at first impeded in their action, become so habituated to their new state, that they resume their functions. This is particularly the case with bones which move in every direction, and have round heads; but, in ginglymoid joints, the heads of the bones are only imperfectly dislocated, and the motion is greatly restrained by the extent of surface; while some of the numerous ligaments are only sprained, not ruptured. These causes promote the occurrence of ankylosis.

Ankylosis may follow contusions of the joints, and such shocks, as the articular surfaces experience in leaping, or falling on the feet, from great heights. This is more likely to happen, when the inflammatory symptoms, resulting from such violence, have not been properly counteracted by bleeding, and other general remedies. Sprains, which violently twist the joints, very often on this account, cause an ankylosis, especially when the inflammation has long hindered such joints from being at all moved.

When diseases of joints end in a complete ankylosis, the occurrence is to be looked upon as a very favourable one. In fact, it is as much a means of cure, as the formation of callus is for the union of broken bones. The disease of the vertebræ,

described by Pott, is cured as soon as the bones ankylose, nor can the patient be considered well, before this event has taken place. *W.H. Maller de Anchylosi*, Lugd. 1707. *L'Encyclopédie Méthodique, Partie Chirurgicale*, Tom. 1. art. *Anchylose*. *J. L. Petit, Traité des Mal. d'Os*. T. 2. *J. Chir.* T. 3. p. 223, edit. 4.

* ANEURISM, or ANEURYSM, (from *aneurysma*, to dilate.) The tumours which are formed by a preternatural dilatation of a part of an artery, as well as those swellings, which are occasioned by a collection of arterial blood, effused in the cellular membrane, in consequence of a rupture, or wound of the coats of the artery, receive the name of aneurisms. According to these opinions, aneurisms are of two kinds; the first being termed *true*, the second *spurious*, or *false*. Some modern writers have ventured to reckon another form of aneurism, which is said to happen, when the external coats of an artery being weakened by mechanical injury, or disease, the internal coat protrudes through the breach in the outer coat, so as to form a tumour distended with blood. This case has been denominated the *internal mixed aneurisms*, or *aneurisma herniam arteriæ sistens*. The reality of this form of disease was believed by Dr. W. Hunter; and some delicate experiments, instituted by Haller on the mesenteric arteries of frogs, appear to have been the first ground of the opinion. Such an aneurism, however, has not been universally admitted, not that any body doubted the correctness of what Haller advanced, but because there might not always be a perfect analogy between the results of an experiment on animals, and those afforded by the observation of the diseases of the human body.

When Haller asserted, that, by separating the muscular from the inner coat of the arteries, he could, when he pleased, produce an aneurism in these animals; and when Hunter declared, that such an experiment made the artery firmer than ever, in consequence of the adhesive inflammation taking place; the character and veracity of these eminent men naturally lead to the question, whether the experiments were conducted exactly in the same manner. Now, says Mr. Wilson, when we know, that Haller did not suffer the surrounding parts to unite, and that John Hunter did, we can no longer be at a loss to account for the different conclusions. (See *Wilson's Anatomy, Pathology, &c. of the Vascular System*, p. 378.)

However this may be with respect to the experiments made on certain animals, I am disposed to consider it fully proved by Mr. J. Hunter, Sir. E. Home, and Professor Scarpa, that in the human subject, an aneurism will not arise from the kind of weakness, which is caused by cutting or even stripping off the external coat of a sound artery, whether the wound be closed or not.

This fact would at least appear to be well established, with respect to the generality of the arteries; but, how far it is in relation to the aorta, is another question, the inner membrane of which vessel is alleged to be more elastic than that of common arteries. Dubois and Dupuytren, in fact, are stated to have presented to the Faculty of Medicine at Paris preparations, which exhibit the lining of the aorta protruding through the middle coat, in form of a sac filled with blood. (See *Dict. des Sciences Méd. art. Aneurisme*, and *Breschet in Trans. of Mr. Hodgson's work*, p. 130.)

By the term *mixed aneurism*, Dr. A. Monro, senior, implied the state of a true aneurism, when its cyst had burst, and the blood was diffused in the adjacent cellular substance; an event which is frequent. Besides these varieties of aneurism, the *aneurismal varix*, or *venous aneurism*, and the *aneurism from anastomosis*, constitute diseases which are usually regarded as cases pertaining to the present subject, though incapable of being comprised under the ordinary definition of an aneurism.

Nothing can be more manifest, than the fact, that, previously to the discovery of the circulation of the blood, no correct, nor valuable opinions could have prevailed, respecting the diseases, which now go under the name of aneurisms. Indeed, it was not until after the days of Aristotle, that any distinction was made between the swellings of veins and those of arteries, such vessels not having been at that early period distinguished from each other. Their differences were first pointed out by Rufus of Ephesus. (*Et. Tertab. 4, Serm. 2. c. 51, col. 716.*)

Down to Galen, however, nothing like consistency was established in the notions respecting aneurism. His opinion was, that all tumours of this nature were produced either

by anastomosis, or by rupture, and though he has described their symptoms, he has not informed us of the characters by which each of these cases was distinguishable, one from the other. Paulus Aegineta divides aneurism into two sorts, both of which he says are attended with extravasation, and of course with rupture.

Vesalius, who first applied anatomy to the investigation of disease, has described an aneurism arising from the rupture of a dilated aorta; the first specimen, I believe, on record of this form of disease. (*Bontus Sepulch. Anat. lib. 4. Sect. 2.*)

The combination of rupture with dilatation of the artery, was afterwards more particularly noticed by Nuck. (*Oper. Chir. &c. Lugd. 1692.*)

It was Fernelius who first promulgated the doctrine, that aneurisms were always dilated arteries. (*Univ. Medicina, De Extern. Corp. Affect. lib. 7. cap. 3, Vend. 1564.*)

This opinion was espoused by Forrestus, Diemerbroeck, and others; but at length, the inaccuracy of attempting to refer every aneurism solely to dilatation of the coats of the vessel, was established by the observations of Lancisi, Friend, Guattani, and Morgagni. In short, as Mr. Hodgson has stated, these authors proved, that aneurism may be produced either by the rupture, or the dilatation of the coats of an artery, or by a combination of both circumstances, the dilatation having preceded the rupture. (*On the Diseases of Arteries, &c. 8vo. Lond. 1815.*)

This admission of aneurism by dilatation, and of aneurism by rupture of the coats of an artery, together with the frequent combination of both circumstances, was indeed the prevailing undisturbed doctrine of every surgical school, until Professor Scarpa, inclining to the tenets of Sylvaticus (*De Aneurymate. Tract. Venetiis, 1600, 4to.*) ventured to question the correctness of the common opinion about the dilatation of all the arterial coats. However, after the very clear and satisfactory elucidation of this disputed point by my friend Mr. Hodgson, the accurate views of the first subject, taken by Morgagni, and the other eminent writers specified above, may be regarded as established beyond the possibility of dispute. At the same time, it is not to be supposed, that Scarpa means to say, that the arteries are not subject to a morbid dilatation; on the contrary, he gives a particular description of this affection, which he carefully discriminates from aneurism.

Previously to offering a more particular account of the doctrine taught by Scarpa, respecting the formation of aneurism, as well as of the chief facts, which may be adduced against a part of such doctrine, it seems proper to make the reader acquainted with the various species of the disease, their ordinary symptoms, and a few other circumstances.

When any part of an artery is dilated, (st-

tended with particular circumstances, marking its difference from another form of dilatation, which, as I shall explain, perhaps ought not to be set down as aneurismal,) the swelling is commonly named a *true*, or *genuine aneurism*. In such cases, the artery is either enlarged at only a small part of its track, and the tumour has a determinate border, or the vessel is dilated for a considerable length, in which circumstance the swelling is oblong, and loses itself so gradually in the surrounding parts, that its margin cannot be exactly ascertained. The first case, which is the most common, is termed the *circumscribed true aneurism*; the last, the *diffused true aneurism*; a case, however, which would be looked upon by Scarpa only as a specimen of dilatation, different in several particulars from aneurism, as will be hereafter noticed. When blood escapes from a wound, or rupture, of an artery, into the adjoining cellular substance, the swelling is denominated the *spurious*, or *false aneurism*. In this instance, the blood either collects in one mass, distends the cellular substance, and condenses it into a cyst, so as to form a distinctly circumscribed tumour; or it is injected into all the cavities of the surrounding cellular substance, and extends along the course of the great vessels, from one end of the limb to the other, thus producing an irregular, oblong swelling. The first case is named the *circumscribed false aneurism*; the second, the *diffused false aneurism*. (*Richter's Anfangsgr. B. 1.*)

These appellations are in my opinion preferable to the term *cylindrical*, applied by Sauvages to true aneurisms, or *sacciform*, proposed by Morgagni for false aneurisms. (*Advers. Anat. 2, Aortæ Animadv. 38, et Epist. Anat. 17, No. 27.*) Because, as we shall see in the course of this article, though true aneurisms (including dilatations of all the arterial coats of every kind,) do mostly affect the whole circumference of the vessel, and must therefore partake of a cylindrical shape, there are exceptions, in which a distinct circumscribed sac, composed of all the coats of the vessel, projects from one side of an artery, the diameter of which may not be at all increased. Here the disease might rather be named *sacciform*, the very appellation suggested by Morgagni for false aneurisms, in which the disease generally originates in this shape, from whatever particular side of the vessel the inner coats have given way. We see also that the subject actually demands more numerous distinctions, since aneurisms undergo in their progress various changes, which sometimes make an immense, and even a very sudden difference in their shape, cases which were at first circumscribed, afterwards becoming diffused.

The symptoms of the circumscribed true aneurism take place as follows: The first thing the patient perceives is an extraordinary throbbing in some particular situation, and, on paying a little more attention, he discovers there a small pulsating tumour,

which entirely disappears when compressed, but returns again as soon as the pressure is removed. It is commonly unattended with pain, or change in the colour of the skin. When once the tumour has originated, it continually grows larger, and, at length, attains a very considerable size. In proportion as it becomes larger, its pulsations become weaker, and, indeed, they are almost quite lost, when the disease has acquired much magnitude. The diminution of the pulsation has been ascribed to the coats of the artery losing their dilatable and elastic quality, in proportion as they are distended and indurated, and, consequently, the aneurismal sac being no longer capable of an alternate diastole and systole from the action of the heart. The fact is also imputed to the lamellated coagulated blood, deposited on the inner surface of the sac, particularly in large aneurisms, in which some of the blood is always interrupted in its motion. Immediately, such coagulated blood lodges in the sac, pressure can only produce a partial disappearance of the swelling. This deposition of lamellated coagulum in the aneurismal sac is a circumstance of considerable importance; for, it has been well explained by Mr. Hodgson, that it is the mode by which the spontaneous cure of the disease is in most instances effected. "One of the circumstances, which, in the most early stage, generally attend the formation of aneurism (says this author,) is the establishment of that process, which is the basis of its future cure. The blood, which enters the sac soon after its formation, generally leaves upon its internal surface a stratum of coagulum, and successive depositions of the fibrous part of the blood gradually diminish the cavity of the tumour. At length the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery, which supplies the disease, forming a firm plug of coagulum, which extends on both sides of the sac to the next important ramifications that are given off from the artery. The circulation through the vessel is thus prevented, the blood is conveyed by collateral channels, and another process is instituted, whereby the bulk of the tumour is removed, &c." (*On the Diseases of Arteries, &c. p. 114.*) Whether there is any truth in Kreysig's conjecture, that some of the lymph may exude from the inside of the sac itself, I cannot pretend to say. He owns, however, that the inner concentric layers presenting the appearance of being deposited last, is a circumstance rather against his surmise, though he adverts to some other circumstances which incline him to look upon the opinion as possibly correct. (*German Transl. of Mr. Hodgson's Work, p. 124.*)

In a preceding paragraph, I have spoken of the diastole and systole of the aneurismal sac; for, it is the general belief, that the pulsation of the tumour is produced by the jet of blood into it at each stroke of the heart. This opinion, however, is disputed by an eminent writer, who asks, Is it

true, that the pulsation of aneurisms proceeds from the entrance of a more considerable stream of blood into the sac, and the distention of the swelling thereby produced? In aneurisms, which have only a narrow communication with the arterial tube, or which are filled with laminated coagula, the idea, says he, is quite inadmissible: the aneurism is rather shaken, as it were, like other different swellings in the vicinity of an artery, by the stroke of the heart occasioning a stretching of the whole arterial system, and at the same time communicating an impulse to the column of blood. (*Kreysig, Germ. Tr. of Mr. Hodgson's Work*, p. 143.) Here, however, I am by no means disposed to coincide with this distinguished physician, whose sentiments appear to me to be refuted by the fact, that, whenever any change happens, calculated to lessen or entirely stop the influx of blood into the sac, the pulsation either diminishes, or ceases in proportion. Thus, when Kreysig adverted to the pulsation of aneurisms, in which much coagulated blood was deposited, he might at the same time have mentioned the effect, which such deposition has in weakening the pulsation, the layers of coagulated blood within the tumour being in the natural mode of cure, as Mr. Hodgson has correctly explained, "the means by which the force of the circulation is removed from the sac, and the fatal termination of the disease by rupture is prevented." (*On Diseases of Art. and Veins*, p. 126.) In proportion as the aneurismal sac grows larger, the communication of blood into the artery beyond the tumour is lessened. Hence, in this state, the pulse, below the swelling, becomes weak and small, and the limb frequently cold, and œdematous. On dissection, the lower continuation of the artery is found preternaturally small and contracted. The pressure of the tumour on the adjacent parts may also produce a variety of symptoms, ulceration, caries, &c. Sometimes (says Richter,) an accidental contusion, or concussion, may detach a piece of coagulum from the inner surface of the cyst, and the circulation through the sac be obstructed by it: nay, he asserts, that the coagulum may possibly be impelled quite into the artery below, so as to induce important changes. The danger of an aneurism arrives when it is on the point of bursting, by which occurrence the patient usually bleeds to death, and this sometimes in a few seconds. The fatal event may generally be foreseen, as the part about to give way becomes particularly tense, elevated, thin, soft, and of a dark purple colour. (*Richter's Anfangsgr. Band. I.*)

A large axillary aneurism, which burst in St. Bartholomew's Hospital some years ago, did not burst by ulceration, but, by the detachment of a small slough from a conical, discoloured part of the tumour; and soon after this case fell under my observation, I had an opportunity of seeing the process, by which an inguinal aneurism burst: at a certain point, the tumour became more con-

cal, thin, and inflamed, and here a slough, about an inch in width, was formed. On the dead part becoming loose, a profuse bleeding began, which was stopped for a short time by pressure, but soon returned with increasing violence, and put an end to the patient's misery. We are then to conclude, that external aneurisms do not burst by ulceration, but by the formation and detachment of a slough. I believe this is a fact, which was first particularly pointed out in the early editions of my work, and it gives me pleasure to find, that it is a statement which entirely coincides with that subsequently made by several writers of eminence, especially Mr. A. Burns (*On Diseases of the Heart*, p. 225,) and Boyer (*Traité des Maladies Chirurgicales*, T. 2, p. 98.)

As far as my information extends, Mr. A. Burns first explained the very different mode of rupture which happens in internal aneurisms; these, he observed, generally burst by actual laceration, and not by sphacelation of the cyst. (*On Diseases of the Heart*, p. 225.) But a still more particular account of the process, by which external and internal aneurisms burst, is delivered by Mr. Hodgson. When the sac points externally, (says this gentleman,) it rarely or never bursts by laceration, but the extreme distention causes the integuments and investing parts to slough, and upon the separation of the eschar, the blood issues from the tumour. A similar process takes place, when the disease extends into a cavity, which is lined by a mucous membrane, as the œsophagus, intestines, bladder, &c. In such cases, the cavity of the aneurism is generally exposed by the separation of a slough, which has formed upon its most distended part, and not by laceration. But, when the sac projects into a cavity lined by a serous membrane, as the pleura, the peritoneum, the pericardium, &c. sloughing of these membranes does not take place, but, the parietes of the tumour having become extremely thin in consequence of distention, at length burst by a crack, or fissure, through which the blood is discharged. (*On the Diseases of Arteries*, &c. p. 85.)

When the aneurism is of considerable size, the collateral arteries, which originate above the swelling, are manifestly enlarged. Boyer informs us, that, in dissecting the lower extremity of a patient, on whom Desault had operated eight months previously for a popliteal aneurism, he found in the substance of the great sciatic nerve an artery, whose diameter was equal to that of the radial at the wrist. This vessel had its origin from the ischiatic artery, and descended to the back part of the knee, where it anastomosed with the upper articular arteries. Boyer had also noticed in the same subject before the operation, that one of the branches of the upper internal articular artery was so much enlarged, that its pulsation could be plainly felt on the internal condyle of the thigh-bone. (*Op. cit.* p. 93.) It is such enlargement of the collateral arteries above the disease, which es-

tures to the limb below the tumour an adequate supply of blood when the obstruction to its passage through the diseased artery becomes considerable, or when this vessel has been rendered totally impervious by a surgical operation performed for the cure of the complaint.

In the advanced stage of an aneurism, the skin is found extremely thin, and confounded, as it were, with the aneurismal sac. The cavities of the cellular substance near the disease are either filled with serum or totally obliterated by adhesion. The adjacent muscles, whether they lie over the aneurism, or to one side of it, are stretched, displaced, dwindled, and sometimes confounded with other parts. It is the same with the large nervous cords situated at the circumference of the tumour: they are pushed out of their natural situation, diminished in size, sometimes adherent to the outside of the sac, and so changed as scarcely to admit of being known again. Lastly, the cartilages and the bones themselves are not exempt from the mischief which the aneurismal swelling produces in all the surrounding parts: they are gradually destroyed, and, at length, not the least trace of their substance remains, just in the same way as the bones of the cranium are destroyed by fungous tumours of the dura mater. (See *Dura Mater*.) Even the cartilages of the larynx, and rings of the trachea, are sometimes destroyed; this tube is pierced, and the blood escapes into it, or the aneurism bursts into the œsophagus. (Boyer, *Traité des Maladies Chirurgicales*, T. 2, l. 99.) As I shall hereafter explain, however, the pressure of an aneurismal tumour more quickly produces an absorption of bone, than of cartilage.

While an aneurism is small and recent, it does not generally cause much pain, nor seriously impede the functions of the limb. But, when it has increased, several complications are produced. Thus, the dragging of the saphenous nerve, by femoral aneurisms, frequently occasions acute pain in the course of this nerve as far as the great toe. The distention of the sciatic nerve by the popliteal aneurism, sometimes brings on intolerable pain, which extends to all the parts to which this nerve is distributed, and which can hardly ever be appeased by the topical use of opiate applications. The compression of the veins and lymphatics gives rise to œdema, numbness, and coldness of the limb. And, finally, the long-continued pressure of the aneurism on the neighbouring bones causes their destruction. (Boyer, p. 105, T. 2.)

In cases of true aneurism, the coats of the artery are not always in the same state, the kind of changes observed depending upon the progress of the tumour. In the early stage of the disease, either the whole cylinder of the vessel, or only a part of its circumference, is dilated; but, this period is generally of short duration, especially in arteries of middling size, because their middle coat is capable of less resistance, than

that of the larger arteries, like the aorta, where this coat is yellowish, firm, and very elastic. As Breschet remarks, this difference of resistance in the middle coat of the aorta, and the branches given off from it, accounts for the rarity of true aneurisms either in the small arteries, or those of middling size, and their greater frequency in the principal trunk of the arterial system.

At length, in consequence of the increasing distention, some of the coats of the artery, possessing the least elasticity, give way, and these are found to be the internal and middle coats, while the external one still makes resistance, and continues to be more and more dilated by the lateral impulse of the blood.

The second stage of true aneurism, is that which is mostly met with, that, in which the tumour increases more rapidly, and therefore begins to excite greater attention. The disease, when it has attained this form, is in point of fact no longer a true aneurism; but a case which Monro distinguished by the name of the *consecutive*, or *external mixed false aneurism*. In this stage, the patient's life is endangered, and death often brought on by the rupture of the tumour. Examinations of the dead subject, under these circumstances, have frequently led to mistaken notions, and, doubtless, if various swellings of this kind had not been found in different degrees, or stages, in the same individual, one might be disposed to join Scarpa in the belief, that no aneurism consists of dilatation of all the arterial coats. (Breschet, *Fr. Transl. of Mr. Hodgson's work*, p. 128, 129.)

The *false aneurism* is always attended with at least a rupture, or giving way of the inner coat of the vessel, and usually with a breach in both this and the muscular coat, the outer elastic tunic forming the pouch in which the blood collects. But, after the swelling has attained a certain size, this coat also bursts, and then the blood either becomes diffused, or a large circumscribed space is formed for it by the condensation of the surrounding cellular membrane. False aneurisms, when produced by a wound, or puncture, are of course from the first attended with a division of all the coats of the vessel. This form of the disease is often seen at the bend of the arm, where the artery is exposed to injury in venesection. (See *Hæmorrhage*.) In this circumstance, as soon as the puncture is made, the blood gushes out with unusual force, and in a bright scarlet, irregular, interrupted current; flowing out, however, in an even, and less rapid stream, when pressure is applied higher up, than the wound. These last are the most decisive marks of the artery being opened; for blood may issue from a vein with great rapidity, and in a broken current, when the vessel is turgid, and situated immediately over the artery, which imparts its motion to it. The surgeon endeavours precipitately to stop the hæmorrhage by pressure, and in general a *diffused false aneurism* is the result. The external wound

in the skin is closed, so that the blood cannot escape; but, this does not hinder it from passing into the cellular substance. The swelling, thus produced, is uneven, often knotty, and extends upward and downward along the track of the vessel. The skin is also usually of a dark purple colour. Its size increases, as long as the internal hemorrhage continues, and, if this should proceed beyond certain bounds, mortification of the limb ensues. Such is the *diffused false aneurism* from a wound.

The *circumscribed false aneurism*, from a wound, or puncture, arises in the following manner. When proper pressure has been made in the first instance, so as to suppress the hemorrhage; but, the bandage has afterwards been removed too soon, or before the artery has healed, the blood passes through the unclosed wound, or that which it has burst open again, into the cellular substance. As this has now become agglutinated by the preceding pressure, the blood cannot diffuse itself into its cells, and, consequently, a mass of it collects in the vicinity of the aperture of the artery, and distends the cellular substance into the form of a sac. Sometimes, though not often, this circumscribed false aneurism, originates immediately after the opening is made in the artery. This chiefly happens when the aperture in the vessel is exceedingly small, and, consequently, when the hemorrhage takes place so slowly, that the blood, which is first diffused, coagulates, and prevents the entrance of that which follows into the cavities of the cellular substance, and of course, its diffusion. False aneurisms, proceeding from the rupture of the inner coats of an artery, are always at first circumscribed by the resistance of the outer tunic.

The circumscribed false aneurism consists of a sac, composed of the external coat of the artery, or, in case this has given way, it is composed of an artificial pouch, formed among whatever parts happen to be in the vicinity of the burst artery. This cavity is filled with blood, and situated close to the artery, with which it has a communication. Hence, in false aneurisms, a throbbing is always perceptible, and is more manifest, the smaller such tumours are. The larger the sac becomes, the less elastic it is, and the greater is the quantity of laminated coagula in it; so that in very large aneurisms of this kind, the pulsation is sometimes wholly lost.

The tumour is at first small, and on compression entirely disappears; but, returns as soon as this is removed. It also diminishes, when the artery above it is compressed, but, resumes its wonted magnitude, immediately such pressure is discontinued. When there is coagulated blood in the sac, pressure is no longer capable of producing a total disappearance of the tumour, which is now hard. The swelling is not painful, and the integuments are not changed in colour. It continually increases in size, and, at length, attains a prodigious magnitude.

The following are generally enumerated,

as the discriminating differences between circumscribed true and false aneurisms: the true aneurism readily yields to pressure, and as readily recurs on its removal; the false one yields very gradually, and returns in the same way; and, as it contains laminated coagula, it cannot be reduced in the same degree by compression, as an aneurism formed by a dilatation of the arterial coats, where such strata of coagulated blood are usually absent. Frequently, a hissing sound is audible, when the blood gushes into the sac. The pulsation of the false aneurism is always more feeble, and, as the tumour enlarges, is sooner lost, than that of the true one, which throbs after it has acquired a considerable volume. (See *Richter's Anfanggr.* B. 1.)

FORMATION OF ANEURISMS.

If the doctrines of Scarpa, published in 1804, had proved correct, the grand distinction of aneurism into *true* and *false* must have been rejected, as erroneous: "for," says he "after a very considerable number of investigations, instituted on the bodies of those who have died of internal, or external aneurisms, I have ascertained, in the most certain and unequivocal manner, that there is only one kind, or form of this disease; viz. that caused by a solution of continuity, or rupture of the proper coats of the artery, with effusion of blood into the surrounding cellular substance: which solution of continuity is occasioned sometimes by a wound, a steatomatous, earthy degeneration, a corroding ulcer, or a rupture of the proper coats of the artery, I mean the internal and muscular, without the concurrence of a preternatural dilatation of these coats being essential to the formation of this disease; and, therefore, that every aneurism, whether it be internal, or external, circumscribed, or diffused, is always formed by effusion." (*Treatise on Aneurism; Transl. by Wishart, Pref.*)

According to Scarpa, it is an error to suppose, that the aneurism at the curvature, or in the trunk of the aorta, produced by a violent and sudden exertion of the whole body, or of the heart in particular, and preceded by a congenital relaxation of a certain portion of this artery, or a morbid weakness of its coats, ought always to be considered, as a tumour formed by the distention, or dilatation of the proper coats of the artery itself, that is, of its internal and fibrous coats. Scarpa considers it quite demonstrable, that such aneurisms are produced by a corrosion and rupture of these tunics, and, consequently, by the effusion of arterial blood under the cellular sheath, or other membrane, covering the vessel. If ever there be a certain degree of preceding dilatation, it is not essential to constitute the disease: for it is not a constant occurrence, most aneurisms are unpreceded by it, and, in those rare cases, in which an aneurism is preceded and accompanied with a certain degree of dilatation of the whole diameter

of the curvature of the aorta, there is an evident difference between an artery simply enlarged in diameter, and the pouch, which forms an aneurismal sac.

Careful dissections, says Scarpa, will prove, that the aorta contributes nothing to the formation of the aneurismal sac and that this is merely the cellular membrane, which, in the sound state, covered the artery, or that soft cellular sheath, which the artery received in common with the neighbouring parts. This is raised by the blood into the form of a tumour, and is covered, in common with the artery, by a smooth membrane.

This eminent professor does not deny, that, from congenital relaxation, the proper coats of the aorta may occasionally yield and become disposed to rupture; but, he will not admit, that dilatation of this artery precedes and accompanies all its aneurisms, or that its proper coats ever yield so much to distention, as to form the aneurismal sac. *The root of an aneurism of the aorta never includes the whole circumference of the artery;* but the aneurismal sac arises from one side in the form of an appendix, or tuberosity. On the contrary, the dilatation of the artery always extends to its whole circumference, and, therefore, differs essentially from aneurism. Thus, he urges, that there is a remarkable difference between a dilated and an aneurismatic artery, although *these two affections are sometimes found combined together*, especially at the origin of the aorta. If we also consider that the dilatation of an artery may exist, without any organic affection, the blood being always in the cavity of the vessel: that in an artery so affected, there is never collected any grumous blood, or polypous layers; that the dilatation never forms a tumour of considerable bulk; and, that while the continuity of the proper coats remains uninterrupted, the circulation of the blood is not at all, or not so sensibly changed, we shall be obliged to allow, that aneurism differs essentially from one kind of dilatation of an artery.

Some additional remarks on this topic, more recently published by Scarpa, will be presently considered.

By dissections of arteries, both in the sound and morbid state, Scarpa endeavours to demonstrate what share the proper and constituent coats of the artery have in the formation of the aneurismal sac, and what belongs to the cellular covering, and other adventitious membranes surrounding the artery.

The covering of an artery is merely an adventitious sheath, which the vessel receives in common with the parts in the vicinity of which it runs. On cutting an artery across in its natural situation, the segment of the cut vessel retires and conceals itself in this sheath.

This cellular covering is most evident round the curvature and trunk of the aorta, the carotid, mesenteric, and renal arteries; it is less dense round the trunks of the brachial, femoral, and popliteal arteries. The pleura lies over the cellular sheath of the

arch of the aorta, and over that of the thoracic aorta; while that of the abdominal aorta is covered by the peritoneum. Both these smooth membranes adhere to, and surround, two-thirds of the circumference of the vessel. The great arteries of the extremities are not covered, in addition to the cellular substance, by any smooth membrane of this sort, but by a cellular sheath, which is demonstrably distinct from the adipose membrane, and serves to inclose the vessels, and connect them with the contiguous parts.

When air, or any other fluid, is injected by a small hole made artificially, between the cellular covering, and the subjacent muscular coat of the artery, the injected matter elevates into a tumour the cellular membrane, which closely embraces the artery, without properly destroying its cells, which it distends in a remarkable manner. When melted wax is injected, and pushed with much force, the cellular sheath of the artery is not only raised over the vessel, like a tumour, but, the internal cells of that covering are also lacerated, and, on examining afterwards the capsule of the artificial tumour, it appears as if it were formed of several layers, rough and irregular internally, smooth and polished externally. The same thing happens when any injection is pushed with such force into an artery, as to rupture the internal and muscular coats at some point of their circumference. Nicholls performed this experiment several times before the Royal Society. (*Philos. Trans. an. 1728.*) As soon as the internal coat is ruptured, the muscular one also gives way; but, the external cellular sheath, being of an interlaced texture, and the thin laminae, of which it is composed, being not simply applied to one another, but, reciprocally intermixed, is capable of supporting great distention, by yielding gradually to the impulse of the blood, without being torn, or ruptured.

Scarpa is farther of opinion, that the same phenomena may be observed, when the internal coat of the aorta becomes so diseased, as to be ruptured by the repeated jets of blood from the heart. In this circumstance, the blood, impelled by the heart, begins immediately to ooze through the connexions of the fibres of the muscular coat, and gradually to be effused into the interstices of the cellular covering, forming, for a certain extent, a kind of *ecchymosis*, or *extravasation of blood*, slightly elevated upon the artery. Afterwards, the points of contact, between the edges of the fibres of the muscular coat, being insensibly separated, the arterial blood, penetrating between them, fills and elevates, in a remarkable manner, the cellular covering of the artery, and raises it after the manner of an incipient tumour. Thus, the fibres and layers of the muscular coat being wasted or lacerated, or simply separated from each other, the arterial blood is carried with great force, and in greater quantity than before, into the cellular sheath of the artery,

which it forces more outwards; and, finally, the divisions between the interstices of the cellular coat, being ruptured, it is converted into a sac, which is filled with polypous concretions, and fluid blood, and at last forms, strictly speaking, the aneurismal sac. The internal texture, although apparently composed of membranes placed one over the other, is, in fact, very different from that of the proper coats of the artery, notwithstanding the injured vessel and aneurismal sac are both covered externally, in the thorax and abdomen, with a smooth membrane.

Scarpa has examined a considerable number of aneurisms, of the arch, and of the thoracic, and abdominal trunk, of the aorta, without finding a single one, in which the rupture of the proper coats of the artery was not evident, and in which, consequently, the sac was produced by a substance completely different from the internal and muscular coats.

The aneurismal sac never comprehends the whole circumference of the vessel. At the place where the tumour joins the side of the tube, the aneurismal sac presents a kind of constriction, beyond which it becomes more or less expanded. This would never happen, or rather the contrary circumstance would occur, if the sac were formed by an equable distention of the tube and proper coats of the affected artery. In incipient aneurisms at least, the greatest size of the tumour would then be in the artery itself, or root of the swelling, while its fundus would be the least. But, *whether aneurisms be recent and small, or of long standing and large, the passage from the artery is always narrow, and the fundus of the swelling greater in proportion to its distance from the vessel.* The sac is always covered by the same soft dilatable cellular substance, which united the artery in a sound state to the circumjacent parts. Such cellular substance, in aneurisms of the thoracic aorta, is covered by the pleura, and, in those of the abdominal aorta, by the peritoneum, which membranes include the sac and ruptured artery, presenting outwardly a continued smooth surface, just as if the artery itself were dilated. But, if the aorta be opened lengthwise on the side opposite the constriction, or neck of the tumour, the place of the ulceration, or rupture, of the proper coats of the artery, immediately appears within the vessel on the side opposite to that of the incision. The edge of the fissure, which has taken place, is sometimes fringed, often callous, and hard, and through it it was, that the blood formed itself a passage into the cellular sheath, which is converted into the aneurismal sac. If, as sometimes happens in the arch of the aorta near the heart, the artery, before being ruptured, has been somewhat dilated, it seems, at first, as if there were two aneurisms; but, the constriction, which the sac next to the artery, presents externally, points out exactly the limits, beyond which the internal and muscular coats of the aorta had not been able to resist the distention, and where of course they have been ruptured.

The partition, which may always be seen dividing the tube of the artery from the aneurismal sac, and which is lacerated in its middle, consists of nothing else than the remains of the internal and muscular coats of the ruptured artery.

By carefully dissecting the proper coats of the ruptured aorta in its situation, and comparing them with the cellular substance forming the sac, Scarpa affirms, that the truth of the preceding statement may be indisputably demonstrated.

When an incision is made lengthwise in the side of the vessel opposite the rupture, its proper coats are found either perfectly sound, or a little weakened and studded with earthy points, but still capable of being separated into distinct layers. On the contrary, in the opposite side of the aorta, where the rupture is, the proper coats are unusually thin, and are only separable from each other with difficulty, or even not at all; they are frequently brittle, like an egg-shell, and are disorganized and torn at the place where they form the partition between the ruptured artery and the mouth of the aneurismal sac. Continuing to separate these coats, from within outwards, we arrive at the cellular sheath surrounding the aorta. This sheath being much thickened in large aneurisms, and very adherent to the subjacent muscular coat of the artery at the place of the constriction of the sac, is very apt to be mistaken for a dilated portion of the vessel itself. But, even in such cases, we may at last separate it, without laceration, from the tube of the artery, above and below the injury, and, successively from the muscular coat, as far as the neck of the aneurism. Then it is clear, the muscular coat does not pass beyond the partition, separating the cavity of the artery from that of the aneurismal sac, over which it is not prolonged, but terminates at the edge of the rupture like a fringe, or in obtuse points. Errors are more apt to occur in consequence of the aorta and sac being both covered by the pleura, or peritoneum.

The portion of the aorta, within the pericardium, being only covered by a thin reflected layer of this membrane, such layer may also be lacerated, when the proper coats give way, and blood be effused into the cavity of the pericardium. Examples of this kind are related by Walter, Morgagni, and Scarpa himself. In the latter instance, on making an incision into the concave part of the aorta, opposite the tumour which had formed under the layer of the pericardium, which had also burst by a small aperture, its internal coat, corresponding to the base of the swelling, was quite rough, interspersed with yellow hard spots, and actually ulcerated for the space of an inch in circumference. The preparation is preserved in the museum at Pavia.

But, all other parts of the aorta having, between them and the pleura and peritoneum, a cellular sheath of a stronger and more yielding nature, which allows itself to be distended into a sac, and being strength-

ened internally, by polypous layers, and, externally, by the pleura or peritoneum, oppose for a long while the fatal effusion of blood.

Scarpa believes, that what he calls the slow, morbid, steatomatous, fungous, squamous, degeneration of the internal coat of the artery, is more frequently the cause of its bursting, than violent exertions of the whole body, blows, or an increased impulse of the heart. This kind of diseased change is very common in the curvature, and thoracic and abdominal trunks, of the aorta. In the incipient state of such disease, the internal coat of the artery loses, for a certain space, its beautiful smoothness, and becomes irregular and wrinkled. It afterwards appears interspersed with yellow spots, which are converted into grains, or earthy scales, or into steatomatous, and cheese-like concretions, which render the internal coat of the artery brittle, and so slightly united to the adjoining muscular coat, that, upon being merely scratched with the knife, or point of the nail, pieces are readily detached from it, and, on being cut, it gives a crackling sound, similar to the breaking of an egg-shell. This ossification cannot be said to be proper to old age, since it is sometimes met with in subjects not much advanced in life. The whole of the side of the artery, in that part which is occupied by the morbid affection, is, for the most part, hard and rigid, sometimes soft and fungous, and, in most cases, the canal of the artery is preternaturally constricted. In the highest degree of this morbid disorganization, true ulcerations are found on the inside of the artery, with hard and fringed edges, fissures, and lacerations of the internal and fibrous coats of the artery.

Having presented the reader with an abridged account of the most important remarks made by Scarpa, in support of the doctrine he defends, I now annex his conclusions. 1. That this disease is invariably formed by the rupture of the proper coats of the artery. 2. That the aneurismal sac is never formed by a dilatation of the proper coats of the artery, but, undoubtedly, by the cellular sheath, which the artery receives in common with the parts contiguous to it; over which cellular sheath the pleura is placed in the thorax, and the peritoneum in the abdomen. 3. That if the aorta, immediately above the heart, appears sometimes increased beyond its natural diameter, this is not common to all the rest of the artery, and when the aorta, in the vicinity of the heart, yields to a dilatation greater than natural, this dilatation does not constitute, properly speaking, the essence of the aneurism. 4. That there are none of those marks regarded by medical men as characteristic of aneurism from dilatation, which may not be met with in aneurism from rupture, including even the circumscribed figure of the tumour. 5. That the distinction of aneurism into *true* and *spurious*, adopted in the schools, is only the production of a false theory; since observation shows, that there is only one form of

the disease, or that caused by a rupture of the proper coats of the artery, and an effusion of arterial blood into the cellular sheath, which surrounds the ruptured artery. (See *Treatise on Aneurism*, by A. Scarpa, trans. by J. H. Wishart, Edin. 1808.)

Such were the inferences made by Scarpa, in 1804, one of the most distinguished anatomists and surgeons of the present day upon the continent. It has been already stated, that great as this authority is, several eminent modern surgeons, as Richerand, Boyer, Dubois, Dupuytren, Sabatier, Breschet, &c. did not yield to it, but still contended that in some aneurisms, the coats of the artery were dilated. These professors in France coincided with what has been usually taught upon this subject in the surgical schools of Great Britain. Every lecturer here has been accustomed to describe the distinctions of aneurisms into true and false, or into some cases which are accompanied with dilatation, and into others, which are attended with rupture of the arterial coats. A few years ago, Mr. Hodgson, of Birmingham, published a valuable treatise on aneurism, in which work he differs from Scarpa, and joins those surgical writers who believe in the occasional dilatation of the coats of the arteries in this disease. He inquires: "Is every aneurism produced by a destruction of the internal and middle coats of the vessel, and does not a partial dilatation of these coats occasionally precede, and give rise to their destruction; I believe that this is frequently the case. We have seen that the disorganization of the coats of an artery, by destroying their natural elasticity, will give rise to permanent dilatation of the whole circumference of the vessel; and there is every reason to expect, that a loss of its elasticity in a portion only of the diameter of the vessel will give rise to a partial dilatation of its coats. Indeed, the proofs of a partial dilatation of the coats of an artery, particularly of the aorta, are incontestably established by the possibility of tracing the coats of the vessel throughout the whole extent of the expansion, and by the existence of those morbid appearances in the sac, which are peculiar to the coats of the arteries.

"In the year 1811, (says Mr. Hodgson,) I dissected an aneurism of the aorta, which was removed from the body of a young woman by my friend Dr. Farre. The sac was as large as a small melon, and had proved fatal by bursting into the posterior mediastinum, and subsequently into the cavity of the thorax. This aorta exhibited the formation of aneurism by partial dilatation in three distinct stages. The internal coat was throughout inflamed, and presented a fleshy and irregular appearance. At the arch of the aorta, there was a dilatation not larger than the half of a small pea. About two inches lower in the same vessel, was a second dilatation, which would have contained a hazel nut, and immediately above the diaphragm was the large aneurism, which had proved fatal. I removed that

portion of the vessel, which contained the smallest dilatation, and macerated it until its coats could be separated without violence. I found that the dilatation existed equally in the three coats of the vessel, and, when separated, each presented the appearance of a minute aneurism. The second dilatation exhibited the same circumstances in a more advanced stage. The coats of the vessels were more intimately adherent to each other, than in a natural state, but, it was evident, that the dilatation consisted in a dilatation of the internal, the middle, and the external coats of the aorta. In the large aneurism, the disorganized internal and middle coats could be traced for some distance into the sac, when the parts contained in the posterior mediastinum, and the vertebrae, formed the remainder of the cyst. There can be little doubt, that this sac commenced in a dilatation of the coats of the vessel, similar to those appearances which existed in the superior portion of the artery, and the dissection appeared to illustrate the formation of aneurism by partial dilatation in three distinct stages" (*Hodgson on the Diseases of Arteries and Veins*, p. 66, 68.) As far as Kreysig's information extends, nobody before Mr. Hodgson, had examined the structure of an aneurismal sac in this accurate manner, viz. by maceration, and the results, he thinks, are not liable to the slightest objections. (See the *German Transl. of Mr. Hodgson's work, with notes by Kreysig and Koberwein*, p. 109, Hanover, 1817.)

Mr. Hodgson has seen this partial dilatation in almost all the arteries, which are subject to aneurism: at the division of the carotids, and iliaes; in the arteries of the brain, &c.; and he agrees with Dr. Baillie, (*Morbid Anatomy, &c.*) Laennec, *Ceruttius Beschreib. d. Krankh. Preparate d. Anat. Theatres zu Leipz.* p. 408, 8vo 1819,) and others, that aneurisms at the origin of the aorta are generally formed by dilatation of the coats of the vessel.

"Partial as well as general dilatation (says Mr. Hodgson,) frequently precedes the formation of aneurism in the arteries of the extremities. A gentleman had a large aneurism in the thigh, which had undergone a spontaneous cure. Upon examining the limb after death, the popliteal artery was found to be thickened and covered with calcareous matter. A small pouch, which would have contained the seed of an orange, originated from the side of this artery. This little sac was evidently formed by a dilatation of the coats of the vessel; for, the internal and middle coats could be traced in its circumference, and the former in that situation exhibited the same morbid appearances, which it possessed in other parts of the vessel. A man died from the sloughing of an aneurism in the ham: in the femoral artery there was a small aneurism, about as large as a walnut. The external coat was dissected from the surface of the tumour to a considerable extent. The internal and middle coats were

evidently dilated, and contributed to the formation of the sac. The dilatation of these coats was gradual, and they continued for a considerable distance to form the sac, when they were inseparably blended with the surrounding parts." (*Op. cit.* p. 70.)

When Mr. A. Burns bears testimony to the fidelity and accuracy of Scarpa's general detail, he adds, that perhaps it may not be uniformly found, that "the root of an aneurism never includes the whole circumference of the tube of an artery." We have, says he, a preparation, in which the reverse has taken place. In this case, the whole cylinder of the vessel, from the heart to beyond the curvature, is equally dilated; and dilated to such an extent, that the tumour measures no less than ten inches in circumference. Scarpa limits dilatation, says Mr. Burns, to that state of an artery, in which the coats remain in their natural relation to each other, and in which they are not altered in their texture, nor lined on their inner surface with "polypous layers." "This, however, was not the case in the instance which I have brought forward. In it you have seen that the coats were much dilated, and also very much altered in their structure. Externally and internally, they had assumed the look of the membranes of the foetus, only they were thicker and denser, but they were equally gelatinous and nearly as transparent; and, on their inner surface, they were crusted over with laminae of coagulating lymph. By peeling off this incrustation after the sac had been inverted, we saw plainly, that although the internal coats were round the complete cylinder of the vessel much diseased, and considerably dilated, yet they were not dilated in the same degree as the external coverings of the artery. At irregular distances, longitudinal rents were formed in the fibrous coats, and these chasms were filled with coagulating lymph. The internal coats, over the whole circumference of the vessel, had assumed the diseased condition, which in aneurism is generally confined to a part of the cylinder. In this tumour, all the coats continued for a time to dilate equally, but at length the internal gave way, forming longitudinal rents, through which the external coats could be seen, after the lymphatic coating had been scraped off. In this instance, had the sac been dissected in the early stage, it would have presented precisely the same appearances as those described by Dr. Monro, and the one (the aneurism) lately examined by the surgical editor of the *London Med. Review*." Mr. Burns afterwards expresses doubts, whether the sac can ever acquire a large size without dilatation. The case, reported in the latter periodical work, was the largest, that he knew of, in which all the coats were found uniformly dilated. The sac, which was as large as the fist, was lined throughout with flakes of bone, and though the internal coat of the vessel was thus patched, and extremely thin and brittle, it did not, on minute inspection, anywhere exhibit a solution

of continuity. Mr. A. Burns further states, that the above case reported by himself, was the only one out of fourteen, which did not corroborate Scarpa's description. (*On Diseases of the Heart, &c. p. 204.*) Mr. Wilson, after mentioning the frequency of aneurism in the aorta, carotid, subclavian, and axillary arteries, and its rarity in the brachial, tells us, that he knows of no example of aneurism below the elbow, where the swelling could not be traced to a wound of the coats of the artery. He adds, that true aneurism has not unfrequently occurred in the internal and external iliac arteries, in the inguinal, femoral, and very frequently in the popliteal. It has taken place in the posterior tibial artery, but he knows of no instance of it in the anterior tibial, or peroneal arteries. "I have (says he) met with only one instance of true aneurism affecting any of the branches of the aorta, which are distributed to the abdominal viscera. In the year 1809, on inspecting the body of a clergyman, in the presence of the late Sir W. Farquhar, a tumour, very much resembling the heart in colour, shape, and size, appeared to hang down from the under surface of the left lobe of the liver. When this tumour was opened, and carefully inspected, it appeared to have been formed by the left branch of the hepatic artery having become very much enlarged and aneurismal. It had burst, and the blood, which had escaped, was found in an imperfect cyst, partly in a fluid, and partly in a coagulated state, forming a large proportion of the tumour." This preparation is in Windmill Street. (See *Lectures on the Blood, and on the Anatomy, Physiology, and Surgical Pathology of the Vascular System, p. 379, 380, Soc. Lond. 1819.*)

The facts adduced by Mr. Hodgson appear sufficiently conclusive, and from them the following doctrine is clearly deducible.

First, That numerous aneurisms are formed by destruction of the internal and middle coats of an artery, and the expansion of the external coat into a small cyst, which giving way from distention, the surrounding parts, whatever may be their structure, form the remainder of the sac.

Secondly, That sometimes the disease commences in the dilatation of a portion of the circumference of an artery. This dilatation increases until the coats of the vessel give way, when the surrounding parts form the sac, in the same manner as when the disease is in the first instance produced by destruction of the coats of an artery. (*P. 74.*)

The conclusions of Mr. Hodgson, as he himself explains, are supported by the observations of numerous writers.

The learned Sabatier says, there can be no doubt, that many aneurisms depend upon the dilatation of the arterial coats; but, continues he, when this happens, the cases present remarkable differences. Sometimes the three arterial tunics are dilated altogether. In other instances, only the two internal coats are affected with dilatation. While, in far more numerous examples, the internal tunics are ruptured, and it is the cel-

lular coat alone, which separates from them, and enlarges, so as to form the aneurismal sac; "*de sorte que les artères, qui sont dans ce cas, sont diloriquées, suivant l'expression de Lancisi.*"

It is difficult to conceive, observes Sabatier, how all the coats of an artery can dilate, and yield sufficiently to form the investment of such immense tumours as some aneurisms are. Indeed, that very tunic, which composes the greater part of the thickness of the vessel, and which is termed the *muscular coat*, is known to consist of fibres whose texture is firm, and little capable of bearing extension. However, Sabatier states, that there are some observations, which prove, that the muscular tunic may become dilated as well as the others. Haller, in describing a very large aneurism, situated in the aorta near the heart, relates, that the innermost coat of this vessel was ruptured and torn, the loose jagged edges of the laceration being visible in the aneurismal sac. These were squamous, bony, and of little thickness; while the muscular and cellular coats were quite sound. Donald Monro noticed the same thing in five different aneurisms, which occurred in the course of the femoral and popliteal arteries of a man, who had been confined a long while to his bed, after submitting to the operation for bubonocoele. Monro succeeded in tracing the fibres of the muscular coat over the swellings, so that he had no doubt of this tunic being dilated. Sabatier thinks, that it is not to be inferred, that all such writers, as have related the histories of true aneurisms, proceeding from a dilatation of all the arterial coats, can have been mistaken, although they may not have minutely described the texture of the sac, in which the blood was contained. He inclines to the opinion, however, that most of these aneurisms were similar to those, which result from the rupture of the internal tunics of the arteries, and the dilatation of the cellular coat; for the fragments of the lacerated coats are often blended with osseous, steatomatous, or purulent matter, and confounded with the cellular coat that forms the exterior investment. (See *Médecine Opératoire, T. 3. p. 160—162.*)

According to Richerand, when an aneurism is recent and of small size, the dissection of the tumour exhibits a simple dilatation of the arterial coats; while, in other cases, where the aneurism is large, and has existed a considerable time, the internal and middle coats of the vessel are invariably lacerated. In the early stage of the disease, the blood, which fills the aneurismal sac, is fluid, and on the contrary, in cases, where the internal tunics of the artery are ruptured, the sac contains more or less coagulated lymph. The external, or cellular coat, composes the greater part of the cyst; and the coagulated lymph, with which it is filled, is arranged in layers, the density of which is described as being greater in proportion to the length of time, which they have been deposited. Such as are nearest the sac are, therefore, represented as being most

compact, and containing the smallest quantity of the colouring matter of the blood; more deeply, the concretions of lymph resemble simple coagula; and lastly, the blood which is still nearer the arterial tube, retains its fluidity.

After the aneurismal sac has been cleansed from the lymph and coagulated blood, which it contains, its parietes will appear to be almost entirely formed of the cellular coat of the artery. Towards the bottom may be observed the aperture, arising from the laceration of the internal and middle coats, which, being much less elastic than the external, are ruptured in an early stage of the disease. It is when these two tunics give way, that the aneurismal tumour undergoes a sudden and considerable increase in its size; for, then, the cellular coat alone has to sustain all the pressure of the blood, which, now becoming effused into a more ample cyst, loses a great deal of its impetus, coagulates, and forms fibrous masses; circumstances to which may be ascribed the hardness of the swelling, the weakness of its pulsation, &c. (*Nos. Chir. T. 4. p. 82. Ed. 2.*)

But, this author seems to venture far beyond the bounds of accuracy, when he represents every small aneurism, as exhibiting a dilatation of the arterial coats, unless his meaning refer more particularly to the outer coat alone.

The reality of what are called true internal aneurisms was ably urged by C. F. Ludwig, in a programma written expressly on that subject. (*Diagnostices Chir. Fragm. de Aneurymate Interno; Lips. 1805.*) But an interesting case, exemplifying an aneurismal dilatation of all the coats of the abdominal aorta, has been recently published by Professor Nægele, of Heidelberg. The swelling was as large as a man's head, and weighed about five pounds. The aorta began to be dilated at the point, where it passes into the cavity of the abdomen between the crura of the diaphragm. This dilatation extended gradually down to a point, about four finger-breadths from the bifurcation of the aorta into the iliac arteries, at which point, strictly speaking, the large aneurismal sac commenced. The length of the whole dilated part of the vessel was eleven inches, that of the sac, six, and its diameter five inches. The artery was not equally dilated in every direction, the expansion being most considerable laterally, and forwards. Professor Nægele and Ackermann found, that the three coats of the aorta, the internal, muscular, and cellular, were all equally dilated. These gentlemen traced the muscular coat with a scalpel from the top to the bottom of the tumour, and not the slightest doubt could be entertained, that the case was a true aneurism. (*F. C. Nægele, Epistola ad T. F. Baltz, quâ Historia et Descriptio Aneurysmatiz, quod in aorta abdominali observavit, continetur, Heidelberg. 1816.*)

After the clear demonstration of an aneurismal sac being occasionally composed of all the coats of an artery, as afforded in the dissections and pathological preparations, to which a reference has been made, the reader

will be better prepared to judge of the difference existing upon this subject between Scarpa and other modern writers, and as far as I can judge, the question is now reduced to one, whether any of the dilatations on record, said to comprise all the arterial coats, merit the name of aneurism. We have seen, that he has always unequivocally admitted that the arteries may be dilated, though the kind of dilatation, to which he alludes, is thought by him, as well as by A. Burns, and my friend Mr. Hodgson, (*On Diseases of Arteries, &c. p. 58.*) to require discrimination in a pathological point of view. "It is proved (says Scarpa) by dissection, that the morbid dilatation is circumscribed by the proper coats of the diseased artery; and that the inner surface of the sac, formed by the partial, or total protrusion of the arterial tube, is never filled with poly-pous laminæ, or layers of fibrine disposed over each other; (a fact particularly dwelt upon by Mr. Hodgson, p. 82.) which layers never fail to be formed in greater or smaller quantity in the cavity of an aneurism. "The opinion, that these layers of coagula are not met with in small dilatations of arteries, but are found in large expansions of them, he says, is contradicted by numerous careful observations, and especially by a specimen, actually before him when he was writing, where a morbid dilatation of the arch of the aorta, in the vicinity of its origin from the heart, six inches in length, and five in breadth, was entirely free from any of the lamellated coagula, always found in aneurisms. On the contrary, the sac of the aneurism is formed from the parts surrounding the wounded, or ruptured artery, into which pouch, the blood, entering as into a natural receiver, and quite out of the current of the circulation, moves only slowly, and constantly deposits these layers of fibrine, and this sometimes in such quantity as to fill the whole cyst. Scarpa, at the same time, particularly explains, that, if accidentally furrows, or fissures exist on the inside of the morbid dilatation, the fibrine may be deposited in these rough places, but only in them. These fissures and inequalities of the internal surface of the morbidly dilated artery, he regards strictly as so many beginnings of another disease of the vessel, quite different from dilatation, that is, of aneurism subsequent to dilatation. See *Memoria sulla Legatura delle principali Arterie degli Arti, con una Appendice all' Opera sull' Aneurisma* fol. Pavia, 1817, or the *Treatise on Aneurism*, transl. by Wishart, Ed. 2, p. 119, Edinb. 1819.

In this manner, no doubt, Scarpa would account for the presence of lamellated coagula in the case reported by Mr. A. Burns, (*On Diseases of the Heart, p. 306.*) though the latter gentleman himself, for reasons already detailed in the foregoing pages, did not regard the expansion of all the coats of the artery, as corresponding to the morbid dilatation implied by Scarpa. Thus Scarpa further agrees with other modern writers, in admitting the possibility of aneurism becoming ingrafted, as it were, in one of these

unnatural dilatations, more than one example of which combination were indeed recited in his first work. In that treatise, he has asserted, that what he calls morbid dilatation, always extends to the whole circumference of the vessel. But, this point seems from the appendix to be renounced, as he now observes, "Where the morbid dilatation is partial, or on one side of the artery, like a thimble, (for, very frequently, even in the arch of the aorta, this partial dilatation does not exceed the size of half a bean,) the entrance for the blood into this capsule is as large as the bottom of the sac." (*Transl. by Wishart, p. 120, Ed. 2.*) According to Scarpa, where the morbid dilatation occupies the whole circumference of the arterial tube, the tumour always retains a cylindrical or oval form; and, if situated in such manner, that it can be compressed, it yields very readily to pressure, and almost disappears; and, after death, is found much smaller, than during life. On the contrary, aneurism, whether preceded by dilatation, or not, constantly originates from one side of the ruptured artery. The entrance for the blood is small, compared with the size of the fundus of the sac; the tumour assumes an irregular shape; yields with difficulty to pressure; retains nearly the same size in the dead, that it had in the living body; and, its sac, instead of becoming thinner as the swelling enlarges, like the coats of an artery do, when they are simply affected with dilatation, attains greater thickness, the larger the aneurism grows. These essential differences, between the two diseases, are illustrated by an interesting case, met with by Professor Vacca, where a patient died with an aneurism of one subclavian artery, and a simple morbid dilatation of the whole circumference of the other. (*See Sprengel, Storia delle Operaz. di Chir. Trad. Ital. Parte 2, p. 294.*)

When these two different affections are situated in the thorax, or abdomen, it is impossible to discriminate them from each other before death. The symptoms, occasioned by the pressure of the tumour on the viscera, must be nearly the same, whether caused by a morbid dilatation, or an aneurism. The means for retarding their fatal termination is also the same in both forms of the disease. With regard to the possibility of cure, however, Scarpa says, that there is great difference; for, when the case is an internal aneurism, there may be some slight hope of a radical cure by the efforts of nature and art, which hope can never be entertained in a case of morbid dilatation; a fact, which is accounted for by no laminated coagula being deposited in the latter disease. (*On Aneurism, transl. by Wishart, p. 124, Ed. 2.*) A great deal of the latter statement coincides with the observations of Mr. Hodgson, who particularly notices, that he has never met with lamellated coagula in such sacs, as consist either in a general, or partial dilatation of the coats of the vessel. (*On diseases of Arteries, &c. p. 82.*) Whether this ever takes place in such cases may still

be a question, because if Professor Nægele has given a correct description of the aneurism of the abdominal aorta, already mentioned, which aneurism was of large size, and consisted of a dilatation of all the coats of the vessel, there was in this rare example a large quantity of these layers of coagulated blood. Yet, whether the professor actually means the fibrine, arranged in laminæ, or only common coagulated blood, which, as every one knows, may be found either in the cysts of dilated, or of ruptured arteries, may admit of doubt. The statement, therefore, made by Hodgson and Scarpa, may not be contrary to what was really seen by Nægele and Ackermann. The following case, however, observed by Laennec, and quoted by a modern writer, must (if correctly reported,) afford not only an unequivocal specimen of aneurism by dilatation of all the coats of the aorta, but, of laminated coagula within its cavity. "In homine enim, qui repente sub atrocissimis pectoris doloribus corruit, præter aortum adscendentem in aneurysma ita expansam, ut neonati infantis caput æquaret, cystidem aneurismaticam immediate supra arteriæ celiacæ ortam magnitudine nucis juglandis invenit, quæ luculenter ostendit sinum communicantem cum arteriæ cylindro per foramen magnitudine amygdalæ, diametro totius arteriæ illo loco non mutato. Saccus hic cultro anatomico accurate ac subtiliter subjectus, eandem structuram, easdem ostendit membranas, quibus gaudebat arteria, e cujus latere excreverat; cæterum massis grumosis, sive fibrosis erat impletus. Inde igitur patet, hoc aneurysma sacciforme et laterali et partiali quidem tunicarum aortæ dilatatione ortum esse." (*J. H. G. Ehrhardt, De Aneurysmate, Aortæ, p. 13, 4to. Lips. 1820.*)

From what has been stated, it appears then, that there is only one principal point of difference between Scarpa and other writers, and this resolves itself into the question, whether a dilatation of an artery, arising at one particular side of the vessel, and lined by its internal coat, ought not to be regarded as an aneurism, because its communication with the tube of the artery is more capacious, than what exists in other aneurisms, where the inner coat has given way, and because it rarely (perhaps never) contains laminated coagula, unless fissures should happen to exist at some points of the inner arterial tunic thus expanded.

The greater number of aneurisms increase gradually, and sooner or later incline to the side, on which the least resistance is experienced. De Haen mentions an aneurism of the aorta, which first made its appearance between the second and third ribs of the left side, and, which instead of growing larger, as is usual, subsided, and could neither be seen, nor felt, for more than a month before the patient's decease, although, on opening the body, a tumour of the arch of the aorta was found, three times as large as the first. De Haen imputes the sudden disappearance of the swelling to its weight, the yielding of the parts with which it was connected, and to

its gravitating into the chest, when the patient lay on his right side; for, the difficulty of breathing, and other complaints, produced by the pressure on the lungs, underwent a material increase, as soon as the tumour ceased to protrude.

The pulsations which accompany true aneurisms, continue to be strong, until the inner coats of the vessel give way, or the layers of coagulated blood, lodged in the sac, are numerous. Hence, when soft swellings, situated near any large arteries, lose their pulsatory motion, their course, precise situation, and other circumstances, ought to be most carefully investigated, before any decision is made about the mode of treatment.

In St. Bartholomew's hospital, I saw a man, about three years ago, who had a large swelling of great solidity, occupying the ham, and apparently extending a good way forwards round the condyles of the femur. Its hardness, shape, large size, and entire freedom from pulsation, not only then, but at an earlier period, as far as could be collected from the patient's own account, led to the belief, that the case was probably a tumour complicated with exostosis of the femur, and as this opinion seemed to be confirmed by no fluid escaping from a puncture made with a lancet, amputation was performed. To our surprise, however, dissection proved, that the disease was a large diffused popliteal aneurism, in which the spontaneous cure by an obliteration of the sac with coagula was taking place. (See *Med. Chir. Trans. Vol. 8, p. 497.*)

In many instances, the most fatal accidents have happened, in consequence of incisions having been made in aneurisms, which were mistaken for abscesses, because there was no pulsation. Vesalius was consulted about a tumour of the back, which he pronounced to be an aneurism. Soon afterwards, an imprudent practitioner made an opening in the swelling, and the patient bled to death in a very short time. Ruysch relates, that a friend of his, having opened a tumour near the heel, which was not supposed to be an aneurism, the greatest difficulty was experienced in suppressing the hemorrhage. De Haen speaks of a patient, who died in consequence of an opening, which was made in a similar swelling at the knee, although Boerhaave had given his advice against the performance of such an operation. Palfin, Schlitting, Warner, and others, have recorded mistakes of the same kind. (*Sabatier, Tom. 3. p. 167.*) Riche-rand informs us, that Ferrand, head surgeon of the Hôtel-Dieu, mistook an axillary aneurism for an abscess, plunged his bistoury into the swelling, and killed the patient. "*J'ai été témoin d'erreurs semblables, commises par les praticiens non moins fameux; et si des anéurismes externes on passe à ceux des artères placées à l'intérieur, les erreurs ne sont ni moins ordinaires ni de moindre conséquence.*" (*Nosogr. Chir. T. 4, p. 75, Ed. 2.*)

Notwithstanding a pulsation is one of the most prominent symptoms of an aneurism, it is not to be inferred, that every swelling

which pulsates is unquestionably of this description; for, as Mr. Warner has explained, it does happen, that mere imposthumations, or collections of matter, arising from external as well as internal causes, are sometimes so immediately situated upon the heart itself, and, at other times, upon some of its principal arteries, as to partake, in the most regular manner, of their contraction and dilatation.

"A few years ago," says he, "I saw an instance of a boy, about thirteen years of age, who had his breast-bone much fractured by a fall; on this account, he was admitted into Guy's Hospital; but, not till a fortnight after the accident had happened.

"Upon examination, there was an evident separation of the broken parts of the bone, which were removed some distance from each other. The intermediate space was occupied by a tumour of a considerable size; the integuments were of their natural complexion. The swelling had as regular a contraction and dilatation as the heart itself, or the aorta could be supposed to have. Upon pressure, the tumour receded; upon a removal of the pressure, the tumour immediately resumed its former size; all these are allowed to be distinguishing signs of a recent true aneurism. The situation and symptoms of this swelling were judged sufficient reasons for considering the nature of the disease as uncertain; on which account it was left to take its own course.

"The event was, the tumour burst in about three weeks after his admission; discharged a considerable quantity of matter; and the patient did well by very superficial applications." (*Cases in Surgery, Edit. 4. p. 155.*)

An extraordinary form of disease, having very much the appearance of an aneurism, sometimes presents itself. A swelling, attended with considerable pain, and a strong pulsation, is gradually produced high up the arm; and at length attains a very large size. The strength of the throbbings at first leads to the suspicion, that the case must be an aneurism; but, on careful examination, the humerus is found to have given way at a point involved in the disease, and here to be as flexible, as if there were a fracture. This circumstance, and the extension of the swelling too far away from the track of the artery, in time raise doubts about the case being an aneurism. The patient ultimately falls a victim to the effects of the disease on the constitution, and, when the arm is dissected after death, the tumour is found to consist of a sarcomatous, or medullary mass, occupying the central portion of the limb, and accompanied with a solution of continuity extending completely through the whole thickness of the bone. Two cases of this description have been admitted into St. Bartholomew's hospital in the course of the present year (1820.) One of these patients, a woman, I had an opportunity of seeing; and, since her death, the real nature of the disease has been proved by dissection. My friend Mr. Vincent has seen a

similar disease in the leg, resembling aneurism in the circumstance of pulsation, but attended with destruction of a part of the tibia, and a moveableness of the separated ends of the bone.

A few years ago, I saw a large abscess in the situation of the quadratus lumborum muscle, which pulsed so strongly, that the case was supposed by several experienced men to be an aneurism of the abdominal aorta. The patient was a boy, belonging to Christ's Hospital, and under the care of the late Mr. Ramsden, surgeon to that establishment, by whose discernment the real nature of the case was detected. It is curious, that, in this instance, the pulsations of the swelling suddenly ceased, after having continued in a very strong and manifest way, and without interruption, for several weeks, during which it was under the observation of the above eminent practitioner.

As Mr. Wilson has observed, any encysted or even solid tumour, situated in the neighbourhood of, or upon a large artery, may have a considerable degree of motion communicated to it from the pulsation of the artery. The thyroid gland, when a bronchocele is formed, occasionally receives a pulsatory motion from the carotid arteries. This may be mistaken for an aneurism, from which disease, however, it can be discriminated by placing our fingers behind the tumour, and drawing it forwards when the pulsation ceases. But, there are other criteria for distinguishing a swelling on or near an artery, from an aneurism. In such a case, the whole tumour moves at once, without any alteration of size. In an aneurism, the swelling does not simply move, it expands. A tumour of the thyroid gland, having apparently a pulsatory motion, may be known not to be an aneurism of the carotid, by observing, that, from its connexion with the larynx, it follows the movements of the latter in deglutition. Aneurisms, which are not of very long standing, and do not contain a large mass of laminated coagula, may also be diminished or rendered more or less flaccid, by pressing the artery leading to the disease. (See *Wilson's Lectures on the Blood, Anatomy, Pathology, &c. of the Vascular System*, p. 385, and *Burns on the Heart*, p. 257.)

The following case recorded by Pelletan, shows, that an artery running more superficially, than natural, may, under particular circumstances, give rise to the suspicion of an aneurism. A strong robust man, about forty years of age, was in the habit of going on foot to dine, three leagues from Paris, every day, on the completion of his business. One day, having been this distance, and returned, he felt an acute pain along the leg, and in the right ankle. The pain did not subside, and a tumour appeared at the lower third of the leg, opposite the space between the two bones. The skin was of a yellowish colour from effused blood, and a pulsation existed, by which the hand of an examiner was lifted up. There seemed

every reason for concluding, that the case was an aneurismal swelling. In comparing the affected limb with the sound one, however, Pelletan perceived in the latter a similar kind of throbbing. In short, in both legs, the pulsation of an arterial tube could be felt for three inches, and, Pelletan distinctly ascertained, that in the diseased member, the throbbing did not extend to the whole of the tumour, but only lengthwise. By a particular disposition in this individual, the anterior tibial artery, which usually runs along the interosseous ligament, covered by the tibialis anticus, and extensor communis digitorum pedis, came out from between these muscles, at the middle of the leg, and lay immediately under the skin and the fascia. The patient, curious about the circumstance, which had been mentioned to him, examined the legs of the whole of his family; and it appeared, that his daughter was the only one, in whom the anterior tibial artery ran directly under the skin, in the same way, as it did in himself.

By confining the patient to his bed, says Pelletan, we were soon convinced, that the disease was not an aneurism; for the swelling and ecchymosis were gradually dispersed, and, it is more than probable, that the symptoms originated from the rupture of some muscular fibres, in the exertion of walking so great a distance. (See *Pelletan's Clinique Chirurgicale*, T. 1. p. 101, 102.)

Whenever an aneurismal sac of an immoderate size beats violently, and, for a long while against a bone, as the sternum, ribs, clavicle, and vertebrae, the bones are in the end invariably destroyed, so that the aneurismal sac elevates the integuments of the thorax, or back, and pulsates immediately under the skin. Scarpa, with the best modern writers, attributes the effect to absorption, in consequence of the pressure.

J. L. Petit saw the condyles of the femur, and the upper head of the tibia, almost destroyed by an aneurism of the popliteal artery; and another case, in which the caries and absorption of bone were very extensive, is reported by Rosenmüller. (*Anhang zu Scarpa ab. d. Pulsadergeschwulste*, p. 364.) According to Mr. Hodgson, the carious and corroded state of the bones in aneurism is never attended with the formation of pus; "at least, the discovery of pus in its vicinity has not been remarked by those, who have examined such cases. In this respect, therefore, it differs essentially from common caries, or ulceration of bones. Exfoliation also is very rarely attendant upon it; from which circumstance, one important practical observation is deducible, namely, that if the aneurism be cured, the bones will recover their healthy state, without undergoing those processes which take place in the cure of caries or necrosis." (*On the Diseases of Arteries and Veins*, p. 80.)

The same author confirms the remark made by Dr. W. Hunter, (*Med. Obs. and Inquiries*, p. 348;) Scarpa, (*On Aneurism*, p.

100, Ed. 2.) and others, that cartilage is less rapidly destroyed by the pressure of an aneurism than bone. This fact is strikingly illustrated in a case of aneurism of the thoracic aorta, recorded in another modern publication: the bodies of the vertebræ from the fourth down to the ninth were carious; the four lowermost particularly so; yet, the intervertebral cartilages were not materially affected, (F. L. Kreysig, *Die Krankheiten des Herzens*, B. 3, p. 176, 8vo. Berlin. 1817.)

A case is related by Pelletan, which is highly interesting, not only as exemplifying the degree, in which internal aneurisms may injure the vertebræ; but also as showing the occasional possibility of such diseases being mistaken for rheumatism, or a lumbar abscess, with or without caries of the spine.

After various complaints, like those of rheumatism, an oval tumour, imperfectly circumscribed, presented itself in the right iliac region, in the track of the psoas muscle. It was attended with a distinct fluctuation, and might easily have been mistaken for a collection of matter. But, on attentive examination, pulsations were felt, which, as they increased from day to day, left no further doubt concerning the nature of the swelling.

On opening the body after death, an aneurismal tumour of prodigious size was discovered. It filled the cavity of the abdomen, from the lumbar and iliac regions of the right side, to the lumbar region of the left side, and it extended from the trunk of the celiac artery down to the bifurcation of the aorta. The trunk of the aorta divided the tumour into two pouches, of which the right was far the largest, occupying the iliac and lumbar regions. The swelling enveloped the right kidney, and was externally covered by the peritoneum, which membrane was pushed to some distance from the bowels. The quantity of blood, which the aneurism contained, was about five pints; three of which were in its right cavity, and two in its left. This fluid was nearly all in a coagulated state, the coagula being arranged in concentric layers, as is usual in such cases. The centre of the disease presented an oval opening, about three inches long, and one broad, formed in the posterior part of the aorta, between the celiac and superior mesenteric arteries. Opposite to this aperture, the bodies of the two last dorsal, and of the two first lumbar vertebræ, were destroyed; an ordinary effect of aneurism on such bones as happen to be near them, but which effect Pelletan had never previously seen take place in so considerable a degree. In fact, in this case, while the patient was alive, the lowermost dorsal vertebræ had actually caused a deformed appearance externally, from the effect of the pressure of the tumour on that part of the spine. This was the largest aneurism Pelletan ever saw; and he ascribes the man's death to nearly the whole mass of the blood being in the aneurismal sac, as most of the vessels, and the heart itself,

were quite empty. (*Clinique Chir. T. 1, p. 97, 100.*)

CAUSES OF ANEURISM.

Aneurisms often seem to originate spontaneously, it being in many instances exceedingly difficult to assign any cause for the commencement of the disease. Among the circumstances, which predispose to aneurisms, however, the large size of the vessels may undoubtedly be reckoned. Those trunks, which are near the heart, are said to have much thinner parietes, in relation to the magnitude of the column of blood, with which they are filled, than the arteries of smaller diameter; and since the lateral pressure of this fluid against the sides of the arteries is in a ratio to the magnitude of these vessels, it follows, that aneurisms must be much more frequent in the trunks near the heart, than in such as are remote from the source of the circulation. (Richerand, *Nosogr. Chir. T. 4, p. 72. Edit. 2.*) The whole arterial system is liable to aneurisms; but, says Pelletan, experience proves that the internal arteries are much more frequently affected, than those which are external. (*Clinique Chirurgicale, Tom. 1. p. 54.*)

The curvatures of the arteries are another predisposing cause of the disease, and, according to Richerand, such cause has manifest effect in determining the formation of the great sinus of the aorta, the dilatation, which exists between the cross and the origin of this large artery, and is the more considerable, the older the person is: Monro even thought, that one half of old persons have an aneurism at the beginning of the aorta. * And with respect to aneurisms in general, which are preceded by calcareous depositions, thickening, and disease of the coats of the vessel, they are most frequently met with in persons of advanced age. Aneurisms from wounds are of course often seen in individuals of every age. In old people, the coats of the arteries are subject to a disease, which renders them incapable of making due resistance to the lateral impulse of the blood. The disease, here alluded to, is what is described in a foregoing part of this article, one common effect of which is the deposition of calcareous matter between the inner and muscular coats of the arteries. "People in the early part of life, says Mr. Wilson, are not very subject to these calcareous depositions; but, I have occasionally met with them in the arteries of very young people. I have seen a well-marked deposition of the phosphate of lime in the arteries of a child under three years of age." He adds, that few persons, above the age of sixty, are free from these ossifications. (See *Lectures on the Blood, and on the Anatomy, Pathology, &c. of the Vascular System, p. 375, Lond. 1819.*)

Though spontaneous aneurisms are most common in old persons, the disease is not absolutely confined to them; for I assisted Mr. Docker at Canterbury in an operation

for the cure of a popliteal aneurism in a position, whose age must have been under thirty; and Mr. Wilson says, that he has met with several instances of the disease in the aorta and other vessels, where the patients were not more than forty years of age. (*Op. cit.* p. 376.)

Richerand affirms, that, out of twelve popliteal aneurisms, which he has seen in hospital, or private practice, ten were caused by a violent extension of the leg. This statement, he says, will derive confirmation from the following experiment.

Place the knee of a dead subject on the edge of a firm table, and press on the heel, so as forcibly to extend the leg far enough to make the ligaments of the ham snap. Now dissect the parts, cut out the artery, and examine its parietes in a good light, when the lacerations of the middle coat will be observable, and rendered manifest by the circumstance of those places appearing semitransparent, where the fibres are separated, the parietes at such points merely consisting of the internal and external tunics. (*Nosographie Chir. Tom. 4, p. 73, 74, Edit. 2.*) But, the insufficiency of this explanation is clear enough from the fact, that such violence, as is requisite to break the ligaments of the knee, cannot be imagined to happen in the accidents which ordinarily bring on aneurism in the ham.

The implicit belief also which Richerand seems to place in the idea, that the laceration of the middle coat of an artery will bring on an aneurism, while the inner coat is perfect, will appear to be unfounded, when it is remembered, that Hunter, Home, and Scarpa, even dissected off the external and middle coats of arteries, without being able in this manner to cause an aneurism. Nay, where the experiment has been made of applying a tight ligature to an artery, and immediately removing it again in order to determine whether the division of both the inner coats of the vessel would terminate in an obliteration of the tube of the vessel, no aneurism has been the consequence.

Pelletan accounts for the frequency of popliteal aneurisms somewhat differently from Richerand: speaking of the two principal motions of the knee, viz. extension and flexion, he remarks, that the first of these is so limited, that it is actually an incipient flexion, necessarily produced by the curvature backward both of the condyles of the femur, and those of the tibia. This curvature, which would seem to protect the popliteal artery against any dangerous elongation, that might otherwise be caused by a forcible extension of the joint, becomes the very source of such an elongation in persons, who are accustomed to keep their limbs bent, or who, from this state, proceed hastily and violently to extend the leg. The arterial tubes are really shortened, when the limbs are in the state of flexion, and lengthened, when the extension of the members renders it necessary. Hence, says Pelletan, it is manifest, that an habitual shortened state of these vessels, and their

sudden elongation, must be attended with hazard of rupturing their parietes. (*Clinique Chirurgicale, Tom. 1. p. 112.*)

The opinion of Pelletan, however, is quite untenable; because Mr. Hodgson has several times repeated the experiment mentioned by Richerand, and found, as this gentleman did, that the coats of the artery were never lacerated, unless the degree of violence had been such as to rupture the ligaments of the knee. (*On Diseases of Arteries, &c. p. 64.*)

Aneurisms are exceedingly common in the aorta, and they are particularly often met with in the popliteal artery. The vessels, which are next to these the most usually affected, are the crural, common carotid, subclavian, and brachial arteries. The temporal and occipital arteries, and those of the leg, foot, forearm, and hand, are far less frequently the situations of the present disease. But, although it is true, that the larger arteries are the most subject to the ordinary species of aneurisms, the smaller arteries seem to be more immediately concerned in the formation of one peculiar aneurismal disease, now well known by the name of the *aneurism by anastomosis*, of which I shall hereafter speak.

According to surgical writers, the causes of aneurisms operate either by weakening the arterial parietes, or by increasing the lateral impulse of the blood against the sides of these vessels. It is said to be in both these ways, that the disease is occasioned by violent contusions of the arteries, the abuse of spirituous drinks, frequent mercurial courses, fits of anger, rough exercise, exertions in lifting heavy burdens, &c. In certain persons, aneurisms appear to depend upon a particular organic disposition. Of this description was the subject, whose arteries, on examination after death, were found by Lancisi affected with several aneurisms of various sizes. I have known a person have an aneurism of one axillary artery, which disease got spontaneously well, but, was soon afterwards followed by a similar swelling of the opposite axillary artery, which last affliction proved fatal. I have seen another instance, in which an aneurism of the popliteal artery was accompanied with one of the femoral in the other limb. Boyer mentions a patient, who died of a femoral aneurism in la Charité, at Paris, and who had also another aneurism of the popliteal artery, equal in size to a walnut. (*Boyer's Traité des Maladies Chirurgicales, &c. p. 102. T. 2.*) The most remarkable case, however, proving the existence of a disposition to aneurisms in the whole arterial system, is mentioned by Pelletan. "J'ai pourtant vu plusieurs fois ces nombreux aneurismes occupant indistinctement les grosses ou les petites artères, mais surtout celles des capacités: j'en ai compté soixante-trois sur un seul homme, depuis le volume d'une aréline jusqu'à celui de la moitié d'un œuf de poule." (*Clinique Chirurgicale, Tom. 2. p. 1.*)

Aneurisms, and those diseases of the coats of arteries, which precede the formation of aneurism, are much less frequently met with in women than men. (*Lassus Pathologie, Chir. T. 1. p. 348.*) A few years before John Hunter died, Mr. Wilson heard him remark, that he had only met with one woman affected with true aneurism. (*Anatomy, Pathology, &c. of the Vascular System, p. 376.*) Mr. Hodgson drew up the following table, exhibiting the comparative frequency of aneurisms in the two sexes in different cases of this disease, and also in the different arteries of the body, as deduced from examples, either seen by himself during the lives of the patients, or soon after their death.

	Total.	Males.	Females.
Of the ascending aorta, the arteria innominata, and arch of the aorta - -	21	16	5
Descending aorta - - -	8	7	1
Carotid artery - - -	2	2	
Subclavian and axillary -	5	5	
Inguinal artery - - -	12	12	
Femoral and popliteal -	15	14	1
	63	56	7

This table does not include aneurisms arising from wounded arteries, nor aneurisms from anastomosis. (See *Hodgson's Treatise on the Diseases of Arteries and Veins, p. 87.*)

It was observed by Morgagni, and it has been noticed in this country, that popliteal aneurisms occur with particular frequency in postilions and coachmen, whose employments oblige them to sit a good deal with their knees bent. In France, the men who clean out the dissecting rooms, and procure dead bodies for anatomists, are said almost all of them to die of aneurismal diseases. Richerand remarks, that he never knew any of these persons, who were not addicted to drinking, and he comments on the debility, which their intemperance and disgusting business together must tend to produce. (*Nosogr. Chir. T. 4. p. 74, Edit. 2.*)

Aneurisms are supposed by Roux to be much more frequent in England than France; a circumstance, which, before he proves it to be a fact, he vaguely refers to the mode of life, and kind of labour, to which a large part of the population of England are subjected. Indeed, he connects this surmise with a reason for the very cultivated state of this part of knowledge in England, thinks, that we have been placed in favourable circumstances for perfecting the treatment of aneurisms, and acknowledges, that we have contributed more than his countrymen, both in the last and present century, to the improvement of this branch of Surgery. (*Roux Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, &c. p. 249.*) But, ere M. Roux ventured into such conjectures, he ought at least to have specified what particular occupations and

kind of labour are known by Englishmen themselves to be frequently conducive to aneurism, for, with the exception of postilions and coachmen, of whom there are also abundance in France, I am not aware that any determinate class of persons are found in this country to be affected with particular frequency.

In some instances, aneurisms of the axillary artery appear to have arisen from violent extension of the limb. (See the cases recorded by Pelletan in *Clinique Chirurgicale, Tom. 2. p. 49, and 83.*) In other examples, related by the same interesting practical writer, aneurisms arose from reiterated contusions and rough pressure on parts. (*Op. cit. p. 10, P. 14.*)

The extremity of a fractured bone may injure an artery, and give rise to an aneurism, instances of which are recorded by Pelletan, (*Op. cit. Tom. 1, p. 178.*) and Duverney (*Traité des Mal. des os, T. 1.*) In Pelletan's case, the disease followed a fracture of the lower third of the leg. An aneurism of the anterior tibial artery, from such a cause, is also described by Mr. C. White. (*Cases in Surgery, p. 141.*)

The following case of an aneurism of the humeral artery, after amputation, is recorded by Warner: C. D. was afflicted with a caries of the joint of the elbow, which was attended with such circumstances, as rendered the amputation of the limb necessary. The operation was performed at a proper distance above the diseased part, and the vessels were taken up with needles and ligatures.

In a few days the humeral artery became so dilated above the ligature upon it as to endanger its bursting. Hence it was judged necessary to perform the operation for the aneurism, which was done, and the vessel secured by ligature, above the upper extremity of its distended coats. Every thing now went on, for some time, exceedingly well, when suddenly the artery again dilated, and was in danger of bursting above the second ligature. These circumstances made it necessary to repeat the operation for the aneurism. From this time, every thing went on successfully, till the stump was on the point of being healed; when, quite unexpectedly, the artery appeared a third time diseased in the same manner as it had been previously, for which reason, a third operation for aneurism was determined on, and performed.

The last operation was near the axilla, and was not followed by any relapse.

Could the several aneurisms of the humeral artery, (says Mr. Warner) be attributed to the sudden check alone, which the blood met with from the extremity of the vessel being secured by ligature; or is it not more reasonable to suppose, that the coats of the artery, nearly as high up as the axilla, were originally diseased and weakened? The latter, in the opinion of this judicious writer, seems the most probable way of accounting for the successive returns of the disease of the vessel; since it is found from

experience, that such accidents have been very rarely known to occur after amputations, either of the arm, or thigh, where nearly the same resistance must be made to the circulation in every subject of an equal age and vigour, who has undergone such operation.

If it should be supposed, that the several dilatations of the coats of the vessel, continues Mr. Warner, arose merely from the check in the circulation, it will not be easy to account for the final success of this operation; and, especially when we reflect, that the force of the blood is increased in proportion to its nearness to the heart. (See *Cases in Surgery*, p. 139, 140, *Edit.* 4.) Ruysch has related an observation somewhat similar. (*Obs. Anat. Chir. T. 1 p. 4.*)

Aneurisms sometimes follow the injury, which a large artery suffers in gunshot wounds. The passage of a bullet through the thigh, in one example, gave rise to a femoral aneurism. (See the *Parisian Surgical Journal*, vol. 2. p. 109.) The same cause produced an aneurism high up the thigh of a soldier, who was under the care of my friend Mr. Collier at Brussels, after the battle of Waterloo.

PROGNOSIS.

In cases of aneurism, the prognosis varies according to a variety of important circumstances. The disease may generally be considered as exceedingly dangerous; for, if left to itself, it almost always terminates in rupture, and the patient dies of hemorrhage. There are on record some examples, however, in which a spontaneous cure took place, and aneurismal swellings have been known to lose their pulsation, become hard, smaller, and gradually reduced to an indolent tubercle, which has entirely disappeared. After death, the artery, in such instances, has been found obliterated, and converted into a ligamentous cord, without any vestige of the aneurism being left. Aneurisms are also sometimes attacked with mortification; the sac and adjacent parts slough away; the artery is closed with coagulum; and thus a cure is effected. Lastly, tumours, having all the character of aneurisms, have been known to disappear under the employment of such pressure, as was certainly too feeble to intercept entirely the course of the blood. Such examples of success, however, are not common, and whenever they happen, it is because the entrance of blood into the sac is prevented by that already contained in it having coagulated, and because the artery above the swelling becomes filled with coagulum. They must, in fact, have been cured on the very same principle, which renders the surgical operation successful.

Nothing is subject to more variety, than the duration of an aneurism previously to its rupture, the tumour bursting sooner or later, according as the patient happens to lead a life of labour, or ease, of intemperance, or moderation. Even the bursting of an internal aneurism may not immediately kill the patient, as the following uncommon instance proves; a stonecutter died in the

hospital Saint Louis with an enormous aneurism, situated on the left side of the lumbar vertebrae. The body was opened by Riche-rand, who found, that the external tumour consisted of blood, which had been effused into a cyst, that was formed in the midst of the cellular substance of the loins. This fluid had passed into the situation specified, by making its way through the muscles. The tract, through which it came, led into another aneurismal sac, contained in the abdomen, and situated behind the peritoneum, on the left side of the lumbar vertebrae. In endeavouring to discover, whence the extravasated blood proceeded, Riche-rand found, that the abdominal aorta was entire, though in contact with the swelling. The original affection consisted of an aneurismal dilatation of the inferior portion of the thoracic aorta, which had burst at the point, where it lies betwixt the crura of the diaphragm. The blood had probably escaped very slowly, and it had accumulated in the cellular substance, which surrounds the kidney, so that three cysts had burst successively, before the patient died. (*Nosogr. Chir. T. 4. p. 82. Edit. 2.*)

Every aneurism so situated that it cannot be compressed, nor tied above the swelling, is for the most part absolutely incurable. But, it should be recollected, that sometimes the size of the swelling appears to leave no room for the application of a ligature above it, while things are in reality otherwise, in consequence of the communication between the sac and the artery, bearing no proportion to the magnitude of the tumour itself. At the present day, also, enlightened by anatomical knowledge, and encouraged by successful experience, surgeons boldly follow the largest arteries, even within the boundaries of the chest and abdomen, as we shall presently relate, and numerous facts have now proved, that few external aneurisms are beyond the reach of modern surgery. It being certain, that aneurisms cannot commonly be cured, except by an obliteration of the affected artery, it follows, that the circulation must be carried on by the superior and inferior collateral branches, or else the limb will mortify. Experience proves, that the impediment to the passage of the blood, through the diseased artery, obliges this fluid to pass through the collateral branches, which gradually acquire an increase of size. It is therefore a common notion, that it must be in favour of the success of the operation, if the disease be of a certain standing; and in direct opposition to the sentiments of Kirkland, Boyer even asserts, that the most successful operations have been those performed on persons, who have had the disease a long while. (*Traité des Maladies Chirurg. T. 2. p. 116.*)

There is this objection to delay, however, that the tumour becomes so large, and the effects of its pressure so extensive and injurious, that, after the artery is tied, great inflammation, suppuration, and sloughing, often attack the swelling itself, and the patient falls a victim to, what would not have

occurred, had the operation been done sooner.

The large size of an aneurism, as Mr. Hodgson has rightly observed, is a circumstance, which materially prevents the establishment of a collateral circulation. When the tumour has acquired an immense bulk, it has probably destroyed the parts, in which some of the principal anastomosing branches are situated; or by its pressure it may prevent their dilatation. (See *Hodgson on the Diseases of Arteries and Veins*, p. 259.) The practice of permitting an aneurism to increase, that the collateral branches may become enlarged, (says this gentleman) is not only unnecessary but injurious, inasmuch as that the increase of the tumour must be attended with a destruction of the surrounding parts, which will render the cure of the disease more tedious and uncertain. (P. 266.)

The most successful operations, which I have seen, were performed before the aneurismal swellings were very large. However, notwithstanding the great disadvantages of letting the swelling become bulky before the operation, the fact appears scarcely yet to have made due impression, and surgeons are yet blinded with the plausible scheme of giving time for the collateral vessels to enlarge: at least, I infer, that things are so, from having lately seen a patient, who had been advised to let the operation be postponed on such a ground, though the swelling in the ham was already as large as an egg.

The surgeon should not be afraid of operating, although appearances of gangrene may have taken place on the tumour; for, as Mr. Hodgson remarks, should it burst afterwards, it is probable, that both extremities of the artery in the sac will be closed with coagulum. (*Hodgson*, p. 305.) Mr. A. Cooper tied the external iliac artery in two cases of inguinal aneurism, when gangrene existed, and though the tumours burst, no hemorrhage ensued. The coagulum was discharged; the sac granulated; and the sores gradually healed. (*Medico Chir. Trans.* Vol. 4. p. 431.)

The effects of the pressure of aneurisms upon the bones, are justly regarded as an unpleasant complication, when they take place in an extensive degree, and, according to writers, they may sometimes induce a necessity for amputation. (*Boyer, Traité des Mal. Chir. t. 2. p. 117.*) However, I have never seen a case of this description; and Mr. Hodgson, as we have already explained, informs us, that the affection of the bones is hardly ever attended with exfoliations, or the formation of pus, so that if the aneurism can be cured, the bones will recover their healthy state, without undergoing those processes which take place in the cure of caries, or necrosis. (*On Diseases of Arteries and Veins*, p. 80.) At the same time, there can be no doubt, that where the tumour has been allowed to attain a large size, before an attempt is made to cure it, and where, from this cause, both the neighbouring soft parts and the

bone have suffered considerably, the completion of a cure, that is to say, the full restoration of the use of the limb, must be far more distant than in other cases, where the cure is attempted in an earlier stage. Here, then, we see another reason against the pernicious doctrine of waiting for the enlargement of the anastomosing vessels, in addition to that which has been urged in the previous column.

The age, constitution, and state of the patient's health, are also to be considered in the prognosis; for they undoubtedly make a great difference in the chance of success after the operation.

The operation, however, should not be rejected on account of the age of the patient, if the circumstances of the case in other respects appear to demand it; for it has often succeeded at very advanced periods of life. "I have seen several aneurisms cured by the modern operation, in patients above sixty years of age." (*Hodgson*, p. 304.) A fact to which my own opportunities of observation enable me also to bear witness.

When an aneurism exists in the course of the aorta, the violent action of the heart, excited by an operation in the extremities, may cause it to burst, and prove instantaneously fatal. Two cases have recently occurred in this metropolis, in which the patients died from such a cause during operations for popliteal aneurisms. (See *Hodgson on Diseases of Arteries*, p. 306. *London Med. Review*, vol. 2. p. 240. and *Burns on Diseases of the Heart*, p. 226.) Were the coexistence of the internal aneurism known, the operation for the other tumour would be improper, and the surgeon should limit the treatment to palliative means.

Experience confirms, however, that the circumstance of there being two aneurisms in the limbs should not prevent the operation, which is to be practised at separate periods. Facts in support of this statement are quoted by Mr. Hodgson. (P. 310.)

OF THE SPONTANEOUS CURE, AND GENERAL TREATMENT OF ANEURISMS.

The obliteration of the sac, in consequence of a deposition of lamellated coagulum in its cavity, as Mr. Hodgson has well described, is the mode by which the spontaneous cure of aneurism is in most instances effected. The blood soon deposits upon the inner surface of the sac a stratum of coagulum; and successive depositions of the fibrous part of the blood by degrees lessen the cavity of the tumour. At length, the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery on both sides of the sac as far as the giving off of the next large branches. The circulation through the vessel is thus prevented; the blood is conveyed by collateral channels; and another process is instituted, whereby the bulk of the tumour is removed. (*Hodgson on the Diseases of Arteries*, &c. p. 114.) Such desir-

ble increase of the coagulated blood in the sac is indicated by the tumour becoming more solid, and its pulsation weak, or ceasing altogether.

Another mode in which the disease is spontaneously cured, happens as follows: an aneurism is sometimes deeply attacked with inflammation and gangrene; a dense, compact, bloody coagulum is formed within the vessel, shutting up its canal, and completely interrupting the course of the blood into the sac. Hence the sphacelation which follows, and the bursting of the integuments and aneurismal sac, are never accompanied by a fatal hemorrhage; and the patient is cured of the gangrene and aneurism, if he has strength sufficient to bear the derangement of the health necessarily attendant on so considerable an attack of inflammation and gangrene.

When a patient dies of hemorrhage, after the mortification of an aneurism, it is because only a portion of the integuments and sac has sloughed, without the root of the aneurism, and especially the arterial trunk, being similarly affected. For cases illustrative of this statement, refer to *Hodgson on Diseases of Arteries*, p. 103, &c.

A third way, in which an aneurism may be spontaneously cured, is by the tumour compressing the artery above, so as to produce adhesion of its sides, and obliteration of its cavity. This mode of cure must be uncommon: it has been adverted to by Sir E. Home, Scarpa, Dr. John Thomson, and others; but some facts, tending to prove it, have been collected by Mr. Hodgson, and are published in his useful work. (See p. 107, &c.)

"The surgical treatment of aneurism (says this gentleman,) consists in the obliteration of the cavity of the artery communicating with the sac, so that the ingress of the blood into the latter is either entirely prevented, or the stream which passes through it is supplied only by anastomosing branches, and consequently the force of the circulation is so much diminished, that the increase of the tumour is prevented, and the deposition of coagulum is promoted. By the absorption of its contents, and the gradual contraction of the sac, the cure is ultimately accomplished. The blood is conveyed to the parts, which it is destined to supply, by collateral vessels, some of which being gradually enlarged, constitute permanent channels for the circulation. The obliteration of the artery is effected by the excitement of such a degree of inflammation in its coats, as shall produce adhesion of its side. These objects have been attempted by the compression or the ligature of the artery. The latter method constitutes the operation for aneurism." (P. 165.)

According to Scarpa, a complete cure of an aneurism cannot be effected, in whatever part of the body the tumour is situated, unless the artery, from which the aneurism is derived, be, by nature or art, obliterated and converted into a perfectly solid, ligamentous substance,

for a certain extent above and below the place of the ulceration, laceration, or wound. When aneurisms are cured by compression, the cure is never accomplished, as some have supposed, by the pressure strengthening the dilated proper coats of the artery, and restoring, especially to the muscular coat, the power of propelling the blood along the tube of the artery, as it did previously to its supposed dilatation. M. Petit, and Foubert, thought, that the natural curative process sometimes consisted in a species of clot, which closed the laceration, ulceration, or wound of the artery, and resisted the impulse of the blood, so as still to preserve the continuity of the coats of the artery, and the pervious state of the vessel. Haller imbibed a similar sentiment, from experiments made on frogs.

If the foregoing statement of Scarpa, respecting the obliteration of the tube of the adjacent portion of the artery, when an aneurism is cured, had been delivered merely as what is the most common course of things, it would not have been incorrect; but when he denies the possibility of the calibre of the vessel being ever preserved, whether the disease be cured by art or nature, he is exceeding the bounds of accuracy.

Notwithstanding aneurisms cannot in general be cured, as Scarpa has explained, unless the artery be rendered impervious for some extent above and below the tumour, I believe we must make an exception to this observation with respect to the few aneurisms of the aorta (especially those of its arch,) which, according to the records of surgery, have been diminished and cured by Valsalva's treatment. In such examples, we are not to suppose that the aorta becomes obliterated at its very beginning; but that the diminution of the quantity of circulating blood, the reduced impetus of this fluid, the lessened distention of the aneurismal sac, the general weakness induced in the constitution, and the increased activity of the lymphatic system, all necessary effects of Valsalva's method, have combined to bring about a partial subsidence of the tumour.

"It is a common opinion (says Mr. Hodgson,) that the radical cure of an aneurism cannot take place, without the obliteration of the artery, from which the disease originates. It is probably owing to this idea, that aneurisms of the aorta have generally been considered as incurable diseases, and consequently that so little attention has been given to their treatment." (P. 118.) The facts, however, which this gentleman has related, satisfactorily prove, 1st. That a deposition of coagulum may take place in an aneurismal sac, to such an extent as entirely to preclude the communication between its cavity and that of the artery from which it originates. Secondly, that a sac, thus filled with coagulum, cannot prove fatal by rupture; and thirdly, that the gradual absorption of its contents, and the consequent contraction of the sac, may proceed

to such an extent as to effect the cure of the disease, without any obstruction taking place in the calibre of the vessel from which it originates. See cases 20, 21, 22, &c. (*Hodgson on Diseases of the Arteries*, &c. p. 119, &c.) In support of this doctrine, some facts are also cited from Corvisart. (*Essai sur les Maladies du Cœur*, p. 313, &c.)

A part of these cases, it is true, are not viewed exactly in this light by Kreysig, who argues (as I think without much probability,) that they might have been only adipose swellings connected with, or formed in the parietes of the artery, a disease described by Stenzel. (*German Transl. of Mr. Hodgson's Book*, p. 174.)

That a punctured artery may occasionally be healed in this manner, Scarpa himself proves, by a case which he examined, where an aneurism took place from the wound of a lancet in bleeding. In the article *Hemorrhage*, we shall see, that Jones's experiments show the same thing, and the particular circumstances in which it may happen. But the occurrence is rare, and Scarpa says, that it can hardly be called a radical cure, as the cicatrix is always found in a state ready to burst and break, if the arm is, by any accident, violently stretched or struck where the wound was situated.

In the spontaneous cure of aneurisms, arising from arteries of inferior size to that of the aorta, repeated examinations have proved, that the deposition of coagulum does not in general merely fill up the sac, but obliterates the tube of the artery above and below the disease to the next important ramifications. Yet, even here, exceptions probably take place; for Mr. Hodgson has brought forward one instance, in which a small sac, which originated from the anterior artery of the cerebrum, was completely filled with firm coagulum, which did not extend into the cavity of the vessel. (*On Diseases of Arteries*, p. 132.) And he reports the particulars of a true femoral aneurism, communicated to him by Mr. A. Cooper, in which, after the patient's death, the femoral artery was found dilated into a sac, which was lined on all sides with very firm layers of coagulum, in the centre of which was an irregular canal, through which the circulation was continued. As the inside of this canal presented a membranous appearance, it was inferred that the aneurism had been cured. (*Op. cit.* p. 134.) Here I may be permitted to remark, that if this case be correctly reported, viz. if it were a true aneurism by dilatation of all the arterial coats, and the inside of it was every where lined by firm layers of coagulum, it amounts to a proof that such a deposition is not entirely confined to aneurisms by rupture, as Scarpa supposes. And, in addition to this fact, I may mention, as referring to the same question, a case of aneurism from dilatation of the arterial coats, observed by Guattani, where the same process took place. "Arteriæ iliacæ ovalem hanc partem aneurysmaticam polyposa substantia variæ densitatis adeo infarctam esse denotebam, ut tuni-

carum ejusdem forma penitus destructa in uniformem massam, spongiæ cera imbutæ similem, transformata videretur." (*Hist. 17. Collect. Lauth*, p. 158.)

Whenever the ulcerated, lacerated, or wounded artery is accurately compressed against a hard body, like the bones, it ceases to pour blood into the surrounding cellular sheath, because its sides, being kept in firm contact, for a certain extent above and below the breach of continuity, become united by the adhesive inflammation, and converted into a solid, ligamentous cylinder. Molinelli, Guattani, and White, have given examples and plates illustrative of this fact. When aneurisms get well spontaneously, the same fact is observed after death, as Valsalva, Ford, &c. have demonstrated. I have myself seen, in St. Bartholomew's hospital, an instance in which a man had had a spontaneous cure of an aneurism in the left axilla, but afterwards died of hemorrhage from another aneurismal swelling under the right clavicle: the artery on the left side was found completely impervious. My friend, Mr. Albert, had under his care, in the York Hospital, Chelsea, a dragoon, who recovered spontaneously of a very large aneurism of the external iliac artery: the tumour sloughed, discharged about two quarts of coagulated blood, and then granulated and finally healed up. Paoli relates a similar termination of a popliteal aneurism. Molinichen and Guattani relate other examples. Hunter found the femoral artery quite impervious, and obliterated, at the place where a ligature had been applied fifteen months before. Boyer noticed the same fact in a subject eight years after the operation. Petit describes the spontaneous cure of an aneurism at the bifurcation of the right carotid: the subject having afterwards died of apoplexy, the vessel, on dissection, was found closed up and obliterated from the bifurcation, as far as the right subclavian artery. Desault had an opportunity of opening a patient, in whom a spontaneous cure of a popliteal aneurism was just beginning: he found a very hard, bloody thrombus, which extended for three finger-breadths, within the tube of the artery, above the sac, and was so firm, as to resist injection, and make it pass into the collateral branches.

Both the spontaneous and surgical cures of aneurisms have generally two stages: in the first, the entrance of the blood into the aneurismal sac is interrupted; in the second, the parietes of the artery approach each other, and, becoming agglutinated, the vessel is converted into a solid cylinder. This doctrine is corroborated by the tumour first losing its pulsation, and then gradually diminishing and disappearing.

In order that compression may make the opposite sides of an artery unite, and thus produce a radical cure of an aneurism, Scarpa says, the degree of pressure must be such as to place these opposite sides in firm and complete contact, and such as to excite the adhesive inflammation in the coats of the

artery. The point of compression must also fall above the laceration or wound of the artery; for when it operates below, it hastens the enlargement of the tumour; and Scarpa adds, that in practice, bandages which are expulsive and compressive are more useful for making pressure than any tourniquets or instruments, many of which are contrived to operate, without retarding the return of blood through the veins.

In order that pressure may succeed, the coats of the vessel, at the place where it is made, must be sufficiently free from disease to be susceptible of the adhesive inflammation. When the arterial coats, round the root of the aneurism, are much diseased, Scarpa considers them as insusceptible of the adhesive inflammation, although compressed together in the most scientific manner, and, even when tied with a ligature, which only acts by making circular pressure on the vessel.

This statement would appear to derive confirmation from the following fact: Mr. Langstaff amputated the thigh of a person seventy-five years of age; but the vessels were so ossified, that they could not be effectually tied, and the patient died within twenty-four hours. It is generally supposed, says Mr. Lawrence, that this condition of the arterial coats is incompatible with their union under the application of the ligature. The opinion should be received, however, with some limitation. In a man fifty-nine years of age, bleeding took place nearly a month after amputation, from the ossified femoral artery, and Mr. Lawrence was therefore obliged to expose and tie that vessel again for the suppression of the hemorrhage, when he found a hard tube, which cracked immediately the ligature was tightened: the bleeding, however, never returned. (*See Med. Chir. Trans. Vol. 6, p. 193.*) This case is mentioned, however, not with any view of encouraging surgeons to apply ligatures round diseased portions of arteries, a thing which should always be avoided when possible, but to let them be aware, that an ossified artery is sometimes susceptible of being permanently closed, when a ligature is put round it. With respect to Scarpa's idea of making pressure operate so as to place the two opposite parietes of the artery at the mouth of the aneurismal sac, completely in contact, in order that they be united by the adhesive inflammation, and the cavity of the vessel be obliterated, I should think with Mr. Hodgson, that if pressure will succeed only under these circumstances, it will answer very seldom, because, in almost all aneurismal sacs, a sufficient deposition of coagulum will have taken place to prevent the possibility of placing the opposite sides of the artery at the mouth of the aneurism in a state of complete contact. (*On Diseases of Arteries, &c. p. 172.*) Possibly, however, Scarpa's directions refer to a point of the vessel, rather beyond the usual limits of the laminated coagula; and he is particular in recommending the practice only where the aneurism is soft and small.

Some advise trying compression in every case of aneurism, whether small, circumscribed, soft, flexible, indolent, or elevated, diffused, hard, and painful. But, in the latter case, Scarpa represents compression as decidedly hurtful. He says also, that every bandage which compresses the aneurism, and also circularly constricts the affected part, is always injurious. The bandage, likewise, which compresses only the aneurism, and directs the point of pressure below the rupture in the vessel; that which, on account of the great size, exquisite sensibility, depth of the root of the aneurism, and fleshy state of the surrounding parts, cannot effectually compress the artery against the bones, so as to bring the opposite side of the vessel into contact; and, lastly, the compression applied to a spontaneous aneurism, attended with a steatomatous, ulcerated, earthy disease of the arterial coats, ought to be considered as more likely to do harm than benefit. In cases of a completely opposite description, bandages have produced, and may produce, a radical cure, and should not be entirely disused. (*Scarpa, on Aneurism, ed. 2. p. 221.*)

Guattani first employed compression systematically for the cure of aneurisms, and out of fourteen cases in which he adopted the plan, four were cured by it. Mr. Freer details other examples; but, in general, pressure has hitherto been applied to the tumour itself, a method less likely to answer than that of making pressure on a sound part of the artery. Mr. Freer recommends the employment of Sennio's instrument, or the following method: first place a bandage, moderately tight, from one extremity of the limb to the other; then put a pad upon the artery, a few inches above the tumour; next, surrounding the limb with a tourniquet, let the screw be fixed upon the pad, having previously secured the whole limb from the action of the instrument, by a piece of board wider than the limb itself, by which means the artery only will be compressed, when the screw is tightened. The tourniquet should now be twisted till the pulsation in the tumour ceases. In a few hours the limb will become oedematous and swelled, when the tourniquet may be removed, and the pressure of a pad and roller will afterwards be enough. By experiments which this gentleman made on the radial arteries of horses, these vessels were found to become inflamed, and to be rendered impervious by such a process. (*Freer, p. 112.*) In a modern work, Dubois is stated to have cured an aneurism of the thigh by steady pressure on the vessel for twenty-four hours. (*Med. Chir. Trans. vol. 4. p. 437.*)

Mr. A. Cooper describes another machine for compressing the femoral artery, in cases of popliteal aneurism: it was used by Sir W. Blizard.

"The points of support for this instrument, were the outer part of the knee, and the great trochanter, a piece of steel passing from one to the other; and to the mid-

ble of this a semicircular piece of iron was fixed, which projected over the femoral artery, having a pad at its end, moved by a screw, by turning which, the artery was readily compressed, and the pulsation in the aneurism stopped, without any interruption to the circulation in the smaller vessels." But although the patient on whom it was tried possessed unusual fortitude, he was incapable of supporting the pressure of the instrument longer than nine hours. (*Med. and Phys. Journal*, vol. 8.) Few patients, indeed, can endure the pressure of such instruments a quarter of this time, when they are put on sufficiently tight to afford any chance of obliterating the artery; and, on account of the suffering which they produce, they are rarely used by modern surgeons.

Whenever the treatment by pressure is attempted, the plan should be assisted with repeated bleedings, spare diet, and perfect quietude in bed. Digitalis has also been sometimes prescribed, with the view of lessening the impetus of the circulation. It is likewise a favourite plan with some practitioners, to apply snow, or powdered ice to the tumour, as I shall notice in describing Valsalva's treatment of aortic aneurisms. These last applications have been employed for the purpose of promoting the coagulation of the blood within the aneurismal sac, and the consequent obliteration of the cavity of the aneurism and the artery. Various examples, in which it has been thought to have produced a cure, are recorded by Guérin. (*Recueil Périod. de la Soc. de Santé de Paris*, No. 3, *Pelletan Clinique Chir. and Ribes, Bulletins, de la Faculté de Méd. de Paris*, 1817, No. 1. and 2. p. 284.) The employment of ice, however, is not considered proper in every case. Breschet says, that, when the swelling is large, the parts very tense, their texture changed, and the skin thin, the practice is likely to accelerate the formation of a slough; and he confirms a remark made by Mr. Hodgson, that some patients cannot continue this treatment longer than a few minutes, while others find it absolutely insupportable. (*Fr. Transl. of Mr. Hodgson's Work*, t. 1. p. 212—229.)

The grand means, most to be depended upon, for curing aneurisms, is tying the artery above the tumour. This more certainly prevents the great ingress of blood into the sac, and, what is more important, more certainly excites the adhesive inflammation within the tied part of the vessel, and, by holding the opposite sides of it steadily in contact, brings about their union, and an obliteration of the tube of the vessel, with tolerable regularity. The chief current of blood into the sac is thus stopped, the contents of the aneurism are afterwards gradually absorbed, and the tumour dwindles away in proportion. The natural course of the blood being now permanently interrupted in the arterial trunk, it passes more copiously into the collateral branches, and these enlarging and anastomosing with others, which originate from the large arte-

ries beyond the obstruction, the necessary circulation is carried on. (See *Anastomosis and Inosculation*.)

The ligature of the superficial femoral artery, may be performed with the same confidence of success, as the ligature of the brachial artery, (that is, without any fear of destroying the circulation, or depriving the subjacent limb of its vitality. Indeed, the numerous and conspicuous anastomoses, which are met with all round the knee, correspond exactly with those which are observed round the elbow, and at the bend of the arm. This is not a peculiarity of the arteries of the extremities, but it is a general rule which nature has followed in the distribution of all the arteries, that the superior trunks communicate with the inferior, by means of the lateral vessels. After the principal trunk of an artery is tied, its lateral branches not only carry on the circulation in the parts below the ligature, but do so with greater quickness and activity than they did previously, while the course of the blood was unimpeded through the principal trunk. This evidently arises from the increased determination of blood into the lateral vessels, as well as from the enlargement of the diameter of these vessels. After the amputation of the thigh, while the blood flows in a full stream from the superficial femoral artery, very little or no blood is poured out of the lateral vessels; but as soon as that artery is tied, the blood issues with impetuosity from the small arteries, which run along, within the vasti and cruræus muscles; and on these smaller arteries being also tied, the blood immediately oozes out from the minute arterial vessels of the muscles and cellular membrane. When the principal trunk of an artery is tied, its lateral branches gradually acquire a much larger diameter. After amputation of the thigh, on account of a popliteal aneurism, the size and situation of which could not fail materially to impede the course of the blood through the trunk of the femoral artery, it has been often remarked, that, although both the trunk and the greater and smaller branches had been tied with the greatest accuracy, the patients have been in danger of losing their lives, on account of the repeated copious hemorrhages from the innumerable small lateral vessels that had become unusually enlarged. In several cases, during the treatment, and especially after the radical cure of popliteal aneurism, by tying the superficial femoral artery, in the upper third of the thigh, all the ramifications of the recurrent popliteal arteries have been felt beating strongly round the knee. We have already noticed, that Boyer found, in a man who some years previously had been operated on for a popliteal aneurism, but had afterwards died from a caries of the tibia, that an arterial branch, which runs in the substance of the sciatic nerve, was dilated so much, as to be equal in diameter to the radial artery. White, in dissecting the arm of a lady, who, fifteen years before, had been operated on for an aneurism in the

bend of the arm, found the brachial artery obliterated, and converted into a solid cylinder, for three inches below the place of the ligature, and as far as the division into the radial and ulnar arteries; but the recurrent radial and ulnar branches had become so much enlarged, that, taken together, they exceeded the size of the brachial artery, above the situation of the ligature. In the dead body it is found, that an anatomical injection will pass more freely from one extremity to the other of an aneurismatic, than of a sound limb, and this even when no vessels are visibly enlarged. Although it be self-evident, that the circulation through the collateral vessels ought to be much more easy and quick the lower down the ligature is applied to the principal trunk; yet experience shows, that this difference is not to be estimated very high; for in cases of popliteal aneurism, *cæteris paribus*, the success is the same, whether the femoral artery be tied very low down, or very high up in the thigh. (Scarpa.)

This facility of the passage of the blood through the lateral vessels, is not the same in subjects of all ages; and, in the same subject, it is not the same in the inferior, as in the superior extremity. An age under forty-five, and the operation being done on the arm, which is nearer the source of the circulation, than the lower extremity, increases the chance of success. However, notwithstanding these are the opinions of Scarpa, and as general ones may not be incorrect, surgeons in England now operate for aneurisms of the lower extremity, and on patients much older than forty-five, with a degree of confidence, which nothing but great success could inspire.

According to Scarpa, the circumstances chiefly preventive of success, especially in the popliteal and femoral aneurisms, are the following: rigidity, atony, or disorganization of the principal anastomoses, between the superior and inferior arteries of the arm and leg; sometimes depending on an advanced age, or on it, together with the large size of the aneurism, which, by long continued pressure, has caused a great change in the neighbouring parts; or sometimes on catenatous, ulcerated, earthy, cartilaginous disorganization of the proper coats of the artery, not confined to the seat of the rupture, but extending a great way above and below the aneurism, and also to the principal popliteal recurrent arteries, tibial arteries, and, occasionally, to portions of the whole track of the superficial femoral artery. Sometimes the pressure of large aneurisms renders the thigh bone carious. In such circumstances, the ligature is apt to fail in closing the trunk of the artery; and, if it should succeed, the state of the anastomosing vessels will not admit of a sufficient quantity of blood being conveyed into the lower part of the limb. Hence, when the patient is much advanced in life, languid, and sickly; when the internal coat of the artery is rigid, and incapable of being united by a ligature; when the aneurism is of long

standing, and considerable size, with caries of the os femoris, or tibia; when the leg is weak and cold, much swelled, heavy, and cedematous; Scarpa considers the operation contra-indicated. I must, however, declare in this place, that I have seen very large aneurisms, as well as aneurisms in persons of advanced age, cured by the Hunterian plan, in St. Bartholomew's Hospital; and, with respect to the affection of the bones, though it may be an unfavourable circumstance, its consequences are not so serious as those of ordinary caries, as I have already explained.

It appears, then, that the obliteration of the artery, for a certain extent above and below the place of rupture, forms the primary indication in the radical cure of aneurism, whether compression or the ligature be employed; all other means are only auxiliary. Internal remedies may be useful, inasmuch as they tend to moderate the determination of the blood towards the place, where the artery has been tied or compressed.

In the articles *Hæmorrhage*, and *Ligature*, I have related in detail the effects of the ligature upon a tied artery, and particularly the various processes which arise from its application, and terminate in the permanent obliteration of the vessel. In the same places, I have explained what are the best ligatures for use, as well as the safest manner of using them. Confining myself in the sequel of this article, to what expressly relates to aneurism, I shall here merely annex the following general directions, as stated by Mr. Hodgson.

First, The cord should be thin and round, such a ligature being most likely to effect a clean division of the internal and middle coats of the vessel, and not liable to occasion extensive ulceration or sloughing.

Secondly, The ligature should be tight, in order to ensure the complete division of the internal and middle coats, and to prevent its detachment, it being almost impossible, even with the thinnest ligature, entirely to cut through a healthy artery.

Thirdly, the vessel should be detached from its connexions only to such an extent as is necessary for the passage of the ligature underneath it.

Fourthly, The immediate adhesion of the wound should be promoted by all such means as are known to promote that process in general. (*On the Diseases of Arteries*, p. 225, 226.)

In the course of his experiments upon brutes, to ascertain the operation of the ligature, Dr. Jones arrived at a fact, which offered the probability of leading to an improvement in the operation for aneurism. (*Treatise on Hæmorrhage*, chap. 3.) When a small firm ligature is applied to an artery, it causes a division of the internal and middle coats; and if it be afterwards removed, an effusion of lymph takes place between the cut surfaces into the cavity of the vessel. If several divisions of the internal and middle coats be thus affected in the vicinity of each other, the effusion of lymph was

found by Dr. Jones to be sufficiently extensive to obliterate the cavity of the vessel. In the year 1800, Mr. C. Hutchinson tied the brachial arteries of two dogs, and removed the ligatures immediately after their application: in both instances, as he assures us, the complete obliteration of the canal of the artery was the consequence of the operation. (See *his Practical Observations in Surgery*, p. 103.) If immediately after the operation for aneurism, the ligature could be removed, and yet the vessel become obliterated, it would be highly advantageous, as there would then be left in the wound no extraneous substance to prevent its union, or promote secondary hemorrhage by extending the sloughing, or ulcerative process too far. It is to be regretted, that success has not attended the repetition of the experiment by others. Mr. Hodgson tried it, but the artery did not become impervious. (See *Experiments, A. & B.* p. 228, 229, of this gentleman's work.) Mr. Dalrymple, of Norwich, made the experiment not less than seven times on the horse, and three times on sheep, and failed in every instance in obtaining the same result as Dr. Jones. Not only was no coagulum formed, but, even where the animal had been suffered to live until the thirteenth, fifteenth, and eighteenth days after the operation, the canal of the artery was not found obliterated. In every instance, indeed, its calibre was contracted; but it was still capable of transmitting a lessened column of blood. (Travers, in *Med. Chir. Trans.* Vol. 4, p. 442.) Thus, it appears, that an effusion of lymph is an invariable consequence of the operation, and as Mr. Travers has observed, the want of union is therefore owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion. The presence of the ligature, in the common mode of its application, effects this object; and for the success of Dr. Jones's experiment, it appeared only necessary, that the opposite sides of the wounded vessel should be retained in contact, until their adhesion was sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but, the inconveniences attending such a degree of pressure, as would retain the opposite sides of an artery in contact at the bottom of a recent wound, are too great to permit its employment. It occurred to Mr. Travers, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to ensure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger produced by the residence of a ligature upon an artery, arises from the irritation, which, as a foreign body, it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application of a ligature; whilst it

is an ascertained fact, that lymph is in a favourable state for organization in less than six hours, in a wound the sides of which are preserved in contact. (Jones, *chap. 4, exp. 1.*) If it be sufficient, therefore, to ensure their adhesion, that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may in a great degree be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained, that if a ligature were kept six, two, or even one hour upon the carotid artery of a horse, and then removed, the adhesion was sufficiently advanced to effect the permanent obliteration of the canal. It appeared probable, that the same result would be obtained upon the healthy artery of a human subject. (See *Travers's Obs. in Med. Chir. Trans.* Vol. 4 and *Hodgson's Treatise on the Diseases of Arteries and Veins*, p. 228, *et. seq.*)

Mr. A. Cooper appears to have performed one operation for a popliteal aneurism, with a view of ascertaining the efficacy of such a method on the human subject. He completely stopped the flow of blood for thirty-two hours, and then removed the ligature; but the pulsations of the tumour commenced again. He next applied the ligature for forty hours longer, at the end of which time, no pulsation recurred on the ligature being taken away. On the twelfth day, however, a considerable bleeding took place, and it was necessary to take up the vessel anew.

Mr. A. C. Hutchinson has tried this method, as modified by Mr. Travers, in an operation, which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery. The ligatures were tied with loops, or slip-knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumour, was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed, without the slightest disturbance of the vessel. In less than half a minute afterwards, the artery became distended with blood, and the pulsations in the tumour were as strong as they had been before the operation. Mr. Hutchinson then applied two fresh ligatures; hemorrhage afterwards came on; amputation was performed, and the patient died. (See *Practical Observations in Surgery*, p. 102, *4c.*) Now, as Mr. Hutchinson chose to apply other ligatures, on finding that the pulsation returned, the above case only proves, that the artery is not obliterated in about six hours, and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hemorrhage which occurred, I think it might have been expected, considering the dis-

turbance and irritation, which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas, only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures, which were employed; an essential piece of information in forming a judgment of the merits of the preceding method. The application, removal, and reapplication, of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones, and have, in more instances than that recorded by Mr. Hutchison, brought on ulceration of the artery and hemorrhage.

The limits of this work prevent me from entering into the particulars of the very interesting experiments, undertaken by Mr. Travers, upon the arteries of animals, for the purpose of ascertaining the earliest period when a ligature might be removed from an artery, without any risk of the vessel not being duly obliterated. A full detail of them may be seen in another work, (See *Med. Chir. Trans. Vol. 4 and 6*;) and others in relation to the same question may likewise be perused in Scarpa's appendix to his great work on aneurism. (*Memoria sulla Legatura delle principali Arterie degli Arti, &c. Fol. Pavia, 1817.*) The cases, above related, and other considerations, long ago satisfied me, that, flattering as the suggestion of Dr. Jones was, the plan of removing the ligature, previously to its natural separation, would never answer in the operation for the cure of aneurism, unless either an obliteration of the arterial tube would follow with reasonable certainty the taking away of the ligature directly after it had been applied, and it had divided the inner coats of the vessel; or, at all events, unless the ligature could be withdrawn at a determinate period, when either the same obliteration would surely ensue, or be already complete; and, all this, with such regularity and infallibility in every case, that the surgeon would have no chance of being called upon to apply another ligature, do a second operation, or disturb the artery in any kind of way whatsoever.

Mr. Travers, in the prosecution of this inquiry, in which he has evinced a full determination to be guided by no motive, but the love of truth, at length tried the temporary application of the ligature in a case of brachial aneurism, which he operated upon Feb. 14, 1817. The artery was tied an inch and a half above the bend of the elbow with a noose ligature. The pulsation in the radial artery immediately ceased. On the 16th, at four o'clock in the afternoon, the ligature was removed with little difficulty after having remained on the artery *fifty hours*. No pulsation ensued in the vessel below the point where the ligature had been applied, and the case was completely successful.

On the 28th November, 1817, in a case of popliteal aneurism, Mr. Travers tied the fe-

moral artery at one o'clock. On the 29th, at four in the afternoon, the ligature was removed without difficulty, after having been on the vessel *twenty-seven hours*. At this period, no pulsation could be felt in the sac; but, at seven in the evening a faint pulsation was perceptible. On the 30th, the pulsation, though very distinct, was less strong, than before the operation. On the 2d, 3d, and 6th of December, the pulsation is described as still continuing. On the latter day, pressure was applied by means of a roller from below the knee to the groin, and was continued for a month, during which time the pulsation in the sac evidently became more feeble. On the 10th of January, the tumour became tense, and severely painful, and no pulsation in it could be distinguished. The next day, the swelling was more diffused and less prominent; and on the 12th, as the disease underwent no amendment, Mr. Travers tied the artery again, about two inches above the place, where the former ligature had been applied. The next day, the pain had diminished. The ligature was afterwards allowed to separate of itself; and the case went on favourably to the cure. According to Mr. Travers, the first of these cases tends to prove, that the continuance of the ligature upon the artery, for a period of *fifty hours*, as certainly and completely answers the purpose of its application, as if allowed to remain until thrown off by the natural process.

In the second case, Mr. Travers infers from the suspension of pain, and the diminished strength of the pulsation, for a month after the application of the temporary ligature, that a degree of impediment to the current of blood in the artery had been produced; circumstances, which once led him to entertain hopes, that the cure of the aneurism was gradually accomplishing. At length, however, the increase of the tumour, and the aggravation of pain, and inflammatory symptoms, dispelled such expectation, and it was thought necessary to tie the femoral artery a second time, and adopt the common mode.

There are one or two points, about this case, on which the author does not particularly dwell, though they require consideration, ere one can form a correct judgment of the accuracy of one of his positions, "that non-pulsation of the sac is a sign auspicious, or otherwise, simply as it stands connected with increase or diminution of bulk, and pain." (*Med. Chir. Trans. Vol. 9. p. 415.*) The first question is, how are we to account for the sudden accession of pain, the absence of pulsation, the increase of the swelling, and the other changes which happened on the 10th of January? Judging from the particulars given, I should say, that at this period, the aneurismal sac gave way, and the disease changed from the circumscribed into the diffused form; an alteration which would account for the pulsation being entirely lost, the increase of pain, and the extension of the swell-

ing, &c. Now, although the circumstance of the sac giving way, or the increase of pain, swelling, &c. on the 10th of January, may be taken as an argument, that the application of the ligature for *twenty-seven hours* had failed in producing obstruction enough in the vessel to retard the progress of the disease, we ought to remember, that, at the time when these changes happened, a trial of pressure was making, to which one might impute the change of the aneurism from the circumscribed to the diffused form, with quite as much probability, as to the enlargement of the sac by blood sent into it through the imperfectly obliterated artery. However this may be, certain it is, that the second operation was done, when no pulsation existed in the swelling; and perhaps, therefore, the case would have been doubly interesting, had the artery not been tied a second time, until circumstances had unequivocally proved, that this cessation of pulsation, attended as it was with an inflammatory state of the tumour, would not ultimately have ended in the cure of the disease.

Here, however, I may be speaking rather in the spirit of an experimenter, whose curiosity has not been fully satisfied, than as a surgeon, who should always be governed by the paramount consideration of extricating his patient from danger; and, this will appear the more likely, when I add, that my mind has long been made up about the inexpediency of the temporary ligature, as an innovation in surgery. The last case induced Mr. Travers to relinquish the temporary ligature; and among other reflections, which incline him to give up the practice, he candidly states, "that the adhesive union is prevented by the enclosure of a foreign body in the wound, long before suppuration has commenced. Suppuration is as certain to take place, though the ligature be removed after a few hours, as if it were left to be cast off; and the granulating process is more languidly performed, after an interruption in its early stage, for the purpose of removing the obstacle to union, than where no such interruption has been given, and the obstacle has been removed by nature's own means. Hence, it follows, that the theory, which, in removing the ligature within a given time, proposed the double advantage of a quicker, as well as a surer process, fails in both points, when brought to the test of practice upon the human subject." (See *Med. Chir. Trans.* p. 416-17.)

We have seen, that, when a temporary ligature, which had been applied to the brachial artery *fifty hours*, was withdrawn by Mr. Travers, pulsation in the aneurismal tumour at the bend of the elbow did not return, and the disease was cured; but, that, in another instance, where the ligature had been allowed to remain on the femoral artery only *twenty-seven hours*, a feeble pulsation was renewed a few hours afterwards in a popliteal aneurism, and as the swelling became painful and more diffused, some

weeks after this experiment, though no pulsation could then be perceived, the femoral artery was tied a second time, and the ligature left to separate in the usual manner.

But, from a case more recently published, it would seem, that the employment of a temporary ligature for only *twenty-four hours* on the femoral artery, may obliterate the vessel, and accomplish the cure of a popliteal aneurism. The patient was a seafaring man, aged 32; and the operator, Mr. Roberts, of Carnarvon; Mr. Evans and Mr. Carrey, other surgeons of that town, being present at the application, and also at the removal of the ligature. No pulsation recurred in the tumour; the edges of the wound were brought together with adhesive plaster; and, in eleven days, the part was quite healed. (*Med. Chir. Trans.* Vol. eleven, p. 100.) This is the strongest case, I believe, which has been adduced in support of the use of the temporary ligature, whether we consider the little time, which it was applied, the permanent cessation of all pulsation, the quickness with which the wound healed, or the complete recovery of the use of the limb; for when the patient was met six months after the operation, "he could go to the mast-head with as great facility as at any period of his life." This fact proves also, that there is a degree of irregularity in the period, when the temporary ligature may be removed, without the pulsation in the tumour below the constricted part ever returning. Whether the variety is to be referred to temperament, the kind of ligature used, its greater tightness in one case, than another, or other circumstances, is not at present determined.

The greatest advocate, which this practice has gained, is Scarpa, whose sentiments, however, about the most advantageous form of ligatures, and mode of applying them in cases of aneurism, are very much at variance with what is inculcated by the best, and most experienced surgeons in this country. Instead of using a fine ligature, composed of a single piece of thread, twine, or silk, he employs a cord consisting of from four to six threads, according to the size of the artery, which is to be tied; and, instead of aiming expressly at the division of the internal coats of the vessel with his ligature, as the generality of English surgeons do, for reasons explained in another part of this work, (See *Hemorrhage*.) he prefers a largish ligature, and interposing between the artery and the knot a small cylinder of linen spread with ointment, with the view of preventing the inner coats of the vessel from being divided. His reasons for this practice may be explained in a few words: he admits, that whenever there is a concurrence of all the circumstances, capable of inducing in the tied artery, the proper degree of adhesive inflammation, above and below the place where a single circular ligature has been applied, this method is adequate to produce the speedy and steady closure of the arterial tube. But, says he, it sometimes happens, at least in man, that

the pressure made by the circular ligature produces the ulcerative process more quickly in the artery, than the adhesive inflammation. In fact, the circular ligature ulcerates the artery in general about the third day after the operation; and the adhesive inflammation does not always complete its course in this period of time. During this delay of the adhesive inflammation, the ulcerative process, occasioned by the pressure of the ligature, attacks more quickly even than surgeons generally suppose, the external cellular sheath of the artery, and penetrates into the cavity of the yet pervious vessel—and this of course with increased quickness, when the inner coats of the artery are already divided by the ligature. The dangers of non-adhesion and too rapid ulceration of the artery, Scarpa thinks are placed at the greatest distance by preserving undivided all the three coats of the vessel under the pressure of the ligature; and hence, his partiality to larger ligatures, than are now used by the best surgeons in England, and to the interposition of a cylinder of linen between the knot and the vessel, as recommended by Paré, Heister, and Platner. If, however, he has had reason to suspect, that a simple circular ligature has frequently failed in England, because other innovations have been occasionally substituted for it, and because *we should not have sought for a better, if we had already had the best*, how much more vulnerable is his own practice on a similar principle; since, generally speaking, it has not retained half so many approvers as they who still express their preference to other methods, and more especially to the use of a single ligature, uncomplicated with other extraneous substances. Is it probable, he asks, that the single circular ligature, which was formerly used with doubtful success by the greatest surgeons, should now have become, as is pretended, the most certain means of preventing secondary hemorrhage? "It is now wished (says he) to ascribe the failures of Mr. Hunter, and of many other operators, not to the circular ligature, but to the improper treatment of the wound in general, and in particular to the introduction into it of lint, and, more especially, to the irritation occasioned by the ligature of reserve." On the contrary, it is argued by Scarpa, that, though Mr. Hunter, after his first trials, simplified the local treatment, though all skilful surgeons merely covered the wound with a pledget of soft ointment, and most of them omitted the reserve-ligature, yet, notwithstanding these reforms, secondary hemorrhage after the use of a simple circular ligature was not rendered less frequent. (*On Aneurism*, p. 23, ed. 2.) With respect to the latter general assertion, its incorrectness may be learned by reference to the details of Mr. Hunter's own operations, and by going into the principal hospitals of this metropolis, where the use of a simple circular ligature for the cure of aneurisms very rarely fails, as far as secondary hemorrhage

is concerned. Why then did the operation more frequently fail here in former times? The answer is plain: the kind of ligature now employed in England, cannot be compared to what was used in Mr. Hunter's time, or even to what was here in fashion five and twenty years ago. And, besides the universal rejection of ligatures of reserve, practitioners now have a more thorough comprehension of what ought to be avoided in the operation, have a just fear of separating and disturbing the artery too much, know how to appreciate the advantage of closing the wound, and attach due importance to the choice of smaller or more eligible ligatures. (See *Hemorrhage* and *Ligature*.) When, therefore, Scarpa supposes, that in England the practice with the circular ligature in the treatment of aneurism, is materially the same now, as heretofore, and that secondary hemorrhage is as frequent, he has not availed himself of all the information on this subject, which he might have acquired from Mr. Wishart, the able translator of his writings on aneurism, or from an attentive perusal of Mr. Hodgson's valuable treatise.

In an equality of circumstances, conducive to the success of the Hunterian operation, Scarpa thinks, that the fact is not proved, as it is presumed to be, that the rupture of the internal and middle coats of the artery does excite the adhesive inflammation and union of the artery more effectually, than is done by the simple compression and close contact of its two opposite internal parietes in a sound and uninjured state. This remark is partly true, and partly incorrect, at the same time that it involves a question, which must be deferred till we come to the article *Hemorrhage*. The truth in the observation is, that an artery may generally be rendered impervious with tolerable certainty, by compressing its opposite parietes steadily and firmly together for a certain time, without dividing its inner coats: the inaccuracy of it depends upon the fact, that, surgeons have no instrument, nor contrivance (not excepting even the ligature of four or six threads, with the interposition of the cylinder of linen spread with ointment,) which can retain the opposed undivided surfaces of the inner coats of the vessel closely together in the manner commended by Scarpa, and for the due time, without the objection of denuding more of the artery, than need be done in the application of a small ligature, or without the serious inconvenience, and risk, necessarily attending the introduction of a larger quantity of extraneous matter into the wound, than is desirable, with the view of averting all chance of the ulceration of the artery reaching beyond prudent limits. And, when metallic instruments are used for the same purpose, objections not less real are incurred, as will be hereafter more particularly explained.

Scarpa considers his mode of ligature ought to be preferred, as combining the triple advantage of preserving entire all the

three coats of the artery; of exciting quickly, and in a proper degree, the adhesive inflammation in them; and of retarding, as much as possible, the ulcerative process of the arterial tube.

Partly impressed, however, with the truth of the tenets laid down by Dr. Jones (See *Hæmorrhage*;) Scarpa enjoins attention to the following rules. 1. *Not to insulate and detach the artery any further, than is necessary for allowing a ligature to be passed around it.* 2. *Not to let the cylinder of linen exceed a line in length, or a little more above and below the breadth of the tape, which is about a line for the large arteries of the extremities.* 3. *That the ligature be not too tight.* 4. *And that it be never applied immediately below the origin of a large lateral branch.* (See *Scarpa on Aneurism*, p. 44, Ed. 2.)

Some further consideration of Scarpa's mode of applying the ligature will be introduced in the article *Hæmorrhage*; and I now proceed to notice his sentiments concerning the advantage which may be derived from removing the ligature in cases of aneurism, as soon as the tube of the vessel has been obliterated by the adhesive inflammation. Now, from the facts recorded by Scarpa, it is inferred, that, with the kind of ligature and the cylinder of linen used in his practice, the closure of the artery by the adhesive inflammation and the two internal coagula is sufficiently far advanced on the third, or fourth day after the operation, to resist the impulse of the blood; and hence (says he) there is no rational motive for waiting beyond this time for the spontaneous separation of the ligature, or for allowing it, by its further presence, to ulcerate, and even open the artery at the principal point of adhesion. He then comments on the advantages to the wound, derived from the removal of all extraneous matter from it on the third, or fourth day. With respect to the general period of such removal, however, he makes one exception, viz. the case of great and evident debility from sickly constitution, or very advanced age, as it is observed, that, in such patients, the reunion of a simple wound is frequently protracted to the sixth day. In cases of this description, Scarpa recommends delaying the removal of the ligature to the completion of the fifth or sixth day, but under the express condition, that the ligature has been applied with the interposition of a cylinder of linen; as it is proved, that a common circular ligature causes ulceration of the artery before the third day, and it is not till the sixth day that the external coat of the vessel begins to ulcerate, when the other modification of the ligature is adopted. (p. 50.)

Scarpa supports the preceding advice by four cases, in which his kind of ligature was applied, and withdrawn at the end of the third, or fourth day, and the arterial tube obliterated. However, I do not think, that in England, these cases, when minutely and attentively considered, will be regarded as inducements to persevere in the use of temporary ligatures. In every instance,

the wound is described as suppurating, and sometimes plentifully. In one, the foot mortified, and amputation became necessary. In another, the very day after the disturbance of removing the ligature, the thigh was attacked with erysipelas, and, on the eighth day, the wound is represented as being foul, and the erysipelas not yet cured.

Independently of the uncertainty of the period, when the arterial tube is closed by the adhesive inflammation in various patients, it appears to me, that the disturbance of the vessel and wound, by the steps necessary for the loosening and removal of the ligature, will ever form an insuperable objection to the practice. Scarpa appears to have some apprehension of this kind himself; for he remarks, "In the act of removing the ligature, there can be no doubt it is of great consequence, that the artery be not rudely handled, or stretched. And, indeed, if, on untying the running knot, the subjacent knot could be with the same facility untied, we could not wish for a better mode of performing this part of the operation. But, the knot, although a simple one, is not so readily untied, as the running knot, on account of the moisture, with which the threads forming the ligature are soaked, or because the ligature has been previously waxed." (P. 64, Ed. 2.) In fact, his apprehensions then lead him to suggest the scheme of placing, previously to making the knot, a thread longitudinally, on each side of the cylinder, and at the time of removing the ligature, the threads are to be drawn in opposite directions, in order to undo the knot, without displacing, or stretching the artery. Thus, instead of one small ligature, which is all that an English surgeon leaves in the wound, Scarpa recommends his ligature of four, or six threads, a roll of linen, and two other threads; a quantity of extraneous substances, which cannot fail to be a source of irritation and serious mischief. I shall therefore take leave of the proposal of removing the ligature on the third, or fourth day, or any other particular day, with expressing my belief, that, if there were only the following objection to the plan, it would never be adopted in this country; namely, the advocates for this practice are necessarily obliged to renounce the infinite advantage of bringing the edges of the wound together directly after the operation. Had the suggestion of Dr. Jones proved invariably correct, and the ligature admitted of being withdrawn immediately after the inner coats of the vessel had been divided by it, the case would have been very different, as there would then have been no foreign body at all left in the wound; the parts might have been immediately brought together with the greatest chance of union by the first intention, and no subsequent disturbance either of the artery, or of the wound, would have been incurred.

The next practice, which I shall notice, is that of applying two ligatures to the artery, and cutting it through in the interspace. This suggestion may be said to be as ancient as

the time of Celsus, who has advised this method to be followed in the treatment of a wounded artery: "*Quæ (arteriæ) sanguinem fundunt apprehendendæ, circaque id quod ictum est duobus locis deligendæ intercidentæque sunt, ut in se ipse cocant, et nihilominus ora reclusa habeant.*" (*De Medicina, Lib. 5, c. 26, § 21.*) The fact is curious, though I mention it without the least intention of detracting from the great merits of several modern surgeons, that the Greeks were acquainted with the practice, lately recommended, of tying and dividing the trunk of the artery high above the tumour, as will appear from the following extract: (*Æti. 4. Serm. Tetr. 4. cap. 10.*) *At vero quod in cubiti cavitate fit aneurisma, hoc modo per chirurgiam aggredimur: primum arteria superne ab ala ad cubitum per internam brachii parte simplicem sectionem, tribus, aut quatuor digitis infra alam, per longitudinem facimus, ubi maxime at tactum arteria occurrit: atque ea paulatim denudata, deinceps incumbens corpuscula sensim excoriamus ac separamus, et ipsam arteriam cæco uncino attractam duobus fili vinctis probe adstringimus, mediamque inter duo vincula dissecamus; et sectionem polline thuris explemus, ac linamentis inditis congruas deligationes adhibemus.* Afterwards we are directed to open the aneurismal tumour at the bend of the elbow, and when the blood has been evacuated, to tie the artery twice, and divide it again. If the ancients had only omitted the latter part of their operation, they would absolutely have left nothing to be discovered by the moderns.

This method of applying two ligatures to the artery, and dividing the vessel between them, was revived in France about half a century ago by Tenon, who, as well as some later surgeons, was totally unacquainted with its antiquity. (See *Pelletan's Clinique Chirurgicale, T. 1. p. 192.*) At one time, it had also modern advocates in Mr. Abernethy and Professor Maunoir, of Geneva, each of whom supposed the plan an invention of his own. (See *Surgical and Physiol. Essays, Part 3, Sec. Lond. 1797, and Mémoires Physiologiques et Pratiques sur l'Aneurisme &c. Sec. Geneve, 1802.*)

When an artery is laid bare, and detached from its natural connexions, and the middle of such detached portion tied with a single ligature, as was Mr. Hunter's practice, Mr. Abernethy conceived, that the vessel, so circumstanced, would necessarily inflame, and be very likely to ulcerate. The occurrence of bleeding from this cause at first led to a practice, which this gentleman justly censures, viz. applying a second ligature above the first, and leaving it loose, but ready to be tightened, in case of hemorrhage. As the second ligature, however, must keep a certain portion of the artery separated from the surrounding parts, and must, as an extraneous substance, irritate the inflamed vessel, it must make its ulceration still more apt to follow. The great object, therefore, which Mr. Abernethy insisted upon, was that of applying the ligature close to that part of the artery, which lies among its natural con-

nexions; a just principle, the truth and utility of which still remain incontrovertible, though there may be a better way of accomplishing what Mr. Abernethy intended, than the measures which this gentleman was led to recommend.

The peculiarity in Mr. Abernethy's first operation consisted in applying two ligatures round the artery, close to where it was surrounded with its natural connexions. For this purpose, he passed two common sized ligatures beneath the femoral vessels, and having shifted one upwards, the other downwards, as far as these vessels were detached, he tied both the ligatures firmly.

The event of this case was successful. An uneasy sensation of tightness, however, extending from the wound down to the knee, and continuing for many days after the operation, made Mr. Abernethy determine, in any future case, to divide the artery between the two ligatures, so as to leave it quite lax.

Mr. Abernethy next relates a case of popliteal aneurism, for which Sir Charles Blicke operated, and divided the artery between the ligatures. The man did not experience the above kind of uneasiness; and no hemorrhage ensued when the ligatures came away, although there was reason to think, that the whole arterial system had a tendency to aneurism, as there was also another tumour of this kind in the opposite thigh.

The reasoning, which induced this gentleman to revive this ancient practice, was ingenious; for, when the artery was tied with two ligatures, and divided, in the foregoing manner, it was argued, that it would be quite lax, possess its natural attachments, and be as nearly as possible in the same circumstances as a tied artery upon the face of a stump. Strictly speaking, however, as Mr. Hodgson first pointed out, an artery tied in two places, and divided in the interspace, cannot be regarded as placed exactly in the same condition, as an artery tied in amputation. In the latter case, the retraction of the vessel corresponds with that of the surrounding parts, which are divided at the same instant, and therefore its relative connexions stand as before the operation. But, in the operation for aneurism, the retraction of the artery takes place, without being attended with a corresponding retraction of its connexions. How far the retraction of the artery is beneficial, or injurious, is by no means evident; and the advantages arising from it may in most situations be obtained, without dividing the vessel, by placing the limb in a bent position. One important object, however, is gained by the division of the artery; namely, that it is generally in that case tied close to its connexions; and it is very evident how liable the application of the ligature in the middle of a denuded extent of the vessel must be to produce ulceration or sloughing of its coats. The same object, however, will be gained by tying the undivided artery close to its connexions at the end nearest to the heart; and the existence of a single ligature at the bottom of the wound will be less liable to give rise to supuration and the formation of sinuses, than

the employment of two. When an artery is divided, the portions situated beyond the ligatures must slough, and prove an additional cause of suppuration in the wound. Experience has amply proved the safety of employing a single ligature, and it is at present used by many of the most experienced operators in this country. (See *Hodgson's Treatise on the Diseases of Arteries*, &c. p. 221, &c.)

According to Scarpa, numerous examples of the failure of the plan of applying two ligatures, and cutting through the artery in the interspace, are already generally known to the profession, and there are many expert and ingenious surgeons, who do not dissemble the disadvantage and uncertainty of this practice. He speaks of one failure, which occurred to Mr. Abernethy himself. But, I entertain doubts how far any inference against the method can be drawn from Monteggia's instance, in which a ligature of reserve had been used. Nor can I understand, how a circumstance, which Scarpa strongly insists upon, can be well founded, I mean, the danger of the ligature being forced off the mouth of the artery by the impulse of the blood. Any risk of this kind cannot exist if the ligature be duly applied, as Dr. Jones has particularly explained; and, at all events, how can it be greater here, than after amputation, where it is not usually made a subject of complaint? Indeed, the several examples of secondary hemorrhage, after this method, quoted by Scarpa from the practice of Monteggia, Morigi, and Assalini, may be more rationally imputed either to reserve ligatures having been also used, or the common fear in Italy of applying the ligatures tightly; in which event, one can readily suppose, that the ligature might really slip, or by remaining a long time on the vessel might give rise to dangerous ulceration. Thus, Morigi speaks of one case, in which the bleeding occurred on the nineteenth day. (*Scarpa on Aneurism*, p. 14, Ed. 2.) On the whole, I am disposed to believe, that when this method has been executed precisely according to Mr. Abernethy's directions, it has not often failed; and I am acquainted with only one case in London, in which it was followed by secondary hemorrhage. However, in the year 1807, Mr. Norman, of Bath, tied the femoral artery with two ligatures, and divided the vessel between them; the upper ligature came away on the sixteenth day after the operation; the lower one on the fifteenth; and the following day a profuse hemorrhage came on, the patient losing a pound of blood. Pressure with a compress and wet bandage was continued for some time, and the wound healed. (See *Med. Chir. Trans.* Vol 10, p. 123.) This is the only case of secondary hemorrhage, which he has met with after operating for aneurisms.

Scarpa very properly urges, that the application of two ligatures, and dividing the artery in the interspace, can never be an eligible mode, where the smallness of the space, the depth of the artery, and the im-

portance of the surrounding parts, do not permit the vessel to be separated and insulated to such an extent, as is required for dividing it, with a probability of the division of it being sufficiently distant from the two ligatures. Such, for example, are the cases of ligature of the carotid in the vicinity of the sternum; of the iliac, above Poupart's ligament; of the internal iliac, a little below its origin from the common iliac; of the axillary artery between the point of the coracoid process and the acromial portion of the clavicle; or of the subclavian in its passage between the scaleni muscles. Scarpa then comments on the difficulty and even impossibility of taking up the end of the truncated artery again in many situations, were hemorrhage to ensue; and he joins Mr. Hodgson in thinking the advantages of the method, even where it is practicable, by no means demonstrated. Nay, he goes further; for he agrees with Heister, Callisen, and Richter in setting it down as worse than useless, on account of the portion of the artery between the ligatures being converted into a dead and putrid substance, which rests upon the bottom of the wound, from which it cannot be removed, until the two ligatures are separated. Here, deeply impressed with the truth of principles, which perhaps he has rather lost sight of in speaking of his own particular method, he comments on the little probability of the wound uniting, under the disadvantage of two ligatures hanging out of it, and of sloughs at its bottom. He argues correctly, that the laying bare, and insulating a large portion of artery, would often be objectionable on the ground, that it could not be done, without the surgeon being obliged to apply the principal ligature too near the origin of a large lateral branch; as, for example, would be the case in a case of inguinal aneurism, situated *an inch and a quarter* below the origin of the profunda. Thus, a coagulum could not be formed, and the artery would be in danger of not being closed. On the contrary, by employing only a single ligature at *an inch and a quarter* below the origin of the profunda, the operation would be equally simple and successful. (*Scarpa on Aneurism*, p. 19—21, Ed. 2.)

The frequent occurrence of accidents after the introduction of Mr. Hunter's operation, however, might have been ascribed to more probable causes, than the condition of an undivided artery, upon which the ligature was applied. The employment of numerous ligatures gradually tightened, or the introduction of extraneous bodies into the wound, were alone sufficient to produce ulceration of the artery; and such practices were adopted in most of the cases, in which secondary hemorrhage took place.

After the reasons, which have been urged against the plan of tying the artery with two ligatures, and dividing it in the interspace, it may appear superfluous to notice a modification of this practice, intended as a secu-

ity against the slipping of the ligature. But, as the proposal has had the approbation of some men of eminence, and I heard of an instance in which it was practised not long ago, the subject may still be worthy of notice.

Mr. A. Cooper has published a case of popliteal aneurism, in which the femoral artery had been tied with two ligatures, as firmly as could be done without risk of cutting it through. "But (says this gentleman) as I was proceeding to dress the wound, I saw a stream of blood issuing from the artery, and when the blood was sponged away, one of the ligatures was found detached from the vessel. Soon after the other was also forced off, and thus the divided femoral artery was left without a ligature, and unless immediate assistance had been afforded him, the patient must have perished under hemorrhage."

The same kind of accident has occurred in Mr. Cline's practice.

These events naturally induced Mr. A. Cooper to reflect on the means, which were to be employed to obviate them, and the first which suggested itself was to include a larger portion of the artery between the two ligatures. But this plan was given up when it was recollected, that many branches of arteries must be divided, and that it was a mode of security which could only apply to particular cases of aneurism, since in some situations of that disease, there is scarcely any length of vessel between the tumour and principal anastomosing branch of the artery.

Mr. A. Cooper thinks, that a plan of greater security, and more general application, consists in conveying the ligatures, by means of two blunt needles, under the artery, an inch asunder, and close to the coats of the vessel, excluding the vein and nerve, but passing the threads through the cellular membrane surrounding the artery. When these are tied, and the artery is divided between them, the ligatures will be prevented from slipping from the artery by the cellular membrane through which they are passed. Mr. A. Cooper next relates a case of aneurism after bleeding, which he cured by this way of operating.

"But although this plan, as to the event, answered my expectations, yet a different mode of securing the ligature, suggested to me by my young friend Mr. H. Cline, struck me so forcibly for its simplicity and security, that I felt immediately disposed to adopt it.

Mr. A. Cooper put the new plan to the test of experiment in operating for a popliteal aneurism on Henry Figg, aged 29. "An incision being made on the middle of the inner part of the thigh, and the femoral artery exposed, the artery was separated from the vein and nerve, and all the surrounding parts, to the extent of an inch, an eye-probe, armed with a double ligature, having a curved needle at each end, was conveyed under the artery, and the probe cut away. The ligature nearest the groin

was first tied; the other was separated an inch from the first and also tied. Then the needles were passed through the coats of the artery, close to the ligatures between them, and the ends of each thread were again tied over the knots, made in fastening the first circular application of the ligatures. Thus, a barrier was formed, beyond which the ligature could not pass." The event of this operation was successful. (*Med. and Phys. Journ. Vol. 8.*)

Upon the foregoing proposal a few observations are necessary; and these I shall offer with due deference to the eminent surgeon, whose fame alone has attached undue importance to the innovation.

It appears to have been mentioned by Dionis, and to have been noticed by some subsequent writers. In the 13th chapter, on hemorrhage, in Richter's *Anfangsgrunde der Wundarzneykunst*, we read the following passage:

"The artery, when drawn out, is to be twice surrounded with the common ligature. This is to be tied in a knot, and when the artery is large, one end of the ligature is to be passed, by means of a needle, through the vessel before the knot, then both ends are to be tied together, and left hanging out of the wound, as in the ordinary way." Ed. 3. 1799.

What power can possibly force the ligature, when tied with due tightness, off the extremity of the vessel? No action of the heart, or artery itself, no turgid state of this vessel, could do so. If a piece of string were tied round any tube for the purpose of preventing a fluid from escaping from its mouth, provided the string were applied with due tightness, and the knot in such a manner as not to yield, no fluid could possibly escape, however great the propelling power might be, provided the string and structure of the tube did not break. And, if a ligature were applied so slackly as to slip, who can doubt, that hemorrhage would still follow, even though the ligature were carried through the end of the vessel, and tied in the foregoing way?

Where ligatures have slipped off, very soon after being applied, I conclude, that the arteries either could not have been tied with sufficient tightness, perhaps through an unfounded fear of the ligature cutting its way completely through all the coats of an artery, or else that the knot, or noose became slack, from causes, which will be understood by considering, what is said on this matter in the article *Hemorrhage*. The inner coats of the artery, we know, from the experiments of Dr. Jones, ought to be cut through when the artery is properly tied, because the circumstance is always useful in promoting the effusion of lymph, within the vessel, and the process of obliteration by the adhesive inflammation.

The preceding method is so contrary to the grand principle of always avoiding the detachment of the artery from its surrounding connexions, and is so inconsistent with

the wise maxim of doing the operation with as little disturbance of the vessel as possible, that it is not surprising that it should have met with only a small number of followers. In fact, it is not only liable to every objection which can be urged against the double ligature and division of the artery, as formerly proposed by Celsus, and a few of the moderns, but, on account of its greater tediousness, more extensive separation and destruction of the vessel, and other reasons, is still less worthy of imitation.

With respect to ligatures of reserve, the interposition of agaric, cork, and other hard substances between the knot and the artery, these contrivances are now so fully rejected by all good surgeons, for reasons which will be quite intelligible, after the perusal of another part of this work, (See *Hæmorrhage*;) that I shall not at present detain the reader with animadversions on their danger. As for several kinds of metallic compressors, intended to be applied to the exposed artery, for the purpose of rendering it impervious, they are inventions which have been made and extolled by some surgeons of high repute, whose names would give importance even to a less meritorious proposition.

Dubois conceived, that hæmorrhage might sometimes proceed from the circumstance of a ligature making its way too fast through the artery. He thought, also, that the sudden stoppage of the current of blood by a tight ligature might bring on gangrene of the limb, particularly, where the aneurism was not of long standing, so that the collateral branches had not had time to enlarge. Dubois, therefore, proposed a method of gradually stopping the flow of blood through the artery; and, by this ingenious imitation of the process of nature, to promote the gradual dilatation of the collateral arteries, and obviate all risk of gangrene in the lower part of the limb. This gentleman put his plan in execution, and two instances of success are recorded. The cases were popliteal aneurisms. A ligature was passed under the artery in the manner of Hunter; its two ends were then put through an instrument, called a *serre-nœud*, with which the compression was gradually increased. It is stated, that, in one of these cases, the plan made the artery inflame and become impervious, in the course of the first night, so that on the following day the throbbing of the tumour had ceased. (*Richerand, Nosogr. Chir. T. 4, p. 109, Edit. 4.*) Here, however, it is to be suspected, that the pressure of the apparatus was greater, than was calculated; and that the stoppage of the pulsation was more owing either to this cause, or to the coagulation of the blood, in the sac and adjoining portion of the artery, than to the process of obliteration, which could hardly have been so rapidly accomplished.

Assalini's compressor is an instrument, calculated, as its inventor states, to produce an obliteration of the trunks of arteries,

without dividing, or injuring their coats. It is nothing more, than a small pair of silver forceps, the blades of which are broad and flat at their extremities, between which the artery is compressed. A spring, composed of a piece of elastic steel, is attached to the inside of one of the handles, and by pressing against the opposite handle, retains the flat ends of the blades in contact. This spring is intended to be very weak in its operation; but, by means of a screw, which passes through the handles, the pressure admits of being regulated and increased at the option of the surgeon.

A representation of Assalini's compressor may be seen in his *Manuale di Chirurgia, parte Prima, p. 113*. In the same book, or, in my friend Mr. Hodgson's valuable *Treatise on the Diseases of Arteries and Veins*, which every practical surgeon ought to possess, a case may be perused, in which this instrument was successfully employed by Professor Monteggia, and withdrawn entirely, as early as sixty hours after its application. This last distinguished surgeon also used the compressor in an example, in which the femoral artery was wounded, and bled in an alarming degree. After forty hours, the pressure was lessened, and, in four hours more, as not a drop of blood issued from the vessel, and there seemed to be no good in leaving an extraneous body in the wound any longer, the instrument was taken out altogether. (See *Assalini's Manuale di Chirurgia, p. 110.*)

When Assalini was in England, he acquainted Mr. Hodgson, that, in two cases of popliteal aneurism, in which he had himself employed this means of obliterating the femoral artery, the instrument was removed at the expiration of twenty-four hours; no pulsation returned in the tumours; and the patients were speedily cured.

With respect to the particular merit of this invention, it certainly possesses the recommendation of ingenuity; but, it operates much in the same manner, as several other mechanical contrivances, the *serre-nœud* of Desault, the *presse-artere* of Deschamps, that of Mr. Crampton, (See *Med. Chir. Trans. Vol. 7.*) the pincers of Baron Percy, &c. If there be a real advantage in the division of the internal coats of an artery by the ligature, as the experiments of Jones seem to prove, and as many of the best surgeons in this country inculcate, (See *Hæmorrhage and Ligature*;) then the compressor cannot be an eligible means of obliterating an artery. It may be said, however, that experience has proved its efficacy; but, let it be recollected, that almost every method of operating for aneurisms has sometimes answered. Further experience is requisite to determine, whether Assalini's compressor would succeed as often as, or more frequently than, the scientific application of the right kind of ligatures (See *Ligature*) which may perhaps seem slower in their effect, only because they are not in general removed as early as Assalini's instrument. In fact, the experi-

ments of Mr. Travers have now proved, that the ligature is the quickest in its operation. (See *Med. Chir. Trans.* Vol. 6, p. 643, &c.)

In 1816, some ingenious observations were published by Mr. Crampton, on the effects of the ligature and of compression in obliterating arteries. The purport of his remarks is to prove, like the later observations of Scarpa; 1st, That the obliteration of an artery can *very certainly* be effected, independently of the rupture, or division of any of its coats; 2dly, That this operation of the ligature, so far from being essential to the process, not unfrequently defeats it. (See *Med. Chir. Trans.* Vol. 7, p. 344, 345.)

With respect to the first of these assertions, I presume that all practical surgeons have known and admitted it, especially, if the words *very certainly* be left out. Every system of surgery, for half a century past, has recorded the occasional cure of aneurism by different modes of compression, by which the adhesive inflammation is excited in the artery, or the coagulation of the blood in the aneurismal sac brought about. As, however, the most experienced surgeons have found the method less certain than the use of the ligature, it is not represented by any modern writers, as deserving equal confidence; though there are circumstances, in which simple pressure may be sometimes tried, with a hope of doing away all occasion for an operation. The cases, however, in which compression is applied directly to the artery itself by means of ligatures, with the intervention of other substances, as advised by Scarpa, &c. or by various contrivances, like those of the *serre-nœud*, the *presse-artère*, and Assalini's forceps, all require the exposure of the artery; and if commendable, therefore, cannot be so on the principle of saving the patient the pain of an operation, but because they are more effectual than the employment of the ligature. This last point remains to be proved. From the comparatively small number of instances, in which the preceding modes of compression have been practised, I could quote several examples of failure, were it necessary.

With regard to Mr. Crampton's second assertion, that the division of the inner coats of the vessel, so far from being essential to the process of obliteration, not unfrequently defeats it, I think the last part of the observation is altogether unproved. We must admit, that the division of the inner coats is not essential, because arteries sometimes become obliterated under a variety of circumstances, in which such division is not made; but still, the great question remains, whether it renders the process more certain. Mr. Crampton founds his conclusion, that it not unfrequently prevents the obliteration, and gives rise to secondary hemorrhage, upon a few very uncommon cases, in which aneurismal swellings have taken place above the ligature. (See *Warner's Case*, p. 123 of this Dictionary.) Here Mr. Crampton presumes, without proof, that the oc-

currence happened from the division of the inner coats of the artery, though Mr. Warner himself suspected, with more probability, that it proceeded from a diseased state of the vessel. Besides, this event, be it produced in whatever manner it may, is so rare, that I only know of three examples of it on record, and have never known it occur during the last 23 years, that I have been in the constant habit of seeing numerous operations performed. In Mr. Warner's time, such large ligatures were also in use, that it appears to me, they were more likely merely to press the sides of the artery together, like Mr. Crampton's *presse-artère*, than effect a complete division of the inner coats of the vessel, as is accomplished by the small ligatures in modern use.

Those metallic instruments, intended to be applied directly to an exposed artery, for the purpose of obliterating it by compression, are liable, as Scarpa remarks, to all the inconveniences, which are inseparable from the presence of hard bodies, introduced, and kept for several days in the bottom of a wound; especially when this is recent, in which case, they cannot be retained in a proper direction without difficulty, or exactly at such a depth, as will not be attended with hurtful pressure upon the wound itself, and important parts in its vicinity. And, with regard to the forceps of Assalini, Monteggia has observed, "*if the obliteration of the artery is retarded, the forceps equally divides the artery by causing the death of the included portion. I also saw, in one case, the extremity of the instrument resting at the bottom of the wound on the subjacent femoral vein, rupture its anterior half also, although we were sure it had not been included by it.*" (*Instituz. di Chir.* Ed. 2, T. 2.) And although Cumano, in a case of popliteal aneurism, obtained on the fourth day, the closure of the femoral artery, by means of Assalini's forceps, he does not conceal that the cure of the wound was rather difficult; and in comparing the ligature with the forceps, he adds his belief, that if an equal result is derived from both, the preference will be given to the ligature, unless the other instrument be brought to such perfection that the inconveniences will be removed, from which he found it not exempt, though the operation succeeded. (*Annali di Med. del Dottore Omodei, Settembre 1807*, p. 309, and *Scarpa on Aneurism*, p. 45, Ed. 2.) Some experiments were a few years ago instituted by Mr. Travers, in order to determine the merit of Assalini's forceps, compared with the ligature: and his conclusion from the facts elucidated in the investigation is, that the ligature is a more powerful means for affecting the obliteration of the tube of an artery. (See *Med. Chir. Trans.* Vol. 6, p. 643, &c.)

My friend, Mr. Lawrence, a few years ago, extended to operations for aneurism the method of tying the artery with a very small firm silk ligature, the whole of which is immediately afterwards cut off, with the exception of the noose and knot, and an endeavour then made to heal the wound

by the first intention. In a case of popliteal aneurism, Mr. Carwardine, late of Thaxted, tied the femoral artery in this manner, and the wound united entirely by the first intention, not a particle of pus having been formed at any time; and the part continued perfectly sound at the distance of some months from the operation. On the 29th of March, 1817, I saw Mr. Lawrence try the practice in a similar case: with the exception of the integuments, the wound united by adhesion. However it continued to discharge a small quantity of matter till the end of May, when the ligature came away, and it healed firmly. In an aneurism of the humeral artery, Mr. R. Watson, of Stourport, Worcestershire, tied that vessel and cut off the ends of the ligature, as proposed by Mr. Lawrence. The operation was done on the 2d of March, and the wound was quite healed by the 10th of April. On the 3d of May, a small tubercle which had been felt under the skin, in the centre of the cicatrix, appeared above the skin, and proved to be the knot of the ligature. There was no inflammation or discharge; but, the ring of the ligature was firmly impacted in the centre of the cicatrix. In about a week from this time, the whole of it was expelled. In another case, where Mr. Hodgson tied the ulnar artery, and cut off the ends of the small ligature, the skin healed over the vessel, but a firm almost cartilaginous knot gradually formed, from the centre of which the bit of ligature was extracted five or six months afterwards by a small puncture. For additional observations on this part of the subject, See *Med. Chir. Trans.* Vol. 8, p. 490, &c.

Mr. Carwardine's case is a strong one in favour of this method: but, I am not aware, that sufficiently numerous trials of it have been made to enable one to form a correct estimate of its merits. With the exception of the example communicated by Mr. Carwardine to Mr. Lawrence, I apprehend, that, on the whole, the cures on record cannot be said to have been completed sooner, than generally occurs in other instances, in which one end of the small circular ligature is left for the removal of the noose. Thus, in two cases, where the practice was tried by Mr. Norman, of Bath, the results were by no means encouraging. In one of these instances, a part of the wound appeared to have united by the first intention, but *matter afterwards formed, and it was a considerable time before the ulcer healed.* The ligature was never seen to come away; but from the circumstance of the suppuration, Mr. Norman apprehends, that it must have been voided. In a second example, the attempt to procure a permanent adhesion of the parts over the ligature did not succeed; a *long and troublesome suppuration ensued, and the wound was not healed till the latter end of April, though the operation was done on the 7th of March, (Norman, in Med. Chir. Trans. Vol. 10, p. 120—121.)* As catgut, however, was employed for the ligatures in these two operations, I do not know, that it is fair to consider the method exactly as

that recommended by my friend Mr. Lawrence, who particularly directs very small ligatures of dentist's silk to be used. But, besides the different material employed, we are left uninformed of the thickness of the catgut; and, in this respect also there would probably be no greater similarity between the ligatures of these gentlemen, than there is in regard to the substances, of which such ligatures were made. In favour of catgut, as a ligature, when the ends of it are to be cut off, a case published by Mr. A. Cooper deserves particular notice. The wound was found completely united on the fourth day after the operation, notwithstanding the patient was eighty years of age. The catgut, previously to its application, was softened in warm water. The recovery was complete; a fact, strongly proving the propriety of not rejecting an operation on account of age, if no other objections exist. (See *Surgical Essays*, part 1, p. 126.)

Alluding, however, to silk ligatures, if we take into the account the little ulcerations, suppurations, and hard knots, which occurred even after their use in this manner, I fear, that, though these complaints might be attended with no severe inconvenience, they will deter many surgeons from adopting the innovation; unless it can be proved that these inconveniences, slight as they were, were counterbalanced by the quicker healing of the incision, or some other decided benefit. As a mode, attended with the least possible risk of being followed by secondary hemorrhage, however, I consider it inferior to no practice, which has yet been suggested; nor do I know of any serious objections to it in any point of view, provided exactly such ligatures are used as Mr. Lawrence recommends.

In cases of aneurism, a single small ligature, composed of dentist's silk, inkle, or twine, is now usually preferred by the majority of the best surgeons in England; but, as the right qualities of ligatures are elsewhere considered, (See *Hemorrhage and Ligature*) I need not here dwell upon the subject. It is not meant to assert, that the use of a single ligature is never followed by secondary hemorrhage; for this would be untrue. The accident I believe will sometimes happen after this, or any other mode, under certain circumstances, and in unfavourable subjects. A fact of this kind we find recorded, which happened in the practice of a truly eminent and experienced surgeon; (See *A. Burns on Diseases of the Heart*, p. 230;) but, from the inquiries, which I have made, it appears to me proved, that, *cæteris paribus*, a single small ligature, applied with as little disturbance and detachment of the artery as possible, will be more rarely followed by secondary hemorrhage, abscesses, sinuses, &c. than any other known method. Thus, in the several cases, reported by Mr. Norman, the single ligature was never followed by any of those inconveniences, which, he justly thinks, will be rarer after this practice, than any other, "if the artery be not removed from its situation, or more detached, than the liga-

ture separates it." (See *Med. Chir. Trans.* Vol. 10, p. 123.)

Before entering into the consideration of particular aneurisms, I wish to mention a few other circumstances, worthy the attention of every practical surgeon. The first is the partial entrance of blood into the aneurismal sac, after the artery has been tied at some distance from the tumour. This fact was first particularly pointed out, and its reasons explained by Sir E. Home, who published three examples of its occurrence. (See *Tran. of a Soc. for the improvement of Med. and Chir. Knowledge*, vol. 1, p. 173, & vol. 2, p. 239.) But, the circumstance had never, I believe, been considered with due attention, until Mr. Hodgson made it one of the subjects of his reflections in his valuable treatise.

"When an artery is tied close to an aneurismal sac, the ingress of blood into the latter is in most instances prevented; the coagulum, which it contains, is absorbed, and the membranes of which the sac is composed, gradually contract, until its cavity is permanently obliterated. But, when the artery is tied at a distance from the disease, the ingress of blood into the latter is not altogether prevented; for, the anastomosing branches, which open into the trunk, below the seat of the ligature, convey a stream, which passes through the aneurism. The impulse of this current, however, is so trifling, that the enlargement of the sac not only ceases, but the deposition of coagulum in it increases, in consequence of the languid state of the circulation. The coagulum accumulates, until the cavity, of the sac, and the mouth of the artery leading into it, are obliterated," &c. (See *Hodgson on the Diseases of Arteries*, p. 266.)

This fact, which is of great importance, both in a practical and pathological point of view, is proved, (says this gentleman,) 1st, by the occasional recurrence of pulsation in the tumour after the operation; 2dly, by cases in which the cavity of the sac has been exposed, and hemorrhage has been the consequence; and 3dly, by dissection, in which it has been found, that the cavity of the aneurism, as well as that of the artery, from which it originated, was pervious, from the part which was obliterated by the direct operation of the ligature.

For a detail of the facts relative to this interesting point, the reader is referred to Mr. Hodgson's valuable publication (*P. 267, et. seq.*)

Some very uncommon instances are recorded, in which the return or continuance of pulsation in the tumour is said to have prevented the cure; the aneurismal sac having begun to enlarge again. The two cases of this kind, however, which happened in the practice of Pott and Guérin, (*Tran. of a Soc. for the Imp. of Med. Chir. Know.* vol. 1, p. 172, & *Journ. de la Soc. de Santé*, No. 3, p. 197.) cannot be well depended upon, as it may be doubted, whether the artery had really been tied. Some better established facts, relating to this part of

the subject, have been very recently published. One is a case by Dr. Monteath, jun. of Glasgow, which is very remarkable; as the disease, viz. a popliteal aneurism, recurred nine months after the femoral artery had been unequivocally tied in the upper third of the thigh. On the 27th of February, 1819, this gentleman performed the operation, using a single ligature, the pulsation of the tumour in the ham instantly ceased; and the wound healed by the first intention, except where the ligature was situated, which came away on the thirtieth day. By this time, the tumour was diminished to one half of its original size, and, in two months more, only a hard knot was perceptible, in which no pulsation whatever could be felt. After the considerable lapse of time, above specified, the patient informed Dr. Monteath, that the tumour had reappeared, being rather larger than a plum. The pulsation in it was distinct, though not so strong as an ordinary aneurism. As the size of the swelling, and strength of the pulsation, increased gradually, a compress and bandage were applied, without confinement; but, as this treatment was ineffectual, the patient was afterwards kept in bed, bled, and put on a spare diet. A thick compress was placed over the tumour, and, the limb was firmly bandaged from the toes to the groin. A trial of this plan for three days not having produced any benefit, a tight tourniquet was applied over the tumour; but the pain was such in half an hour, that the instrument was taken off, from which moment no pulsation was felt. Next day the tumour not only did not throb, but had a firm feel; and, the bandage being continued, the cure was gradually completed. Had the disease not yielded to these means, Dr. Monteath meant to have tied the inguinal, or external iliac artery, with the view of cutting off the supply of blood to the sac, through the anastomosing branches. (*Scarpa on Aneurism by Wishart*, p. 510—512, Ed. 2.)

The external iliac artery was taken up by Mr. Norman, of Bath, for the cure of an inguinal aneurism, and when the collateral circulation was fully established a few days after the operation, the tumour was again supplied with blood in sufficient quantity to produce a distinct pulsation; "a fact," (says Mr. Norman) of practical importance, as it shows, that though the ligature on the iliac artery stops the direct influx of blood into the tumour, and is the means, by which the disease is cured, yet that there exists a necessity for employing strict rest, the antiphlogistic regimen, and in some cases, the abstraction of blood, to assist nature in her operation of obliterating the aneurism." And, in another instance, after the same gentleman had tied the femoral artery for the cure of popliteal aneurism, the pulsation, though stopped for a time in the tumour, afterwards recurred in such a degree, that much doubt was entertained whether the disease would have been cured by the ligature, on the femoral artery, had

not continued and rather powerful pressure been adopted (*Med. Chir. Tran. Vol. 10, p. 99, 118, &c.*)

M. Roux, in a late work, has offered some criticisms on the English method of operating for aneurisms. It would hardly be fair play to endeavour to offer a serious refutation of them, because when he wrote, it was his misfortune not to be duly informed of all the facts and experiments recorded in the inestimable treatise on hemorrhage by the late Dr. Jones. "Still less confident, than we are (says Roux,) in the treatment by compression, and in the use of topical remedies for the cure of external aneurisms, the English surgeons have immediate recourse to the operation with the ligature. Hunter's method is that which they universally practise. They will not even allow, that there are any cases, in which the operation by opening the sac should be preferred, &c. And it is singular, the very same motive, which would incline us in some cases of aneurisms, properly so called, to adopt the operation of opening the sac, is alleged by the English surgeons as a circumstance in favour of the Hunterian method. Let us suppose an aneurism so formed, that near the centre of the tumour, or rather near the opening, by which the artery communicates with the swelling, are situated the orifices of the collateral arteries, which would be useful for the re-establishment of the circulation. Here, it is clear, that in practising the operation by the Hunterian method, that is to say, in tying the artery above the tumour, the last ramifications are not indeed sacrificed; but the orifices and first branches of these collateral arteries. Let there be, for example, at the upper part of the femoral artery an aneurism, which, though formed originally below the origin of the profunda, now extends above it. Here it is manifest that, in tying the femoral artery above the swelling, we should lose the important resource of the profunda for re-establishing the circulation in the lower part of the limb. The desire and hope of saving the profunda would, in such a case, make us adopt the operation of opening the sac, in preference to the Hunterian method; and Scarpa himself, so great an advocate for this last mode, Scarpa, who seems only to have composed his work to cry up this method, makes an exception of the case, which I have just been supposing. The English surgeons, on the contrary, would urge the following objection to the operation by opening the sac in this, and other analogous examples. They contend, that the ligatures would be applied too near to the origin of the collateral arteries, which are to receive the blood after the operation. They are prepossessed with the idea, that, when an arterial trunk is tied at a given point, the too great proximity of the principal collateral arteries disposes to subsequent hemorrhage; &c." (*p. 256, 257.*) a circumstance, which M. Roux, seems to doubt.

Now, before attempting to reply to these

observations, we ought to know what exact distance Roux means, when he speaks of the profunda, or a large collateral artery, originating near the opening by which the aneurism communicates with the main artery. Here he is not at all precise; and were he to tie the femoral artery immediately below the point, where the profunda arises, he would expose his patient to great danger of bleeding. I say this, well aware of the case which he has adduced to prove the contrary. In the example brought forward, he applied several ligatures: (*p. 260.*) some of which were the *ligatures d'attente*, or loose ligatures left ready to be tightened in case of need. These were of course higher up, than the ligature, which was tightened. It is therefore impossible, that this last could have been close to the origin of the profunda. There must have been room left for the application of the *ligatures d'attente*; and be it also recollected, that the French still persist in the use of large flat cords, and not small firm round ligatures, which are now found to be most advantageous. (*See Hemorrhage.*) In this part of the dictionary, we shall find, that the nearness of a collateral vessel impedes the formation of the internal coagulum, which has a material share in the process by which the artery is closed.

With respect to the circumstance of hemorrhage being more likely to follow, when the ligature is placed close below, than at some distance from a great collateral artery, there cannot be a doubt of the fact. Roux, when in London, saw an occurrence of this kind himself, and has published it in his book. It was a case, in which Mr. A. Cooper tied the external iliac artery; but the patient died of hemorrhage a fortnight afterwards, and on opening the body, it was ascertained, that the obturator artery, which usually arises either from the trunk of the internal iliac, or from the epigastric, proceeded from the external iliac, and arose immediately above the point, to which the ligature was applied. (*See Parallele de la Chir. Angloise avec la Chir. Francoise, &c. p. 278, 279.*)

From a preparation, spoken of by Mr. Travers, and some experiments made by the same gentleman, it would appear, that the presence of a collateral branch hinders the formation of the internal coagulum, and will not always prevent the closure of the vessel by the adhesive inflammation. In the preparation referred to, a ligature was applied to the external iliac, between the epigastric and circumflex iliac arteries, "and having been in contact with the former at the angle which it makes at its origin from the iliac, ulceration had taken place, and the bleeding had proved fatal. There was no coagulum formed in the iliac trunk, though the operation had been performed several days, the circulation through the epigastric having continued. But the lymph-plug at the seat of the ligature on the iliac artery was complete." *Med. Chir. Trans.*

Vol. 6, p. 656.) Indeed, it must be allowed, with this gentleman, that the fluidity of the blood does not prevent the adhesive process, a fact, which, he observes, is also proved in the indirect obstruction of a vessel, by means of a temporary ligature or compressor. When, therefore, the vicinity of a large branch to the ligature is spoken of as a circumstance conducive to secondary hemorrhage, I mean, that it is so inasmuch as the internal coagulum is regarded as useful in promoting the closure of the vessel, and its formation is prevented.

Brasdor first, and afterwards the celebrated Desault conceived, that, when an aneurism was so situated, that a ligature could not be applied to the artery leading to the swelling, a cure might possibly arise from tying the vessel, on that side of the tumour, which was most remote from the heart. Desault conjectured, that by this means, the circulation through the sac would be stopped, the blood in it would coagulate, that the circulation would go on by the collateral arteries, and that the tumour would be finally absorbed. These speculations, however, were not found to answer in practice. Deschamps tied the femoral artery below an inguinal aneurism; but the progress of the disease, instead of being checked, seemed to be accelerated by this novel experiment. The operator was obliged, as a last resource, to open the tumour, and try to take up the vessel. In this attempt, the patient lost a large quantity of blood, and died eight hours afterwards. (See *Œuvres Chir. de Desault par Bichat*, Tom. 2, p. 563, and *Recueil Périodique de la Société de Médecine de Paris*, Tom. 5. No. 17.)

The operation of tying the artery below the tumour was some time ago repeated by Mr. A. Cooper, not for an aneurism of the femoral artery in the groin, but for an aneurism of the external iliac, where tying the artery above the swelling was impracticable. The femoral artery was therefore tied immediately below Poupart's ligament, between the origins of the epigastric and the profunda. The pulsations of the tumour continued; but, the progress of the disease was checked. After a time, indeed, the swelling decreased, and this in so considerable a manner, that hopes began to be entertained, that perhaps the external iliac artery might soon admit of being tied above the disease. The ligatures came away without any unfavourable occurrence, and when the wound was healed, the patient was sent into the country for the benefit of the change of air. The tumour, however, gave way, an extravasation of blood took place in the abdomen and cellular membrane of the pelvis, and the patient died. Mr. A. Cooper had no opportunity of seeing the case, and the body could not be opened, so that further particulars were not obtained.

The memorable instance, in which this gentleman tied the aorta, in a case of inguinal aneurism, extending very high up, and already burst, I shall notice under the head *Aorta*.

I shall finish these general observations on the treatment of external aneurisms, or such as admit more particularly of surgical treatment, with observing, that, in England, surgeons now lose few patients either from gangrene of the limb or secondary hemorrhage; and this notwithstanding they may sometimes prefer applying a ligature above the profunda to cutting open the aneurismal tumour. I firmly believe, that such matchless success is to be totally ascribed to the perfections in their mode of operating; the choice of a proper kind of ligature; the right plan of applying it; the rejection of the employment of several ligatures at a time; and the great care which is taken to promote the healing of the wound, as quickly as possible; the avoidance of all unnecessary and hurtful extraneous substances in the wound; and above all, the relinquishment of the formidable proceeding of cutting open the tumour.

In the consideration of particular aneurisms, I shall begin with those which may be cured by a surgical operation; and, here we shall be fully satisfied, that, "*l'art de guérir ne triomphe jamais plus heureusement que lorsqu'il peut employer la médecine efficace, c'est à dire, les moyens chirurgicaux ou opératoires.*" (*Clinique Chirurgicale*, Tom. 1, p. 110.)

OF THE POPLITEAL ANEURISM, AND OPERATION FOR ITS CURE.

Notwithstanding the solitary example in which M. A. Severinus, early in the 17th century, tied the femoral artery near Poupart's ligament in a case of aneurism, (*De Efficac. Med. Lib. 1, p. 2. c. 51.*) the practice of tying arteries, wounded either by accident or in the performance of surgical operations, and even the plan of tying the humeral artery for the cure of the aneurism at the bend of the arm, were known long before the operation for the relief of the popliteal aneurism was attempted. The considerable size of the femoral artery; its deep situation, the urgent symptoms of the disease, and ignorance of the resources of nature for transmitting blood into the limb, after the ligature of the vessel, are the circumstances, which appear to have deterred former surgeons from this operation.

Valsalva treated popliteal aneurisms on the debilitating method, and published one or two equivocal proofs of its success. In Pelletan's first memoir on aneurism, and in the third vol. of Sabatier's *Médecine Opératoire*, as I shall hereafter notice again, are two cases of axillary aneurisms, which were cured by Valsalva's treatment. But, encouraging as such examples may be, experience is not yet sufficiently favourable to this practice to allow it to bear a comparison, in point of efficacy, with the surgical operation, or to justify the general rejection of this last more certain means of cure. As Pelletan admits, Valsalva's treatment is extremely severe; the event of it doubtful;

and should the plan fail, the patient might not be left in a condition to bear an operation, for the success of which it seems necessary, that a certain strength of vascular action should exist, in order that the blood may be freely transmitted through such arterial branches, as are to supply the places of the main trunk, after this last has been tied.

The time, therefore, has not yet arrived, when surgical operations for the relief of aneurisms should be relinquished. (*Pelletan, Clinique Chirurgicale, T. 1. p. 114.*)

The cure of popliteal aneurisms by means of compression is occasionally effected; but, it happens too seldom to claim a great deal of confidence, or to lessen in any material degree the utility and importance of operative surgery in this part of practice. Pelletan records the cure of one popliteal aneurism by compression and absolute repose, during eleven months (*T. 1. p. 115.*) Boyer relates two instances, (*Traité des Mal. Chir. p. 204, T. 2.*) one is mentioned by Richerand (*Dict. des Sciences Méd. T. 2, p. 96*;) the practice of Dubois is said to have furnished several examples of the same success (*Vol. cit. p. 97*;) and a case, in which Dupuytren effected a cure by compressing the femoral artery by means of an instrument applied just above the place where the vessel perforates the tendon of the triceps muscle, is detailed by Breschet. (*Fr. Transl. of Mr. Hodgson's work, T. 1, p. 249, &c.*)

The circumstances, under which the employment of compression affords the best chance of success, have been already mentioned, as well as the prudence of assisting this plan with perfect quietude, venesection, spare diet, and cold astringent applications, especially ice, which was first recommended by Donald Monro, and has subsequently been most highly praised by Guerin.

Aneurisms in general, and, among them, the popliteal case, are all attended with some little chance of a spontaneous cure; yet this desirable event is too uncommon to be a judicious reason for postponing the operation, especially, as it is the usual course of the disease to continue to increase; while in the early stage the cure may be more speedily accomplished. In fact, the experience of modern operators leaves no room for apprehending, that the anastomoses will not suffice for the due nourishment of the leg and consequently proves, that waiting beyond a certain time for the enlargement of the collateral vessels to take place is altogether an unnecessary and disadvantageous method. Popliteal aneurisms, as well as other external tumours of the same nature, stand the best chance of a spontaneous cure, when any cause induces a general, violent, and deep inflammation all over the swelling; for, then the communication between the sac and artery is likely to become closed with coagulating lymph, and the pulsation of the tumour to be suddenly and permanently stopped. If in this state, the

disease sloughs, and the patient's constitution holds out, the coagulated blood in the sac and the sloughs, are gradually detached, leaving a deep ulcer, which ultimately heals. An example, in which a popliteal aneurism was cured by such a process, is related in the *Trans. of a Society for the Improvement of Med. and Surgical Knowledge, Vol. 2, p. 268.*

In former times, when all hopes of curing a popliteal aneurism by Valsalva's method, by compression, or a natural process, were at an end, amputation of the limb was considered as the sole and necessary means of saving the patient's life. But, about fifty years ago, the confidence of surgeons in the sufficiency of the anastomosing vessels or the continuance of the circulation began to increase, and, in opposition to the tenets of J. L. Petit, and Pott, experience soon proved, that, in general, not only might the patient's life be saved, but his limb also, and this, without any operation, that could be compared with amputation, in regard to severity. On looking back to the history of amputation, we shall find, that A. N. Guenault was one of the earliest writers, who disapproved of amputation, as not truly indispensable for the cure of popliteal aneurism.

It is alleged, that Teislere, Molinelli, Guattani, Mazotti, and some other celebrated Italian surgeons, were the first, who ventured to tie the popliteal artery for the cure of aneurism. The path, as Pelletan remarks, had been pointed out to them by Winslow and Haller, whose valuable descriptions and plates of the arterial anastomoses about the knee joint, showed by what means the lower part of the limb would be nourished, after a ligature had been placed on the principal arterial trunk. For almost thirty years, however, the practice of tying the popliteal artery was confined to the Italian surgeons. Pelletan believes, that he was the first, who attempted such an operation at Paris nearly thirty years ago, (alluding to about the year 1780, the *Clinique Chirurgicale* being dated 1810.)

However, this operation of opening the tumour and tying the popliteal artery itself, was a severe and often a fatal proceeding, and does not admit of being compared with the Hunterian operation, in point either of simplicity, safety, or success, as I shall explain, after the detail of a few particulars relating to the popliteal aneurism.

On whatever side of the artery the tumour is produced, it can be plainly felt in the hollow between the hamstrings, and in general its nature is as easily ascertained by the pulsation in every part of the tumour. Though the disease may not occur in the popliteal artery so often as in the aorta itself, it certainly is seen more frequently in the former vessel, than any other branch, which the aorta sends off. As Sir E. Home has observed, this circumstance has never been satisfactorily explained; and, what is rather curious, in many recent instances of this disease, the patients have been coachmen

and postillions. Morgagni found aneurisms of the aorta most frequent in guides, post-boys, and other persons, who sit almost continually on horseback; a fact, which he imputes to the concussion and agitation to which such persons are exposed. Some allusion to this subject has already been made in the foregoing pages. Whether an explanation of the frequency of popliteal aneurisms can be correctly referred to the obstruction, which the circulation in the artery must experience, when the knee is in a state of flexion, may be questioned, though it is on a similar principle, that the great frequency of aneurisms of the curvature of the aorta is attempted to be solved. (*Home in Trans. of a Society for the Improvement of Med. and Chir. Knowledge, Vol. 1, &c. and Monro in Ed. Med. Essays, Vol. 5.*)

Were this the only, or even the principal cause, surely one could have reason to expect aneurisms to be at least as frequent in the axilla, and at the bend of the elbow, as in the ham.

The popliteal aneurism was generally supposed to arise from a weakness in the coats of the artery, independently of disease. If this were true, we might reasonably conclude, that, except at the dilated part, the vessel would be sound. Then the old practice of opening the sac, tying the artery above and below it, and leaving the bag to suppurate and heal up, would naturally present itself. Mr. Hunter, finding, that the arterial coats were altered in the structure higher up, than the tumour, and that the artery, immediately above the sac, seldom united when tied; but, that, when the ligature came away, the bleeding destroyed the patient; concluded, that some disease affected the coats of the vessel, before the actual occurrence of the aneurism. Dissatisfied with Haller's experiments on frogs, showing that weakness alone could give rise to aneurism, he tried what would happen in a quadruped, whose vessels were very similar in structure to the human. Having denuded above an inch of the carotid artery of a dog, and removed its external coat, he dissected off the other coats, layer after layer, till what remained was so thin, that the blood could be seen through it.

In about three weeks, the dog was killed, when the wound was found closed over the artery, which was neither increased nor diminished in size.

It being conjectured, that the prevention of aneurism, perhaps, arose from the parts being immediately laid down on the weakened portion of the artery, Sir E. Home stripped off the outer layers of the femoral artery of a dog, placed lint over the exposed part of the vessel to keep it from uniting to the sides of the wound, and, in six weeks, killed the animal, and injected the artery, which was neither enlarged, nor diminished, its coats having regained their natural thickness and appearance.

These experiments strengthened Mr. Hunter's belief, that aneurismal arteries are diseased; that the morbid affection frequently

extends a good way from the sac along the vessels; and that the cause of failure in the old operation, arose from tying a diseased artery, which was incapable of uniting, before the ligature separated. These reflections led him to propose taking up the artery in the anterior part of the thigh, at some distance from the diseased portion, so as to diminish the risk of hemorrhage, and be enabled to get at the vessel again, in case it should bleed. The stream of blood into the sac being stopped, he concluded, that the sac and its contents would be absorbed, and the tumour gradually disappear, so as to render any opening of it unnecessary.

The first operation of this kind, ever done, was performed on a coachman, by Mr. Hunter, in St. George's Hospital, December, 1785. An incision was made on the anterior and inner part of the thigh, rather below its middle, which wound was continued obliquely across the inner edge of the sartorius muscle, and made large, in order to facilitate doing whatever might be necessary. The fascia, covering the artery, was then laid bare, for about three inches, after which the vessel itself could be felt. A cut, about an inch long, was then made through the fascia, along the side of the artery and the fascia dissected off. Thus the vessel was exposed. Having disengaged it from its connexions with the knife and a thin spatula, Mr. Hunter put a double ligature under it, by means of an eye-probe. The doubled ligature was then cut, so as to make two separate ones. The artery was now tied with both these ligatures, but, *so slightly as only to compress the sides together*. Two additional ligatures were similarly applied a little lower, with a view of compressing some length of artery, so as to make amends for the want of tightness, as it was wished to avoid great pressure on any one part of the vessel. The ligatures were left hanging out of the wound, which was closed with sticking plaster. On the second day, the aneurism had lost one third of its size, and, on the fourth, the wound was every where healed, except where the ligatures were situated. On the ninth, there was a considerable discharge of blood from the apertures of the ligatures, but it ceased on applying a tourniquet, and did not recur. On the fifteenth day, after the operation, some of the ligatures came away, followed by a small quantity of matter, and about the latter end of January 1786, the man went out of the hospital, the tumour having become still less. In the course of the spring, abscesses in the vicinity of the cicatrix followed, and some pieces of ligature were occasionally discharged. In the beginning of July, a piece of ligature, about one inch long, came away, after which the swelling went off entirely, and the man left the hospital again on the 8th, perfectly well, there being no appearance of swelling in the ham.

This subject died of a fever in March, 1787, and, on dissection, the femoral artery was found impervious from the giving off of the arteria profunda down to the place

of the ligature, and an ossification had taken place for an inch and a half along the course of this part of the vessel. Below this portion, the vessel was pervious, till just before it came to the aneurismal sac, where it was again closed. What remained of the sac was somewhat larger than a hen's egg, and it had no remains of the lower opening into the popliteal artery. The rest of the particulars of this dissection are very interesting. (See *Trans. of a Society for the Improvement of Med. and Chir. Knowledge*, Vol. 1, p. 153.)

This celebrated case completely established the important fact, that simply taking off the force of the circulation is sufficient to cure an aneurism, as the tumour is afterwards diminished and removed by the action of the absorbent vessels.

In order to confirm the same fact, Sir E. Home related a case of femoral aneurism, which got well without an operation, but, on a similar principle, to what occurs, when the artery is tied. A trial of pressure had been made without avail. The tumour became very large, and such inflammation took place in the sac and integuments, that mortification was impending: no pulsation could now be felt in the tumour, or the artery above it. The correct inference of Sir E. Home was, that a coagulum, which we know always occurs in an artery previously to mortification, seemingly to prevent bleeding, had formed in this instance, and in conjunction with the effusion of coagulable lymph about the root of the aneurism, had kept the blood from entering the sac.

Mr. Hunter's second operation was on a trooper. Instead of using several ligatures, which were found hurtful, he tied the artery and vein with a single strong one; but, unluckily, the experiment was made of dressing the wound from the bottom, instead of attempting to unite it at once: and the event was, that the man died of hemorrhage.

After this case, Mr. Hunter's practice was to tie the artery alone with one strong ligature, and unite the wound as speedily as possible.

Having recorded Mr. Hunter's cases, which first established the present method of operating for the cure of popliteal aneurisms, I shall not repeat the strong reasons which exist against the employment of reserve-ligatures, metallic compressors; two ligatures, with the division of the vessel between them; the interposition of pieces of linen, wood, cork, agaric, &c. between the knot and the vessel; for the use of large ligatures; and other contrivances, the merits, or rather demerits, of which have been already fully considered in the preceding section. My next duty is to explain the method of performing the Hunterian operation, as brought to its modern state of improvement, and adapted to the wise principles, which first emanated from the valuable experiments and investigations of Dr. Jones. (See *Hemorrhage*.)

In the arrangement of the assistants, one of them should be so placed, that if re-

quired, in consequence of any accidental wound of that vessel in the operation, he can compress the femoral artery as it passes over the brim of the pelvis; but, as Scarpa justly observes, no pressure of this kind is to be made, unless the accident referred to should happen, because the pulsations of the artery, inasmuch as they indicate the track of the vessel, must tend materially to facilitate the operation. The surgeon, says Scarpa, is to explore with his forefinger the course of the artery from the crural arch downwards, and when he comes to the place, where the vibration of this vessel begins to be less distinctly felt, this point is to be fixed upon for the lower end of the external incision. This angle of the wound will fall nearly on the inner edge of the sartorius, just where this muscle crosses the track of the femoral artery, and at the very apex of the triangle formed by the convergence of the triceps and vastus internus. A little more than three inches above the place here fixed upon, the surgeon is to begin with a convex-edged bistoury, the incision through the integuments and cellular substance, and carry the wound down the thigh, in a slightly oblique line, from without inwards, so as to make it follow the course of the artery, as far as the apex of the above-mentioned triangular space, or the point where the vessel passes under the inner edge of the sartorius muscle. In order to make this first external incision with correctness, I consider it a good rule always to take particular notice of the line described by the sartorius on the thigh, the inner margin of which muscle at the place where it meets the artery, as we have seen, forms at once the lower boundary of the incision, and an important guide to the vessel itself. By observing the track of the sartorius attentively, we shall likewise avoid all chance of making the wound too low down, so as to have this muscle intervening between the incision and the artery; a greater source of embarrassment in the operation, and of troublesome consequences afterwards than, perhaps, any other error; for, when this has happened, and the surgeon has not room enough afforded by the higher part of the wound to get at the artery above the sartorius, he is compelled to dissect and raise up this muscle from its natural connexions, ere he can plainly discover the vessel. This inconvenience made a deep impression on me in the first case, where I tied the femoral artery, for the intervention of the sartorius in a stout soldier, upon whom the operation was done, threw me into the dilemma of either dissecting at the outer edge of this muscle and drawing it inwards, or of enlarging the wound upwards. The latter proceeding was that to which I gave the preference, because it seemed to me an excellent maxim in this operation, to avoid making any further detachment of parts from their natural connexions, than is absolutely necessary, and I knew, that when the wound was extended a little higher up, the artery would present

itself more superficially, quite unconcealed by any muscle, whatever. Strongly, therefore, as my principles have led me to condemn Scarpa's modification of the ligature, his use of from four to six threads, and his interposition of a roll of linen between the knot and the vessel, I feel pleasure in expressing my conviction of one excellence in his mode of operating; an improvement, which is now obtaining, if it has not already obtained, the universal approbation of the surgical profession. This amendment consists in making the incision in the upper third of the thigh, or a little higher, than the place, where Mr. Hunter used to make the wound. Scarpa's reason for this practice is to avoid the necessity of removing the sartorius muscle too much from its position, or of turning it back, to bring the artery into view, so as to be tied. I have seen the best operators, even professors of anatomy, embarrassed, by having the sartorius muscle immediately in their way after the first incision, and as the vessel is more superficial a little higher up, the place is further from the diseased part of the artery, and there is no hazard of the anastomoses failing to keep up the circulation; this part of Scarpa's practice is highly deserving of imitation.

"The part of the limb (observes Mr. Hodgson,) in which the femoral artery can be tied with the greatest facility, is between four and five inches below Poupart's ligament. The profunda generally arises from the femoral artery an inch and a half, or an inch and three quarters, below Poupart's ligament; it very rarely arises so low as two inches. If, therefore, the ligature be applied to the femoral artery at the distance of four or five inches below Poupart's ligament, the surgeon will not be embarrassed by meeting with the profunda during the operation, and the chance of causing secondary hemorrhage, by tying the artery close to the origin of this vessel, will be obviated." (*On the Diseases of Arteries*, &c. p. 434.)

The trouble, arising from cutting too low down, so as to have the sartorius intervening between the outer wound and the artery, may be more accurately estimated, when it is known that Desault, for the removal of this inconvenience considered it right actually to make a complete transverse division of that muscle, a thing, which, it is said, may be done, without any ill consequences. (*Boyer's Traité des Mal. Chir.* T. 2, p. 145.) I shall not presume, however, to second this last piece of advice, because, though it may have been done by Desault, it appears to me, that the artery can always be taken up very well, without the proceeding here recommended.

A few years ago, Mr. C. Hutchinson published a tract, in which he advocated the practice of making the incision at the outer edge of the sartorius, and then raising that muscle, and drawing it inwards, in order to arrive at the artery. This advice proceeded from the apprehension, that the plan of

taking up the femoral artery at the inner edge of the sartorius was attended with risk of injuring the saphena vein, and large lymphatics. (*Letter on the Operation for popliteal Aneurism*, 1811.) The same method is commended by Boyer, and Roux, (*Nouveaux Elémens de Méd. Opératoire*, T. 1. p. 729) when the operation is done low down in the thigh. But, as operating in this situation is liable to the several objections of approaching too near the disease, of aiming at taking up the artery where it lies more deeply, than it does higher up, and, of every inconvenience which may arise from the interposition, dissection, and reflection of the sartorius muscle, the method must be rejected, unless it can be proved, that so many disadvantages are fully counterbalanced by other considerations. If the plan which I shall presently recommend be adopted, there will never be the slightest risk of wounding the saphena vein; and, therefore, I do not consider it advisable or necessary, for the avoidance of this accident, to make the wound *precisely upon the sartorius*, as my intelligent friend Mr. Hodgson suggests; a method, attended with the inconvenience of having the fibres of that muscle between the external wound, and the artery, and perhaps inconsistent with the excellent directions which he afterwards delivers, concerning the right mode of performing the external incision, when he says, with Scarpa, that this cut should be "continued down to the fibres, which form the inner margin of the sartorius." (*On Diseases of Arteries*, &c. p. 436.)

Now, if the point where this margin first lies over the artery, be the proper place for the lower termination of the external incision, we shall clearly be deviating from the precise course of the vessel by letting the higher portion of the wound be over the fibres of that muscle. And, when it is further reflected, that the serious evils of wounding the trunks of the lymphatics in this operation are not demonstrated in modern practice, while the saphena vein may always be avoided with certainty and facility, I cannot admit, that there is any solid reason for letting the situation and direction of the external wound be determined by such apprehensions. At all events, for the motives above explained, it should be a fixed maxim in this operation never to extend the wound lower than the point, where the inner margin of the sartorius crosses the artery; and then all detachment and displacement of this muscle will be unnecessary, and every embarrassment, which might proceed from its interposition between the outer wound and the artery, will be completely avoided.

The skin and cellular substance are to be divided, in the situation, and to the extent above specified down to the femoral fascia, under which the artery lies, and may be felt beating. The next object, therefore, is to divide the fascia, which is here much thinner than at the outer side of the limb, and may be cut with another stroke of the bistoury;

• (what is safer with the view of abstaining from all chance of wounding the artery) a slight cut may first be made in the fascia, the division of which may then be made to the requisite extent by introducing under it a grooved director, on which the further incision may be made with perfect security. The fascia is to be divided in the direction of the external wound; but, to what extent is a point on which surgical writers differ, and, indeed, they must here differ, as long as they are not unanimous about the method of applying the ligature round the artery; because, if it be intended to use a broad ligature, with a cylindrical piece of linen interposed between it and the artery, or especially if it be designed to apply two ligatures and divide the vessel in the interspace, more of the artery must be exposed, and of course more of the fascia must be cut, than when it is simply meant to surround the vessel with a single small ligature. Such operators also as have contracted the pernicious habit of insulating the artery all round sufficiently far to let them thrust their finger under it, will likewise require an extensive opening in the fascia. Such detachment of the vessel for an inch or more, for the purpose of placing the finger under it, is a measure which deserves to be condemned in the strongest terms, as it is the very thing, which produces some risk of injuring the saphena vein, and has a tendency to bring on secondary hemorrhage, inasmuch as it occasions unnecessary handling, stretching, and disturbance of the artery and surrounding parts, and an inevitable division of the vessels, by which the arterial coats are supplied with blood.

According to Mr. Hodgson, the extent of the cut in the fascia should be about an inch; for he wisely avoids all unnecessary separation of the artery from its surrounding parts. On the contrary, Scarpa, who insulates and raises the vessel, previously to tying it, insists upon the prudence of cutting the fascia, the whole length of the external wound; for, says he, if this practice be neglected, it most frequently happens, that, in the succeeding inflammatory stage, the bottom of the wound swells and becomes very tense, and the matter, which is formed under the fascia, not finding a ready exit, occasions abscesses which seriously retard the cure. But, Scarpa, instead of planning a method of relieving the consequences, might have employed himself more to the purpose in considering how they were to be prevented, and why in his method they most frequently happen. Now, without laying any stress upon two waxed ligatures, each composed of six threads, with an additional extraneous substance, viz. a roll of linen in the noose, we should be more surprised to hear, that the wound after his method did not become affected with swelling, tension, and suppuration, than that these were the usual effects. After describing the division of the fascia, he observes; "With the point of the forefinger of the left hand, already touching the femoral

artery, the surgeon will separate it from the cellular substance, which ties it laterally and posteriorly to the contiguous muscles; and making the point of the same finger pass gradually under and behind the femoral artery (supposing the surgeon has not enormously large fingers) he will raise it alone from the bottom of the wound, or (when it cannot be avoided) along with the femoral vein. If it is along with the femoral vein, the surgeon, holding the artery and vein thus raised, and almost out of the wound, will cautiously separate the vein from the artery with a bistoury, or spatula, or simply with his fingers, &c." (See Scarpa on Aneurism, p. 280, Ed. 2.)

When we combine the irritation and mischief of all this work with the ill effects of filling the bottom of the wound with soft lint, I would ask, what more certain plan could Scarpa, or any other person, have suggested for bringing on the unpleasant state of the wound, which he describes as most frequently taking place?

I shall suppose the fascia has now been divided, under which the surgeon distinctly feels the pulsations of the femoral artery, which is still invested by the cellular sheath. The femoral vein lies directly under this vessel, while the branches of the anterior crural nerve, separated from it by dense cellular substance, are more externally, yet somewhat more deeply situated. The next object, therefore, is to pass a single ligature round the artery, without including, or, in any manner meddling with the subjacent femoral vein, or, detaching and disturbing the artery. For this purpose, the best direction is that given by my friend, Mr. Lawrence: "after dissecting down to the artery, a slight scratch or incision may be made through the sheath, close to the side of the vessel. Then, with a narrow aneurism needle, nearly pointed at the end, and made as thin at its edge as it can be without cutting, a single silk ligature is to be conveyed round it, the point of the needle being kept in contact with the artery. A needle of this form makes its way easily through the cellular substance, and the vessel is detached only in the track of the instrument." (See *Med. Chir. Trans.* Vol. 6.)

Of the kind of ligature to be employed, I need only say here, that it should be a single one, composed of firm materials, in order to avoid the necessity for increasing its diameter more than would be desirable, for reasons elsewhere considered. (See *Hemorrhage and Ligature*.) The ligature having been put under the artery, one end of it is to be drawn completely through the track made for it by the needle, which instrument is then to be taken away, leaving the ligature under the vessel. The ligature is now to be tied in a steady firm manner, but without any immoderate force, which can never be necessary even for the division of the inner coats of the vessel. In this part of the operation, a few practitioners give the preference to what is termed the surgeon's knot, and commend this plan of fastening the ligature; a plan, which con-

sists in putting the end of the cord twice through the noose, before the constriction is made. The only good of the surgeon's knot is, that it does not so readily slip and loosen as a common one; but Scarpa thinks a simple knot best, as it does not, like the other, prevent the surgeon from calculating the force, with which the artery is constricted. (*On Aneurism, p. 281, Ed. 2.*) And, besides this reason against the surgeon's knot, another objection to it is the irregularity, with which a ligature in this form will lie round the vessel. A simple noose should therefore be first made and tightened, and then a second one, so as to form a common knot; and, now, as a matter of precaution against the possibility of the ligature slipping and becoming loose, the surgeon, if he pleases, can tie the knot once again. One end of the ligature is next to be cut off near the knot; and the sides of the wound are to be brought together with strips of adhesive plaster, the irritation of sutures being carefully avoided. The remaining end of the ligature should always be brought out at the nearest point of the external wound to the knot on the artery.

The effects, which in general immediately follow the operation, are a total cessation of the pulsation of the aneurismal tumour, a manifest sinking and flaccidity of the swelling; a diminution of pain in the seat of the disease; and a strong vibration of the articular arteries round the knee. As Mr. Hodgson has remarked, the unusual influx of blood into the minute ramifications, when a main artery is suddenly rendered impervious, is generally attended with a remarkable increase in the temperature of the limb. After tying the femoral artery for the cure of popliteal aneurism, the same phenomenon occurs, at least after a short time, during which the temperature of the leg and foot frequently continues lower, than that of the sound limb. But, in a few hours, it generally rises, and is sometimes several degrees higher, than that of the opposite member. This state lasts several days, at the end of which time, the heat of the limb, which has been operated upon, will be found to be about the same as that of other parts of the body. (*Hodgson on Diseases of Arteries, &c. p. 256.*) It is only while the limb is colder than natural, that it ought ever to be fomented, or covered with flannel. In particular examples, there is no increase of temperature in the limb at any period after the operation; a fact, which Mr. Hodgson refers to the probability of a collateral circulation having already been established, in consequence of the obstruction to the passage of the blood through the main artery by the accumulation of the coagulum in the aneurismal sac. Of course, unless a collateral circulation be established, the operation cannot succeed, as the limb will mortify: it behoves us, therefore, to be aware of the circumstances, which may prevent the due transmission of the blood to the inferior part of the limb. These are ably explain-

ed and commented upon in Mr. Hodgson's work; 1st, An extensive transverse wound, by which the principal anastomosing branches are divided. 2dly, Tight bandages and pressure, operating so as to obstruct the same vessels. 3dly, The immense bulk of the tumour, and the pressure upon the principal collateral arteries. 4thly, Calculous depositions in the coats of the arteries of the limb. 5thly, Advanced age. 6thly, A languid state of the circulation; a fact, indicating the wrongness of venesection; as a general practice after the operation, though it may yet be right to adopt this treatment, where the pulsations return in the tumour with unusual strength, and appear to stop the diminution of the swelling, as already mentioned. 7thly, The abstraction of heat from the limb by cold evaporating lotions; a plan, which can only be right, when there is a great increase of heat in the limb, a tendency to inflammation, or a return of strong pulsations in the tumour.

When the operation is done, according to the principles laid down in this article, the patient is not too old, nor enfeebled, and the after-treatment is properly conducted, mortification may now be said to be a rare event. I have seen but one example of gangrene, and in that, only one toe, and a portion of the skin of the instep, sloughed in a very debilitated subject. This partial gangrene of the foot has been particularly noticed by Deschamps and Scarpa, the latter of whom regards it as an unusual thing, only likely to happen in old, weak, or unhealthy subjects; and "at any rate, (says he,) if this should happen in any of these enervated individuals, the patients may console themselves for the loss of one, or two of their toes, with the cure of a popliteal aneurism, and the avoidance of a painful and dangerous incision in the ham, and of the tedious suppuration, which would have followed it."

When the operation succeeds, a considerable portion of the artery above the aneurismal tumour is rendered impervious, the vessel indeed being sometimes converted into a solid cord from the origin of the profunda to that of the tibial arteries. (*A. Cooper, Med. Chir. Trans. Vol. 2, p. 254.*) In general, however, the obliteration of the artery is less extensive; a fact particularly noticed in one of Mr. Hunter's cases, (*Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge, Vol. 1, p. 153.*) and vainly urged by Deschamps, as a proof of the insufficiency of the new method. (*See Observations et Reflexions sur la Ligature des principales Arteres blessées et particulièrement sur l'Aneurisme de l'Artère poplitée, p. 76, Paris, 1797.*) It appears from the observations of Mr. Hodgson, that the artery generally becomes impervious, for the space of three, or four fingers' breadth, at the place where the ligature is applied; below which part its tube is unclosed, and continues so for some distance, when the obliteration again commences, and descends along a

considerable extent of the popliteal artery to the origin of the inferior articular, or tibial arteries. Thus, says this author, an insulated portion of the femoral artery preserves its cavity, from each of which considerable anastomosing branches arise: the upper branches convey blood into the vessel, and the lower transmit it into anastomosing channels, that originate below the knee. (*On Diseases of Arteries, &c.* p. 278.) Now, as Mr. Hodgson is unacquainted with any case, except that recorded by Mr. A. Cooper, where after the modern operation, the artery was obliterated from the seat of disease in the ham to the part, at which the ligature was applied, he thinks it probable, that, in most instances, a double collateral circulation exists in the limb, after this method of cure.

In consequence of the motion of the blood being more or less impeded in the aneurismal sac by the application of the ligature to the femoral artery, the aneurismal cavity soon becomes completely filled with coagula, which even block up the adjoining portion of the arterial tube. The coagulated blood in the sac is afterwards absorbed; and a gradual diminution, and final disappearance of the aneurism in the ham ensue; with the exception of a slight induration, which sometimes remains, composed of a remnant of the sac itself, or of the fibrous part of the blood. This slight hardness, which occurs in the bottom of the cavity of the ham, occasions no inconvenience, and does not hinder the patient from performing the motions of the knee and leg with quickness and safety. (*Scarpa, p. 257, Ed. 2.*)

When the advantages of the foregoing method of operating are contrasted with the dangers and severity of the practice of laying open the aneurismal tumour, and applying ligatures round the diseased part of the vessel, it is surprising to find any living surgeons still expressing a preference to the latter mode of treatment under any circumstances whatsoever. Yet, Boyer, Roux, and a few of the modern French surgeons are in this way of thinking, which reminds me of their slowness to adopt, at every opportunity, union by the first intention, one of the greatest and most decided advances to perfection ever made in the practice of surgery. The severity and difficulties of the old method of operating, in cases of popliteal aneurism, are most faithfully depicted by Scarpa. In the ham, says he, the artery lies very deep. The space is limited and narrow, within which it can be brought into view and tied, without risk of tying along with it, or of destroying, some of the principal anastomoses formed by the articular arteries of the knee. On account of the depth of the artery, it is difficult to pass any instrument round it, without including other parts, and it is no less difficult to draw the ligature on the vessel with a proper degree of tightness. Scarpa then comments on the disadvantages of tying the lacerated, diseased part of the vessel, which is sometimes so high up, that, in order to apply the

ligature above it, it is necessary to cut through the long head of the triceps and make a passage through into the thigh. Or, the diseased, or lacerated part of the artery is situated so low down in the calf of the leg, that it is impossible to avoid including, either in the incision, or the ligature, the lower anastomosing articular arteries, on the preservation of which the circulation and life of the subjacent part of the limb in a great measure depend. We must add to all this the violence, which must be done to the great sciatic nerve, which an assistant must hold drawn to one side of the wound nearly the whole time of the operation. The proceeding is also liable to other great difficulties, as may be seen from a case reported by Masotti, (*Dis. sul Antrypoma, p. 53.*) where the popliteal artery was so firmly united, and, as it were, confused with the vein, the nerve, the tendons of the neighbouring muscles, and the periosteum, that the cavity of the ham presented the appearance of an intricate mass of parts, not easily separable from one another. Lastly, the operation leaves a large deep wound, laying open the whole cavity of the ham, and followed by copious suppuration, sinuses, and necrosis of the heads of the femur and tibia. If the patient be not hurried into his grave by these affections, and even if the parts in the ham heal, the patient is almost always left with an incurable contraction of the knee, and perpetual lameness. Thus, Masotti (*Op. cit. p. 17.*) relates one case, where the subsequent effects were such as to destroy the soft parts in the cavity of the ham, in such a degree, as not to leave any vestige of artery, vein, or sciatic nerve, and the patient remained all the rest of his life with a paralytic leg, and ulcers and fistulae all round the knee. (*Scarpa on Aneurism, p. 251-253, Ed. 2.*)

I shall now advert to a few facts in the history of surgery, which eventually led to the bold and successful operations, adopted in modern times, for the cure of aneurisms of the femoral and popliteal arteries. The earliest case, of which the particulars are recorded, amounting to a satisfactory proof, that the lower extremity might be duly supplied with blood, notwithstanding the femoral artery had been tied high up in the thigh, is the example, related by M. A. Severinus, of a false aneurism of the thigh, about eight fingers' breadth below the groin, caused by a musket-ball wound. In this instance, Severinus tied the femoral artery above and below the aperture in it, and not only was the patient's life saved, but the use of the limb also preserved. (*Chirurgia Efficax, P. 2. Enarratoria.*) The next authentic case of the ligature of the femoral artery, is that reported by Saviani, where M. Bontentuit, in 1688, tied this artery on account of a false aneurism, the result of a sword wound at the inner and upper part of the thigh. The surgeons, called into consultation, were immediately convinced, that the only thing to be done was

to take up the femoral artery; but, they were fearful, lest the patient should perish of bleeding, ere the opening in the vessel could be found, and, in case the artery were secured, they apprehended the obstruction of the circulation would be followed by mortification of the limb. The patient was therefore first prepared for his fate by the administration of the sacrament. A band was then applied round the upper part of the limb, and tightened by means of a stick, with which it was twisted, a piece of pasteboard being put under the knot, in order to render the constriction less painful. The tumour was then opened, the clotted blood extracted, and the opening in the artery detected by slackening the tourniquet. A curved needle, armed with a double ligature, was then introduced under the femoral artery, and one of the cords was tied above, and the other below, the wound in the vessel. Then follows a curious passage, showing the operator's judgment at that time, respecting the impropriety of interposing any cylinder of linen between the knot of the ligature and the artery, as some of the old surgeons at that time used to do, as well as a few of the moderns. "*On ne mit point de petites compresses sur le corps de l'artère au dessus du nœud, comme font quelques uns, parceque l'on jugea qu'il étoit d'une grande conséquence, de lier très-étroitement une artère si considérable, ce que l'on n'autoit pas été sûr de faire en interposant la petite compresse, &c.*" For greater security, assistants, who relieved each other in turn, kept up constant pressure on the tied part of the vessel for twenty-four hours. In six weeks, the patient recovered, and afterwards enjoyed such good health, that he went through several campaigns. (*Saviard, Nouveau recueil d'Observations Chir. Obs. 63, 12mo. Paris, 1702.*)

Now, with respect to these two cases, it merits attention, that, though Heister, Morgagni, and others, endeavoured to explain the success, by supposing, that each of the patients in question must have had two femoral arteries, both Severinus, and Saviard, were wise enough to avoid making any such erroneous inference themselves. At a later period, Guattani laid bare the femoral artery, as it passed under Poupart's ligament, compressed it against the ramus of the pubes, by means of graduated compresses, retained with a firm roller, and thus obtained the speedy obliteration of the vessel, and cured the aneurism, which had been first injudiciously opened. (*De Externis Aneurysmatibus, Hist. 15, 4to Romæ. 1772.*) In the same book is given the case of an inguinal aneurism, which when it had continued three months, and become equal in size to a large fist, was attacked with gangrene, whereby the aneurismal sac was quickly destroyed, and the femoral artery was obliterated for a considerable extent from the crural arch downwards. The sloughs were thrown off, however, and the ulcer had in a great measure healed, when the patient fell a victim to debility. (*Hist.*

17.) Here it is to be remarked, that, during the five weeks this man lived after the obliteration of the femoral artery, above the origin of the profunda, not only the circulation and life of the whole limb were preserved, but the auxiliary arteries, coming from within the pelvis, proved capable of limiting the progress of the mortification of the parts round the aneurism, and of commencing the healing process, in a manner, which raised great hopes of a cure. A similar fact is also recorded by Dr. Clarke. (*Duncan's Med. Comment. Vol. 3.*)

These, and other cases, which might be quoted, furnished ample proof of the efficiency of the anastomosing vessels in the support of the limb, though the femoral artery had been tied, or obliterated in a very high situation.

Besides these facts, surgeons derived every encouragement to attempt the cure of popliteal aneurism, by the ligature of the artery above the tumour, from the elucidations given by Winslow and Haller concerning the numberless inosculations, which exist between the upper and lower articular arteries. Haller even drew the conclusion, that, if the course of the blood were intercepted in the popliteal artery, between the origins of the two orders of articular branches, such anastomoses would suffice for carrying on the circulation in the leg. And at length, Heister, weighing the anatomical observations of Winslow and Haller, and the facts recorded by Severinus and Saviard, first proposed applying to popliteal aneurisms, an operation, which, with the exception of those two cases, had until that time been restricted chiefly to aneurisms of the brachial artery. (*Dis. de genium Structuræ eorumque morbis. Disp. Chir. Halleri, T. 4.*)

It was in Italy that the earliest operations were undertaken for the cure of popliteal aneurisms, by Guattani or rather by a German surgeon, named Keyser, as would appear from a letter written by Testa, to Cotonni. (*See Pelletan's Clinique Chir. T. 1.*) The success, obtained by those surgeons, soon emboldened others to imitate them, and by degrees the practice of tying the femoral artery became common both in cases of aneurism and wounds; and from the observations of Heister, (*Haller Disp. Chir. T. 5.*) Acrell, (*Murray de Aneurysm. Femoris.*) Leslie, (*Edinb. Med. Comment.*) Hamilton, (*B. Bell's Surgery, V. 1.*) Burschall, (*Med. Obs. and Inq. Vol. 3.*) Leber, (*Dehaen, Ratio Medendi, T. 7.*) and Jussy, (*Ancien. Journ. de Med. T. 42.*) it was proved beyond the shadow of a doubt, that the circulation might continue in the limb, after the obliteration of the femoral artery, whether such obliteration were effected by direct pressure, or the ligature.

The exact period when the first operation of laying open the tumour and tying the popliteal artery, was performed in England, is not, as far as I know, particularly specified. However, judging from the observations made on this practice in the writings

of Pott, (*Remarks on Palsy, &c.* 8vo. Lond. 1779,) of Wilmer (*Cases and Remarks in Surgery*, 8vo. Lond. 1779,) of Kirkland (*Thoughts on Amputation*, 8vo. Lond. 1780,) and of others, it is clear, that this method of treatment had been often done in this country earlier than the dates of those works, and as would appear with little, or no success. The earliest attempt of this kind in France was made by Chopart in 1781, (*Roux. Nouveaux Elemens de Med. Operatoire*, T. 1, p. 556,) about five and twenty years after the examples set by Guattani in Italy; but Chopart failed in his endeavours to repress the bleeding from the exposed cavity of the tumour, and was therefore obliged to amputate the limb. Subsequently to this attempt, the operation was undertaken by Pelletan in two instances, the terminations of which were successful: consequently, this surgeon may be regarded as entitled to the honour of having proved to his countrymen the possibility of curing the popliteal aneurism by laying open the tumour, and securing the artery in the ham.

The severity and frequent ill success of this method of operating I have already noticed, nor shall I repeat the objections to it. With respect to the Hunterian practice, the great peculiarities of which were tying the artery at some distance above the disease, and not opening the swelling at all, Richerand seems offended, that Hunter's name should be affixed to an operation, which he conceives was in reality the invention of Guillemeau. Here we observe, *Ætius* again puts in a prior claim, and with much more effect, because the method, of which he speaks, truly resembled Mr. Hunter's, inasmuch as the vessel is directed to be tied at some distance above the swelling, while Guillemeau only tied the artery close above the disease, and opened the swelling, a serious deviation from the Hunterian practice.

Guillemeau, a contemporary, and disciple of Ambrose Paré, having to treat an aneurism, at the bend of the arm, the consequence of bleeding, exposed the artery above the tumour, tied this vessel, then opened the sac, took out the coagulated blood, and dressed the wound, which healed by suppuration. After more than a century, Anel, on being consulted about a similar case, tied the artery above the swelling, which was left to itself. The pulsations ceased, the tumour became smaller, and hard, and after some months, no traces of the disease were perceptible.

In 1785, Desault operated in the same manner for a popliteal aneurism: the swelling diminished by one half, and the throbbings ceased: on the 20th day, it burst, coagulated blood and pus were discharged in large quantities, and the wound, after continuing a long time fistulous, at length healed. Towards the end of the same year, says Richerand, Hunter applied the ligature somewhat differently; instead of placing it close to the swelling or directly above it,

he put it on the inferior part of the femoral artery. (See *Nosogr. Chir.* T. 4, p. 98, 99, edit. 2.)

Unquestionably, Anel did, in one solitary instance, tie the humeral artery immediately above an aneurism at the bend of the arm, and effected a cure without opening the swelling. (*Suite de la Nouvelle Méthode de guérir les fistules lachrymales*, p. 251, Turin, 1714;) but he did not think of applying the plan to the femoral artery, or draw the attention of the French surgeons sufficiently to the matter, to make the latter imitate his operation; on the contrary, the method fell into oblivion, and was never repeated. With regard to Desault's operation, said to have been done in an earlier part of 1785, than Mr. Hunter's first operation, it is only necessary to say, that Desault tied the popliteal artery itself, while the grand object in Mr. Hunter's method was to take up the femoral artery, at a distance from the disease, and that it is this last mode alone, which has gained such approbation, and been attended with unparalleled success.

The French surgeons have not practised the Hunterian operation with the same degree of success, with which it is now performed in England, and, consequently, they very commonly pursue the old method of opening the sac, &c. Even professor Boyer avers his relinquishment of what he calls Anel's plan. (*Traité des Mal. Chir.* T. 2. p. 148.) But, we shall not be surprised at their ill success, when we hear that they neglect the right principles, on which ligatures ought to be applied to arteries, as explained by Dr. Jones in his work on hemorrhage. Even Baron Dupuytren adheres to the use of ligatures of reserve; and Boyer applies four loose ligatures round the artery, besides two tight ones; and consequently a large portion of the vessel lies separated from its natural connexions, and irritated by these extraneous substances. Hunter's first operation nearly failed also on account of so many ligatures, none of which were tightened so as to cut through the inner coats of the artery, and thus promote its closure. (See *Hemorrhage*.) In reference to the operation for popliteal aneurism, *Rosenmüller's Chir. Anat.* Plates deserve to be consulted, Part 3, Tab. 8 & 9. Scarpa's matchless engravings, and Haller's *Icones*, should likewise be examined.

ANEURISMS OF THE LEG, FOOT, FOREARM AND HAND.

Doubts were not long ago entertained respecting the possibility of curing an aneurism at the upper part of the calf of the leg by tying the femoral artery in the middle of the thigh. (*Instituto Ital. di Scienze ed Arti.* Vol. 1, Parte 2, p. 266.) The author, here referred to, was led by this uncertainty to have recourse in one instance to the severe method of laying open the tumour, in order to get at the vessel lower down. On this case, Scarpa

makes some correct reflections; the operator (says he) assured himself, that, on compressing the femoral artery at the upper part of the thigh, the tumour at the top of the calf ceased to pulsate; and that, when the compression was continued for some time, the swelling partly disappeared, and became softer. It ought to have been evident, therefore, that the aneurism might have been cured by tying the trunk of the femoral artery, as described in the foregoing section. In Scarpa's work is a case, in which an aneurism at the bifurcation of the popliteal artery was cured by the ligature of the femoral artery. (See p. 451, Ed. 2.) Mr. Hodgson has seen three aneurisms, situated at the commencement of the tibial arteries, cured by the same operation. (*On Diseases of Arteries*, &c. p. 437.) But, as Scarpa remarks, though the Hunterian operation answers in the cure of aneurism in the bend of the arm, and at the upper part of the calf of the leg, it is not so effectual for aneurisms situated on the back or palm of the hand, or the dorsum, or sole of the foot. The free communication, which the ulnar and radial arteries keep up with each other in the hand, and the tibial arteries have in the foot, prevent the operation from succeeding, whether the brachial, or femoral artery, or one of the two large arteries of the forearm, or leg, be tied. In proof of this statement Scarpa cites two cases of aneurism seen by himself; one on the instep; the other in the sole of the foot; and a third case of the same disease in the latter situation; all of which were found to be incurable by the ligature of the anterior tibial artery. (P. 311.) He thinks, however, that the operation of tying this vessel where it passes over the dorsum of the foot, might succeed, if aided by compression, applied so as to stop the current through the other main channel; and he seems to approve of this practice, because the plan of tying the artery above and below the disease (which is the most certain means of cure) could not be done, without extensive incisions in the sole of the foot. In an aneurism at the lower part of the leg. Mr. Hodgson judiciously insists upon the prudence of tying the artery, as near as possible to the tumour, because the recurrent circulation, through the large anastomoses in the foot, might still cause the swelling to enlarge, in consequence of the blood sent into the sac from the lower extremity of the vessel, passing through the aneurismal cavity into branches arising from the artery between the aneurism and the ligature. (P. 438.) In the same manner, when an aneurism arises from the ulnar, or interosseous arteries near the elbow, tying the brachial will suffice; but, if the disease be lower down, the vessel from which it proceeds must be taken up near the swelling. (*Op. cit.* p. 393.) Scarpa mentions a case, where the dorsal artery of the thumb was wounded; but, as the hemorrhage returned several times, and pressure failed in suppressing it, the surgeon took up

the radial artery at the wrist. After cutting off this direct current of blood towards the injured vessel, pressure on the wound proved effectual. Three months afterwards, the patient having died, the radial artery was found impervious for three fingers' breadth below where the ligature had been applied, and the dorsal artery was likewise obliterated from the root of the thumb to the beginning of the palmar arch.

The manner of exposing, and tying, the principal arteries of the leg and forearm will be described under the term *Arteries*.

OF ANEURISMS HIGH UP THE FEMORAL ARTERY.

Several facts, already specified in the preceding columns as having occurred many years before the operation of tying the external iliac artery was attempted, amounted to a full proof, that the circulation might go on in the lower extremity, notwithstanding the artery in the groin were tied, or obliterated. On this point, some of Guattani's cases were most decisive.

The ligature of the external iliac artery, for aneurisms of the femoral artery in the bend of the groin, has now been practised so frequently, and the instances of success are so numerous, that all doubt concerning the propriety and utility of the attempt has entirely ceased. The French, who have evinced great backwardness in espousing the Hunterian method of operating for aneurisms, though it be decidedly one of the greatest improvements in modern surgery, have also shown great reluctance even to believe, much less to practise, the operation of tying the iliac artery. A Parisian surgeon, however, who was recently in London, saw the thing done, and his brethren in the capital of France now begin to have their eyes a little more open. Still, as Roux remarks, "We cannot but blame the indifference, with which the operation is mentioned in some of the latest French surgical publications. At this moment, (1815,) we can reckon twenty-three facts, relative to tying the external artery, and, on fifteen of the patients, it has perfectly succeeded. In these twenty-three operations, I comprehend the two which were done in France; one at Brest, by Delaporte, and the other at Lyons, by Bouchet; cases, of the authenticity of which we cannot doubt. In the number of successful cases, is to be comprised Bouchet's operation, since the patient lived more than a year afterwards, and then died of the consequences of an inguinal aneurism of the opposite side. Of the other twenty-one operations, fifteen have been performed in London only, in the several hospitals of this metropolis, by Abernethy, Ramsden, A. Cooper, Brodie, and Lawrence, gentlemen who would never publish forged cases.

"Mr. A. Cooper alone had tied the external iliac artery six times before my journey to London, and during my stay there, I saw him perform the operation

once. Four of his patients were entirely well; one of the three others died, the thirteenth week after the operation, of the bursting of an aneurism of the aorta. At this period, the circulation in the limb had been re-established. I saw the limb, after it had been dissected, among Mr. Cooper's anatomical preparations. Large and beautiful anastomoses existed round the pelvis, between the dilated branches of the internal iliac and femoral arteries. With respect to the sixth patient, the leg mortified, and the thigh was amputated without success. The seventh died of an hemorrhage, which took place the fourteenth or fifteenth day after the operation. (*Parallele de la Chir. Angloise avec la Chir. Francoise*, p. 275—276.)

The many facts which have been already published, exemplifying the propriety of this operation, must be highly gratifying to Mr. Abernethy, by whose judgment it was first suggested, and by whose enterprising hand it was first practised.

Mr. Abernethy has been called upon in several cases to take up the external iliac artery, and they all proved, that the anastomosing vessels were fully capable of conveying blood enough into the limb below, and that a vessel even of this size could become permanently closed after being tied. Three of the operations done by this gentleman, I was an eyewitness of, and, it is therefore with confidence that I can speak of the ease and simplicity of the requisite measures for securing the external iliac artery. (See *Abernethy's Surg. and Physiol. Essays*; and *Surgical Observations*, 1804; *Edinb. Med. and Surg. Journal for January*, 1807.)

In Mr. Abernethy's first operation of this kind, performed in 1796, an incision, about three inches in length, was made through the integuments of the abdomen, in the direction of the artery, and thus the aponeurosis of the external oblique muscle was laid bare. This was next divided, from its connexion with Poupart's ligament, in the direction of the external wound, for the extent of about two inches. The margins of the internal oblique and transverse muscles being thus exposed, Mr. Abernethy introduced his fingers beneath them to protect the peritoneum, and then divided them. Next he pushed this membrane with its contents upwards and inwards, and took hold of the external iliac artery with his finger and thumb. It now only remained to pass a ligature round the artery, and tie it; but, this required caution, on account of the contiguity of the vein to the artery. These Mr. A. separated with his fingers, and introducing a ligature under the artery with a common surgical needle, tied it about an inch and a half above Poupart's ligament, (*Surg. Essays*.)

The following was the method, which Mr. Abernethy adopted, the second time of tying the external iliac artery.

An incision, three inches in length, was made through the integuments of the abdo-

men, beginning a little above Poupart's ligament, and extending upwards; it was more than half an inch on the outside of the upper part of the abdominal ring, to avoid the epigastric artery. The aponeurosis of the external oblique muscle being exposed, was next divided, in the direction of the external wound. The lower part of the internal oblique muscle was uncovered, and the finger being introduced below the inferior margin of it and of the transversalis muscle, they were divided with the crooked bistoury for about one inch and a half. Mr. Abernethy now introduced his finger beneath the bag of the peritoneum, and carried it upwards by the side of the psoas muscle, so as to touch the artery about two inches above Poupart's ligament. He took care to disturb the peritoneum as little as possible, detaching it to no greater extent than was requisite to admit his fingers to touch the vessel. The pulsations of the artery made it clearly distinguishable, but Mr. Abernethy could not put his finger round it with facility. In order to be able to do so, he was obliged to make a slight incision on each side of it. Mr. A. now drew the artery gently down, so as to see it behind the peritoneum. By means of an eye-probe, two ligatures were conveyed under the vessel; one of these was carried upwards as far as the artery had been detached, and the other downwards: they were firmly tied, and the vessel was divided in the interspace between them. (*Surg. Observ.* 1807.)

In a third instance of tying this vessel. Mr. Abernethy operated exactly as in the foregoing case, and with complete success, (*See Edinb. Surg. Journ. Jan.* 1807.)

Mr. Freer, of Birmingham, who may be said to claim the honour of having seconded Mr. Abernethy in this new practice, made an incision about one inch and a half from the spine of the ilium, beginning about an inch above it, and extending it downwards about three inches and a half, so as to form altogether an incision four inches and a half long, extending to the base of the tumour. The tendon of the external oblique being exposed, was carefully opened, and also the internal oblique, when the finger, being introduced between the peritoneum and transversalis, served as a director for the crooked bistoury, which divided the muscle. Avoiding all unnecessary disturbance, Mr. Freer separated the peritoneum with his finger, till he could feel the artery beating, which was so firmly bound down, that he could not get his finger under it without dividing its fascia. The vessel having been separated from the surrounding parts, a curved blunt needle, armed with a strong ligature, was put under it, and tied very tight, with the intention of dividing the internal coats of the vessel. The operation led to a perfect cure. (*Freer on Aneurism*, p. 83; 4to. 1807.)

Mr. Tomlinson, of the same town, was also an early performer of the operation; he applied only one ligature, and, of course,

left the artery undivided: the event was attended with perfect success.

The following is Mr. A. Cooper's mode of operating, as described by Mr. Hodgson. A semilunar incision is made "through the integuments, in the direction of the fibres of the aponeurosis of the external oblique muscle. One extremity of this incision will be situated near the spine of the ilium: the other will terminate a little above the inner margin of the abdominal ring. The aponeurosis of the external oblique muscle will be exposed, and is to be divided throughout the extent and in the direction of the external wound. The flap, which is thus formed, being raised, the spermatic cord will be seen passing under the margin of the internal oblique, and transverse muscles. The opening in the fascia, which lines the transverse muscle, through which the spermatic cord passes, is situated in the midspace between the anterior superior spine of the ilium, and the symphysis pubis. The epigastric artery runs precisely along the inner margin of this opening, beneath which the external iliac artery is situated. If the finger, therefore, be passed under the spermatic cord, through this opening in the fascia, it will come into immediate contact with the artery, which lies on the outside of the external iliac vein. The artery and vein are connected together by a dense cellular membrane, which must be separated to enable the operator to pass a ligature, by means of an aneurism needle, round the former." (*On Diseases of Arteries*, p. 421—422.)

The foregoing incision, the convexity of which is turned outward, and downward, extends from within and a little above the anterior superior spinous process of the ilium to above and a little within the middle part of Poupart's ligament.

Mr. Norman, of Bath, who has tried both modes of operating, found that proposed by Mr. A. Cooper, a more easy way of finding the external iliac artery, than the longitudinal incision practised by Mr. Abernethy. "The objection, (says Mr. Norman,) to Mr. Cooper's mode of operating in cases, where the tumour extends high up, is by no means well founded; for the lower part of the bag, of the peritoneum, lying on the edge of Poupart's ligament, must in every case be exposed and detached, in order to get at the artery, which lies behind the posterior part of that membrane, and this is most easily effected by an incision in the direction of Poupart's ligament; whilst two-thirds of the longitudinal incision are made on a part of the peritoneum, which lines the abdominal muscles, and the lower portion only of the incision, reaches that part of the membrane, which is to be separated. The consequences of this are, that the peritoneum is in much greater danger of being wounded, and that the probability of a hernia forming after the cure, is much increased by the extensive division of the oblique muscles." (*See Med. Chir. Tran.* vol. 10, p. 101.) As far as I am able to

judge, these remarks are well founded, and they coincide with some observations, which were made some years ago by Roux, who, while he inclined to Mr. Abernethy's method, saw the disadvantage of letting the direction of the wound in this instance correspond to the course of the artery. Hence, after many trials on the dead subject, he laid down the rule, that the beginning of the wound should never be further, than half an inch from, and a very little higher, than the anterior superior spine of the ilium, and that it should be carried very obliquely downwards, to the middle of Poupart's ligament. (*See Nouveaux Elements de Med. Op. T. 1, p. 147. &c.*)

In a case, operated upon by Mr. Kirby, a hernia followed, in the situation where the abdominal muscles had been divided. (*See Cases with Observations*, p. 109, *Svo. Lond.* 1819.)

Dr. Post in one case found the peritoneum so thickened and diseased, that he could not raise it from the subjacent parts, and he was obliged to make an opening in it. The protruding viscera were then pushed back, and, with a needle, a ligature was introduced under the artery, the peritoneum being also included in the ligature. Notwithstanding the disadvantageous method of operating, and the return of pulsation in the swelling, the patient had so far recovered in three months, as to have regained the use of the limb. (*See American Med. and Phil. Reg. vol. 4, p. 443.*)

In one remarkable case, Mr. Newbiggin, by tying the external iliac artery, cured both an inguinal and popliteal aneurism together. (*See Edin. Med. & Surg. Journal*, for Jan. 1816, p. 71, &c.)

The many operations, which have now been done on the external iliac artery, have impressed me with a conviction, that in subjects under a certain age, there is no reason to fear, that the anastomoses will not generally suffice for the supply of the lower extremity. Out of twenty-five cases, I only know of three, in which the limb was attacked with gangrene. These three were patients of Mr. A. Cooper, Bouchet, of Lyons, and Mr. Collier. The proportion is not so much as one in eight. The three instances of gangrene were not all in the circumstances, which permitted the event to be imputed to the anastomoses not having had sufficient time to enlarge, though perhaps Mr. Collier's case was such. On the other hand, we are to notice, that Dr. Cole's patient was operated upon a few days after the wound, and yet the limb was duly supplied with blood, and did not become gangrenous. It appears therefore to me, that the occasional occurrence of gangrene cannot be admitted as a just reason for delay, until the collateral vessels have had time to enlarge. I believe, that in all aneurismal diseases, early operating is the best, and most judicious practice. This was one principal cause, as Kirkland observes, which occasioned the bad success of the old surgeons in the treatment of pop-

lital aneurisms, and he foretold many years ago, that operations for the cure of aneurisms would answer better, if not deferred so long as formerly. (See *Thoughts on Amputation*, &c. 8vo. Lond. 1780.) I join Kirkland in this sentiment, not without recollecting, that all aneurisms are attended with a chance of getting spontaneously well in the course of time. I saw the inguinal aneurism which did so, under Mr. Albert, in the York hospital; but as this also is a rare incident, I do not believe, that it ought to influence us against having speedy recourse to an operation. Besides, the cure by inflammation and sloughing, appears to me to be attended in reality with more peril, than a well-executed operation, and consequently, has less recommendations, than many may imagine. Had not Mr. Albert's patient been a very strong man, he would certainly have fallen a victim to the extensive disease, which the bursting and sloughing of the tumour created. Thus, Delaporte's patient died of the mass of disease, which the tumour itself made; for it had been suffered to attain too large a size, so that when it inflamed, the effects were fatal. (See *Richerand, Nosog. Chir. T. 4, p. 113, edit. 4.*)

I believe Dr. Wilmot's observation is perfectly correct, that, if a comparison were made between the operation of tying the external iliac artery and that of tying the artery in the thigh, we should find the recoveries after the first more frequent, in proportion to the number of times it has been done, than after common operations lower down. (See *Dublin Hospital Rep. &c. vol. 2, p. 214.*)

I subjoin a list of some of the successful examples of this operation. Mr. Abernethy, two cases, (*Surgical Works, vol. 1.*) Freer and Tomlinson, 2, (*Freer on Aneurism, 1807.*) Mr. A. Cooper, 4, (*Hodgson on Diseases of Arteries, p. 417.*) Goodlad, 1, (*Edin. Med. & Surg. Journ. vol. 8. p. 32.*) Mr. Brodie, 1, (*Hodgson, op. cit. p. 419.*) Lawrence, 1, (*Med. Chir. Trans. vol. 6. p. 205.*) J. S. Soden, 1, (*Same work, vol. 7. p. 536.*) G. Norman, 1, (*Same work, vol. 10. p. 95, &c.*) Bouchet, 1, (*Roux Med. Opératoire, T. 1. p. 744.*) J. S. Dorsey, (*Elements of Surgery, vol. 2, p. 180, Philadelphia, 1813.*) Moulard, 1, (*Bulletins de la Faculté de Médecine de Paris, T. 5. p. 535.*) Dupuytren, 1, (*French Transl. of Mr. Hodgson's Work, T. 2. p. 125.*) Dr. Cole, 1, (*Rapport des Travaux de la Société d'Emulation de la Ville de Cambrai, 1817, or Lond. Med. Repository.*) Dr. Wilmot, 1, (*Dublin Hospital Reports, vol. 2. p. 208, &c.*) Kirby, 1, (*Cases with Observations, &c. 8vo. Lond. 1819.*) Dr. Post, 1, (*American Med. & Philos. Register, vol. 4.*) Newbiggin, (*Edin. Med. & Surg. Journ. January, 1816.*)

Some particulars of the case of ruptured inguinal aneurism, in which Mr. A. Cooper tied the aorta, will be hereafter noticed. (See *Aorta.*)

Rosenmüller's Chir. Anat. Plates, in illustration of the operation of tying the external

iliac artery, merit notice. (See *part 3, tab. 2, 7, and 9.*)

CASES OF GLUTÆAL ANEURISM CURED BY TYING THE INTERNAL ILIAC ARTERY.

The glutæal artery is large; from its situation, liable to wounds; from its size, subject to aneurism. Dr. Jeffray, of Glasgow, was consulted in a case, where the glutæal artery had been wounded. He urged the propriety of tying the vessel where it had been injured. This sensible advice was at first rejected, and when the friends at last consented, the operation was too late, as while preparation was making for it, the tumour burst, and the patient expired in a few moments.

Theden also mentions an instance, in which the glutæal artery was wounded in the dilatation of a gunshot wound, and the patient lost his life. (See *Scarpa on Aneurism, p. 407, Ed. 2.*)

Mr. John Bell, however, tied the glutæal artery in a case where it was wounded, and the patient was saved.

Mr. Stevens, surgeon in Santa Cruz, the gentleman who has proved the practicableness of putting a ligature round the internal iliac artery, informs us, that "one of the first surgeons in London had a patient with glutæal aneurism. The tumour was large; allowed to burst; and the person bled to death.

"I sincerely trust, says he, that the following case may be the means of preventing such an occurrence in future.

"Maila, a negro-woman, from the Bambara country in Africa, was imported as a slave into the West Indies in the year 1790. She was purchased for the estate Enfield Green; now the property of the heirs of P. Ferrall, Esq. I saw her first in the beginning of December, 1812. She had a tumour on the left hip, over the sciatic notch. It was nearly as large as a child's head, and pulsating very strongly. She could assign no cause for the disease. It had commenced about nine months before, with slight pain in the part; and had gradually increased to its present size. She was now much reduced, in great misery, and ready to submit to any operation." (See *Medico-Chir. Trans. Vol. 5. p. 425.*)

After a few more particulars, Mr. Stevens notices, that he had tied the internal iliac on the dead body, and that he believed it might be done with safety on the living.

The following is some account of this operation, as practised upon the above negro-woman.

"On the 27th December, 1812, (says Mr. Stevens,) I tied the artery in the presence of Dr. Lang, Dr. Van Brackle, Mr. Nelthropp, and Mr. Ford, the manager of the estate.

"An incision, about five inches in length, was made on the left side, in the lower and lateral part of the abdomen, parallel with the epigastric artery, and nearly half an

inch on the outer side of it. The skin, the superficial fascia, and the three thin abdominal muscles, were successively divided; the peritoneum was separated from its loose connexion with the iliacus internus and psoas magnus; it was then turned almost directly inwards, in a direction, from the anterior superior spinous process of the ilium, to the division of the common iliac artery. In the cavity, which I had now made, I felt for the internal iliac, insinuated the point of my fore-finger behind it, and then pressed the artery betwixt my finger and thumb. Dr. Lang now felt the aneurism behind; the pulsation had entirely ceased, and the tumour was disappearing. I examined the vessel in the pelvis; it was healthy and free from its neighbouring connexions. I then passed a ligature behind the artery, and tied it about half an inch from its origin. The tumour disappeared almost immediately after the operation, and the wound healed kindly. About the end of the third week the ligature came away, and in six weeks the woman was perfectly well."

This is the first example, in which the internal iliac has been tied. The operation was not attended with much difficulty, nor pain, and not an ounce of blood was lost.

Mr. Stevens had no difficulty in avoiding the ureter, which, when the peritoneum was turned inwards, followed it. Had it remained over the artery, Mr. Stevens says, that he could easily have turned it aside with his finger. (See a particular history of this case in *Medico-Chirurg. Trans. Vol. 5, p. 422, &c.*)

A second instance, in which the internal iliac artery was tied, was some time ago communicated to the public. The operation was performed by Mr. Atkinson, of York, on account of a glutæal aneurism. The following are a few of the particulars, as related by this gentleman: Thomas Cost, aged 29, presented himself at the York County Hospital, April 29th, 1817. He was a tall, strong, active bargeman, not corpulent, but very muscular. He was enduring great pain from a large renitent, pulsating tumour, situated under the glutæus of the right side; an obvious aneurism. It had existed about nine months, and was the consequence of a blow from a stone. In a consultation with Dr. Lanson and Dr. Wake, the necessity of the operation was determined upon, and it was performed on the 12th of May, without any material difficulty, or interruption, except such as was the consequence of the division of, and bleeding from, the small muscular arteries. Having got command of the internal iliac artery within the pelvis, (which, says Mr. Atkinson, required the complete length of the fingers to accomplish,) it was tied. Sufficient proof of its being the identical artery was repeatedly obtained, by the pressure upon it stopping the pulsation, and causing a subsidence of the tumour. Dr. Wake, Mr. Ward, and all the pupils, were quite assured of the circumstance. The artery being then tied,

the pulsation of the swelling entirely ceased. Some delay in placing the ligature arose from the needle not being sufficiently pliable; but, for future operations of this kind, Mr. Atkinson very properly recommends the ligature to be put round the artery by means of an instrument, resembling a catheter, the wire of which has a little ring at its extremity, and can be pushed out some way beyond the end of the tube.

The patient went on tolerably well for some time after the operation; the pulse never exceeded 130, and after a time sunk to 85 or 90. He became exhausted, however, partly by the discharge, and partly by hemorrhage, and died on the 31st of May, about nineteen days after the operation. In the dissection, the cavity, on the external part of the peritoneum, in the situation of the incision, was completely filled with coagulated blood. "The ligature, on moving a part of this (blood) with a sponge, readily followed it, and, without doubt, had been disengaged for some days." The internal iliac, which appeared to have been tied, had separated about an inch and a half from the bifurcation with the external iliac. By "separated" I conclude Mr. Atkinson means that the upper part of the internal iliac was separated from the continuation of the same vessel. (See *Medical and Phys. Jour. vol. 38, p. 267, &c.*) Although this gentleman has not given a very clear account of some part of the dissection, and he has also omitted to describe the place of his external incision, or the exact parts, which he divided in the operation, yet, I think that all the circumstances of the case taken together, leave not the smallest doubt, of the internal iliac artery having been actually tied. The complete stoppage of the pulsation, as soon as the ligature was applied, and the testimony of several respectable practitioners, who were present, seem, indeed, to remove all ambiguity. The profession, I think, are much indebted to Mr. Atkinson for this important communication, which was in some measure, required, in order to confirm Mr. Stevens's similar case, as, it is well known, that some distinguished anatomists and surgeons in this metropolis have expressed very strong doubts of the practicable nature of the operation.

In a modern publication are given a few particulars of a case, which was supposed to be an aneurism of the glutæal artery, and cured by means of pressure, a light vegetable diet, gentle laxatives, and digitalis. (See *Trans. of the Fellows, &c. of the King's and Queen's College of Physicians in Ireland, vol. 1, p. 41, 8vo. Dub. 1817.*) From the very imperfect account here given of the tumour, it is impossible to form any conclusion, respecting its nature.

Sandifort has recorded an instance of an aneurism of the internal iliac artery itself. (See *Tabulæ Anatomicae, &c. Præcedit Obi. de Aneurysmate Arteriæ Iliacæ internæ, rariore ischiadis Nervosæ causa. fol. Lugd. 1804.*)

ANEURISMS OF THE BRACHIAL ARTERY.

Surgical writings contain many histories of aneurisms in the bend of the arm, produced by the puncture of the brachial artery in venesection, or caused by a deep wound inflicted at the bend of the arm, along the inner side of the humerus, or in the axilla. Such cases must indisputably be formed by effusion. Although Morand, &c. have found, that, along with aneurisms, caused by a wound of the brachial artery, the diameter of the vessel is sometimes unusually enlarged through its whole length, above the seat of the tumour, this enlargement, which is very rare, might have existed naturally, before the puncture occurred. Even were it frequent, such an equable longitudinal expansion of the tube of the artery could not explain the formation of the aneurismal sac in the bend of the arm, along the inner side of the humerus, or in the axilla, after wounds. (*Scarpa, p. 160.*) The proximate cause of these cases may invariably be traced to the solution of continuity in the two proper coats of the artery, and the consequent effusion of blood into the cellular substance. The effect is the same, whether from an internal morbid affection, capable of ulcerating the internal and fibrous coats of the artery, the blood be effused in the neighbouring cellular sheath surrounding the artery, which it raises after the manner of an aneurismal sac; or, the wound of the integuments having closed, the blood issue from the artery, and be diffused in the surrounding parts. The cellular substance, on the outside of the wounded vessel, is first injected, as in ecchymosis; the blood then distends it, and elevates it in the form of a tumour, and, the cellular being destroyed, converts it at last into a firm capsule, or aneurismal sac. (*Scarpa, p. 367.*)

The circumscribed or the diffused nature of the aneurism, and the rapidity or slowness of its formation, depend on the greater or less resistance to the impetus of the blood, during the time of its effusion, by the interstices of the cellular substance surrounding the artery, and by the ligamentous fasciæ and aponeuroses, lying over the sac. The aponeurosis of the biceps muscle, being only half an inch broad, and situated lower than the common place for bleeding, cannot, at least in most cases, materially strengthen the cellular substance surrounding the artery, as is commonly supposed. (*Scarpa, p. 168—170.*) This author refers the greatest resistance to the intermuscular ligament, which after having covered the body of the biceps muscle, extends over the whole course of the humeral artery, and is implanted into the internal condyle. This ligamentous expansion has a triangular shape, the base of which extends from the tendon of the biceps, to the internal condyle, while the apex reaches upward along the inner side of the humerus towards the axilla, in the course of the artery. The humeral artery and median nerve, kept in their si-

tuation by the cellular sheath and this ligamentous expansion, run in the furrow, formed between it and the internal margin of the biceps. (*Scarpa, 171.*) This author anatomically explains many circumstances relative to the diffusion, circumscription, shape, &c. of brachial aneurisms, from this intermuscular ligament. While aneurisms, from an internal cause, are not unfrequent in the aorta, thigh, and ham, they are very rare in the brachial artery; though a few such instances are recorded. (*Scarpa, 174, Pellen's Clinique Chir. T. 2, p. 4.*)

The mode of distinguishing a wound of the brachial artery, in attempting to bleed, and the method of trying to effect a cure by pressure, are described in the article *Hæmorrhage*.

Anel was the first, who tied the brachial artery, for the cure of the aneurism at the bend of the arm, in the same way that Hunter did the femoral, for the cure of aneurisms in the ham, viz. with one ligature above the tumour, without making any incision upon, or into, the sac itself.

The operation is performed as follows:—the surgeon having traced the course of the brachial artery, and felt its pulsations above the aneurism, he may either cut down to the vessel immediately above the tumour, or much higher in the long space between the origins of the superior and inferior collateral arteries. The integuments are to be divided in the course of the artery, and also the cellular sheath, for the space of about two inches and a half. The surgeon now introducing his left fore-finger to the bottom of the wound, will feel the denuded vessel, and, if it is not sufficiently bare, he must divide the parts which still cover it, observing to introduce the edge of the knife, on the side next to the internal margin of the biceps, to avoid dividing any of the numerous muscular branches, which go off from the opposite side of the artery. He is then to insulate, with the point of his finger, the trunk of the vessel, alone if he can, or together with the median nerve and vein, and raise it a little from the bottom of the wound. He is to separate the median nerve and vein, for a small space from the artery, and with an eyed needle is to pass a ligature under the latter, and then tie it with a simple knot.

In the operation, it should always be recollected, that the median nerve lies on the inside of the artery, and, therefore, that the instrument, used for putting the ligature under the vessel, should be passed from within outwards, by which means the inclusion of the nerve may be most easily avoided. (*Boyer, Traité des Maladies Chirurgicales, &c. T. 2, p. 193.*)

The operation is well described by Mr. Hodgson: "The surgeon divides the integuments along the ulnar margin of the biceps muscle, by an incision two inches and a half in length. The thin fascia, which surrounds the arm, will thus be exposed, and must be cautiously divided in the direction of the external wound. The artery lies immedi-

lately under the fascia, close to the margin of the biceps. The median nerve is situated on the ulnar side of the artery, which lies between its two venæ comites. The internal cutaneous nerve is also situated under the fascia in the middle of the arm, and lies on the ulnar edge of the median nerve. The cellular membrane, which connects these parts, is to be divided, until the coats of the artery are fairly exposed. This part of the operation will be effected with facility, if an assistant compress the artery above the wound, so as to stop the circulation through it, and render it in some degree flaccid. The point of an aneurismal needle is then to be introduced close to the ulnar, and brought out on the radial side of the artery, so as to avoid including the median nerve, or the veins which accompany the artery." (See *Hodgson's Treatise on Diseases of the Arteries*, &c. p. 391.)

Whoever, after the above directions, says Scarpa, shall have the treatment of a *circumscribed* aneurism in the bend of the arm, will no longer, it is to be hoped, follow the method of those, who, supposing the tumour to be formed by the dilatation of the artery, used first to divide the integuments over the tumour, insulated the sac, and sought for the vessel above and below the aneurism, in order to tie it in two places; and then endeavoured to make the sac slough away. The operation is now reduced to the greatest simplicity, viz. tying the artery merely above the tumour. (See *Scarpa*, p. 358, 359.)

When the aneurism is *diffused*, and accompanied with violent inflammation and swelling of the whole arm, from the excessive distention of the clots of effused blood, Scarpa recommends the old operation of opening the tumour, and tying the artery at the bottom of the sac, above and below the wound made by the lancet. In this method, a tourniquet must be applied to the upper part of the arm, near the axilla; or, if the limb be very painful and swelled, it is better to let an assistant compress the artery from above the clavicle, against the first rib. The incision having been made into the tumour, and the blood discharged, a probe is to be introduced into the puncture in the vessel, from below upwards, so as to raise the artery. This, being separated from the parts beneath, and the median nerve, for a small extent, is to have two ligatures put under it, one of which is to be tied above, the other below, the wound in the vessel. Then the tourniquet, or pressure, is to be taken off, and if there be no bleeding, the wound is to be brought together. (See *Scarpa*, p. 359.) In reference to this operation, Rosenmüller's *Chir. Anat. Plates*, Part 2. Tab. II. and Camper's *Demonstr. Anat. Pathol. Lib. 1.* are worth consulting.

It was on the brachial artery, that Mr. Lambert, (*Med. Ob. & Inquiries*, Vol. 2.) made the experiment of closing the puncture in the vessel by means of the twisted suture, under an idea, that the plan would not, like compression, obliterate the arte-

rial tube, and therefore, that the risk of gangrene would be lessened. Now, although in the trial which was made, the bleeding was permanently stopped, Lambert was mistaken in supposing, that the pervious state of the wounded part of the artery, was preserved by the adoption of the twisted suture, instead of pressure or the ligature. If ever a small puncture in an artery heal, so as to leave the tube of the vessel pervious, it is under the circumstances pointed out by Dr. Jones. (See *Hemorrhage*.) Had Lambert had an opportunity of examining the state of the vessel, some time after the above operation, he would have found its canal obliterated; and had he known the freedom with which the collateral arteries anastomose with the recurrent arteries of the forearm, he would have known how to explain more correctly the re-establishment of the pulse. I need merely add, that as the false idea of preserving the perviousness of the artery was the only foundation for the method, the practice ought never to be revived, as not affording equal security from hemorrhage to what is obtained by the ligature, or even compression.

AXILLARY ANEURISMS.

Aneurisms occasionally take place in the axilla, and make it necessary to tie the subclavian artery. A question, here naturally presenting itself, is, whether the surgeon should attempt the operation in an early period of the disease, or wait till circumstances are urgent; the aneurism large and far advanced; the arm œdematous and insupportably painful; and the tumour in danger of bursting? In all cases of aneurism, unquestionably, there is a certain chance of the disease getting spontaneously well; and one axillary aneurism, in a man in St. Bartholomew's hospital a few years ago, had certainly disappeared of itself, as was proved by the account which the patient while living gave of his case, and by the obliteration of the artery, found on inspection after death.

I believe, however, we ought not to suffer our conduct to be too much influenced by the hope of so unfrequent an event, and, from the observations, which I have made on this subject, it is my decided opinion, that the operation should never be delayed, so as to allow the tumour to acquire an immoderate size. The operation is always difficult; but, the difficulty is seriously increased, when the swelling has extended far towards the breast, and has become so large as to push the clavicle considerably upwards. The several examples, in which the subclavian artery has now been tied, have furnished abundant proof, that the anastomoses are fully competent to the supply of the limb with blood. The plan, therefore, of delaying the operation long, with the view of allowing the inosculating arteries to enlarge, must be as questionable here, as in some other cases of aneurism, and at

all events, the maxim may be safely advanced, that, previously to the operation, the tumour should never be suffered to acquire an enormous size.

That the limb would receive an adequate supply of blood was well proved, even without the performance of the operation, by cases in which the axillary and subclavian arteries had been rendered impervious by disease, as, for instance, by the pressure of an aneurism of the aorta. (For an account of such facts, the reader is particularly referred to *Hodgson's Treatise on the Diseases of Arteries*, p. 111; *Journal de Médecine* by *Corvisart, Leroux and Boyer*, T. 2, p. 29; *Corvisart, Essai sur les Maladies du Cœur*, p. 215.)

"In these cases (says Mr. Hodgson) the only unusual circumstances, which was observed during the life of the patients, was the deficiency of the pulse at the wrist. The limbs were well nourished, although a considerable extent of the main artery (the subclavian) was obliterated, even before it had given off any branches." (P. 47.)

This vessel was tied by a Mr. Hall in Cheshire, when it had been wounded with a scythe, and its ends exposed; the arm was preserved, though it remained somewhat weakened, which might be owing to the division of some large nerve. (See *J. Bell, on Wounds*, p. 60, edit. 3, and *Scarpa*, p. 372.) Mr. White, of Manchester, relates another instance of this vessel being tied, in the case of a wound; but, mortification of the limb and death followed. Three of the nerves were found included in the ligature. (*London Med. Journ.* V. 4.) In cases of wounds of the axillary, or any other large arteries of the extremities, the surgeon, before proceeding to apply a ligature, should first ascertain the precise place of the wound in the artery; and, for this purpose, it may sometimes be proper, in certain wounds of the shoulder, to make an incision in the axilla so as expose the injured part of the vessel; or, if circumstances do not forbid it, the external wound may be dilated, until the exact part where the artery has been wounded is discovered. In proof of the propriety of acting in this manner, and applying a ligature above and below the wound in the vessel, *Scarpa* quotes a case, in which such practice was successful on a patient under M. Maunoir, of Geneva: the artery had been injured with a sabre near the head of the humerus: but, after the wounded part of the vessel had been traced, and secured in the way above suggested, the patient, a boy fourteen years of age, was saved from the dangers of hemorrhage and recovered the use of his arm, as fast as this was possible, with the loss of the first phalanges of the three last fingers from gangrene. (See *Scarpa on Aneurism*, p. 412, Ed. 2, and *Journ. de Méd.* T. 40, Mars 1811.)

There are two modes of operating for axillary aneurisms; one by cutting below the clavicle, in order to take up the axillary artery itself; the other, by making the

wound above the bone, for the purpose of securing the subclavian artery at the point where it emerges from behind the anterior scalenus muscle.

The first of these methods has been attempted by Desault, Pelletan, Mr. Keate, Mr. Chamberlaine, &c. It was in a case of wound of the axillary artery, that Desault operated. An incision, six inches long, was made below the external third of the clavicle; two thoracic arteries cut were immediately tied; the two lower thirds of the great pectoral muscle were next divided with a bistoury guided on a director: a large quantity of coagulated blood was now discharged; and the artery was directly taken hold of, and tied, together with the brachial plexus of the nerves. The arm mortified, and the patient died. This case, we must agree with *Scarpa*, was not a fair trial of the operation, inasmuch as the inclusion of the plexus of nerves in the ligature was an improper measure, and must have promoted the occurrence of sphacelus. It seems also probable from the account, that the vein was likewise tied; another serious and objectionable proceeding. Besides, it is worthy of notice that the case was a wound of the axillary artery, attended with a copious effusion of blood in the cellular membrane. In all examples of this kind, gangrene is more readily induced, than when the case is a mere circumscribed aneurismal tumour. (See *Œuvres Chir. de Desault par Bichat*, Tome 2, p. 553.) As for Pelletan's example, it hardly deserves recital, because the operation in fact was not achieved. His colleagues objected to dividing the pectoral muscle; a random thrust was made with a needle and ligature; but, the artery was not included, and the experiment was not repeated. (See *Clinique Chirurgicale*, Tom. 2, Obs. 7, p. 49.)

In a case of axillary aneurism, which had actually burst, and the hemorrhage from which could only be stopped by pressing the artery against the first rib, Mr. Keate, the surgeon-general, practised the following operation, which was attended with completely successful consequences. This gentleman determined on taking up the artery, above the diseased and ruptured part, in its passage over the first rib. Accordingly, he made an incision obliquely downwards, divided the fibres of the pectoral muscle, that were in his way, and, when he came to the artery, passed a curved, blunt-pointed, silver needle, armed double, as he conceived under the artery, and tied two of the ends. After a careful examination, finding that the artery pulsated below the ligature, he determined on passing another ligature higher up, and nearer to the clavicle: he, therefore, passed the needle more deeply, so as evidently to include the artery. In a few days the swelling of the arm began to subside, the wound suppurated, and the ligatures came away with the dressings. The arm afterwards recovered its feeling, and the patient regained, in a great measure,

the entire motion of the shoulder, &c. (See *Med. Review and Magazine for 1801.*)

Mr. Keate's operation is objectionable, inasmuch as it was a dive made with a needle, and attended with great danger of wounding and tying parts which should be left undisturbed.

Mr. R. Chamberlaine, of Kingston, Jamaica, took up the axillary artery below the clavicle, in a patient, who had an aneurism in the left axilla, occasioned by a wound with a cutlass on the fifth of October, 1814. On the 10th of January, the tumour had considerably increased, and was less compressible than it had been when first seen by Mr. Chamberlaine. The operation was done on the 17th of January, 1815: "a transverse incision, of three inches in length, was made through the skin and platysma myoides, along and upon the lower edge of the clavicle, three fingers' breadth from the sternal end of that bone, and terminating about an inch from the acromion scapulae. This incision divided a small artery, which was immediately secured. A second incision, of three inches in length, was also made obliquely through the integuments over the deltoid and pectoral muscles, meeting the first nearly in the centre. The cellular membrane and fat, lying between them at the upper part, were now removed. The next step consisted in detaching the clavicular portion of the pectoralis major, and taking away the fat and cellular membrane lying over the subclavian vessels. The artery was now brought into view, and its pulsations made it clearly distinguishable from the contiguous parts." After several ineffectual efforts, Mr. Chamberlaine succeeded in conveying a ligature under it, by means of an eye-probe, curved for the purpose, and the point of which was brought up with the aid of a pair of forceps. On the 22d of February, the wound was completely healed; the aneurismal tumour reduced to the size of a turkey's egg, and very solid; the arm smaller than its fellow, but its muscular power improving. (See *Medico-Chir. Trans. Vol. 6, p. 128, &c.*) Mr. Chamberlaine expresses his conviction, that the operation would have been much facilitated, had he been furnished with the instruments described in Mr. Ramsden's work for passing the ligature under the artery.

The subclavian artery might be got at below the clavicle, as follows: the surgeon is to make an incision, through the integuments, about an inch from the sternal end of this bone. The cut is to run in the direction towards the acromion, deviating a little downward from a line parallel to that of the clavicle. This wound will bring into view some fibres of the great pectoral muscle originating from the last-mentioned bone. These are next to be divided. Some cellular substance will be found underneath, which is to be carefully raised with a pair of dissecting forceps, and cut. The operator will thus arrive at the great subclavian vein, and cephalic vein uniting with

it. Under the subclavian vein, and a little further backward, more under the clavicle, the subclavian artery may be felt and tied. (See *C. Bell's Operative Surgery, Vol. 2. p. 370.*)

On the whole, however, I think, Mr. Hodgson's directions for the performance of this operation, are the best which have been given. A semilunar incision through the integuments, which is to have its convexity downwards, and to begin about an inch from the sternal end of the clavicle, being continued towards the acromion for the extent of three or four inches, so as to end near the anterior margin of the deltoid muscle, without reaching into the space between the deltoid and pectoral muscle, in order to avoid wounding the cephalic vein. This incision will expose the fibres of the pectoral muscle, which are now to be divided in the direction and extent of the external wound. The flap is then to be raised, by dividing the loose cellular membrane, which connects the pectoral muscle to the parts underneath it. The pectoralis minor will now be seen crossing the inferior part of the wound; and by introducing his finger between the upper edge of this muscle and the clavicle, the surgeon may feel the pulsations of the axillary artery. Here one of the cervical nerves lies above, but in contact with the artery; the other nerves are behind it. In the dead subject, the axillary vein is situated below it; but, in the living, the vein is distended, and conceals the artery. The cellular membrane, connecting these parts, is to be separated by careful dissection, or by lacerating it with a blunt instrument. A ligature having been drawn under the artery with an aneurism-needle, the ends of the cord are to be raised, and a finger passed down, so as to compress the part surrounded by the ligature. If the artery be included, the pulsation in the aneurism will immediately cease. This precaution is highly necessary, lest one of the cervical nerves should be tied, instead of the artery. (See *Hodgson on Diseases of Arteries, &c. p. 362.*)

When an aneurism extends a certain way inwards, or towards the trachea, the operation below the clavicle becomes impracticable, and it is now requisite to make the incision above that bone, and take up the subclavian artery at the point, where it comes out from between the scaleni muscles, and lies on the flat surface of the first rib.

In the dead subject, without any tumour under the clavicle, this operation is easy enough; but in a living patient, the difficulty is much increased, by a large axillary aneurism, for then the clavicle becomes so much elevated, and the artery lies so deeply below it, that the vessel can hardly have a ligature carried under it, without a particular needle for the purpose. This was the case in an attempt which I once saw made to tie the artery, and in which one of the cervical nerves, affected by the pulsation of the artery, was mistaken for it, and tied, so

that the aneurism soon afterwards burst, and a fatal hemorrhage arose. Hence, the advice given by my friend Mr. Hodgson always to operate in this case while the tumour is small, cannot be too well remembered. The chief difficulty in the operation is that of passing the ligature under the artery; but, it may be done with the aid of an ingenious needle, which Mr. Ramsden has described, and which is exactly similar in principle to Desault's *aiguille à ressort*.

In order to avoid the inconveniences of the needles ordinarily used for conveying ligatures under deep arteries, Desault (says Bichat) invented "une aiguille à ressort," composed of a silver tube, or sheath, which was strait at one end, and bent at the other in a semicircular form. This sheath enclosed an elastic wire, the projecting extremity of which was accurately fitted to the end of the sheath, and perforated with a transverse eye. The instrument was passed under the artery, and, as soon as it had reached the other side of the vessel, the sheath was kept fixed, while an assistant pushed the elastic wire, which, rising from the bottom of the wound, presented the aperture or eye to the surgeon, who now passed the ligature through this opening. The wire was next drawn back into its sheath again, and the whole instrument brought from beneath the artery, by which means the ligature was conveyed under the vessel. (See *Œuvres Chir. de Desault, par Bichat, Tom. 2, p. 560.*)

The invention of this needle makes a material diminution in the difficulty of taking up the subclavian artery from above the clavicle; nor can it be wondered, that, without such an instrument, the operation should have baffled even so skilful a surgeon as Mr. A. Cooper. (See *Lond. Med. Review. Vol. 2, p. 200.*)

The following example is the first, in which the attempt to tie the subclavian artery by cutting above the clavicle, was ever accomplished.

John Townly, a tailor, aged thirty-two, addicted to excessive intoxication, of an unhealthy and peculiarly anxious countenance, was admitted into St. Bartholomew's Hospital on Tuesday the 2d of November, 1809, on account of an aneurism in the right axilla. The prominent part of the tumour in the axilla was about half as big as a large orange, and there was also much enlargement and distention underneath the pectoral muscle, so that the elbow could not be brought near the side of the body.

"The temperature of both arms," says Mr. Ramsden, "was alike, and the pulse in the radial artery of each of them was correspondent. After the patient had been put to bed, some blood taken from the left arm, and his bowels emptied, his pulse, which, on his admission, had been at 130, became less frequent; his countenance appeared more tranquil; and he experienced some remission of the distressing sensations in the affected arm: this relief, however, was of short duration; the weight and in-

cumbrance of his arm soon became more and more oppressive, and, in resistance to every medical assistance, his nights were again passed without sleep, and his countenance reassumed the anxiety which had characterized it when he first presented himself for advice."

On the sixth day after his admission, it was agreed, in consultation, that as the tumour (although increasing) did not appear immediately to endanger the life of the patient, from any probability of its bursting suddenly, it would be advisable yet to postpone the operation, for the purpose of allowing the greatest possible time for the anastomosing vessels to become enlarged; and, in the meanwhile, that the case should be most vigilantly watched.

About this period of the case, the pulsation of the radial artery of the affected arm gradually became more obscure, and soon after either ceased, or was lost in the œdema of the forearm and hand.

On the evening of the twelfth day, a dark spot appeared on the centre of the tumour, surrounded by inflammation, which threatened a more extensive destruction of the skin. A farther postponement of the operation being deemed inadmissible, Mr. Ramsden performed it the next day in the following manner:

"A transverse incision was made through the skin and platysma myoides along, and upon the upper edge of the clavicle, about two inches and a half in length, beginning it nearest to the shoulder, and terminating its inner extremity at about half an inch within the outward edge of the sterno-cleido-mastoideus muscle. This incision divided a small superficial artery, which was directly secured. The skin, above the clavicle, being then pinched up, between my own thumb and finger, and those of an assistant, I divided it, from within, outwards and upwards, in the line of the outward edge of the sterno-cleido-mastoideus muscle, to the extent of two inches.

"My object, in pinching up the skin for the second incision, was to expose at once the superficial veins, and by dissecting them carefully from the cellular membrane, to place them out of my way, without wounding them. This provision proved to be useful, for it rendered the flow of blood during the operation very trifling, comparatively with what might otherwise have been expected; and thereby, enabled me with the greatest facility to bring into view those parts, which were to direct me to the artery.

"My assistant having now lowered the shoulder, for the purpose of placing the first incision above the clavicle, (which I had designedly made along and upon that bone) I continued the dissection with my scalpel, until I had distinctly brought into sight the edge of the anterior scalenus muscle, immediately below the angle, which is formed by the traversing belly of the omohyoideus, and the edge of the sterno-cleido-mastoideus, and having placed my finger

on the artery, at the point where it presents itself between the scapuli, I found no difficulty in tracing it without touching any of the nerves to the lower edge of the upper rib, at which part, I detached it with my finger nail for the purpose of applying the ligature.

"Here, however, arose an embarrassment, which (although I was not unprepared for it) greatly exceeded my expectation. I had learned from repeatedly performing this operation, many years since, on the dead subject, that to pass the ligature under the subclavian artery, with the needle commonly used in aneurisms, would be impracticable; I had, therefore, provided myself with instruments of various forms and curvatures to meet the difficulty, each of which most readily conveyed the ligature underneath the artery; but, would serve me no farther; for, being made of solid materials, and fixed into handles, they would not allow of their points being brought up again at the very short curvature, which the narrowness of the space, between the rib and the clavicle, afforded, and which, in this particular case, was rendered of unusual depth, by the previous elevation of the shoulder by the tumour.

"After trying various means to overcome this difficulty, a probe of ductile metal was at length handed me, which I passed under the artery, and bringing up its point with a pair of small forceps, I succeeded in passing on the ligature, and then tied the subclavian artery at the part, where I had previously detached it for that purpose. The drawing of the knot was unattended with pain, the wound was closed by the dry suture, and the patient was then returned to his bed." (See *Practical Observations on the Sclerocèle, &c. to which are added four cases of operations for Aneurisms*, p. 276, &c.)

It only seems necessary for me to add, that immediately, the artery was tied, the pulsation of the swelling ceased; that the arm of the same side continued to be freely supplied with blood, and was even rather warmer than the opposite arm; that the operation, which was severe from the length of time it took up, was after a time followed by considerable indisposition; that the patient died about five days after its performance; that, after the artery had been tied, the œdema of the arm, and the aneurismal tumour partly subsided; and, that on examination after death, nothing, but the vessel, was found included in the ligature.

In this publication are descriptions of instruments, which will be of great service to any future performer of this operation. The chief one is a needle, resembling that, which was invented and used by Desault, and of which I have already endeavoured to give an idea. By means of this instrument, I conceive, that the main difficulty of the operation will not in future be experienced. Had Mr. Ramsden had its assistance, his patient would have been detained a very little time in the operating theatre, and the

event of the case might have been completely successful. Having witnessed all the circumstances of the case, the inference, that I drew from them was, that, if the operation could have been done in a moderate time, which now seems practicable with the aid of the *aiguille à ressort*, the case in all probability would have ended well. The preceding case is particularly memorable, as being the first instance, in which the subclavian artery was scientifically tied, without any random thrust of a needle, and without the inclusion of any part besides the artery in the ligature. It furnished encouragement to repeat the experiment, held out the hope, that axillary aneurisms might be cured as well as inguinal ones; and confirmed the competency of the anastomosing arteries to nourish the whole upper extremity, when the subclavian is tied where it emerges from behind the anterior scalenus muscle.

In the year 1811 the subclavian artery was tied in the London Hospital, in a case of axillary aneurism, by Sir W. Blizard, who found no difficulty in getting the ligature under the artery, with a common aneurism needle. A single ligature was applied. At first, hopes of recovery were entertained; but the patient, who was old and debilitated, afterwards sunk, and died on the fourth day. (See *Hodgson's Treatise*, p. 375.)

In the year 1815, Mr. Thomas Blizard tied the subclavian artery, in the same hospital. The case was an aneurism in the left axilla, and, like all the other examples of this kind upon record, was attended with great pain in the tumour and limb. There was no pulse in the left radial artery, though there was scarcely any difference in the temperature of both arms. "An incision, about three inches in length, was made through the integuments at the root of the neck, on the acromial side, and parallel with the external jugular vein. The platysma myodes being divided, the cellular membrane was separated with the finger, until the pulsation of the subclavian artery was felt where the vessel passes over the first rib. The finger being pressed upon this part of the artery, the cellular sheath investing it was carefully opened with the point of a knife. A ligature was then conveyed underneath the artery, by a common aneurism-needle with the greatest facility." As soon as the ligature was tied, the pulsation in the tumour ceased. On the second day after the operation, the left arm began to have more feeling, and was as warm as the right. However, difficulty of breathing, twitches, delirium, &c. afterwards ensued, and the patient died on the evening of the eighth day, previously to which event the ring and middle fingers turned black. On opening the body, the pericardium exhibited the effects of a high degree of inflammation, and the heart was covered with flakes of lymph, its posterior surface being of a deep red colour. The inner membrane of the ascending aorta was of a bright scarlet hue, was much diseased and studded

with white patches. A reddish appearance was also noticed in the lining of the right carotid, left subclavian, and even the abdominal aorta. The boundaries of the aneurismal tumour were in a state of sphacelation. These are all the circumstances which I wish here to notice; but more particulars may be perused in Mr. Hodgson's work, p. 602.

It is remarkable, that in the cases operated upon in the London Hospital, there was no difficulty experienced in passing the ligature under the artery with a common aneurism-needle, a circumstance which must have depended upon the space between the clavicle and the first rib having been less deep in these instances than the two which fell under my own observation, or in others which occurred in the practice of Dr. Colles and Mr. A. Cooper. (See *Lond. Med. Review*, vol. 2. p. 200, and *Edinb. Med. and Surg. Journ.* January, 1815.)

In Dr. Colles's first case, the artery was tied before it reached the scaleni muscles, as the tumour, which was in the right subclavian artery, extended from the sternal origin of the sterno-mastoid muscle along the clavicle, a little beyond the arch of that bone, and rose nearly two inches above it, in a conical form, the apex of the cone being situated at the outer edge of the foregoing muscle. After a tedious dissection, it was found, that only a quarter of an inch of the artery was sound, and on this portion the ligature was placed. Great difficulty was encountered in passing it round the artery, and the pleura was supposed to have been slightly wounded. Before tightening the ligature, the breathing became laborious, and the patient complained of oppression about the heart. These symptoms, indeed, were so violent, that it was judged prudent not immediately to tighten the ligature. On the fourth day, however, the artery was constricted, when the pulse at the wrist ceased, the patient not seeming to suffer much from what had been done. The patient then went on pretty well till the ninth day, when he was seized with a sense of strangling, and pain about his heart, and becoming delirious, died in nine hours after the beginning of this attack. On dissection, the aorta was found diseased, and the disease extending into the subclavian artery.

In another instance, Dr. Colles tied this vessel at the point, where it emerges from between the scaleni muscles, without any particular difficulty. The operation, however, was soon followed by a train of severe symptoms, delirium, and mortification, and the patient died on the fifth day. (See *Edinb. Med. and Surg. Journ.* January, 1815.)

The first case, in which complete success attended the operation of tying the subclavian artery, where it first comes from behind the anterior scalenus muscle, was that under the care of Dr. Post, of New-York. The patient was a gentleman, with an aneurism in the left axilla. Dr. Post performed the operation on the 8th of September, 1817,

in the following manner. "An incision, commencing at the outer edge of the tendon of the mastoid muscle, was carried through the integuments about three inches in length, in a direction deviating a little from a parallel line with the clavicle. This divided the external jugular vein, the bleeding of which required a ligature for its suppression; and, in proceeding with the operation, three or four arterial branches were cut, which it was also necessary to secure. The subclavian artery was then sought for immediately external to the scaleni muscles, and was easily laid bare. Passing over the artery at this place, in contact with it, were three considerable branches of nerves, running downwards towards the chest, from the plexus above. These were separated, and a ligature passed under the artery, with great facility, by the instrument well adapted to this purpose, invented by Drs. Parish, Hartshorne, and Hewson, of Philadelphia. On tying the ligature, all pulsation ceased in the limb." In the afternoon, the temperature of the limb was observed to be rather higher, than that of the other arm. On the 17th of September, the aneurismal tumour burst, and about three ounces of dark coagulated blood were discharged. On the 26th the ligature came away from the subclavian artery. Oct. 11, the wound was entirely healed, and on the 16th of the same month, the patient required no further attendance, his only complaints being now a little occasional pain in the fingers, and a superficial sinus at the part where the tumour burst. (See *Medico-Chir. Trans.* vol. 9. p. 185, &c.)

The instructions, delivered by Mr. Hodgson, for the performance of this operation, are the best with which I am acquainted. When the subclavian artery (says this gentleman) has emerged from behind the anterior scalenus muscle, it passes obliquely over the flat surface of the first rib, with which it is in immediate contact. The cervical nerves are situated above, and a little behind the artery: the subclavian vein passes before it, and underneath the clavicle. If the finger be passed down the acromial margin of the anterior scalenus muscle, the artery will be found in the angle, formed by the origin of that muscle from the first rib. The shoulder being drawn down as much as possible, the skin is to be divided, immediately above the clavicle, from the external margin of the clavicular portion of the mastoid muscle, to the margin of the clavicular insertion of the trapezius. No advantage whatever is gained by cutting the clavicular attachment of the sternocleido-mastoideus. The exposed fibres of the platysma myodes are now to be carefully divided, without wounding the external jugular vein, which lies immediately under them, near the middle of the incision, and should be detached, and drawn towards the shoulder with a blunt hook. The cellular membrane, in the middle of the incision, is then to be cut, or separated with the finger, until the surgeon arrives at the acro-

mial edge of the anterior scalenus. He passes his finger down the margin of this muscle, until he reaches the part where it arises from the first rib, and in the angle, formed by the origin of the muscle from the rib, he will feel the artery. The ligature is now to be conveyed under the vessel, with an aneurism-needle, or that recommended by Desault. (*Hodgson on the Diseases of Arteries, &c.* p. 376, &c.)

Breschet thinks, that the safest and easiest method is that adopted by Dupuytren, as follows: an incision, three or four inches long, is to be made at the lower and outer part of the neck, and extended to the clavicle. This first incision, situated behind the external edge of the sterno-mastoid muscle, should go through the skin, the cellular membrane, and platysma myoides. Some venous branches, running into the jugulars, will then be met with, which should be surrounded by a double ligature, and divided in the interspace. A director is then to be introduced under the omohyoideus muscle, in order to facilitate its division, and the surgeon will at length reach the external edge of the anterior scalenus. A curved probe-pointed bistoury is then to be gradually and cautiously passed behind that muscle, with the flat surface of the blade against it, and deeply enough to divide the external third, or half of the fibres of the same muscle, or even all of them, if requisite. The insulated artery will then be felt at the bottom of the wound, situated in the area of a triangle, the upper side of which is formed by the brachial plexus, the lower by the subclavian vein, and the inner by the scalenus. A ligature is then conveyed under the artery by means of the needle invented by Deschamps. (See *French Transl. of Mr. Hodgson's work, T. 2, p. 126.*) Whether cutting the anterior scalenus and omohyoideus will facilitate the operation is questionable; but the assertion, that these measures increase its safety, is what I cannot understand.

With respect to the mode of tying the subclavian artery on the tracheal side of the scalenus, we have seen that it was performed by Dr. Colles, and the event of the case was fatal. Descriptions of the operation may be found in Mr. Hodgson's work, p. 382. When I consider the manner in which the subclavian artery, before it passes behind the anterior scalenus, is surrounded by parts of great importance, I can scarcely bring my mind to think, that the measures, requisite for taking up the vessel in this situation, will ever leave the patient much chance of recovery. "Between the aorta and scaleni muscles (says Mr. A. Burns) the subclavian arteries are connected with several important vessels and nerves. They are in the vicinity of the nervus vagus, of the recurrent laryngeal nerve, of the sympathetic nerve, of the phrenic nerve, and the subclavian vein; and, on the left side, the subclavian artery is intimately connected with the termination of the thoracic duct. These parts are all grouped together

in a very narrow space, and the perplexity of their dissection is further increased by the interlacement of the different nerves with one another. The natural connexions of these parts are best shown by merely raising the sternal extremity of the sterno-mastoid muscle. If this be done, the nervus vagus will be brought into view, lying on the forepart of the subclavian artery, almost directly behind the sternal end of the clavicle; and exactly opposite to the nervus vagus, but behind the artery, the lower cervical ganglion of the sympathetic nerve will be brought into view. The recurrent nerve, on the right side, hooks round the subclavian artery, and, in its course towards the larynx, ascends along the tracheal side of the sympathetic nerve. On the left side, it twines round the arch of the aorta, and, in mounting upward, is interposed between the subclavian artery and œsophagus. The subclavian vein lies anterior to the artery, and, in the collapsed state, sinks nearer to the thorax; but, when distended in the living body, it overlaps the artery. The thoracic duct enters the subclavian vein, about the eighth of an inch nearer to the acromion than the point, where the internal jugular vein empties itself into the subclavian vein. The termination of the thoracic duct is situated between the sternal and clavicular portions of the sterno-mastoid muscle. (*A. Burns, on the Surgical Anatomy of the Head and Neck, p. 28.*)

It has been proposed to tie the arteria innominata in cases of aneurism of the subclavian artery. From a variety of facts, specified by a late interesting writer, it seems probable, that the brain and arm would receive an adequate supply of blood, although the arteria innominata were obliterated. On the whole, however, I fully coincide with Mr. Hodgson in condemning the proposal. The chief objections to it arise from the difficulty of the operation in the living subject; from the inflammation likely to be thereby excited among the important neighbouring parts; from the danger of hemorrhage, in consequence of the adhesion of the vessel being likely to be broken by the force of the circulation; and, lastly, from the equal practicableness of tying the subclavian artery, in most cases, on the tracheal side of the scalenus. (See *Hodgson on Diseases of Arteries, p. 384.*)

A case, in which an axillary aneurism, unattended with pulsation, was punctured, and the child bled to death, is noticed in a modern periodical work. (See *Med. Chir. Journ. vol. 4. p. 73.*)

For anatomical views of the parts concerned in the operation of taking up the subclavian artery, consult *Rosenmüller's Chir. Anat. Plates, Part 2, Tab. 8 and 9.*

Some valuable anatomical remarks, in relation to the operation, are given by Mr. A. Burns. (*Surgical Anatomy of the Head and Neck, p. 28, &c.*)

CAROTID ANEURISMS.

There is no part of the body where the diagnosis of aneurisms is more liable to mistake, than in the neck. Here the disease is particularly apt to be confounded with tumours of another nature. We have already cited, in this article, examples in which aneurisms of the arch of the aorta so resembled those of the carotid, as to have deceived the surgeon who was consulted. The swelling of the lymphatic glands, or of the cellular substance which surrounds the carotid artery; the enlargement of the thyroid gland; and especially abscesses, may resemble an aneurism by the pulsations, communicated to them by the neighbouring artery. On the other hand, aneurisms of long standing, which no longer throb, and the integuments over which are changed in colour, and likely to burst, may the more easily be mistaken by an inattentive practitioner for chronic abscesses, as the neck is remarkably often the seat of such diseases. (*Boyer, Traité des Maladies Chirurgicales, t. 2, p. 185.*)

Scarpa mentions one unfortunate patient, who was killed by a knife being plunged in a carotid aneurism, on the supposition that the case was an abscess.

I need scarcely observe, that by opening a carotid aneurism, a surgeon would expose himself to the disgrace and mortification of seeing the patient die under his hands, as happened in the example cited by Harderus. (*Apian. Observationum, Obs. 86.*)

The possibility of tying the carotid artery, in cases of wounds and aneurisms, without any injurious effect on the functions of the brain, is now completely proved. Petit mentions, that the advocate Viellard, had an aneurism at the bifurcation of the right carotid, for the cure of which he was ordered a very spare diet, and directed to avoid all violent exercise. Three months after this prescription, the tumour had evidently diminished; and, at last, it was converted into a small, hard, oblong knot, without any pulsation. The patient having died of apoplexy, seven years afterwards, the right carotid was found closed up and obliterated, from its bifurcation, as low down as the right subclavian artery. (*Acad. des Sciences de Paris, an. 1765.*) Haller dissected a woman whose left carotid was impervious. (*Opuscula Pathol. Obs. 19, Tab. 1.*) An example of the total closure of both carotids, in consequence of ossification, is stated by Koberwein to be recorded by Jadelot. (*German Transl. of Mr. Hodgson's work, p. 293.*) Hebenstreit, vol. 4, p. 266. ed. 3. of his Translation of B. Bell's Surgery, mentions a case, in which the carotid artery was wounded, in the extirpation of a scirrhus tumour. The hemorrhage would have been fatal, had not the surgeon immediately tied the trunk of the vessel. The patient lived many years afterwards. This is probably the earliest authentic instance, in which a ligature was applied to the carotid artery. Mr. Abernethy's case is perhaps

the second; and that in which Mr. Fleming, a naval surgeon, tied the common carotid in a sailor, who attempted suicide, and who was saved by the operation, is still later, not having occurred till the year 1803. (*See Med. Chir. Journ. vol. 3. p. 2.*)

Dr. Baillie knew an instance, in which one carotid was entirely obstructed, and the diameter of the other considerably lessened, without any apparent ill effects on the brain. (*See Trans. of a Society for the Improvement of Med. and Chir. Knowledge, vol. 1. p. 121.*) Mr. A. Cooper has also recorded an example, in which the left carotid was obstructed by the pressure of an aneurism of the aorta; and yet, during life, no paralysis, nor impairment of the intellects had occurred. (*See Med. Chir. Trans. vol. 1. p. 223.*) A similar case is related by Pelletan. (*Clinique Chir. t. 1. p. 68.*)

Mr. Abernethy was under the necessity of tying the trunk of the carotid, in the case of a large lacerated wound of the neck, in which accident the internal carotid and the chief branches of the external carotid were wounded. The patient at first went on well; but, in the night, he became delirious and convulsed, and died about thirty hours after the ligature was applied. This case fell under my own notice, and the inference which I drew was, that the man died more from the great quantity of blood which he lost, and the severe mischief done to the parts in the neck, than from any effect of the ligature of the artery on the brain.

In another instance, in which the common carotid was tied, on account of a wound of the external carotid, by a musket-ball, complicated with fracture of the condyle and coracoid process of the lower jaw, every thing went on favourably until the seventh day after the operation. Neither the intellectual faculties, nor the functions of the organs of sense, had been at all disturbed. But, at that period, stupor, confusion of ideas, restlessness, a small unsteady pulse, discoloration of the face, and loss of strength came on, followed in the evening by a violent paroxysm of fever. On the eighth day, three copious hemorrhages took place from the whole surface of the wound, and, on the ninth, the man died. In this case, however, the affection of the brain, and the other unfavourable symptoms, would be ascribed by nobody to the effects of the ligature on the carotid, but every one would see the cause in the severe and extensive local mischief, produced partly by the musket-ball, and partly by the mode in which the operation was performed, the surgeon having extended his incisions from the parotid gland to within an inch of the clavicle! (*See Journ. Général de Med. &c. par Sedillot.*)

That the carotid may be tied without injuring the functions of the brain, and that aneurisms of this artery admit of being cured by the operation, is not fully proved. The following is the second instance, in which I have been present at the operation

of tying the carotid trunk on account of a wound.

A soldier of the 44th regiment was wounded in the neck, with a pike, at the battle of Waterloo, and was brought to Brussels. After he had been some little time in the hospital, the bleeding, which had stopped, recurred with great violence, both from the mouth and the external wound itself; and it was therefore judged necessary to tie the common carotid, which was done by my friend Mr. Collier. The operation was performed by making an incision along the inner edge of the sterno-cleido-mastoidæus, raising this muscle from the sheath including the artery, &c. and holding aside the jugular and lower thyroid veins, which swelled up every instant to a very large size, so as to overlap the artery. This vessel being disengaged from the nerve, was then tied. Though the operation was done by candle-light, it was skilfully performed, and reflects great credit on Mr. Collier. A detail of the case may be found in a modern work. (*Med. Chir. Trans.* vol. 7. p. 107.)

Another example, in which the carotid artery was tied, and the patient saved, in a case where it was wounded with a penknife, has been recently published by Dr. John Brown, surgeon to the county of Meath Infirmary. (*See Dublin Hospital Reports*, vol. 1. p. 301, &c.) In this instance, the internal jugular vein "did not appear, nor was it a source of the slightest inconvenience during the operation." (P. 305.) A case, very analogous to the foregoing, is recorded by Mr. Hodgson, and the event equally successful. "The jugular vein afforded no trouble in the operation: it was not even seen." A gradual improvement of the power of deglutition marked the gradual subsidence of the tumour, which pressed against the pharynx. Nor was any change perceived in the state of the patient's mind after this operation, who remained as she had been previously, melancholy and dejected. (P. 332.)

Acrel mentions an example, in which the carotid artery was wounded by a gunshot, and the hæmorrhage permanently stopped by compression. A similar case is related by Van Horne, in his annotations to the work of Botallus. (*De Vuln. Sclopetis*.) Baron Larrey has likewise related a case, in which the carotid was wounded by a musket-ball, and life saved by the instant application of pressure. (*Mém. de Chir. Mil.* t. 1. p. 309.) However, considering the size of the vessel, and its unfavourable situation for being effectually and steadily compressed, some doubts may be entertained, whether the vessel wounded might not rather have been one of its branches.

On Friday, November 1, 1806, Mr. A. Cooper operated on Mary Edwards, aged forty-four, who had an aneurism of the right carotid artery. At this time, the tumour reached from the vicinity of the chin to beyond the angle of the jaw, and downward to within two inches and a half from the clavicle.

The swelling had a strong pulsatory motion. The woman also complained of a particular tenderness of the scalp, on the same side of the head, and of such a throbbing in the brain, as prevented her from sleeping.

An incision, two inches long, was made at the inner edge of the sterno-cleido-mastoidæus muscle, from the lower part of the tumour to the clavicle. This wound exposed the omo-hyoideus and sterno-hyoideus muscles, which being drawn aside towards the trachea, the jugular vein presented itself to view. The motion of this vein produced the only difficulty in the operation, as, under the different states of breathing, the vessel sometimes became tense and distended under the knife, and then suddenly collapsed. Mr. A. Cooper introduced his finger into the wound to keep the vein out of the way of the knife, and, having exposed the carotid artery by another cut, he passed two ligatures under this vessel by means of a curved aneurism-needle. Care was taken to exclude the recurrent nerve on the one hand, and the par vagum on the other. The ligatures were then tied about half an inch asunder; but the intervening portion of the artery was left undivided.

The pulsation of the swelling ceased immediately the vessel was tied, and, on the day after the operation, the throbbing in the brain had subsided, while no diminution of nervous energy in any part of the body could be observed.

The patient was occasionally afflicted with bad fits of coughing, but upon the whole, went on at first pretty well. On the eighth day, however, a paralysis of the left leg and arm was noticed, attended with a great deal of constitutional irritation. November 8th, the patient could move her arm rather better; but became unable to swallow solids. Nov. 12th, the palsy of her arm had now almost disappeared. The ligatures came away. November 14th, she was in every respect better; she swallowed with less difficulty; and the tumour was smaller, and quite free from pain. On the 17th, she became very ill; the tumour increased in size, and was sore when pressed. The wound was as large as immediately after the operation, and discharged a sanious serum. Great difficulty of swallowing, and a most distressing cough, were also experienced. The pulse was ninety-six, and the left arm again very weak. On the 21st, the patient died, the difficulty of swallowing having previously become still greater, attended with a further increase of the tumour, the skin over which had acquired a brownish red colour.

On opening the swelling after death, the aneurismal sac was found inflamed, and the clot of blood in it was surrounded with a considerable quantity of pus. The inflammation extended on the outside of the sac, along the par vagum, nearly to the basis of the skull. The glottis was almost closed, and the lining of the trachea was inflamed and covered with coagulating lymph. The

pharynx was so compressed by the tumour, which had been suddenly enlarged by the inflammation, that a bougie, of the size of a goose-quill, could hardly be introduced into the œsophagus. Mr. Cooper concludes with expressing his opinion, that *these causes of failure may, in future, be avoided by operating before the tumour is of such size as to make pressure on important parts; or, if the swelling should be large, by opening it, and letting out its contents, as soon as inflammation comes on.* (See *Med. Chir. Trans.* vol. 1.)

Mr. Cline operated for a carotid aneurism, December 16, 1808, in St. Thomas's Hospital. The tumour was very large, and had increased with great rapidity. The pressure of the swelling was such, as to interrupt both respiration and deglutition, and to put the larynx out of its natural position. The patient had besides a frequent and troublesome cough. The pain was confined to the tumour and same side of the face. These symptoms seemed relieved during the first twelve hours after the operation. They then became worse, particularly the cough and difficulty of breathing, and a violent irritative fever took place. The man died on the 19th of the same month. (See *London Med. Review*, No. 3.)

In the month of June, 1808, Mr. Astley Cooper operated, in Guy's Hospital, on a man, aged 50, who had a carotid aneurism attended with pain on one side of the head, throbbing in the brain, hoarseness, cough, slight difficulty of breathing, nausea, giddiness, &c. The patient got quite well, and resumed his occupation as a porter. There was afterwards no perceptible pulsation in the facial and temporal arteries of the aneurismal side of the face.

On the opposite side, the temporal artery became unusually large. The tumour was at last quite absorbed, though a pulsation existed in it till the beginning of September. The man's intellects remained perfect; his nervous system was unaffected; and the severe pain, which, before the operation, used to affect the aneurismal side of the head, never returned.

The swelling, at the time of the operation, was about as large as a pullet's egg, and situated on the left side about the acute angle, made by the bifurcation of the common carotid, just under the angle of the jaw.

Mr. A. Cooper began the incision opposite the middle of the thyroid cartilage, at the base of the tumour, and extended the wound to within an inch of the clavicle, on the inner side of the sterno-cleido-mastoideus muscle. On raising the margin of this muscle, the omo-hyoideus could be distinctly seen crossing the sheath of the vessels, and the nervus descendens noni was also brought into view. The sterno-cleido-mastoideus was now separated from the omo-hyoideus, when the jugular vein was seen. This vessel became so distended at every expiration as to cover the artery. When the vein was drawn to one side, the par vagum was manifest, lying between that

vessel and the carotid artery, but a little to the outer side of the artery. The nerve was easily avoided.

A double ligature was then conveyed under the artery with a blunt iron probe. The lower ligature was immediately tied, and the upper one was also drawn tight, as soon as about an inch of the artery had been separated from the surrounding parts above the first ligature, so as to allow the second to be tied at this height. A needle and thread were passed through the vessel below one ligature, and above the other. The artery was then divided. In a little more than nine weeks, the wound was quite healed, and the patient entirely recovered. (See *Med. Chir. Trans.* Vol. 1.)

Another successful instance, in which the carotid was tied for the cure of an aneurism, is related in a work, to which I always have the greatest pleasure in referring. (See *Hodgson's Treatise on the Diseases of Arteries*, p. 329.)

Mr. Travers, surgeon to St. Thomas's Hospital tied the carotid artery in a woman who had an aneurism by anastomosis in the left orbit. The disease had pushed the eye out of its socket. Two small ligatures were applied, which came away on the twenty-first and twenty-second day. No hemorrhage, nor impairment of the functions of the brain took place, and the disease in the orbit was effectually cured. (See *Med. Chir. Trans.* Vol. 2.)

Another highly interesting example, in which an aneurism by anastomosis in the orbit was effectually cured by tying the carotid artery, is recorded by Mr. Dalrymple, surgeon at Norwich. This gentleman performed the operation on the 12th of November, 1812. The patient was a female, aged 44. The protrusion of the eye was relieved in proportion as the swelling diminished. The violent headach also subsided; but the eyesight was irrecoverably lost. (See *Med. Chir. Trans.* Vol. 6. p. 111.)

An interesting case, in which my friend Mr. Vincent tied the carotid trunk for an aneurism, is published in the 10th vol. of the latter work. (P. 212, &c.) In this example, the internal jugular vein did not appear to be at all in the way during the operation; some of the fibres of the omo-hyoideus, however, could not be conveniently drawn aside, and were therefore divided. A single ligature was applied; the pulsation in the tumour did not entirely cease, at first, when the artery was tied, but it did so two days afterwards; and the swelling was rapidly diminishing. The ligature came away about three weeks after the operation, and there was every hope of a cure; but between the fourth and fifth week, a considerable swelling occurred between the wound and the jaw, impeding deglutition, but not the breathing. This state was followed by febrile symptoms, increased difficulty of swallowing; an attack of coughing; and impeded respiration. In the hope of affording relief, an incision was made in the tumour, from which a small quantity of

pus and coagulum issued; but, it was in vain, for the patient was dying. On dissection, the carotid artery was found perfectly closed as far as the division of the arteria innominata. But, above where the ligature had been, the vessel was open and inflamed, and pus was found in it. The most remarkable circumstance noticed was globules of air, adhering to the inner surface of the aorta, and other large arteries, and found also under the tunica arachnoidea. The bulk of the swelling in the neck depended upon effusion of serum in the cellular membrane.

In order to get at the carotid artery in the safest manner, Mr. Abernethy has recommended making an incision on that side of it which is next the trachea, where no important parts are exposed to injury, and then to pass a finger underneath the vessel. The par vagum must be carefully excluded from the ligature; for to tie it would be fatal. (*Surgical Observations*, 1804.)

The cure of carotid aneurisms by the operation has now been so often exemplified, that even to refer to every case upon record would demand more space than I can at present afford. A successful instance is reported by Macaulay (*Edin. Med. Surg. Journ.* April, 1814;) another by Dr. Post, who used two ligatures, and divided the artery in the space between them (*New England Journ. of Medicine and Surgery*, Vol. 3, p. 205, Boston, 1814;) another by Mr. Giles Lyford, proving the sufficiency of a single ligature, (*Med. Chir. Trans.* Vol. 11, p. 97, &c.) The case, in which Mr. Goodlad tied the carotid, in order to prevent hemorrhage in the removal of a tumour involving the parotid gland, is contained in Vol. 7, p. 112, &c. of the latter book.

The best anatomical engravings of the parts, concerned in the operation of taking up the carotid artery, are those by Rosenmüller. (See *Chirurg. Anatom. Abbildungen*, Thl. 1, tab. 7, 8, 9.)

For the particulars of a carotid aneurism cured by the ligature of the artery by M. Dumont, (See *Diss. sur l'Aneurisme de l'Artere carotide*, par P. J. Vanderhaghen, Paris, 1815.) Walther of Landshut, in the year 1814, tied the carotid artery for the cure of an aneurism with complete success; he applied only a single ligature. (*Breschet, Fr. Transl. of Mr. Hodgson's work*, T. 2. p. 83.) In this translation are reported several instances, in which Dupuytren and other continental surgeons have applied a ligature to the carotid.

OF ANEURISMS OF THE AORTA, AND VALSALVA'S TREATMENT.

This afflicting and fatal disease is by no means unfrequent, and the arch of the aorta is the most common situation of the tumour. Dr. Hunter was of opinion, that the latter circumstance depended on the forcible manner, in which the blood, propelled from the left ventricle of the heart, must be driven against the angle of the curvature of the vessel.

Mr. A. Burns considered aneurism of the thoracic aorta more frequent, perhaps, than that of any other vessel in the body. "I have had (says he) an opportunity of examining fourteen, who had died of this disease, but have not seen more than three instances of external aneurism." (*On Diseases of the Heart*, &c. p. 215.)

These proportions, however, would not at all correspond to common observation, external aneurisms taken collectively, being supposed to be about as numerous, as those of the aorta alone, a calculation long ago made by Dr. A. Monro, primus.

It was the opinion of Dr. W. Hunter, that the aneurismal sac was composed of the dilated coats of the artery, which parts nature thickened and studded with ossifications, after the origin of the disease, for the purpose of resisting its increase. Mr. Hodgson also in his late excellent publication, declares his decided belief, and adduces facts to prove, that many aneurisms of the aorta are formed by dilatation. Scarpa argues, however, that the generality of aneurisms of the aorta are the consequence of a rupture of the proper coats of this large vessel; and that the cellular sheath of the artery is what becomes distended into the thickened and ossified aneurismal sac.

Dr. W. Hunter considered the ossifications of the sac as consequences of the disease; but Haller looked upon such scales of bone in the aorta as the very cause of the affection, by rendering the artery inelastic and incapable of yielding to each pulsation of the heart.

It is unquestionably true, that aneurisms of the aorta are most common in persons who are advanced in life, and, it is equally well known, that the aorta of every old subject, whether affected with aneurism, or not, is almost always marked in some place or another, with ossifications, or, rather, with calcareous concretions. Such productions appear to occasion a decay, or absorption of the muscular and inner coats of the vessel, so that at length the force of the blood makes the artery give way, and this fluid, collecting on the outside of the laceration, or rupture, gradually distends the external sheath of the artery into the aneurismal sac, which itself becomes at last of considerable thickness, and studded with ossified specks.

"If any person, who is not prejudiced in favour of the common doctrine, with regard to the nature and proximate cause of this disease, (says Scarpa) will examine, not hastily and superficially, but, with care and by dissection, the intimate structure and texture of the aneurism of the aorta, unfolding with particular attention the proper and common coats of this artery, and, in succession, those which constitute the aneurismal sac, in order to ascertain distinctly the texture and limits of both, he will clearly see, that the aorta, properly speaking, contributes nothing to the formation of the aneurismal sac, and, that, consequently, the sac is merely the cellular membrane, which, in the

sound state, covered the artery, or that soft cellular sheath, which the artery received in common with the neighbouring parts. This cellular substance, being raised and compressed by the blood, effused from the corroded or lacerated artery, assumes the form of a circumscribed tumour, covered externally, in common with the artery, by a smooth membrane, such as the pleura in the thorax, and the peritoneum in the abdomen."

Scarpa then comments upon the differences of mere dilatation of an artery from aneurism, a subject which has been already fully considered in the foregoing pages. (*Scarpa on the Anatomy, Pathology, and Surgical Treatment of Aneurism, Transl. by Wishart, p. 55, 56.*)

As I have already explained in the foregoing pages, the sentiments of this eminent anatomist are not adopted by the generality of surgeons; or rather his doctrine is not carried by others to the extent which he has insisted upon, and it would be useless repetition to bring before the reader again the facts, which prove that his statements are liable to many exceptions. A case, however, recited by Roux, which I have met with since the foregoing pages were printed, merits notice; it was an instance, in which a popliteal aneurism, unattended with pulsation, had been mistaken for an abscess, and punctured, whereby the patient lost his life. On dissecting the limb, Roux says, "the three coats of the artery participated in the dilatation, and the case was one of the clearest specimens, which I have ever seen of a true aneurism." (*Nouveaux Elements de Med. Opératoire, T. 4, 517.*)

All arguments, brought against the possibility of a dilatation of the inner coat, and founded on the inelastic structure of that membrane, must likewise be completely refuted by another fact, demonstrated by morbid preparations, collected by Dubois and Dupuytren where the inner coat of the aorta is alone dilated, protruding through the outer tunics, in the form of a distinct swelling, somewhat like a hernia. (*Roux Op. cit. p. 49.*)

In whatever manner aneurisms of the aorta are formed, there are no diseases, which are more justly dreaded, or which more completely fill the surgeon, as well as the patient, with despair. No affliction, indeed, can be more truly deplorable; for, the sufferings, which are occasioned, hardly ever admit even of palliation, and the instances of recovery are so very few, that no consolatory expectation can be indulged of avoiding the fatal end, to which the disease naturally brings the miserable sufferer.

The existence of aneurisms of the aorta is scarcely ever known with certainty, before they have advanced so far as to be attended with an external pulsation, and a tumour, that admits of being felt, or even seen. In very thin subjects, the throbbing of the abdominal aorta is sometimes unusually plain through the integuments and

viscera, and this has occasionally given rise to the suspicion of an aneurism; a circumstance, which deserves to be remembered by every surgeon, desirous of not pronouncing a wrong opinion. The preternatural pulsations, however, which are liable to be mistaken for those of aortic aneurisms, are of various kinds, and form a subject, to which the attention of Dr. Albers of Bremen, the late Mr. A. Burns, and others, has been very usefully directed. (*See Abdomen.*)

While thoracic aneurisms of the aorta are accompanied with no degree of external swelling, the symptoms are all equivocal, and might depend on a disease of the heart, angina pectoris, phthisis pulmonalis, &c. Violent and irregular throbbings frequently occur between the fourth and fifth true ribs of the left side: the same irregularity of the pulse prevails as often proceeds from organic affections of the heart; the respiration is exceedingly obstructed; the voice altered; and, in a more advanced period of the malady, the patient is at times almost suffocated. The pressure of the internal swelling on the trachea, bronchia, and lungs, is sufficient to account for this difficulty of breathing. In many instances, the irritation and compression, produced by the tumour, occasion an absorption of the greater part of the lungs, and abscesses and tubercles throughout the portion which remains. Even the function of deglutition suffers interruption in consequence of the pressure made on the œsophagus, which may even be in a state of ulceration. Thus, in an example recently published, we read that "the cavity of the windpipe was nearly obliterated from the pressure of the aneurism; and the extremities of four of its cartilages lay in the œsophagus, having entered that canal, through an ulcer in its coats." (*Trans. of a Society for the Improvement of Med. and Chir. Knowledge, V. 3, p. 83.*)

After what has been stated, it cannot be surprising, that, ere the disease manifests itself externally, affections of the lungs, or strictures of the œsophagus, should often be suspected. (*Hodgson, p. 91.*)

An aneurism of the arteria innominata, not discovered till after the patient had died of suffocation, gave rise to great difficulty of drawing air into the chest, without any other symptom calculated to throw light on the nature of the disease. The aneurismal swelling was situated behind the first bone of the sternum, and pressed upon the trachea. The front of this tube was pushed in by the tumour, so as to present a convex prominence on the inner surface, which, however, diminished its area in a very slight degree. Mr. Lawrence adduces this fact to prove, that spasm of the aircells may be the cause of great distress in breathing. "The termination of this case (says he) is the more remarkable, inasmuch as in another patient, an aneurism rising out of the arch of the aorta, and pressing on the corresponding part of the trachea, so as to

produce ulceration of the internal membrane, under which there was a slight appearance of coagulated blood, caused no affection of the breath at all. The person died of a different complaint, and the discovery of the aneurismal tumour, which was very small, and filled with firm laminated coagula, was quite accidental." (*Med. Chir. Trans. Vol. 6. p. 227.*)

Thus, we find, in thoracic aneurisms, at least, previously to their attainment of a certain size, that no regularity prevails even with regard to difficulty of breathing, the symptom, which *a priori* one might suppose would invariably be present.

I have mentioned, that the symptoms of thoracic aneurisms, previously to the formation of any outward swelling, often resemble those of phthisis, and the latter is sometimes actually supposed to be the disease under which the patient is labouring. But, there is one distinction between the cases, which is pointed out by Mr. Hodgson, and may be of use, in combination with other circumstances, in facilitating the diagnosis: "in phthisis, the expectoration is either puriform, or thick, and clotted; but, in aneurisms, which are not accompanied with disease in the lungs, as far as I have observed, it always consists of a thin frothy mucus." (*On Diseases of Arteries, &c. p. 93.*)

According to Kreysig's experience, the cough comes on at irregular periods, is violent, and attended with great efforts, the expectorated matter being forced up by the vehemence. He agrees with Mr. Hodgson, respecting the general quality of what is expectorated, where thoracic aneurisms are not complicated with diseased lungs; but, he says, that the matter coughed up, also, frequently consists of masses of lymph, blended with brick-red particles of blood, which masses, when thrown into water, seem as if they were composed of a ball of stringy substances. (*German Transl. of the latter work, p. 187.*)

From a review of many cases of aortic aneurisms, Mr. A. Burns was inclined to think, that when the ascending aorta is aneurismal, the breathing is more affected, than when the arch of the vessel is enlarged, but, that in the latter case, the impediment to deglutition is greatest. (*On Diseases of the Heart, &c. p. 244.*)

The way, in which aneurisms of the thoracic aorta prove fatal, is subject to considerable variety. These swellings do not always destroy the patient by hemorrhage: in numerous instances, the magnitude of the disease so impedes respiration, that death seems induced by suffocation, and not a drop of blood is found internally effused. Frequently, (to use the description of Mr. John Bell) before the awful and fatal hemorrhage has had time to occur, the patient perishes of sufferings too great for nature to bear. The aneurismal tumour so fills the chest, so oppresses the lungs, compresses the trachea, and curbs the course of the descending blood, that the system, with

a poor circulation of ill-oxygenated blood, is quite exhausted. And, thus, though the patient is saved from the most terrible scene of all, he suffers great miseries; he experiences in his chest severe pains, which he compares with the stabbing of knives; terrible palpitations; an awful sense of sinking within him; a sound within his breast, as if of the rushing of waters; a continual sense of his condition; sudden startings during the night; fearful dreams and dangers of suffocation, until with sleepless nights, miserable thoughts by day, and the gradual decline of an ill-supported system, he grows weak, dropsical, and expires. (*See Anatomy of the Human Body, by John Bell, Vol. 2, Edit. 3, p. 234, 235.*)

Mr. A. Burns saw two examples, in which the patients died instantaneously, though their aneurismal tumours were very small, and had not burst. Both these patients were in the early stage of pregnancy. (*On Diseases of the Heart, p. 236.*)

The situations, in which aneurisms of the curvature of the aorta burst, are different in different cases. Sometimes the swelling bursts into the cavity of the chest, or that of the pericardium, and the patient drops suddenly down. When the coats of the aorta give way within the pericardium, where they only receive a slight external membranous covering, this is apt to be also ruptured at the same time, so as to bring on copious effusion of blood, which oppresses the action of the heart, and produces immediate death. In other examples, the blood is effused into the trachea, or bronchia, and the patient, after violent coughings and ejections of blood from the mouth, expires.

Sometimes, after the tumour has become closely adherent to the lungs, it bursts into the air-cells, through which the blood is widely diffused. An example of this termination of the disease was observed by Laennec; who also saw another case, in which, if the patient had lived a little longer, the same occurrence in all probability would have happened. Ebrhardt says, that he is not aware that this mode of rupture has been noticed by other writers. (*De Aneurysmate Aortæ, p. 21, 4to. Lips. 1820.*)

In certain cases, the swelling beats its way through the ribs, destroys the vertebrae, and injures the spinal marrow, so that the patient suffers a species of death, somewhat less violent and sudden. But, although aneurisms in the chest do sometimes present at the back, a circumstance, that depends on the particular situation of the disease, (*See Pelletan's Clinique Chirurgicale, Tom. 1, Obs. 7, p. 84.*) they more commonly rise towards the upper part of the breast, where a throbbing tumour occurs, which has caused an absorption of the opposing parts of the ribs, and sternum: and sometimes dislocated the clavicles. Corvisart saw an instance, in which an aneurism of the aorta had dislocated the sternal extremity of the clavicle; and Duverney makes mention of a case, in which, besides the displacement

and injury of the clavicle, the sternum and scapula were partially destroyed. Guattani speaks of an example, in which the clavicle was bent by a large aneurism, of which a portion, as large as a pigeon's egg, projected above the bone. (*Lauth, p. 168.*) And Morgagni has described a case, where the upper bone of the sternum, the sternal ends of the clavicles, and the adjoining ribs, were destroyed by the pressure of a large aneurism of the front of the curvature of the aorta, and the disease presented itself externally somewhat in the form of a bile. (*Epist. 26, art. 9.*)

The swelling now pulsates in an alarming way. The blood is only retained by a thin covering of livid skin, which is becoming thinner and thinner. At length, a point of the tumour puts on a more conical, thin, and inflamed appearance than the rest; a slough is formed, and, on this becoming loose, the patient is sometimes instantaneously carried off by a sudden gush of blood.

An extraordinary case of aneurism of the aorta is related by Dr. C. W. Wells. The disease, being unattended with any external swelling, it seems, was not comprehended during the patient's lifetime.

The following is an abstract of the symptoms, and particulars of the case. Mr. A. B. a gentleman, thirty-five years of age, and temperate in his habits, became affected in 1789 with symptoms, which were thought to denote the approach of pulmonary consumption. These, however, after some time, entirely disappeared. In 1798, he was attacked with a slight hemiplegia, from which he also recovered, with the exception of an inconsiderable sense of coldness in the foot, which had been paralytic. In March, 1804, he complained of being frequently troubled with a noise in his ears, flatulence in his bowels, and pains in his hands and feet, sometimes attended with slight swellings in the same parts. From one or more of these symptoms, he was never afterwards quite free; but, he did not complain of any unusual feelings in his chest. August 11, 1807, he fatigued himself considerably with walking; ate rather a hearty dinner; and, having refreshed himself with some sleep afterwards, he played about with his children. While thus amusing himself, he was suddenly seized, between eight and nine o'clock, with great oppression in his chest. He soon afterwards became sick, and in the matter thrown up, some streaks of blood were observed. He now went to bed; but, though the weather was warm, and he was covered with bed-clothes, his skin felt cold to the attendants. At midnight, he laboured under a constant cough, and expectorated mucus tinged with blood. His body was moistened with a cold sweat, and his pulse was extremely feeble; sometimes, it was scarcely perceptible. About five in the morning, his pulse was feeble and irregular: his breathing difficult, his skin pale, and cold, and covered with a clammy sweat.

He frequently tossed, and writhed his body, as if he was suffering great pain or uneasiness. The mental faculties, however, seemed unimpaired. Shortly afterwards he expired, having complained, just before his death, of much heat in his chest, and thrown off the bed-clothes.

The most remarkable circumstance found on opening the body, is thus recorded: "The ascending aorta was distended to about the size of a large orange. The tumour adhered to the pulmonary artery, just before its division into the right and left branches. Within the circumference of this adhesion there was a narrow hole, by means of which a communication was formed between the two arteries."

Dr. Wells concludes with observing, that, though such a disease might easily have been imagined, he had found no instance of it in books, and that it had not been observed by any of the surgeons, or anatomists in London. He supposed, that the communication, between the aorta and pulmonary artery, took place on the evening before the patient's death, when the oppression of the chest was first felt: and that, in consequence of the superior strength of the left side of heart, a part of the blood, which was thrown into the aorta, must have been forced into the pulmonary artery, from which circumstance, he conjectures most of the symptoms originated. (*Trans. of a Society for the Improvement of Med. and Chir. Knowledge, Vol. 3, p. 85.*)

The bursting of an aneurism of the aorta into the pulmonary artery is then another possible mode, in which the disease may prove fatal.

Besides the example of this nature, reported by Dr. Wells, several others are detailed by writers. (See *Bulletin de la Faculté de Médecine, No. 3, in which there are two cases; Sue, in Journ. de Med. continué, T. 24, p. 124; and in Bulletin de la Faculté, &c. T. 17, p. 16.*)

Aneurisms of the arch of the aorta are stated to have adhered to, and burst into the right auricle of the heart, and thus to have produced instant death. (See *Med. Chir. Journ. Vol. 6, p. 617. Bulletin de la Société de Médecine à Paris, 1810, No. 3, p. 38.*)

Gases, in which aneurisms of the thoracic aorta, burst into the œsophagus, are uncommon. Bonetus and Morgagni record no examples of this event; nor are there any in the comprehensive treatises of Scarpa and Hodgson. Corvisart speaks of an instance, which had been seen by Dupuytren, of which, however, no description is given. Yet, the possibility of the occurrence is not a matter of speculation, or doubt.

A case of this description is noticed by Matani (*De Aneurism. Præcordiorum Morbis, p. 120;*) another is alluded to by Ehrhard, as being related by Copeland, (*Comment. De Aneurysmate Aortæ, p. 22, et Cerutti Catal. Præp. Pathol.*) and an instance is described by Bertin, (See *Bulletins de la Faculté de Med. 1810, p. 14.*)

Sauvages is one of the few writers, who

have adduced proofs of this mode of rupture: *cadavere aperto, inveni ventriculum septem vel octo libris sanguinis distensum, aortam ad brachii magnitudinem, per spatium septem vel octo pollicum dilatam, et orificium denarii magnitudine aortae et oesophago continuo commune, quod lumen quinque cristae carnae, veluti valvulae ex ambitu orificii oriunda et circumposita potuerunt obturare. Per hoc orificium, sanguis ex aorta fluxerat in oesophagum.* (Nos. Method. T. 2, p. 298.) A similar case has been recently published by Bricheteau. (See *Bulletin de l'Athénée de Med. de Paris*, Dec. 1816.)

Laennec met with an aneurism of the descending aorta, where the tumour had made such pressure on the thoracic duct, that this tube was partly destroyed, and all the lymphatic vessels were found uncommonly turgid. (*Journ. de Med. par Corvisart*, T. 2, p. 15.) With the exception, perhaps, of one instance given on the authority of Lancisi, (*Lauthii Collect.* p. 38,) no other example of this description is upon record.

An instance is reported by Corvisart, in which the pressure of an aneurism of the ascending aorta had nearly obliterated the termination of the lower vena cava, and a fatal attack of apoplexy was the consequence. (*Mal. du Cœur*, p. 342.)

It is well worthy of notice, that aneurisms of the arch of the aorta may occasion a tumour, so much like that of a subclavian aneurism, as to be in danger of being mistaken for the latter disease. An example of this kind is related by Mr. Allan Burns: "a case," says he, "on which several of the most distinguished practitioners in Edinburgh, and almost every surgeon in Glasgow, were consulted. The nature of the disease appeared to be so decided, and its situation in the subclavian artery so clear, that, on that subject, there was no difference of opinion. Some were, however, of opinion, that an operation might be performed, while others were fully convinced, that the case was hopeless. For myself, I must confess, that I was firmly persuaded, that, in the early stage of the disease, an operation might have been beneficial," &c. (*Surgical Anatomy of the Head and Neck*, p. 30.) After death, the vessel, which was supposed to have been most materially affected, was found perfectly healthy. (P. 39.)

After detailing all the particulars of this interesting case, Mr. A. Burns observes, that "it corroborates Mr. A. Cooper's remark, that aneurism of the aorta may assume the appearance of being seated in one of the arteries of the neck; an inference, drawn from the examination of a case, which came under his own observation, and of which he had the goodness to transmit a short history to me, along with a sketch, illustrative of the position of the tumour. In one case, the aneurism was attached to the right side of the aortic arch, and involved a part of the arteria innominata; in Mr. Cooper's the tumour arose from the left side of the arch, from between the roots of the left subclavian and carotid arteries. It formed a Florence

flask-like cyst, the bulbous end of which projected at the root of the neck, from behind the sternum, and so nearly resembled aneurism of the root of the carotid artery, that the practitioner, who consulted Mr. Cooper, actually mistook the disease for carotid aneurism." (*Allan Burns, Op. cit.* p. 41.)

The preceding statement has received full confirmation from the observations of an intelligent writer. "I have seen (says Mr. Hodgson) several cases of aneurism, arising from the superior part of the arch of the aorta, which protruded above the sternum and clavicles, and, in one instance, the space between the tumour and the sternum was so considerable, that it was proposed to tie the carotid artery for an aneurism, which dissection proved to arise from the origin of the arteria innominata; and from the arch of the aorta." (*On the Diseases of Arteries and Veins*, p. 90.)

As we have already noticed, aneurisms of the aorta are most frequent at its curvature; but, they are also met with on the other portion of this vessel in the thorax, and likewise on that part of it, which is below the diaphragm. In subjects, predisposed to aneurisms, such swellings are frequently seen affecting various parts of the aorta at the same time.

When the disease occurs in the abdominal aorta, a preternatural pulsation generally becomes perceptible at some particular point. The pressure of the tumour interferes with the functions of the viscera; the breathing is rendered difficult by the swelling resisting the descent of the diaphragm; the patient suffers at times excruciating internal pains; sometimes he is affected with costiveness; sometimes, with diarrhoea; and not unfrequently with incontinence of the urine and feces. At length, an immense external swelling is formed, which pulsates alarmingly, and, if the patient survives long enough, destroys him by a sudden external, or internal effusion of blood.

Aneurisms, within the thorax and abdomen, being entirely out of the reach of operative surgery, have been too commonly abandoned as unavoidably fatal, and when any thing has been done in such cases, it has generally been only with a view of palliation. Moderating the force of the circulation by bleedings and low diet, avoiding every thing that has the least tendency to heat the body, or quicken the motion of the blood, keeping the bowels well open with laxative medicines, and lessening pain with opiates, have been the means usually employed. Of late years, also, digitalis, which has a peculiar power of diminishing the action of the sanguiferous system and impetus of the blood, has been prescribed, with every appearance of benefit.

That the diminution of the force of the circulation will prevent the increase of an aneurism, Mr. Hodgson considers illustrated by the following circumstance: if two sacs exist in the course of the same artery, the obstruction, which is caused by the passage of blood into the upper, removes the force

of the circulation from the lower, which becomes stationary, or its cavity is obliterated with coagulum. (*On Diseases of Arteries, &c.* p. 149.)

It was the opinion of the celebrated Valsalva, that the utility of a lowering plan of treatment might do more, than merely retard the death of aneurismal patients. It was his belief, that the method might entirely cure such aneurisms as had not already made too much progress; and he put it into practice with such rigour and perseverance, that the treatment became considered as particularly his own. The plan alluded to, is not described in his writings; but was published in the first volume of the Commentaries of the Academy of Bologna, by Albertini, one of his fellow-students; and several persons, who had learnt this method of Valsalva, afterwards imparted it to others. Thus, as Morgagni was passing through Bologna, in 1728, Stancazi, a physician of that place, is said to have informed him of Valsalva's practice. (See on this subject, *Kreysig, über die Herzkrankheiten*, B. 2, p. 728.)

After taking away a good deal of blood by venesection, Valsalva used next to diminish the quantity of food gradually, till the patient at length was allowed only half a pint of soup in the morning, and a quarter of a pint in the evening, and a very small quantity of water, medicated with mucilage of quinces, or with the lapis of osteocolla. When the patient had been so reduced as to be incapable of getting out of his bed, Valsalva used to give him more nourishment till this extreme debility was removed. Valsalva was sure, that some aneurisms, thus treated, had got well, because every symptom disappeared, and his conviction was verified by an opportunity which he had of dissecting the body of a person that had been cured of this disease, and afterwards died of another affection; for the artery, which had been dilated, was found contracted, and in some degree callous.

Morgagni relates, that this method of treating aneurisms, is somewhat like the plan, which Bernard Gengha tried with success, as well as Lancisi, and he refers us to the 24th chapter of the 2d vol. of the Anatomy of the one, and to lib. 2. cap. 4, of the Treatise on the Heart and Aneurisms, of the other. But, Sabatier tells us, that, in consequence of this instruction, he examined both these works, without finding any thing on the subject. However this may be, we are informed by the latter, that he has seen the good effects of the practice in an officer, who had an alarming aneurism in front of the humeral extremity of the clavicle, in consequence of a sword wound in the axilla. The patient, after having been bled several times, was confined to his bed, and kept to an extremely low diet. He was allowed, as drink, only a very acid kind of lemonade. He took pills containing alum, and the swelling was covered with a bag full of tan mill dust, which was every now and then well wet with port

wine. By a perseverance in this treatment, the swelling was reduced to a smallish hard tubercle, having no pulsation, and a perfect cure ensued. (See *Sabatier Médecine Opératoire*, Tom. 3, p. 170—172.)

A French surgeon named Guérin, has written in favour of the efficacy of applying ice water, or pounded ice, to aneurismal swellings; a plan, which he represents, as being often of itself sufficient to effect a cure. This topical employment of cold applications may be rationally and conveniently adopted in conjunction with Valsalva's practice.

The most interesting and convincing facts, in proof of the efficacy of this mode of treatment, were published a few years ago by Pelletan. Indeed, upon the whole, I have no hesitation in saying, that I never read any modern collection of surgical cases, which have appeared to me more valuable, than those which compose the Clinique Chirurgicale of this experienced writer. The following extract from a well-written critique on this work will serve to convey to the reader some idea of the important information contained in the memoir on internal aneurisms. "The intent in the treatment is to reduce the patient gradually to as extreme a degree of weakness, as is possible, without immediately endangering life. It is done by absolute rest, a rigorous diet, and bleeding; to these means, M. Pelletan adds the external application of ice, or cold and astringent washes, &c. He has here detailed many cases from his own practice, of partial, or complete success, which cannot be too generally known, as they may be the means of creating in some, and of confirming in others, a good opinion of the only method of treatment, which has been found at all efficacious in a dreadful, and not unfrequent, organic disease.

"Of the cases here recorded, some appear to have been cured; in others, the treatment had marked good effects. In extreme cases, at best, it afforded but partial and temporary relief. We can notice but a few of these cases, which are, in every respect, highly interesting. In one, a robust man, an aneurism at the root of the aorta, with a pulsating tumour of the size of an egg, projecting between the ribs, (the edges of which were already partly absorbed) was reduced, so as to recede within the ribs in the course of eight days. At the end of this time, the patient refused to submit any longer. The tumour did not appear again for nearly a year, although he returned to very drunken and irregular habits. He died in about two years and a half, with the tumour again appearing, and much increased in volume. The aneurismal sac communicated with the aorta, by a smooth and round opening, opposite to one of the sigmoid valves. There can be no doubt of the efficacy of the treatment in this case; and it is highly probable, that his health and his life might have been long preserved, but for his own indiscretion. In a case

somewhat similar, but not so far advanced, the patient appears to have been cured. There was a swelling on the right side of the breast, about six inches in circumference, with a very strong beating. The pulsation was accompanied with a pain, which stretched towards the scapula and the occiput. It was evident, that the disease was an aneurism of the great arch of the aorta. The patient was a crier, of a strong frame, who was accustomed to drink freely. In the four first days, he was bled eight times, drawing three basins, "palettes," in the morning, and two in the evening. On the fifth, the pains and the beating were much lessened, but the pulse was still full. He was again bled once. The pulse was in a favourable state, as to strength, till the seventh day, when it again rose, and the man was twice bled.

During this time, the man was kept to a most rigorous diet. A cold poultice of linseed and vinegar was placed on the tumour, and renewed when it became warm. At the end of eight days, the good effects of this plan were very evident; the pain and the pulsation were gone. The patient, though weak, was in health and tranquil. He was now allowed more food by degrees. At the end of four weeks from the commencement of the treatment, he left the Hôtel Dieu well. He afterwards led a sober life, and became fatter, without any vestige of disease, except a slight and deep pulsation at the part, in which the aorta may always be felt beating in its natural state. He died two or three years after, of another complaint. His death was not known, and the body was not examined. (See *London Med. Review*, Vol. 5, p. 123.)

Pelletan also cured by similar treatment a large axillary aneurism, which was deemed beyond the reach of operative surgery. On the thirteenth day, the patient was reduced to a degree of weakness, which alarmed many of the observers. From that time, all pulsation in the tumour ceased. The contents were gradually absorbed; and the patient returned to his former laborious life with his arm as strong as ever. The pulse at the wrist was lost in consequence of the obliteration of the axillary artery, and the limb only receiving blood through the branches of the subclavian artery. "*Il y a beaucoup d'exemples, d'aneurismes guéris spontanément et sans le secours de l'art; (says Pelletan) mais on ne peut leur comparer le cas que nous venons de décrire; l'état extrême de la maladie, l'énergie des moyens employés, et l'effet immédiat et successif qui en est résulté, prouvent assez que le succès a été dû tout entier à l'art.*" (*Clinique Chirurgicale*, Tom. 1, p. 80.)

In this work, we find not less than three cases, in which aneurism of the aorta is stated to have been effectually cured. One instance was greatly relieved; but, the disease returned, the next year, in consequence of the patient's intemperate mode of life. In another example, an aneurism at the origin of the aorta was cured; but, the disease

recurred in another part of that vessel further from the heart. Even such cases are proved incurable, to the number of fourteen, all received various degrees of palliation from the treatment adopted.

In a modern work of great merit, several other instances are adduced, in which the utility and efficacy of a debilitating plan of treatment are illustrated. (See *Hodgson's Treatise on the Diseases of Arteries*, p. 146, 147, &c. &c.) In the same publication, as I have previously explained, there are several interesting facts, which tend to prove, that when the aneurism of the aorta is lessened, or cured, this great vessel itself may remain pervious. The progress of the disease is stopped by the blood coagulating in the sac, and closing the communication between the cavity of the aneurism, and that of the artery.

It must be confessed, in regard to Valsalva's mode of treatment, that some experienced men do not place confidence in it. Boyer declares himself against it, as not being really efficacious; and he states, that some time ago, it was tried twice in the Hôtel Dieu of Paris. The first trial was made on a patient with an axillary aneurism, which could not be operated upon on account of its situation; the second a woman, who had an aneurism of the abdominal aorta. In both cases, the tumour was large, and its parietes reduced to the cellular coat, and the surrounding cellular substance. In these two aneurisms, the progress of the swelling was much more rapid, and its rupture happened precisely at the moment when the treatment had been pushed to the utmost, and there ought to have been the greatest hope. (*Traité des Maladies Chir.* T. 2, p. 121.)

Roux expresses his entire disbelief in the possibility of an aneurism of the aorta being ever completely cured by Valsalva's mode of treatment, because he imagines, that such change could not happen without the tube of that great vessel becoming impervious, and of the lower parts of the body then perishing from stoppage of the circulation. But, he bears witness to the utility of such treatment, and recites a case, which he attended himself, where an aneurism made a considerable projection on the left side of the sternum, where the cartilages of the third and fourth ribs were raised, the throbbings very forcible, and the sense of suffocation such, that the patient was obliged to keep himself constantly quiet; yet, says Roux, though the disease now exists, it forms no prominence on the chest; the pulsations can only be obscurely felt between the ribs; respiration is but slightly oppressed; and the patient is capable of attending to his business. (*Nouveaux Elémens de Médecine Opératoire*, T. 1, p. 510, 8vo. Paris, 1813. Fr. Torti, *De Aortæ Aneurysmate Observationes binæ, cum animadv. Pouli Valcarengi*, 8vo. Cremonæ, 1741. D. Sommer, *Dis. Sistens Aneurysma-*

tis Aortæ Pleuritidem mentientis Casum. Sro. Berol. 1816.)

ANEURISMAL VARIX, VARICOSE, OR VENOUS ANEURISM.

By these terms, surgeons mean a tumour, arising from a preternatural and direct communication, formed between a large vein and a subjacent artery. Thus, in venesection, performed immediately over the artery at the bend of the elbow, if the lancet be carried too deeply, it may transfix the vein, and wound the artery, in which event, the arterial blood, in consequence of the proximity of the two vessels, instead of being effused into the cellular substance, will pass directly into the cavity of the vein, which will become dilated in the form of a varix by the jet of arterial blood into it.

Although Sennertus probably referred to an instance of this disease, (*Op. T. 5, l. 5, cap. 43.*) Dr. W. Hunter is undoubtedly the first who gave an accurate description of it. Scarpa is disposed to claim a share of the merit for his countryman Guattani; but, as Mr. Hodgson has remarked, Dr. Hunter's observations on this disease were published in the years 1757, and 1764, whereas, Guattani did not see his first patient until the year 1769, and his book was not published until the year 1772.

"Does it ever happen in surgery," says Dr. Hunter, "that when an artery is opened through a vein, a communication or anastomosis, is afterwards kept up between these two vessels? It is easy to conceive this case, and it is not long since I was consulted about one, that had all the symptoms that might be expected, supposing such a thing to have actually happened, and such symptoms, as otherwise must be allowed to be very unaccountable. It arose from bleeding; and was of some years standing, when I saw it about two years ago, and I understand very little alteration has happened to it since that time. The veins, at the bending of the arm, and especially the basilic, which was the vein that had been opened, were there prodigiously enlarged, and came gradually to their natural size, at about two inches above, and as much below the elbow. When emptied by pressure, they filled again almost instantaneously, and this happened, even when a ligature was applied tight round the fore-arm, immediately below the affected part. Both when the ligature was made tight, and when it was removed, they shrunk, and remained of a small size, while the finger was kept tight upon the artery, at the part where the vein had been opened in bleeding. There was a general swelling in the place, and in the direction of the artery, which seemed larger, and beat stronger, than what is natural, and there was a tremulous jarring motion in the vein, which was strongest at the part, which had been punctured, and became insensible at some distance both upwards and downwards." (*Med. Obs. and Inq. V. 1.*)

In the second volume of this work, Dr.

Hunter adds some further remarks on the aneurismal varix.

"In the operation of bleeding, the lancet is plunged into the artery through both sides of the vein, and there will be three wounds made in these vessels, viz. two in the vein, and one in the artery, and these will be nearly opposite to one another, and to the wound in the skin. This is what all surgeons know has often happened in bleeding, and the injury done the artery is commonly known by the jerking impetuosity of the stream, whilst it flows from the vein, and by the difficulty of stopping it, when a sufficient quantity is drawn.

"In the next place, we must suppose, that the wound of the skin, and of the adjacent, or upper side of the vein, heal up as usual; but, that the wound of the artery, and of the adjacent, or under side of the vein, remain open, (as the wound of the artery does in the spurious aneurism,) and, by that means, the blood is thrown from the trunk of the artery, directly into the trunk of the vein. Extraordinary as this supposition may appear, in reality it differs from the common spurious aneurism in one circumstance only, viz., the wound remaining open in the side of the vein, as well as in the side of the artery. But this one circumstance will occasion a great deal of difference in the symptoms, in the tendency of the complaint, and in the proper method of treating it: upon which account, the knowledge of such a case will be of importance in surgery.

"It will differ in its symptoms from the common spurious aneurism, principally thus:—

"The vein will be dilated, or become varicose, and it will have a pulsating jarring motion on account of the stream from the artery. It will make a hissing noise, which will be found to correspond with the pulse for the same reason. The blood of the tumour will be altogether, or almost entirely fluid, because kept in constant motion. The artery, I apprehend, will become larger in the arm, and smaller at the wrist, than it was in the natural state; which will be found out by comparing the size, and the pulse, of the artery in both arms, at these different places. The reason of which I shall speak of hereafter; and the effects of ligatures, and of pressure upon the vessels above the elbow and below it, will be what every person may readily conceive, who understands any thing of the nature of arteries and veins in the living body.

"The natural tendency of such a complaint will be very different from that of the spurious aneurism. The one is growing worse every hour, because of the resistance to the arterial blood, and if not remedied by surgery must at last burst. The other, in a short time, comes to a nearly permanent state; and, if not disturbed, produces no mischief, because there is no considerable resistance to the blood, that is forced out of the artery.

"The proper treatment must, therefore,

be very different in these two cases, the spurious aneurism requiring surgical assistance, as much, perhaps, as any disease whatever; whereas, in the other case, I presume it will be best to do nothing.

"If such cases do happen, they will no doubt be found to differ among themselves, in many little circumstances, and particularly in the shape, &c. of the tumefied parts. Thus the dilatation of the veins may be in one only, or in several, and may extend lower, or higher, in one case, than in another, &c. according to the manner of branching, and to the state of the valves in different arms. And the dilatation of the veins may also vary on account of the size of the artery, that is wounded, and of the size of the orifice in the artery and in the vein.

"Another difference in such cases will arise from the different manner, in which the orifice of the artery may be united or continued with the orifice of the vein. In one case, the trunk of the vein may keep close to the trunk of the artery, and the very thin stratum of cellular membrane between them, may, by means of a little inflammation and coagulation of the blood among its filaments, as it were, solder the two orifices of these vessels together, so that there shall be nothing like a canal going from one to the other; and then the whole tumefaction will be more regular, and more evidently a dilatation of the veins only. In other instances the blood, that rushes from the wounded artery, meeting with some difficulty of admission and passage through the vein, may dilate the cellular membrane, between the artery and vein, into a bag, as in a common spurious aneurism, and so make a sort of canal between these two vessels. The trunk of the vein will then be removed to some distance from the trunk of the artery, and the bag will be situated chiefly upon the underside of the vein. The bag may take on an irregular form, from the cellular membrane being more loose and yielding, at one place, than at another, and from being unequally bound down by the fascia of the biceps muscle. And if the bag be very large, especially, if it be of an irregular figure, no doubt, coagulations of blood may be formed, as in the common spurious aneurism."

As Scarpa correctly observes, a concurrence of two circumstances is requisite for the production of an aneurismal varix: 1. the incision in the vein, and that in the artery, must be exactly in the same direction: 2. the solution of continuity in the integuments and upper side of the vein must heal, while the wound in the deeper side of that vessel, and the puncture in the upper surface of the artery, remain open, and communicate so readily, that the arterial blood finds greater facility in entering from the artery into the vein, than in being effused from the artery into the surrounding cellular substance.

If one of these two circumstances be wanting, either because the wounding instrument has entered the artery a little obliquely

from the vein, or because the vein has not been sufficiently near to the artery, on account of the cellular substance between them, the arterial blood most frequently does not produce the aneurismal varix; or, if it does, the disease is always complicated with effusion of arterial blood into the cellular substance, or with an aneurism, and aneurismal varix at the same time. In this case, the small aneurismal sac serves as a short canal of communication between the artery and the vein, (*Med. Facts and Obs. Vol. 4, p. 115.*) two distinct diseases in fact being formed from the same cause, and placed one over the other, viz., an aneurism, and an aneurismal varix. (*Scarpa, p. 421, Ed. 2.*) The following marks of distinction, between aneurism and aneurismal varix, are pointed out by the same author: the aneurismal varix forms always a circumscribed tumour; aneurism does not always do so. The cellular substance, which constitutes the sac of the aneurism, does not always resist so strongly the impetus of the arterial blood, as the coats of the vein do. Not unfrequently, therefore, aneurism, from being *circumscribed* at first, becomes *diffused*; extends along the course of the wounded artery; compresses strongly the surrounding parts; occasions acute pain and inflammation; and the parts are threatened with gangrene. On the contrary, the aneurismal varix is always *circumscribed*, increases very slowly, does not produce much pain, and, as it augments, it always extends more or less above and below the place, where venesection has been done; and this extension is in proportion to the greater or less force, with which the arterial blood is thrown from the artery into the vein, and the greater or less resistance made by the valves, situated in the vein below the puncture; and according to the greater or less number of veins, communicating with the aneurismal varix. The seat of the disease is generally the basilic vein, which appears dilated in an unusual manner, forming an oblong tumour, of the size of a walnut, if the disease is recent. In the centre of the swelling is the cicatrix left by the lancet. The vein is less dilated, the further it is from this scar, and, in general, at the distance of two inches and a half above and below this point, the vessel resumes its natural size. The small tumour, as has been explained, pulsates like an artery, with a tremulous motion and hissing noise, which is sometimes so great, that the patient cannot sleep, if he is lying with his head low, and resting on the injured arm. The trunk of the brachial artery, from the axilla down to the place where it has been wounded with the lancet, vibrates with extraordinary force. There is no change of colour, nor inflammation of the skin; and the pain is inconsiderable. The swelling is compressible and yielding; but, it returns as soon as the pressure is removed from it. When the arm is kept for some time raised up towards the head, the tumour diminishes, and the same thing happens, when pressure is made on the communication be-

tween the artery and vein, or when a tight tourniquet is applied near the axilla. If the disease be complicated with aneurism, a second pulsating tumour will be found lying under the aneurismal varix. (Scarpa, p. 424, Ed. 2.)

After relating two cases, illustrative of the nature of aneurismal varix, Dr. W. Hunter proceeds to inquire; "Why is the pulse at the wrist so much weaker in the diseased arm, than in the other? surely, the reason is obvious and clear. If the blood can easily escape from the trunk of the artery directly into the trunk of the vein, it is natural to think, that it will be driven along the extreme branches with less force, and in less quantity.

"Whence is it, that the artery is enlarged all the way down the arm? I am of opinion, that it is the consequence of the blood passing so readily from the artery into the vein, and is such an extension, as happens to all arteries, in growing bodies, and to the arteries of particular parts, when the parts themselves increase in their bulk, and, at the same time, retain a vascular structure. It is well known, that the arteries of the uterus grow much larger in the time of utero-gestation. I once saw a fleshy tumour upon the top of a man's head, as large nearly as his head; and his temporal and occipital arteries, which fed the tumour, were enlarged in proportion. I have observed the same change in the arteries of enlarged spleens, testes, &c. so that I should suppose it will be found to be universally true in fact, and the reason of it in theory seems evident." (See *Med. Obs. and Inq.* V. 2.)

In thin subjects, the median basilic vein is so close to the brachial artery, the track of which it crosses at a very acute angle, that it is almost impossible to open it at this point, without risk of wounding the artery at the same time. The bend of the arm, indeed, is the very situation in which this disease is usually noticed. It is easy to conceive, however, that a venous aneurism may happen wherever an artery of a certain diameter lies immediately under a large vein. Thus, Baron Larrey informs us, that his uncle, surgeon to the hospital at Toulouse, saw a case of aneurismal varix, which had been occasioned by a wound of the popliteal vein and artery, and that a history of the disease accompanied with the pathological preparation, was sent to the former royal academy of surgery at Paris. "The varicose swelling, which was as large as two fists, occupied the whole of the ham in a middle-aged man, who some years previously had been wounded with a sword in that part of the limb. At a consultation, amputation was deemed necessary, and was performed with success. At the bottom of the varicose pouch, the communication between the popliteal vein and artery was observed. The sac itself was evidently composed of the vein, the parts of which, adjacent to the varicose swelling, were dilated, especially the lower continua-

tion of the vessel. The popliteal nerve was rendered flat, like a piece of tape, and adherent to the outside of the cyst. (See *Mem. de Chir. Mil.* T. 4, p. 340. *Boyer, Traité des Maladies Chirurgicales, &c.* T. 2, p. 177.) Two cases are likewise recorded by Mr. Hodgson. In one the disease was caused in the thigh, about four inches below Poupart's ligament, by the point of a heated iron rod, which had passed through the femoral artery and vein. In the other example, the aneurismal varix was situated in the ham, and was the consequence of a wound in that part with a pistol ball. (*Treatise on the Disease of Arteries*, p. 498.) Larrey records one example of aneurismal varix situated under the clavicle.

P. Cadrioux was wounded with a sabre in a duel, on the 20th of November, 1811: part of the attachment of the sterno-mastoid muscle was divided, the anterior scalenus, the subclavian artery and vein at a very deep point, and probably also a portion of the brachial plexus. A most violent hemorrhage took place, followed by syncope. Pressure was applied to the wound, and the patient conveyed to the hospital at Gros-Caillou. The external wound, which was small, did not bleed at all the following morning; but the clavicle was quite concealed by a large tumour, which throbbed with the arteries, particularly at its lower part. A peculiar noise, like that of the passage of a fluid through tortuous metallic tubes, could also be felt more deeply, in the direction of the axillary vein. The arm was quite cold, insensible, motionless, and without any pulse, even in the axillary artery itself. On the 22d, the tumour was not larger, but its throbbings were stronger; the jugular vein on the same side was considerably dilated; and the pulsation of the carotid, and of the arteries of the opposite arm, had augmented. A vein in the right arm was opened, and compresses dipped in camphorated vinegar, muriate of ammonia, and ice, applied to the swelling. It would be superfluous here to detail the diet, bleedings, and other parts of the treatment. On the 8th day, the outer wound was quite healed. On the 10th, the veins of the limb were observed to be swelled, and sensibility and warmth were returning in it; though no pulse could yet be felt. The tumour was much smaller, and restricted to a circumscribed place behind the great pectoral muscle; but, the hissing sound was still plainer. By degrees, the muscles of the arm and fore-arm regained their power of motion. The hand, however, continued useless, and affected with pricking pains. On the 20th day, the tumour was quite gone, but the hissing sound was unaltered, and the throbbings were still evident in the veins of the neck and arm. The arm was not at all emaciated. On the 55th day, a pulse at the wrist could be slightly felt; the hissing sound had become less distinct; the veins were less turgid; and their throbbing diminished.

A second instance of aneurismal varix.

or rather perhaps of a varix, of all the veins of the arm, caused by a sword wound of the axilla, is also recorded by Larrey. He mentions, however, that a pulsation was observable in the most prominent of the enlarged vessels. (See *Mem. de Chir. Mil.* T. 4, p. 341, &c.)

Dr. Dorsey, of Philadelphia, has published a case of aneurismal varix, which is in several respects interesting. A patient was wounded in the leg with buck-shot; and, after the cure of the injury, an aneurismal varix was noticed just below the knee; and, in a little time, the superficial veins of the limb became dilated, and the hissing noise, characterizing this species of aneurism, could be plainly distinguished. The patient was seen by Dr. Dorsey, twelve years after the accident; the veins were then considerably distended from the toes up to the groin, all about which latter part pain was constantly experienced, and some ulcers situated on the foot and ankle could not be healed by any of the remedies, which were tried. The patient was under the care of Dr. Physick and Wistar. The enormous distention of the vessels of the leg, and the uncertainty of finding out the communication between the artery and vein, led these gentlemen to tie the first of these vessels in the middle of the thigh. Gangrene soon ensued, and in this state, the patient was further weakened by an unexpected hemorrhage from one of the distended veins; and though the vessel was secured with a ligature, the bleeding recurred, the patient became more and more enfeebled, and at length expired. When the limb was examined after death, the whole of the trunk of the femoral artery was found preternaturally dilated; while all the veins of the limb were considerably distended; a bougie could readily be passed from the popliteal into the posterior tibial artery, which participated in the dilatation, and from this last artery, the instrument could be passed into the vein, through a cyst, situated on the inside of the leg below the knee. (See *Dorsey's Elements of Surgery*, Vol. 2, p. 210, Philadelphia, 1813.)

Professor Scarpa, Dr. Hunter, Mr. B. Bell, Pott, and Garneri, mention cases of the aneurismal varix, which remained stationary for fourteen, twenty, and thirty-five years. Several cases are related by Brambilla, Guattani, and Monteggia, of a cure having obtained by means of compression. But, as this method of cure, if it does not succeed, exposes the patient to the danger of a complication of the disease with an aneurism, it ought not to be employed, except in recent cases, where the tumour is small, and in slender patients, at an early period of life, and where both of the vessels can be compressed accurately against the bone.

Two cases are recorded, in which it was necessary to operate in consequence of the disease being joined with aneurism of the artery, and even bursting. The sacs were opened, and a ligature applied both

above and below the aperture in the artery. (See *Medical Facts and Obs.* Vol. 4, p. 111, and *Medical Museum*, Vol. 1, p. 65.)

In the winter of 1819, I heard a case read to the Medical and Chirurgical Society, of London, from Mr. Atkinson, of York, who had found it necessary to take up the brachial artery, on account of the large and increasing size of an aneurismal varix: mortification of the limb ensued. When the aneurism, joined with an aneurismal varix, is circumscribed, but the circumstances such as to require the brachial artery to be tied, this vessel should be exposed, and tied above the swelling with a single ligature. It is only when the aneurism is diffused, that opening the swelling, and applying a ligature both above and below the aperture in the artery, are thought necessary. (See *Scarpa on Aneurism*, p. 433, Ed. 2.)

ANEURISM FROM ANASTOMOSIS.

This is the term which the late Mr. John Bell, of Edinburgh, applied to a species of aneurism, which resembles such bloody tumours, (*navi materni*) as appear in newborn children, grow to a large size, and ultimately bursting, emit a considerable quantity of blood.

Clear descriptions of this disease may be traced in writers, though before the publication of Mr. John Bell's *Principles of Surgery*, it was not classed with aneurisms. Thus, Desault has recorded a case of this affection, for the express purpose of proving, that pulsation is an uncertain sign of the existence of an aneurism. (See *Parisian Chirurgical Journal*, Vol. 2, p. 73.)

The aneurism from anastomosis often affects adults, increasing from an appearance like that of a mere speck, or pimple, to a formidable disease, and being composed of a mutual enlargement of the smaller arteries and veins. The disease originates from some accidental cause; is marked by a perpetual throbbing; grows slowly, but uncontrollably; and is rather irritated, than checked by compression. The throbbing is at first indistinct, but when the tumour is perfectly formed, the pulsation is very manifest. Every exertion makes the throbbing more evident. The occasional turgid states of the tumour produce sacs of blood in the cellular substance, or dilated veins, and these sacs form little tender, livid, very thin, points, which burst, from time to time, and then like other aneurisms, this one bleeds so profusely, as to induce extreme weakness.

The tumour is a congeries of active vessels, and the cellular substance, through which these vessels are expanded, resembles, as Mr. John Bell describes, the gills of a turkey cock, or the substance of the placenta, spleen, or womb. The irritated and incessant action of the arteries fills the cells with blood, and from these cells, it is reabsorbed by the veins. The size of the swelling is increased by exercise, drinking, emotions of the mind, and by all causes, which accelerate the circulation.

In this peculiar disease, Dupuytren regards the arteries as being in an aneurismal state, but besides this circumstance, he says, their extreme ramifications intermix in a thousand different ways, intercepting spaces, and representing cavities, like those which are found in the corpora cavernosa; and he imputes the disease to increased activity of the capillary circulation. (*Fr. Transl. of Mr. Hodgson's Work, T. 2, p. 300.*)

In the female subject, the hemorrhage from the aneurism by anastomosis sometimes is a substitute for menstruation, as the following example illustrates: And Vachot, of St. Maury, in Bresse, was born with a tumour on her chin, of the size and shape of a small strawberry, without pain, heat, or discoloration of the skin. As it produced no uneasiness, nor inconvenience whatever, it excited little attention, particularly as it did not seem to increase with the growth of the child. For the first fifteen years, there was but little alteration; but about the menstrual period, it increased suddenly to double the size, and became more elongated in its form. A quantity of red blood was observed to ooze from its extremity. This flux became, in some measure, periodical, and sometimes was sufficiently abundant to produce an alarming degree of weakness. Each period of its return was preceded by a violent pain in the head and numbness.

Before and after the appearance of these symptoms, there was no alteration in the size of the tumour; the only difference was a small enlargement of the cutaneous veins, with an increase of heat in the part, occasioning some degree of tenderness.

The menses at length took place, but, in small quantity, and, at irregular periods, without influencing the blood discharged from the tumour, or the frequency of the evacuation.

The breasts were not enlarged till a late period, nor did the approach of puberty seem to have its accustomed influence on those glands, &c. (*See Parisian Chirurgical Journal, Vol. 2, p. 73, 74.*)

As far as my observations extend, the true aneurism by anastomosis, is a disease with which a surgeon should never tamper; and, if it be decided to try any treatment at all, the only prudent plan is either a complete removal of the disease with a knife, or tying the chief arteries, which supply the swelling with blood. The first is the surest mode of relief, and should be preferred, when not forbidden by the magnitude, or situation of the tumour.

In performing such an operation, as Mr. Wardrop remarks, the surgeon should avoid cutting into the substance of the tumour; for if this be done, the hemorrhage is violent; whereas, by making the incisions beyond the diseased structure, the flow of blood is much more moderate, (*Med. Chir. Trans. Vol. 9, p. 212.*) In a few nævi pressure may be safely tried; but, all attempts to get rid of a true aneurism by anastomosis,

by caustic, I should think by no means advisable.

"This aneurism, as Mr. John Bell observes, is a mere congeries of active vessels, which will not be cured by opening it; all attempts to obliterate the disease with caustics, after a simple incision, have proved unsuccessful, nor does the interception of particular vessels, which lead to it, affect the tumour; the whole group of vessels must be extirpated. In varicose veins, or in aneurisms of individual arteries, or in extravasations of blood, such as that produced under the scalp from blows upon the temporal artery, or in those aneurisms, produced in school-boys by pulling the hair, and, also, in those bloody effusions from blows on the head, which have a distinct pulsation, the process of cutting up the varix, aneurism, or extravasation, enables you to obliterate the vessel and perform an easy cure. But, in this enlargement of innumerable small vessels, in this aneurism by anastomosis, the rule is, not to cut into, but to cut it out.' These purple and ill-looking tumours, because they are large, beating, painful, covered with scabs, and bleeding, like a cancer in the last stage of ulceration, have been but too often pronounced cancers! incurable bleeding cancers! and the remarks, which I have made, while they tend, in some measure, to explain the nature and consequences of the disease, will remind you of various unhappy cases, where either partial incisions only had been practised, or the patient left entirely to his fate. (*Principles of Surgery, Vol. I.*)

The following case, recorded by Mr. Wardrop, affords a valuable illustration of the nature and structure of one form of this disease. A child was born with a very large subcutaneous nævus on the back part of the neck. It was of the form and size of half an ordinary orange. The tumour had been daily increasing, and, when Mr. Wardrop saw it, ten days after birth, the skin had given way, and a profuse hemorrhage had taken place. The swelling was very soft and compressible: squeezed in the hand, it yielded like a sponge, and was reducible to one third of its original size. On removing the pressure, however, the tumour rapidly filled again, and the skin resumed its purple colour. "Conceiving the immediate extirpation of the tumour the only chance of saving the infant, (says Mr. Wardrop,) I removed it as expeditiously as possible, and made the incision of the integuments, beyond the boundary of the tumour; aware of the danger of hemorrhage where such tumours are cut into. So profuse, however, was the bleeding, that, though the whole mass was easily removed by a few incisions, the child expired.

"The tumour having been injected, by throwing coloured size into a few of the larger vessels, its intimate structure could be accurately examined. Several of the vessels, which, from the thinness of their coats, appeared to be veins, were of a large

size, and there was one sufficiently big to admit a full-sized bougie." This vessel was fully as large as the carotid artery of an infant. The boundaries of the tumour appeared distinct, some healthy cellular membrane surrounding it, which was traversed by the blood vessels. On tracing these vessels to the diseased mass, they penetrated into a spongy structure, composed of numerous cells and canals, of a variety of forms and sizes, all of which were filled with the injection, and communicated directly with the ramifications of the vessels. These cells and canals had a smooth and polished surface, and, in some parts, resembled very much the cavities of the heart, fibres crossing them in various directions, like the columnar tendineæ. The opening in the skin, through which the blood had escaped during life, communicated directly with one of the large cells, into which the largest vessel also passed. (*Wardrop in Med. Chir. Trans. Vol. 9. p. 203.*)

In the section on carotid aneurisms, I have mentioned the cases, in which Mr. Travers and Mr. Dalrymple cured aneurisms by anastomosis in the orbit, by tying the common carotid artery. These facts prove, that aneurism by anastomosis, like many other diseases, sometimes admits of being cured, on the principle of cutting off, or lessening the supply of blood to the part affected.

However, surgeons must not be too confident of being always able to cure the disease, by tying the main artery, from which the swelling receives its supply of blood; and the great cause of failure is the impossibility of preventing in some situations the transmission of a considerable quantity of blood into the tumour, through the anastomosing vessels. In fact, every vessel, artery, and vein, around the disease, seems to be enlarged and turgid; and the inosculation is so infinite, that no point of the circumference of the swelling can be imagined, which is free from them. Etienne Dumand was born with two small red marks on the antihelix of the right ear. Until the age of twelve years, the chief inconveniences were a sensation of itching about the part, occasional bleeding from it, and the greater size of this, than of the other ear. The disease now extended itself over the whole antihelix, and to the helix and concha; and the upper part of the ear became twice as large as natural. Slight alternate dilatations and contractions began to be perceptible in the tumour, which was of a violent colour, and covered by very thin skin. Soon afterwards, any accidental motion of the patient's hat, was sufficient to excite copious hemorrhages, which were difficult to suppress, and at the same time, that they produced great weakness, caused a temporary diminution of the tumour and its pulsations. At length, the disease began to raise up the scalp for the distance of an inch around the meatus auditorius, and the hemorrhages to be more frequent and alarming. Pressure was next applied to the temporal, auricular and oc-

cipital arteries; but, as the patient could not endure it, the two first of these vessels were tied, the only benefit from which was a slight diminution in the pulsation and bulk of the swelling. This treatment did not prevent the return of hemorrhage, and, therefore, forty-three days after the first operation, a ligature was applied to the occipital artery, which proceeding was equally ineffectual. As the disease continued to make progress, the patient entered the Hotel-Dieu, where, on the 8th of April, 1818, Dupuytren tried what effect tying the trunk of the carotid artery would produce on the swelling. As soon as the ligature was applied, the throbbings ceased, and the tumour underwent a quick and considerable diminution. On the 17th day, slight expansions and contractions of the diseased part of the ear were again perceptible, though the swelling had diminished one third. An attempt was now made to compress the tumour by covering it with plaster of Paris: a plan which was somewhat painful, though it lessened the size of the disease. After being sixty-three days in the hospital, the patient was discharged, at which period, the tumour was diminished one third; the throbbings had returned; but, no unpleasant noises continued to affect the ear. (*See Breschet's Tr. of Mr. Hodgson's Work, T. 2, p. 296.*)

An infant, six weeks old, was brought to Mr. Wardrop, on account of an aneurism by anastomosis, (a subcutaneous nœvus) of a very unusual size, situated on the left cheek. The base of the tumour extended from the temple to beyond the angle of the jaw, completely enveloping the cartilage of the ear. At its upper part, there was an ulcer, about three inches in diameter, presenting a sloughing appearance. The tumour was soft and doughy; its size could be much diminished by pressure; there was a throbbing in it; and a strong pulsation in the adjacent vessels. The disease was daily increasing, and several profuse hemorrhages had taken place from the ulcerated part. Mr. Wardrop, knowing from the case, to which I have already adverted, the danger of attempting to extirpate so large a tumour of this nature, was led to try what benefit might be obtained by tying the carotid artery. A few hours after this operation, the tumour became soft and pliable, its purple colour disappeared, and the tortuous veins collapsed. On the second day, the skin had resumed its natural pale colour, and the ulceration continued to extend. On the third, the tumour still diminished. On the fourth, the swelling had considerably increased again; the integuments covering it had become livid; and the veins turgid. The inosculating branches of the temporal and occipital arteries had become greatly enlarged. A small quantity of blood had oozed from the ulcer. After remaining without much alteration, the tumour on the seventh day had again evidently diminished. On the ninth the ulceration was extending itself slowly, and the tumour was lessened fully one half. On the twelfth the child's health was mete-

rially improving. The auricular portion of the swelling had now so much diminished, that the cartilage of the ear had fallen into its natural situation. After a poultice had been applied for two days, the central portion of the swelling, which appeared like a mass of hardened blood, was softened, and Mr. Wardrop removed considerable portions of it. On the thirteenth, the child became very ill, and died the following day, exhausted by the irritation of an ulcer, which had involved the whole surface of an enormous tumour. Mr. Wardrop thinks the advantages likely to occur from the plan of tying the main arteries, supplying tumours of this nature with blood, are the diminution of the size of the disease; the lessening of the danger of hemorrhage, if the ulcerative process has commenced; and the rendering it practicable to remove the swelling with the knife, though the operation may previously have been dangerous, or impracticable. (See *Med. Chir. Trans.* Vol. 9. p. 206-214, &c.) Instead of endeavouring to promote ulceration in any of these cases, my own sentiments would incline me to leave the business of removing the diseased mass quietly to the absorbents, or, at most, I would only assist them with pressure, or by covering the tumour with plaster of Paris.

The next case of aneurism by anastomosis, which I shall briefly notice, was one which was under the care of my friend Mr. Lawrence, and situated on the right finger of the right hand, in a young woman about twenty years of age. The disease was attended with painful sensations extending to various parts of the limb and the breast, and the arm was disqualified for any kind of exertion. In January 1815, Mr. Hodgson had taken up the radial and ulnar arteries, and the consequences of the operation were an entire cessation of beating, collapse of the swelling, and relief from pain; but, these symptoms all recurred in a few days. Finding compression unavailing, and the sufferings of the patient increasing, Mr. Lawrence proposed amputation of the finger at the metacarpal joint: but, as this suggestion was not approved of, he recommended the patient to try the effects of a division of all the soft parts, by a circular incision close to the palm, so as to cut off the supply of blood. This operation Mr. Lawrence performed in the presence of Mr. George Young and myself, in as complete a manner as can possibly be conceived. All the soft parts, excepting the flexor tendons, with their theca and the extensor-tendon, were divided. The digital artery, which had pulsated so evidently in the palm of the hand, was fully equal in size to the radial, or ulnar of an adult, and was the principal nutrient vessel of the disease. After tying this and the opposite one, we were surprised at finding so strong a jet of arterial blood from the other orifices of these two vessels, as to render ligatures necessary. I can here only add, that the whole finger beyond the cut swelled very considerably:

the incision healed slowly; the swelling subsided, but did not entirely disappear; the integuments recovered their natural colour; the pulsation and pain were removed; and the patient so far recovered the use of her arm, that she could work at her needle for an hour together, and use the arm for most purposes. (See *Wardrop's Obs. on one species of Nævus in Med. Chir. Trans.* Vol. 9, p. 216.)

This appears to me to be a valuable work, on account of the great many facts and interesting cases, to which it refers. I can here only mention a few things, which are noticed in it. Walther found five small calculi in the veins of the bladder. Stenzel met with a fatty tumour, as large as a hen's egg, in the curvature of the aorta, and several smaller swellings of the same kind in the descending part

of that vessel. The patient's symptoms had been great anxiety, difficulty of breathing, and palpitations. Baillie's case of obliteration of the vena cava, and consequent dilatation of the vena azygos, is noticed. Baader describes an aneurism of the pulmonary artery, accompanied with a dilatation of the aorta. Bleuland mentions a varix of the vena cava, which caused a difficulty of swallowing by its pressure on the œsophagus. Sandifort saw an aneurism of the coronary vessels of the heart. The author records the case of a woman, who died in Jacob's Hospital at Leipzig, of a scirrhus hardness of the brain. She had been for some time previously afflicted with amaurosis. After the fat had been separated from the eye-ball, several oblong roundish prominences, equal in size to a small lentil, appeared through the sclerótica. They arose from the subjacent veins. When the optic nerve was cut through, the central artery was found dilated to the size of a piece of straw. Several vessels of the choroides were varicose, and the retina converted into a beautiful scarlet net work. Malacarne saw aneurisms of the dura mater, as large as a pigeon's egg, arising from several branches of the spinous artery. Sir Gilbert Blane noticed aneurisms of both the internal carotids at the sides of the sella turcica. Varices of the pia mater and plexus chorioides are also recorded. All the rest of this work merits perusal.

ANTHRAX, (αἰθρᾶξ, a burning coal.) See Carbuncle.

ANTIMONIAL POWDER; PULVIS ANTIMONIALIS. In all cases, where it is desirable to promote the secretions in general, and those of the kidneys, skin, and alimentary canal, in particular, it is proper to have recourse to antimonial medicines. In inflammation of the brain and its membranes, and, in every instance, in which there exists an inflammation of a viscus of high importance in the system, antimony should be exhibited, and, in general, the antimonial powder is as eligible a prescription as any. For an adult, from two to five grains may be ordered, and the dose, if requisite, may be repeated, three or four times a day. In order to increase its action on the bowels, it is frequently conjoined with calomel in the form of pills.

ANTIMONIUM MURIATUM. This has often been named, *butter of antimony*, and is employed in surgery as a caustic.

ANTIMONIUM TARTARIZATUM, (*Emetic Tartar*.) This medicine is well known as the most common emetic. For this purpose, it may be given in either of the following ways, as the indications of the case may demand. R. Antimonii Tart. gr. ij. Aq. distil. ℥iv. Misce et cola. Dosis ℥ij. pro emetico; vel ℥ss quadrante quoque horæ, donec supervenerit vomitus. If tartarised antimony be exhibited merely to excite a diaphoresis, half an ounce, or one table spoonful, of the above mixture is to be given once every six hours.

ANTRUM, *Diseases of*. This cavity is

liable to a variety of diseases. Sometimes its membranous lining inflames, and secretes an extraordinary quantity of mucus, or pus; at other times, in consequence of inflammation, or other causes, it is the seat of various excrescences, polypi, and fungi. Even the bony parietes of the antrum are occasionally affected with exostosis, or caries. Sometimes it contains extraneous bodies; and, it is even asserted, that insects may be generated there, and cause, for many years, very afflicting pains.

COLLECTIONS OF MUCUS AND PUS.

Inflammation of the membranous lining of the antrum sometimes produces an extraordinary secretion of mucus within that cavity, and the collected fluid being confined, the bony parietes of the cavity become expanded in a surprising degree. This disease, says Boyer, is sometimes ascribed to a blow on the cheek, to caries of the teeth, or the projection of one of their fangs into the antrum. But, in general, the case takes place unpreceded by any of these causes, and without there being the least ground for suspecting what has given rise to the disorder. It is remarked, however, that collections of mucus within the antrum are most frequent in young subjects: of three patients, seen by Boyer, the eldest was not more than twenty. (*Traité des Mal. Chir. T. 6, p. 139.*) Whether the obliteration of the duct leading to the nose be a cause or only an effect of the disease, is, as Mr. Hunter observes, not easily determined; but, from some of the symptoms there is great reason to suppose it an attendant. "If it be a cause, we may suppose, that the natural mucus of these cavities, accumulating, irritates, and produces inflammation for its own exit; in the same manner, as an obstruction to the passage of the tears through the ductus ad nasum produces an abscess of the lachrymal sac." (*See Hunter's Natural Hist. of the Teeth, p. 174, Ed. 3.*) The most interesting example of the effects of the lodgment of mucus in the antrum is that recorded by Dubois: a boy, between seven and eight years of age, was observed to have at the base of the ascending process of the upper jaw bone, on the left side, a small, very hard tumour, of the size of a nut. As it gave no pain, and did not appear to increase, his parents did not give themselves any concern about it. When he was about sixteen, however, the swelling began to increase, and to be somewhat painful. Before he was eighteen, its augmentation was so considerable, that the floor of the orbit was raised up by it: the eye thrust upwards: the palpebræ very much closed; the arch of the palate pushed down in the form of a tumour; and the nostril almost effaced. Below the orbit, the cheek made a considerable prominence; while the nose was thrown towards the opposite side of the face, and the skin at the upper part of the tumour, below the lower eyelid, was of a purple red colour, and threatening to burst.

The upper lip was drawn upwards, and behind it, all the gums on the left side were observed to project much further, than those on the opposite side of the face, and at this point alone the thinness of the bony parietes of the antrum was perceptible. The patient spoke, and breathed with great difficulty; he slept uneasily, and his mastication was painful. The case was at first supposed by Dubois, Sabatier, Pelletan, and Boyer, to be a fungus of the antrum, and an operation was considered adviseable. In proceeding to this measure, the first thing, which attracted the notice of Dubois, was a sort of fluctuation in the situation of the gum, behind the upper lip; a circumstance which led him to give up the idea of the case being a fungus, though he expected that, on making an opening merely a small quantity of ichorous matter would escape, affording no kind of information. In this place, however, he determined to make an incision, along the alveolar process, whereby a large quantity of a glutinous substance, like lymph, or what is found in cases of ranula, was discharged. A probe was now introduced, with which Dubois could feel a cavity equal in extent to the forepart of the tumour, and in moving the instrument about, with the view of learning, whether any fungus was present, it struck against a hard substance, which felt like one of the incisor teeth, near the opening that had been made. Five days after this first operation, Dubois extracted two incisors and one grinder, and then removed the corresponding part of the alveolar process. As the hemorrhage was profuse, the wound was now filled with dressings, which in two days came away, and enabled Dubois to see with facility all the interior of the cavity. At its upper part, he perceived a white speck, which he supposed was pus, but on touching it with a probe, it turned out to be a tooth, which was then extracted, in doing which some force was requisite. The rest of the treatment merely consisted in injecting lotions into the cavity, and applying common dressings. In about six weeks, all the hollow disappeared; but the swelling of the cheek, and palate, and the displacement of the nose, still continued. In the course of another year and a half, however, every vestige of deformity was entirely removed. (*Dubois, Bulletin de la Faculté de Med. No. 8.*)

With respect to the treatment of collections of mucus in the antrum, by means of injections, thrown into that cavity through the natural opening in it, while the head is inclined to the opposite side, for the purpose of facilitating the escape of the collected fluid, as proposed by Jourdain in 1765. (*Mem. de l'Acad. de Chir. T. 4, p. 357.*) Deschamps and Boyer are of opinion, that the method is objectionable, not only because it is difficult to find the aperture, which, ere the disease forms an outward swelling, is probably obliterated, but also because the thickness of the mucus collected would make it impossible for the surgeon

to wash it out with injections. Hence, Boyer approves of the practice of opening the tumour in an eligible place, and to an extent sufficient for the discharge of the mucus. (*Deschamps, Traité des Maladies des Fosses Navales, et de leurs Sinus, p. 231, 8vo. Par. 1804; Boyer Traité des Mal. Chir. T. 6, p. 145, 8vo. Paris, 1818.*) Indeed, that Jourdain's proposal was attended with too much difficulty for common practice, was the sentence long ago pronounced upon it by a committee of the Royal Academy of Surgeons in France, nominated for the express purpose of inquiring into the merits of the suggestion. The method of making an opening into the antrum, will be considered in the sequel of this article. As a general rule, I may here remark, that except where there is a tumour, or fungus to be extirpated, or a foreign body to be extracted from the antrum, it is quite unnecessary to remove any part of the alveolar process, or cut away any of the bony parietes of the antrum, the drawing of one of the teeth situated below this cavity, and making a perforation in this situation, being the only kind of opening required. This aperture may be preserved as long as necessary by the introduction of a piece of elastic gum catheter, which is to be fastened to the adjacent teeth, and through which the secretion in the antrum may escape, or lotions be injected. (See *Deschamps Traité des Mal. des Fosses Navales, &c. p. 234.*) However, as Hunter remarks, if the forepart of the bone has been destroyed, even though the case be merely a collection of mucus, or pus, an opening may be made on the inside of the lip; but, on account of the difficulty of maintaining such an aperture, he still inclines to the practice of drawing one of the teeth. (*Natural Hist. of the Teeth, p. 176, ed. 3.*)

Of all the above cases, abscesses are by far the most common. Violent blows on the cheek, inflammatory affections of the adjacent parts, and especially, of the pituitary membrane lining the nostrils, exposure to cold and damp, and, above all things, bad teeth, may bring on inflammation and supuration within the hollow of the upper jaw bone. The first symptom is a sensation of pain, at first imagined to be a toothach, particularly if there should be a carious tooth at this part of the jaw. Such pain, however, extends more into the nose, than that usually does, which arises from a decayed tooth: it also affects, more or less, the eye, the orbit, and the situation of the frontal sinuses. (See *Hunter on the Teeth, p. 175, ed. 3.*) But, even these symptoms are insufficient to characterize the disease, the nature of which is not unequivocally evinced, till a much later period. The complaint is, in general, of much longer duration, than one entirely dependent on a caries of a tooth, and its violence increases more and more, until, at last, a hard tumour is perceptible below the cheek bone. By degrees the swelling extends over the whole cheek: but it afterwards rises to a point,

and forms a very circumscribed hardness, which may be felt above the back grinders. This symptom is accompanied with redness, and sometimes with inflammation and supuration of the external parts. It is not uncommon, also, for the outward abscess to communicate with that within the antrum.

The circumscribed elevation of the tumour, however, does not occur in all cases. There are instances in which the matter makes its way towards the palate, causing the bones of this part to swell, and, at length, rendering them carious, unless timely assistance be given. There are other cases, in which the matter escapes between the fangs and sockets of the teeth. Lastly, there are certain examples, in which the matter formed in the antrum, makes its exit at the nostril of the same side, when the patient is lying with his head on the opposite one, in a low position. If this mode of evacuation should be frequently repeated, it prevents the tumour, both from pointing externally, and bursting, as it would do if the purulent matter could find no other vent. But this evacuation of pus from the nostril is not very common; for, according to Mr. Hunter, the opening between the antrum and cavity of the nose, is generally stopped up. This celebrated anatomist even seems inclined to think, as I have already observed, that the disease may sometimes be occasioned by the impervious state of this opening, in consequence of which obstruction, the natural mucus of the antrum may collect there in such quantity, as to irritate and inflame the membrane, with which it is in contact, just like as an obstruction in the ductus nasalis hinders the passage of the tears into the nose, and causes an abscess in the lachrymal sac. This is a point, however, on which even Mr. Hunter would not venture to speak with certainty; for it is by no means impossible that the impervious state of the opening is rather an effect than the cause of the disease, since inflammation in the antrum is often manifestly produced by causes of a different kind, and since the opening in question is not invariably closed.

Abscesses in the antrum require a free exit for their contents, and, if the surgeon neglects to procure such opening, the bones become more and more distended and pushed out, and, finally, carious. When this happens, the pus makes its appearance, either towards the orbit, the alveoli, the palate, or, as is mostly the case, towards the cheek. The matter having thus made a way for its escape, the disease now becomes fistulous.

In all cases, whether the pus be simply confined in the antrum, or whether the case be conjoined with a carious affection of the bones, the principal indication is to discharge the matter.

The ancients seem to have known very little about the treatment of diseases of the antrum. Drake, an English anatomist, is reputed to be the first proposer of a plan

for curing abscesses of this cavity, (*Anthropologia Nova*. London, 1727.) Meibomius, however, a long while before him, had proposed, with the same intention, the extraction of one or more of the teeth, in order that the matter might find an opening for its escape, through the sockets. This plan may be employed with success. The pus frequently has a tendency to make its way outward towards the teeth; it often affects their fangs; and, after their extraction, the whole of the abscess is seen to escape through the sockets. But this very simple plan will not suffice for all cases, as there are numerous instances, in which there is no communication between the alveoli and the antrum.

Drake, and, perhaps, before him, Cowper, took notice of the insufficiency of Meibomius's method, and, hence, they proposed making a perforation through the socket into the antrum with an awl, for the purpose of letting out the matter, and injecting into the cavity such fluids as were judged proper.

The extraction of one or more teeth, and the perforation of the alveoli, being essential steps in treating diseases of the antrum, we must consider what tooth ought to be taken out in preference to others.

A caries, or even a mere continual aching, of any particular tooth, in general ought to decide the choice. But, if all the teeth should be sound, which is not often the case, writers direct us to tap each of them gently, and to extract the one which gives most pain on this being done. When no information can be thus obtained, other circumstances ought to guide us.

All the grinding teeth, except the first, correspond with the antrum. They even sometimes extend into this cavity, and the fangs are only covered with the pituitary membrane. The bony lamella, which separates the antrum from the alveoli, is very thin, towards the back part of the upper jaw. Hence, when the choice is in our power, it is best to extract the third or fourth grinder, as, in this situation, the alveoli can be more easily perforated. Though, in general, the first grinder and canine tooth do not communicate with the antrum, their fangs approach the side of it, and from their socket an opening may readily be extended into that cavity.

When one or more teeth are carious, they should be removed, because they are both useless and hurtful. The matter frequently makes its escape, as soon as a tooth is extracted, in consequence of the fang having extended into the antrum, or rather in consequence of its bringing away with it a piece of the thin partition between it and the sinus. Perhaps a discharge may follow from the partition itself being carious. If the opening, thus produced, be sufficiently large to allow the matter to escape, the operation is already completed. But, as it can easily be enlarged, it ought always to be so when there is the least suspicion of its being too small. However, when no pus makes its appearance, after a tooth is ex-

tracted, the antrum must be opened by introducing a pointed instrument in the direction of the alveoli. Some use a small trocar, or awl; others a gimblet for this purpose.

The patient should sit on the ground, in a strong light, resting his head on the surgeon's knee, who is to sit behind him. Immediately the instrument has reached the cavity, it is to be withdrawn. Its entrance into the antrum is easily known by the cessation of resistance. After the matter is discharged, surgeons advise the opening to be closed with a wooden stopper, in order to prevent the entrance of extraneous substances.

The stopper is to be taken out, several times a day, to allow the pus to escape. This plan soon disposes the parts affected to discontinue the suppuration, and resume their natural state. Sometimes, however, the pus continues to be discharged, for a long time after the operation, without any change occurring, in regard to its quality or quantity. In such instances, the cure may often be accelerated by employing injections of brandy and water, lime-water, or a solution of the sulphate of zinc.

Some surgeons prefer a silver cannula, or a piece of elastic gum catheter, instead of the stopper, as it can always be left pervious except at meals. The examples recorded, in which the extraction of a tooth, and the perforation of the bottom of the antrum, have been the means of curing abscesses in that cavity, are very numerous. (See *Farmer's Select Cases*, No. 9; *Gooch's Cases*, p. 63, new edition; *Palfyn Anatomie*, &c.)

If no opening were made in the antrum, the matter would make its way, sometimes towards the front of this cavity, which is very thin; sometimes towards the mouth; and fistulous openings, and caries would inevitably follow.

When the bones are diseased, the above plan will not accomplish a cure, until the affected pieces of bone exfoliate. A probe will generally enable us to detect any caries in the antrum. The fetid smell, and ichorous appearance of the discharge, also leave little doubt that the bones are diseased; and, in proportion as the bones free themselves of any dead portions, the discharge has less smell, and its consistence becomes thicker.

When there are loose pieces of dead bone, or other foreign bodies, to be extracted, it is requisite to make a larger opening in the antrum, than can be obtained at its lower part. Instances also occur, where patients have lost all the grinding teeth, and the sockets are quite obliterated, so that a perforation from below cannot be effected. Some practitioners object to sacrificing a sound tooth. In these circumstances, it has been advised to make a perforation in the antrum, above the alveolar processes. Lamorier first proposed this method. It consists in making a transverse incision, below the malar process, and above the root

of the third grinder. Thus the gum and periosteum are divided, and the bone exposed. A perforating instrument is to be conveyed into the middle of this incision, and the opening in the antrum made as large as requisite. (See *Mem. de l'Acad. de Chir.* T. 4, p. 351, and *Gooch's Obs. append. p.* 138.) There are some extensive exfoliations of the antrum, where it is absolutely necessary to expose a great part of the surface of the bone, and to cut away the dead pieces which are wedged, as it were, in the living ones. A small trephine may sometimes be advantageously applied to the malar process of the superior maxillary bone.

Surgeons formerly treated carious affections of the antrum in the most absurd and unscientific way, introducing setons through its cavity, and even having recourse to the actual cautery. The moderns, however, are not much inclined to adopt this sort of practice. It is now known, that the detachment of a dead portion of bone, in other terms, the process of exfoliation, is nearly, if not entirely, the work of nature, in which the surgeon can at most act only a very inferior part. Indeed, he should limit his interference to preventing the lodgment of matter, maintaining strict cleanliness, and removing the dead pieces of bone, as soon as they become loose. But, it is to be understood, that there are occasional examples, in which the dead portions of bone are so tedious of separation, and so wedged in the substance of the surrounding living bone, that an attempt may properly be made to cut them away.

TUMOURS OF THE ANTRUM.

Ruysch, Bordenave, Desault, Abernethy, Weinhold, and others, have recorded cases of polypous, fungous, and cancerous diseases of the antrum, and examples of this cavity being affected with exostosis.

The indolence of any ordinary fleshy tumour in the antrum, while in an incipient state, certainly tends to conceal its existence; but such a disease rarely occurs without being accompanied with some affection of the neighbouring parts; and hence, its presence may generally be ascertained before it has attained such a size as to have altered in a serious degree the natural shape of the antrum. This information may be acquired, by examining whether any of the teeth have become loose, or have spontaneously fallen out; whether the alveolar processes are sound, and whether there are any fungous excrescences making their appearance at the sockets, whether there is any habitual bleeding from one side of the nose; any sarcomatous tumour at the side of the nostril, or towards the great angle of the eye. When the swelling, however, has attained a certain size, the bony parietes of the antrum always protrude, unless the body of the tumour should be situated in the nostril, and only its root in the antrum. This case, however, is very uncommon.

As soon as a tumour is certainly known to exist in the antrum, the front part of this

cavity should be opened, without waiting till the disease makes further progress. In a few instances, indeed, we may avail ourselves of the opening, which is sometimes found in the alveolar process, and enlarge it sufficiently to allow the tumour to be extirpated. If the front of the antrum were freely opened, it would in general be better to cut away the disease in its interior.

A swelling of the parietes of the antrum, in consequence of an abscess, or a sarcomatous tumour in its cavity, may lead us to suppose the case an enlargement of the bones, or an exostosis. The symptoms of the two first affections have been already detailed. One sign of an exostosis, besides the absence of the symptoms characterizing an abscess or a sarcoma, is the thickened parietes of the antrum forming a solid resistance; whereas, in cases of mere expansion, the dimensions of the surface of the bone being increased, while its substance is rendered proportionally thinner, the resistance is not so considerable.

When such an exostosis depends upon a particular constitutional cause, and especially upon one of a venereal nature, it must be attacked by remedies suited to this affection. But when the disease resists internal remedies, and its magnitude is likely to produce an aggravation of the case, a portion of the bone may be removed with a trephine, or a cutting instrument. Such operations, however, require a great deal of delicacy and prudence.

Mr. B. Bell, vol. 4, describes a kind of exostosis of the upper jaw, very different from what I have mentioned, since instead of its being distinguishable from other diseases of the antrum by the greater firmness of the tumour, the substance of the bone gradually acquires such suppleness and elasticity, that it yields to the pressure of the fingers, and immediately resumes its former plumpness when the pressure is discontinued. If the bone be cut, it is found to be as soft as cartilage, and, in an advanced stage of the disease, its consistence is almost gelatinous. The swelling increases gradually, and extends equally over the whole cheek, without becoming prominent at any particular point, or only so in the latter periods of the malady, when the soft parts inflame, and become affected. The complaint is described as totally incurable. Cutting and trephining the tumour, as recommended in other cases of exostosis, only aggravate the patient's unhappy condition.

Mr. Abernethy has related an account of a very singular disease of the antrum. The patient, who was thirty-four years of age, when the account was written, perceived, when about ten years old, a small tumour on his left cheek, which gradually attained the size of a walnut, and then remained for some time stationary. About a year afterwards, the tumour having again enlarged, a caustic was applied to the integuments, so as to expose the bone. The actual cautery was next applied, and an opening thus made into the antrum. After the exfoliation, the

antrum became filled with a fungus, which rose out upon the cheek, and could not be restrained by any applications. Part of the fungus also made its way into the mouth, through the socket of the second tricuspid tooth, the other teeth remaining natural. The disease continued in this state nine years, occasionally bleeding in an alarming way. When the patient was in his twentieth year, the whole fungus sloughed away during a fever, and never returned. After this, the sides of the aperture in the bone began to grow outwards, forming an exostosis, which rapidly attained to a great magnitude. A small exostosis took place in the mouth, but became no larger than a horse-bean. The exostosis of the maxillary bone was of an irregular figure, and projected from the whole circumference of the aperture a great way directly forward. Mr. Abernethy compared its appearance, when he was writing, with that of a large teacup fastened upon the face, the bottom of which may be supposed to communicate with the antrum. The diameter of the cup, formed by the circular edge of the bone, was three inches and a half; the depth two inches and seven-eighths. The general height of the sides of the exostosis, from the basis of the face, was two inches; its walls were not thick, and terminated in a thin circular edge. The integuments, as they approached this edge became thinner, and they extended over the edge into the cavity. The exostosis now reached to the nose in front, and to the masseter muscle behind; above it included the very ridge of the orbit, and below it grew from the edge of the alveolar process. A line that would have separated the diseased from the sound bone would have included the orbit and nose, and indeed one half of the face. Mr. Abernethy saw no means of affording the man relief. (*Trans. of a Society for the Improvement of Med. and Chirurgical Knowledge*, vol. 2.) See also a case related by Harrison. (*New Lond. Med. Journ.* vol. 1. p. 1.)

In a case of fungus, which had distended the antrum, hindered the tears from passing down into the nose, raised the lower part of the orbit, caused a protrusion of the eye, made two of the grinding teeth fall out, and occasioned a carious opening in the front of the antrum, through which opening a piece of the fungus projected, Desault operated as follows: the cheek was first detached from the os maxillare, by dividing the internal membrane of the mouth, at the place where it is reflected over this bone. Thus the outer surface of the bone was denuded of all the soft parts. A sharp perforating instrument was applied to the middle of this surface, and an opening made more forward than the one already existing. The plate of bone, situated between the two apertures, was removed with a little falciform knife, which, being directed from behind forward, made the division without difficulty. The opening thus obtained being insufficient, Desault endeavoured to enlarge

it below, by sacrificing the alveolar process. This he endeavoured to accomplish with the same instrument, but finding the resistance too great, he had recourse to a gouge and mallet. A considerable piece of the alveolar arch was thus detached, without any previous extraction of the corresponding teeth, three of which were removed by the same stroke. In this manner an opening was procured in the external and inferior part of the antrum, large enough to admit a walnut. Through this aperture a considerable part of the tumour was cut away with a knife, curved sideways, and fixed in its handle. A most profuse hemorrhage took place; but, Desault, unalarmed, held a compress in the antrum, for a short time; this being removed, the actual cautery was applied repeatedly to the rest of the fungus. The cavity was dressed with lint, dipped in powdered colophony.

On the eighteenth day, the swelling was evidently diminished, the eye less prominent, and the epiphora less visible. But, at this period, a portion of fungus made its appearance again. This was almost entirely destroyed by applying the actual cautery twice. It appeared again, however, on the twenty-fifth day, and required a third and last recourse to the cautery. From this time, the progress of the cure went on rapidly. Instead of fungous excrescences, healthy granulations were now formed in the bottom of the sinus. The parietes of the antrum, gradually approaching each other, the large opening made in the operation was obliterated, and reduced to a small aperture, hardly large enough to admit a probe. Even this little opening was closed in the fourth month, at which time no vestiges of the disease remained, except the loss of teeth, and a very obvious depression just where they were situated.

In all fungous diseases of the antrum, making a free exposure of them is an essential part of the treatment; if you neglect this method, how can you inform yourself of the size, form, and extent of the tumour? How could you remove the whole of the fungus, through a small opening, which would only allow you to see a very little portion of the excrescence? How could you be certain that the disease were extirpated to its very root? Even when the antrum is freely opened, this circumstance can only be learnt with difficulty; and how could it be ascertained, when only a point of the cavity is opened? A portion, left behind, very soon gives origin to a fresh fungus, the progress of which is more rapid, and the character more fatal, in consequence of being irritated by the surgical measures adopted. (*Œuvres Chirurgicales de Desault, par Bichat*, t. 2.) See also other cases, recorded by Canolles, (*Résumé Périodique de la Soc. de Méd.* t. 2. No. 9.) Eichorn, (*Dis. de Polypis in Antro Highmori*, Goett. 1814.) Sandifort, (*Museum Anat.* vol. 2. Tab. 30.) Leveillé, (*Résumé de la Soc. &c.* t. 1. p. 244)

Weinkold, (*Von den Krankheiten der Gesichtsknochen*, p. 27. 4to. Halle, 1818.)

I imagine, that English surgeons, unaccustomed to use the actual cautery, will peruse with a degree of aversion this means, so commonly employed in France by Desault, and other celebrated surgeons. Nor can I expect, that they will altogether approve the use of the mallet and gouge, for making a free opening into the antrum. Perhaps, it might be better to trephine this cavity with a small instrument for the purpose, and then cut the fungus away. After removing as much of it as possible in this manner, some instrument of suitable shape might be used to scrape the part, where the tumour has its root. However, if there be any case in which potent and violent measures, like those of Desault, are allowable, it is the one of which we have just been treating. Inveterate diseases demand powerful means, and tampering with them is generally more hurtful than useful.

There is an interesting case of a fungus in the maxillary sinus, related in the first volume of the *Parisian Chirurgical Journal*. It was at last cured by opening the antrum, applying the cautery, and tying the portion of the tumour which had made its way into the nose. In the second volume of the same work, is an excellent case, exhibiting the dreadful ravages which the disease may produce when left to itself.

INSECTS IN THE ANTRUM.

It is said, that insects in this cavity may sometimes make an opening into it necessary. This case, however, must be exceedingly rare; and even what we find in authors (*Pallas de insectis viventibus intra videntia*) appears so little authentic, that I should hardly have mentioned the circumstance, if there were not, in a modern work, (*Med. Comm. vol. 1.*) a fact, which appears entitled to attention. Mr. Heysham, a medical practitioner at Carlisle, relates, that a strong woman, aged sixty, in the habit of taking a great deal of snuff, was subject, for several years, to acute pains in the antrum, extending over one side of the head. These pains never entirely ceased, but were more severe in winter than summer, and were always subject to frequent periodical exacerbations. The patient had taken several anodyne medicines, and others, without benefit, and had twice undergone a course of mercury, by which her complaints had been increased. All her teeth on the affected side had been drawn. At length, it was determined to open the antrum with a large trocar, though there were no symptoms of an abscess, nor of any other disease in this cavity. For four days, no benefit resulted from this operation. During this space, bark injections, and the elixir of aloes, were introduced into the sinus. On the fifth day, a dead insect was extracted, by means of a pair of forceps, from the mouth of the cavity. It was more than an inch long, and thicker

than a common quill. The patient now experienced relief for several hours: but the pains afterwards recurred with as much severity as before; oil was next injected into the antrum, and two other insects, similar to the former, were extracted. No others appeared, and the wound closed. The pains were not completely removed, but they were considerably diminished for several months, at the end of which time they became worse than ever, particularly affecting the situation of the frontal sinus.

Bordenave has published, in the twelfth and thirteenth volumes of the *Mem. de l'Acad. de Chir. edit. 12mo.* two excellent papers on the diseases of the antrum. In the thirteenth volume, he relates the history of a case, in which several small whitish worms, together with a piece of fetid fungus, were discharged from the antrum, after an opening had been made on account of an abscess of this cavity, attended with caries. (P. 381.) But, in this instance, the worms had probably been generated after the opening had been made in the cavity; for when they made their appearance, the opening had existed nine months. Deschamps refers to another case, in which M. Fortassin, his colleague at La Charité, found in the antrum of a soldier, whom he was dissecting, a worm of the *ascaris lumbricus* kind, which was four inches in length. (*Traité des Mal. des Fosses Nasales, &c.* p. 307.) Such an example is also recorded in one of the volumes of the *Journ. de Med.* Were a case of this description to present itself in a living subject, it would be advisable to inject oil into the cavity of the antrum, and then endeavour to wash out the extraneous substances by throwing into the sinus warm water by means of a syringe. See *Précis d'Observations sur les Maladies du Sinus Maxillaire, par M. Bordenave, in Mem. de l'Acad. Royale de Chirurgie, t. 12. edit. in 12mo.* Also *Suite d'Observations on the same Subject, by M. Bordenave, t. 13, of the said Work.* L. H. Runge, *De Morbis Principis Sinuum Ossis Frontis et Maxillæ Superioris, &c. Rintelii, 1750.* Haller, *Disp. ANUS. The lower termination of the great intestine, named the rectum, is so called, and its office is to form an outlet for the feces.

The anus is furnished with muscles, which are peculiar to it, viz. the sphincter, which keeps it habitually closed, and the *levatori ani*, which serve to draw it up into its natural situation, after the expulsion of the feces. It is also surrounded, as well as the whole of the neighbouring intestine, with muscular fibres, and a very loose sort of cellular substance. It is subject to various diseases, in which the aid of surgery is requisite: of these we shall next treat.

IMPERFORATE ANUS.

This complaint is sometimes met with, though not very often. As it is of the utmost consequence that this and other malformations should not remain long unknown, one of the earliest duties of an accoucheur, after delivery, should be an examination of all the natural outlets of new-born infants.

Such an inspection sometimes evinces, that the place in which the extremity of the rectum, or the anus, ought to be, is entirely, or partly, shut up by a membrane, or fleshy adhesion. In other instances, no vestige of the intestine can be found, as the skin retains its natural colour over the whole space between the parts of generation and the os coccygis, without being more elevated in one place than another. In these cases, the intestine sometimes terminates in one or two culs de sac, about an inch upward from the ordinary situation of the anus. (See *Baillie's Series of Engravings*, Fasc. 4. Tab. 5.) Sometimes it does not descend lower than the upper part of the sacrum; sometimes it opens into the bladder, or vagina. Dr. Palmer dissected a case, where the colon, after reaching the vicinity of the left kidney, begun, as it descended, to form a sigmoid flexure; but, previously to its arrival at the concavity of the left ilium, made a sudden turn to the right; and crossing the psoas muscle, reached the projection of the sacrum, where it terminated, *without at all entering the pelvis*. With this malformation was combined an imperforate meatus

urinaris, and some considerable deviations of the genital organs from their natural structure. (See *Medico-Chir. Journ.* vol. 1. p. 180. Svo. Lond. 1816.)

Sometimes the colon terminates in a sac, and the rectum is entirely deficient. (See *Beauregard*, in *Journ. de Méd.* t. 66.) Instances are also upon record, where the rectum opened into the urethra. (*Bresl. Samml.* 1718, p. 702; *Hist. d'Acad. Royale des Sciences*. 1752; p. 113; *Hochstetter*, in *Med. Wochenblatt*, 1780, No. 18—1783, No. 19; *Kretshmar*, in *Horn's Archiv.* 1 B. p. 350.)

When a surgeon is consulted, he must not lose much time in deliberation; for, if a speedy opening be not made for the feces, the infant will certainly very soon perish, with symptoms similar to those of a strangulated hernia. After ascertaining the complaint, which is an easy matter, he should endeavour to learn, whether the anus is merely shut by a membrane, or fleshy adhesion, or whether the anus is altogether wanting, in consequence of the lower portion of the cavity of the gut being obliterated, or the rectum not extending sufficiently far down.

When a membrane, or production of the skin closes the opening of the rectum, the part producing the obstruction is somewhat different in colour from the neighbouring integuments. It is usually of a purple or livid hue, in consequence of the accumulation of the meconium on its inner surface. The meconium, propelled downward by the viscera above, forms a small roundish prominence, which yields like dough to the pressure of the fingers; but immediately projects again when the pressure is removed. When a fleshy adhesion closes the intestine, the circumstance is obvious to the eye, if the part protrude, which is generally the case. The finger feels greater hardness and resistance than when there is a mere membrane, and the livid colour of the meconium cannot be seen through the obstructing substance.

These last signs alone are enough to convince the surgeon of the necessity of the operation; but they do not clearly show, whether the intestine descends as far as it ought, in order to form a proper kind of anus. Complete information on this point, can only be acquired after the membrane or adhesion has been divided; or else after the child's death, when the operation has proved ineffectual. Though there be no mark to denote where the anus ought to be situated, and no degree of prominence, yielding, like soft dough, to the pressure of the fingers, and rising again when such pressure is removed; yet it may happen, especially on our being consulted immediately after the child is born, that, notwithstanding the absence of such symptoms, denoting the presence of the meconium, and the natural extent of the intestine, as far as where the anus ought to be, the gut may exist, and have a cavity, as far as the membrane, or adhesion, closing it.

When the anus is simply covered with

skin, and its place pointed out by a prominence, arising from the contents of the rectum, we have only to make an opening with a knife, sufficient to let out the meconium. Levret recommends making a circular incision in the membrane; but a transverse cut is sufficient. A small tent of lint is afterwards to be introduced, in order to keep the opening from closing. If the anus should only be partly closed by a membrane, the opening may be dilated with a tent; but, if the aperture should be very small, it is preferable to use the bistoury for its enlargement.

When no external appearance denotes where the situation of the anus ought to be, the case is much more serious and embarrassing; and this, whether the intestine is stopped up by a fleshy adhesion, or the coalescence of its sides, or whether a part of the gut is wanting.

However, it is the surgeon's duty to do every thing in his power to afford relief. For this purpose an incision, an inch long, is to be made in the situation where the anus ought to be, and the wound is to be carried more and more deeply in the natural direction of the rectum. The cuts are not to be made directly upwards, nor in the axis of the pelvis, for the vagina, or bladder, might thus be wounded. On the contrary, the operator should cut backward, along the concavity of the os coccygis, where there is no danger of wounding any part of importance. In all cases of this kind, the surgeon's finger is the best director. The operator, guided by the index finger of his left hand, introduced within the os coccygis, is to dissect in the direction above recommended, until he reaches the feces, or has cut as far as he can reach with his finger. If he should fail in finding the meconium, as death must unavoidably follow, one more attempt ought to be made, by introducing, upon the finger, a long trocar, in such a direction as seems best calculated for finding the rectum.

By the prudent adoption of such proceedings, many infants have been preserved, which would otherwise have been devoted to certain death. Hildanus, La Motte, Roonhuysen, and several others, have successfully adopted the above practice. Mr. B. Bell informs us, that he saw two of these cases, in which the intestine was very distant from the integuments, and in which he was so successful as to form an anus, which fulfilled its office tolerably well for several years; but he found it exceeding difficult to keep the passage sufficiently large and pervious. As soon as he removed the dosils of lint, and other kinds of tents, used for maintaining the necessary dilatation, such a degree of contraction speedily followed, that the evacuation of the intestinal matter became very difficult, for a long while afterwards. He employed, at different times, tents made of sponge, gentian root, and other substances, which swell on being moistened. But these always produced so much pain and irritation, that it

was impossible to persevere in their use. After remarking such inconveniences, he condemns the use of tents. He is of opinion, that whoever makes trial of them upon parts, as sensible as the rectum, will soon find, that the advice to use them is wrong.

Tents, made of very soft lint, dipped in oil, or rolls of bougie plaster, cause less irritation than those composed of any other materials.

Though keeping the opening dilated may seem simple and easy, to such men as have had no opportunities of seeing cases of this description, it is far otherwise in practice. Mr. B. Bell assures us, that he never met with any disease which gave him so much trouble and embarrassment as he experienced in the two cases of this sort, which occurred in his practice. Although in both instances he at first made the openings sufficiently large, it was only by very assiduous attention, for eight or ten months, that the necessity for another operation, and even repeated operations, was prevented. When only the skin has been divided, the rest of the treatment is doubtless more simple; for, then, nothing more is requisite than keeping a piece of lint, for a few days, in the opening made with the knife. But, when the extremity of the rectum is at a certain distance, though we may generally hope to effect a cure, after having succeeded in giving vent to the intestinal matter; yet the treatment, after the operation, will always demand, for a long while, a great deal of attention and care on the part of the surgeon. The difficulty of success may be considered as, in some measure, proportioned to the depth of the necessary incision. In a case, like that recorded by Dr. Palmer, to which I have above adverted, the inutility of any attempt to discharge the feces by an operation, in the usual site of the anus, must be sufficiently obvious. (*Medico-Chir Journ. Vol. I. p. 181.*)

Sometimes, while the anus appears pervious and well-formed, infants suffer the same symptoms, as if there were no anus at all. The reason of this depends upon the intestine being occasionally closed by a membranous partition, situated more or less upward, above the aperture of the anus. (*Courtiat, Nouvelles Obs. sur les Os. p. 147.*) and sometimes the symptoms are owing to the termination of the gut in a cul-de-sac. This erroneous formation may always be suspected, when an infant, whose anus is externally open, does not void any excrement, for two or three days after its birth, and, especially, when urgent symptoms arise, such as swelling of the belly, vomiting, &c. We are now to endeavour to ascertain, whether the rectum is impervious above the anus, by attempting to inject clysters, or to introduce a probe. If the gut be shut up, there is nothing to be done, but having recourse to the method described above, and forming a communication by means of a bistoury guided on the finger, or else with a pharyngotomus. If the ob-

stacle should only consist of a transverse membrane, the operation will be easy, and its success almost certain. But, if there should be a strangulation, or obstruction of the intestine, the case is infinitely more serious. However, as the operation is the only resource for saving the child's life, we ought not to hesitate about performing it.

When the anus is imperforate, the intestine sometimes opens into the vagina, or bladder. (*Dumas in Recueil Periodique de la Soc. de Med. T. 3, N. 13. L'Ereille Rapport des Travaux de la Soc. Philom. Vol. 1, p. 145. Murray Diss. Arresis ani vesicalis. Ups. 1794. Act. Nat. Cur. Vol. 8, Obs. 24, Vol. 9, Obs. 11, Roestel in Mursinna's Journ. für die Chir. 1, B. p. 547. Obs. Med. Decad. 2, No. 2.*) The first of these cases is the least dangerous of all the malformations of this sort. The intestine may also open and terminate at two places, at the same time, viz. at the usual place, so as to form a proper anus, more or less perfect; and also in the vagina.

If these two openings should be ample enough, for the easy evacuation of the excrement, nothing can be done at so tender an age; for, though voiding the feces through the vagina, is a most unpleasant inconvenience, yet, there is no effectual means of closing the opening of the intestine in this situation, nor could one be devised, which would not seriously incommode the infant.

But, when the two openings are exceedingly small, and the alvine evacuations cannot readily pass out, even with the aid of clysters, the opening of the anus ought to be dilated by cannulæ of different sizes. If this method should not avail, the knife must be employed, and the wound dressed, as already explained.

For the most part, the intestine has only one opening in the vagina. In this circumstance, as in the instance in which the feces have no vent at all, we must make an incision in that place, which the anus ought to occupy. The natural course of the feces being opened by this operation, which in such a case is not at all perilous, much less excrement will pass out of the vagina, and, of course, the infirmity will be diminished. By the introduction of a tube into the new anus, the communication between the rectum and vagina, might possibly be obliterated, and a perfect cure accomplished. The opening between the intestine and vagina, may, also, be too small for the easy evacuation of the feces, and even expose the infant to the same sort of dangerous symptoms, as it would be subject to, if the rectum had positively no opening at all.

In male infants, the rectum sometimes opens into the bladder, and, in this circumstance, there is generally no anus. The case is easily known by the meconium being blended with the urine, which acquires a thick greenish appearance, and is voided almost continually, though in small quantities. Only the most fluid part of the meconium is thus discharged. The thicker part

not getting from the rectum into the bladder, nor from the bladder into the urethra, greatly distends the intestines and bladder, and produces the same symptoms as take place in cases of total imperforation. Hence, without the speedy interference of art to form an anus, capable of giving vent to the feces, with which the urinary organs cannot remain obstructed, the infant will inevitably die. This case must, therefore, be treated like the foregoing examples. Though we can hardly hope to prevent altogether the inconveniences, resulting from the rectum opening into the bladder, since even a new passage will not completely hinder the feces from following the other course; yet we shall thus afford the child a very good chance of preservation, and the only one which its situation will allow.

In cases, in which we cannot procure an outlet for the feces, by any of the methods pointed out above, it has been proposed by M. Littre, to make an opening above one of the groins, find out a portion of intestine, open it, fix it in this situation with a few stitches, and thus form an artificial anus. M. Sabatier was only acquainted with one case, in which this proceeding had been actually done, viz. the example where M. Duret, a French naval surgeon operated. This gentleman cut into the abdomen at the lower part of the left iliac region, and having opened the sigmoid flexure of the colon, he fixed it near the wound. The child was saved by the formation of an artificial anus; but at the age of twenty-five months, it continued to be troubled with a sort of prolapsus of the lining of the bowel. (*See Recueil Periodique de la Soc. de Med. T. 4, No. 19, & Sabatier, Med. Operatoire, T. 3, p. 336, Edit. 2.*)

Callisen conceives, that the descending colon may be most conveniently got at by making an incision in the left lumbar region, along the edge of the quadratus lumborum muscle, and he prefers this mode of operating, to that of making the incision above the groin. (*Syst. Chir. Hodiernæ, T. 2, p. 688, 689.*) Its advantages, however, are not obvious, and certainly it is on some accounts objectionable. (*See Médecine Operatoire par Sabatier, Tom. 3, p. 330. Also Remarques sur Differens Vices de Conformation, que les Enfants apportent en naissant, par M. Petit, in Mem. de l'Acad. Royale de Chirurgie, Tom. 2, p. 236, Edit. in 12mo. H. A. Wrisberg, de præternaturali et raro intestini Recti cum vesica urinaria coe-litu, et inde pende-nte ani defectu, 4to. Goll. 1779. Ford, in Med. Facts and Obs. Vol. 1, No. 10, Chamberlaine in Memoirs of the Med. Soc. of Lond. Vol. 5, No. 23. Richerand's Nosographie Chirurgicale, Tom. 3, p. 437, &c. Edit. 5. Callisen's Systema Chirurgiæ Hodiernæ, T. 2, p. 686, Edit. 1800; &c.*)

ABSCESSSES OF THE ANUS.—FISTULA IN ANO.

The custom of giving the appellation of *fistula* to every collection of matter formed

near the anus, has, by conveying a false notion of them, been productive of such methods of treating them, as are diametrically opposite to those which ought to be pursued.

A small orifice or outlet from a large or deep cavity, discharging a thin gleet, or sanies, made a considerable part of the idea, which our ancestors had of a fistulous sore, wherever seated. With the term fistulous, they always connected a notion of callosity: and, therefore, whenever they found such a kind of opening yielding such sort of discharge, and attended with any degree of induration, they called the complaint a *fistula*. Imagining this callosity to be a diseased alteration made in the very structure of the parts, they had no conception that it could be cured by any means, but by removal with a cutting instrument, or by destruction with escharotics: and, therefore, they immediately attacked it with knife or caustic, in order to accomplish one of these ends; and very terrible work they often made.

That abscesses, formed near the fundament, do sometimes, from bad habits, from extreme neglect, or from gross mistreatment, become fistulous, is certain; but the majority of them have not, at first, any one character or mark of a true fistula; nor can, without the most supine neglect on the side of the patient, or the most ignorant management on the part of the surgeon, degenerate, or be converted into one.

Collections of matter from inflammation (wherever formed) if they be not opened in time, and in a proper manner, do often burst. The hole, through which the matter finds vent, is generally small, and not often situated in the most convenient, or most dependent part of the tumour: it therefore is unfit for the discharge of all the contents of the abscess; and, instead of closing, contracts itself to a smaller size, and becoming hard at its edges, continues to drain off what is furnished by the undigested sides of the cavity.

When an abscess about the anus bursts, the smallness of the accidental orifice; the hardness of its edges; its being found to be the outlet from a deep cavity; the daily discharge of a thin, gleety, discoloured kind of matter; and the induration of the parts round about, have all contributed to raise, and confirm the idea of a true fistula.

Upon this idea was built the old pernicious doctrine of free excision, or as free destruction.

Abscesses about the anus present themselves in different forms.

Sometimes the attack is made with symptoms of high inflammation; with pain, fever, rigour, &c. and the fever ends as soon as the abscess is formed.

In this case, a part of the buttock near to the anus is considerably swollen, and has a large circumscribed hardness. In a short time, the middle of this hardness becomes red, and inflamed; and in the centre of it matter is formed.

Vol. I.]

This (in the language of our ancestors) is called in general a *phlegman*; but when it appears in this particular part, a *phyma*.

The pain is sometimes great, the fever high, the tumour large, and exquisitely tender; but however disagreeable the appearances may have been, or however high the symptoms may have risen, before suppuration, yet, when that end is fairly and fully accomplished, the patient generally becomes easy and cool; and the matter formed under such circumstances, though it may be plentiful, yet is good.

On the other hand, the external parts, after much pain, attended with fever, sickness, &c. are sometimes attacked with considerable inflammation, but without any of that circumscribed hardness, which characterized the preceding tumour; instead of which the inflammation is extended largely, and the skin wears an erysipelatous kind of an appearance. In this, the disease is more superficial; the quantity of matter small, and the cellular membrane sloughy to a considerable extent.

Sometimes, instead of either of the preceding appearances, there is formed in this part, what the French call *une suppuration gangreneuse*; in which the cellular and adipose membrane is affected in the same manner, as it is in the disease called a carbuncle.

In this case, the skin is of a dusky red or purple kind of colour; and although harder than when in a natural state, yet it has, by no means, that degree of tension or resistance, which it has either in the phlegmon, or in the erysipelas.

The patient has generally, at first, a hard, full, jarring pulse, with great thirst, and very fatiguing restlessness. If the progress of the disease be not stopped, or the patient relieved by medicine, the pulse soon changes into an unequal, low, faltering one; and the strength and the spirits sink in such manner, as to imply great and immediately impending mischief. The matter formed under the skin, so altered, is small in quantity, and bad in quality; and the adipose membrane is gangrenous and sloughy throughout the extent of the discoloration. This generally happens to persons, whose habit is either naturally bad, or rendered so by intemperance.

In each of these different affections, the whole malady is often confined to the skin and cellular membrane underneath it; and no other symptoms attend, than the usual general ones, or such as arise from the formation of matter or sloughs in the part immediately affected. But it also often happens, that, added to these effects, the patient is made unhappy by complaints arising from an influence, which such mischief has on parts in the neighbourhood of the disease; such as the urinary bladder, the vagina, the urethra, the hæmorrhoidal vessels, and the rectum; producing retention of urine, stranguary, dysury, bearing down, tenesmus, piles, diarrhoea, or obstinate costiveness; which complaints are sometimes so pressing, as to all our attention. On the other hand,

large quantities of matter and deep sloughs are sometimes formed, and great devastation committed on the parts about the rectum, with little or no previous pain, tumour, or inflammation.

Sometimes the disease makes its first appearance in an induration of the skin, near to the verge of the anus, but without pain or alteration of colour; which hardness gradually softens and suppurates. The matter, when let out, in this case, is small in quantity, good in quality; and the sore is superficial, clean, and well-conditioned. On the contrary, it now and then happens, that although the pain is but little, and the inflammation apparently slight, yet the matter is large in quantity, bad in quality, extremely offensive, and proceeds from a deep crude hollow, which bears an ill-natured aspect.

The place also where the abscess points, and where the matter, if let alone, would burst its way out, is various and uncertain. Sometimes it is in the buttock, at a distance from the anus; at other times near its verge, or in the perineum, and this discharge is made sometimes from one orifice only, sometimes from several. In some cases, there is not only an opening through the skin, externally, but another through the intestine into its cavity: in others, there is only one orifice, and that either external or internal.

Sometimes the matter is formed at a considerable distance from the rectum, which is not even laid bare by it; at others, it is laid bare also, and not perforated: it is also, sometimes, not only denuded, but pierced; and that in more places than one.

All consideration of preventing suppuration, is generally out of the question: and our business, if called at the beginning, must be to moderate the symptoms; to forward the suppuration; when the matter is formed, to let it out; and to treat the sore in such manner, as shall be most likely to produce a speedy and lasting cure.

When there are no symptoms which require particular attention, and all that we have to do is to assist the maturation of the tumour, a soft poultice is the best application. When the disease is fairly of the phlegmonoid kind, the thinner the skin is suffered to become, before the abscess be opened, the better: as the induration of the parts about will thereby be the more dissolved, and, consequently, there will be the less to do after such opening has been made. This kind of tumour is generally found in people of full, sanguine habits; and who, therefore, if the pain be great, and the fever high, will bear evacuation, both by phlebotomy, and gentle cathartics: which is not often the case of those, who are said to be of bilious constitutions; in whom the inflammation is of a larger extent, and in whom the skin wears the yellowish tint of the erysipelas; persons of such kind of habit, and in such circumstances, being in general seldom capable of bearing large evacuations.

When the inflammation is erysipelatous, the quantity of matter formed is small, compared with the size and extent of the tu-

mour; the disease is rather a sloughy, putrid state of the cellular membrane, than an imposthumation; and therefore, the sooner it is opened, the better: if we wait for the matter to make a point, we shall wait for what will not happen; at least not till after a considerable length of time; during which the disease in the membrane will extend itself, and consequently, the cavity of the sinus, or abscess, be thereby greatly increased.

When, instead of either of the preceding appearances, the skin wears a dusky, purplish-red colour; has a doughy, unresisting kind of feel, and is very little sensible: when these circumstances are joined with an unequal, faltering kind of pulse, irregular shiverings, a great failure of strength and spirits, and inclination to doze, the case is formidable, and the event generally fatal.

The habit, in these circumstances, is always bad; sometimes from nature, but much more frequently from gluttony, and intemperance. What assistance art can lend, must be administered speedily; every minute is of consequence; and if the disease be not stopped, the patient will sink. Here (says Pott) is no need for evacuation of any kind: recourse must be immediately had to medical assistance; the part affected should be frequently fomented with hot spirituous fomentations, a large and deep incision should be made into the diseased parts; and the application made to it should be of the warmest, most antiseptic kind.

This also is a general kind of observation, and equally applicable to the same sort of disease in any part of the body. Our ancestors have thought fit to call it in some a carbuncle, and in others, by other names; but it is (wherever seated) really and truly a gangrene of the cellular and adipose membrane: it always implies great degeneracy of habit, and, most commonly, ends ill.

Strangury, dysury, and even total retention of urine, are no very uncommon attendants upon abscesses forming in the neighbourhood of the rectum and bladder: more especially if the seat of them be near the neck of the latter.

They sometimes continue from the first attack of the inflammation, until the matter is formed, and has made its way outward: and sometimes last a few hours only.

The two former most commonly are easily relieved by the loss of blood, and the use of gum arabic, with nitre, &c. But in the last (the total retention,) they who have not often seen this case, generally have immediate recourse to the catheter; but the practice is essentially wrong.

The neck of the bladder does certainly participate, in some degree, in the said inflammation. But, the principal part of the complaint arises from irritation, and the disease is, strictly speaking, spasmodic. The manner in which an attack of this kind is generally made; the very little distention which the bladder often

suffers ; the small quantity of urine sometimes contained in it, even when the symptoms are most pressing ; and the most certain, as well as safe, method of relieving it ; all tend to strengthen such opinion.

But whether we attribute the evil to inflammation, or to spasmodic irritation, whatever can, in any degree, contribute to the exasperation of either, must be manifestly wrong. The violent passage of the catheter through the neck of the bladder (for violent in such circumstances it must be) can never be right.

If the instrument be successfully introduced, it must either be withdrawn as soon as the bladder is emptied, or it must be left in it : if the former be done, the same cause of retention remaining, the same effect returns ; the same pain and violence must again be submitted to, under (most likely) increased difficulties. On the other hand, if the catheter be left in the bladder, it will often, while its neck is in this state, occasion such disturbance, that the remedy (as it is called) will prove an exasperation of the disease, and add to the evil it is designed to alleviate ; nor is this all ; for the resistance, which the parts, while in this state, make, is sometimes so great, that if any violence be used, the instrument will make for itself a new rout in the neighbouring parts, and lay the foundation of such mischief as frequently baffles all our art.

The true, safe, and rational method of relieving this complaint (says Pott) is by evacuation and anodyne relaxation : this not only procures immediate ease, but does, at the same time, serve another very material purpose ; which is that of maturing the abscess. Loss of blood is necessary ; the quantity to be determined by the strength and state of the patient : the intestines should also be emptied, if there be time for so doing, by a gentle cathartic ; but the most effectual relief will be from the warm bath, or semicupium, the application of bladders with hot water to the pubes and perineum, and, above all other remedies, the injection of clysters, consisting of warm water, oil, and opium. There may have been cases which have resisted and baffled this method of treatment ; but Pott has never met with them.

A painful tenesmus is no uncommon attendant upon an inflammation of the parts about the rectum.

If a dose of rhubarb, joined with a warm anodyne, such as the conf. mithrid. or such like, does not remove it, the injection of thin starch and opium, or tinct. thebaic. is almost infallible.

The bearing down, in females, as it proceeds in this case, from the same kind of cause (viz. irritation) admits of relief from the same means as the tenesmus.

In some habits an obstinate costiveness attends this kind of inflammation, accompanied, not unfrequently, with a painful distention and enlargement of the hæmorrhoidal vessels, both internally and externally. While a quantity of hard feces are detained

within the large intestines, the whole habit must be disordered ; and the symptomatic fever, which necessarily accompanies the formation of matter, must be considerably heightened. And while the vessels surrounding the rectum (which are large and numerous) are distended, all the ills proceeding from pressure, inflammation, and irritation, must be increased. Phlebotomy, laxative clysters, and a low, cool regimen, must be the remedies : while a soft cataplasm applied externally serves to relax and mollify the swollen, indurated piles, at the same time that it hastens the suppuration.

When the abscesses have formed, and are fit to be opened, or when they have already burst, they may be reduced to two general heads, viz.

1. Those, in which the intestine is not at all interested ; and,
2. Those, in which it is either laid bare, or perforated.

In making the opening, the knife or lancet should be passed in deep enough to reach the fluid ; and, when it is in, the incision should be continued upward and downward, in such manner as to divide all the skin covering the matter. By these means, the contents of the abscess will be discharged at once ; future lodgment of matter will be prevented ; convenient room will be made for the application of proper dressings ; and there will be no necessity for making the incision in different directions, or for removing any part of the skin composing the verge of the anus.

Notwithstanding all these collections of matter are generally called *fistulæ*, and are all supposed to affect the *intestinum rectum*, yet it is very certain that the seat of the abscess, is sometimes at such distance from the gut, that it is not at all interested by it ; and that none of these cases either are, or can be originally *fistulæ*.

In this state of the disease, we have no more necessarily to do with the intestine, than if it was not there ; the case is to be considered merely as an abscess in the cellular membrane.

Suppose a large and convenient opening to have been made by a simple incision ; the contents of the abscess to have been thereby discharged ; and a sore or cavity produced, which is to be filled up.

The term *filling up*, and the former opinion, that the induration of the parts about is a diseased callosity, have been the two principal sources of misconduct in these cases.

The old opinion, with regard to hollow and hardness, was, that the former is caused entirely by loss of substance : and the latter, by diseased alteration in the structure of the parts.

The consequence of which opinion was, that as soon as the matter was discharged, the cavity was filled and distended, in order to procure a gradual regeneration of flesh, and the dressings, with which it was so filled were most commonly of the escharotic

kind, intended for the dissolution of hardness.

The practice is a necessary consequence of the theory. Whoever supposes diseased callosity, and great loss of substance, will necessarily think himself obliged to destroy the former, and to prevent the cavity, formed by the latter, from filling up too hastily. On the other hand, he who regards the cavity of the abscess as being principally the effect of the gradual distraction and separation of its sides, with very little loss of substance, compared with the size of the said cavity; and who looks upon the induration round about, as nothing more than a circumstance which necessarily accompanies every inflammation in membranous parts, more especially in those which tend to suppuration; will, upon the smallest reflection, perceive, that the dressings applied to such cavity ought to be so small in quantity, as to permit nature to bring the sides of the cavity toward each other, and that such small quantity of dressings ought to consist of materials proper only to encourage easy and gradual suppuration.

Suppuration is to be produced and maintained, not by thrusting in such applications, as by their quantity distend, and by their quality irritate and destroy; but by dressing lightly and easily with such as appease, relax, and soften.

If the hollow, immediately it is opened, be filled with dressings (of any kind,) the sides of it will be kept from approaching each other, or may even be farther separated. But if this cavity be not filled, or have little or no dressings of any kind introduced into it, the sides immediately collapse; and, coming nearer and nearer, do, in a very short space of time, convert a large hollow into a small sinus. And this is also constantly the case, when the matter, instead of being let out by an artificial opening, escapes through one made by the bursting of the containing parts.

True, this sinus will not always become perfectly closed; but the aim of nature is not, therefore, the less evident; nor the hint, which art ought to borrow from her, the less palpable.

In this, as in most other cases, where there are large sores, or considerable cavities, a great deal will depend on the patient's habit, and the care that is taken of it: if that be good, or if it be properly corrected, the surgeon will have very little trouble in his choice of dressings; only to take care that they do not offend either in quantity, or quality: but if the habit be bad, or injudiciously treated, he may use the whole farrago of externals, and only waste his own and his patient's time.

By light, easy treatment, large abscesses formed in the neighbourhood of the rectum, will sometimes be cured, without any necessity occurring of meddling with the said gut. But it much more frequently happens, that the intestine, although it may not have been pierced or eroded by the matter, has yet been so stripped or denuded, that no

consolidation of the sinus can be obtained, but by a division; that is, by laying the two cavities, viz. that of the abscess, and that of the intestine, into one.

When the intestine is found to be separated from the surrounding parts by the matter, the operation of dividing it had better (on many accounts) be performed at the time the abscess is first opened, than be deferred to a future one. For, if it be done properly, it will add so little to the pain, which the patient must feel by opening the abscess, that he will seldom be able to distinguish the one from the other, either with regard to time or sensation; whereas, if it be deferred, he must either be in continual expectation of a second cutting, or feel one at a time when he does not expect it.

The intention in this operation is to divide the intestine rectum from the verge of the anus up as high as the top of the hollow in which the matter was formed; thereby to lay the two cavities of the gut and abscess into one; and by means of an open, instead of a hollow or sinuous sore, to obtain a firm and lasting cure.

For this purpose, the curved, probe-pointed knife, with a narrow blade, is the most useful and handy instrument of any. This, introduced into the sinus, while the surgeon's fore-finger is in the intestine, will enable him to divide all that can ever require division; and that with less pain to the patient, with more facility to the operator, as well as with more certainty and expedition than any other instrument whatever. If there be no opening in the intestine, the smallest degree of force will thrust the point of the knife through, and thereby make one: if there be one already, the same point will find and pass through it. In either case, it will be received by the finger in ano; will thereby be prevented from deviating, and being brought out by the same finger, must necessarily divide all that is between the edge of the knife, and the verge of the anus: that is, must by one simple incision (which is made in the smallest space of time imaginable) lay the two cavities of the sinus and of the intestine into one.

Authors make a very formal distinction between those cases in which the intestine is pierced by the matter, and those in which it is not; but although this distinction may be useful when the different states of the disease are to be described, yet in practice, when the operation of dividing the gut becomes necessary, such distinction is of no consequence at all; it makes no alteration in the degree, kind, or quantity, of pain which the patient is to feel; the force required to push the knife through the tender gut is next to none, and when its point is in the cavity, the cases are exactly similar.

Immediately after the operation, a soft dossil of fine lint should be introduced (from the rectum) between the divided lips of the incision; as well to repress any slight hæmorrhage, as to prevent the immediate reunion of the said lips; and the

rest of the sore should be lightly dressed with the same. This first dressing should be permitted to continue, until a beginning suppuration renders it loose enough to come away easily; and all the future ones should be as light, soft, and easy as possible; consisting only of such materials as are likely to promote kindly and gradual suppuration. The sides of the abscess are large; the incision must necessarily, for a few days, be inflamed; and the discharge will, for some time, be discoloured and gleety: this induration, and this sort of discharge, are often mistaken for signs of diseased callosity, and undiscovered sinuses; upon which presumptions, escharotics are freely applied, and diligent search is made for new hollows; the former of these most commonly increase both the hardness and the gleet; and by the latter new sinuses are sometimes really produced. These occasion a repetition of escharotics, and perhaps, of incisions; by which means, cases which at first, and in their own nature were simple and easy of cure, are rendered complex and tedious.

To quit reasoning, and speak to fact only: In the great number of these cases, which must have been in St. Bartholomew's Hospital, within these ten or twelve years, *I do aver, (says Pott) that I have not met with one, in the circumstances before described, that has not been cured by mere simple division, together with light, easy dressings: and that I have not, in all that time, used for this purpose, a single grain of precipitate, or of any other escharotic.*

The best and most proper method of dividing the intestine, in the case of a collection of matter formed juxta anum, we have already described.

The intention to be aimed at by incision in the present case, is exactly the same, and ought to be executed in the same manner.

Let us first suppose the matter to be fairly formed; to have made its point, as it is called; and to be fit to be let out.

Where such point is, that is, where the skin is most thin, and the fluctuation most palpable, there the opening most certainly ought to be made, and always with a cutting instrument, not caustic, as was formerly done.

We have supposed the matter of the abscess to have been formed, and collected; but still to have been contained within the cavity, until let out by an incision.

We are now to consider it, as having made its own way out, without the help of art.

This state of the disease is also subject to some variety of appearance; and these different appearances have produced, not only a multiplicity of appellations, but a groundless supposition also, of a variety of essentially different circumstances.

When a discharge of the matter by incision is too long delayed or neglected, it makes its own way out, by bursting the external parts somewhere near to the funda-

ment, or by eroding and making a hole through the intestine into its cavity; or sometimes by both. In either case, the discharge is made sometimes by one orifice only, and sometimes by more. Those, in which the matter has made its escape by one or more openings, through the skin only, are called *blind external fistulae*; those, in which the discharge has been made into the cavity of the intestine, without any orifice in the skin, are named *blind internal*; and those, which have an opening both through the skin, and into the gut, are called *complete fistulae*.

Thus, all these cases are deemed fistulous, when hardly any of them ever are so: and none of them necessarily. They are still mere abscesses, which are burst without the help of art; and if taken proper and timely care of, will require no such treatment as a true fistula may possibly stand in need of.

The most frequent of all are what are called the *blind external*; and the *complete*. The method whereby each of these states may be known is, by introducing a probe into the sinus by the orifice in the skin, while the fore-finger is within the rectum: this will give the examiner an opportunity of knowing exactly the true state of the case, with all its circumstances.

Whether the case be, what is called a complete fistula, or not; that is, whether there be an opening in the skin only, or one there, and another in the intestine, the appearance to the eye is much the same. Upon discharge of the matter, the external swelling subsides, and the inflamed colour of the skin disappears, the orifice, which at first was sloughy and foul, after a day or two are past, becomes clean and contracts in size; but the discharge, by fretting the parts about, renders the patient still uneasy.

As this kind of opening seldom proves sufficient for a cure, (though it sometimes does) the induration, in some degree, remains; and if the orifice happens not to be a depending one, some part of the matter lodges, and is discharged by intervals, or may be pressed out by the fingers of an examiner. The disease, in this state, is not very painful; but it is troublesome, nasty, and offensive: the continual discharge of a thin kind of fluid from it, creates heat, and causes excoriation in the parts above; it daubs the linen of the patient; and is, at times, very fetid; the orifice also sometimes contracts so, as not to be sufficient for the discharge; and the lodgment of the matter then occasions fresh disturbance.

The means of cure proposed and practised by our ancestors, were three, viz. caustic, ligature, and incision.

The intention in each of these is the same, viz. to form one cavity of the sinus and intestines by laying the former into the latter. The two first are now completely, and most properly, exploded.

Hitherto we have considered the disease either as an abscess, from which the matter has been let out by an incision, made by a

surgeon, or from which the contents have been discharged by one single orifice, formed by the bursting of the skin somewhere about the fundament. Let us now take notice of it, when instead of one such opening, there are several.

This state of the case generally happens when the quantity of matter collected has been large, the inflammation of considerable extent, the adipose membrane very sloughy, and the skin worn very thin before it burst.—It is, indeed, a circumstance of no real consequence at all; but from being misunderstood, or not properly attended to, is made one of additional terror to the patient, and additional alarm to the inexperienced practitioner: for it is taught, and frequently believed, that each of these orifices is an outlet from, or leads to a distinct sinus, or hollow: whereas in truth, the case is most commonly quite otherwise; all these openings are only so many distinct burstings of the skin covering the matter; and do all, be they few or many, lead and open immediately into the one single cavity of the abscess: they neither indicate, nor lead to, nor are caused by distinct sinuses; nor would the appearance of twenty of them (if possible) necessarily imply more than one general hollow.

If this account be a true one, it will follow, that the chirurgic treatment of this kind of case ought to be very little, if at all different from that of the preceding; and that all that can be necessary to be done, must be to divide each of these orifices in such manner as to make one cavity of the whole. This the probe-knife will easily and expeditiously do; and when that is done, if the sore, or more properly its edges, should make a very ragged, uneven appearance, the removal of a small portion of such irregular angular parts will answer all the purposes of making room for the application of dressings, and for producing a smooth, even cicatrix after the sore shall be healed.

When a considerable quantity of matter has been recently let out, and the internal parts are not only in a crude, undigested state, but have not yet had time to collapse, and approach each other; the inside of such cavity will appear large; and if a probe be pushed with any degree of force, it will pass in more than one direction into the cellular membrane by the side of the rectum. But let not the inexperienced practitioner be alarmed at this, and immediately fancy, that there are so many distinct sinuses: neither let him, if he be of a more hardy disposition, go to work immediately with his director, knife, or scissors: let him enlarge the external wound by making his incision freely; let him lay all the separate orifices open into that cavity; let him divide the intestine lengthwise by means of his finger in ano; let him dress lightly and easily; let him pay proper attention to the habit of the patient; and wait, and see what a few days, under such conduct, will produce. By this he will frequently find, that

the large cavity of the abscess will become small and clean; that the induration round about will gradually lessen; that the probe will not pass in that manner into the cellular membrane; and consequently, that his fears of a multiplicity of sinuses were groundless. On the contrary, if the sore be crammed or dressed with irritating, or escharotic medicines, all the appearances will be different: the hardness will increase, the lips of the wound will be inverted, the cavity of the sore will remain large, crude, and foul; the discharge will be thin, gleety, and discoloured; the patient will be uneasy and feverish: and, if no new cavities are formed by the irritation of parts, and confinement of matter, yet the original one will have no opportunity of contracting itself; and may very possibly become truly fistulous.

Sometimes the matter of an abscess, formed juxta anum, instead of making its way out through the skin, externally near the verge of the anus, or in the buttock, pierces through the intestine only. This is what is called a *blind internal fistula*.

In this case, after the discharge has been made, the greater part of the tumefaction subsides, and the patient becomes easier. If this does not produce a cure, which sometimes, though very seldom happens, some small degree of induration generally remains in the place where the original tumour was, upon pressure on this hardness, a small discharge of matter is frequently made per anum; and sometimes the expulsion of air from the cavity of the abscess into that of the intestine may very palpably be felt, and clearly heard; the stools particularly, if hard and requiring force to be expelled, are sometimes smeared with matter; and although the patient, by the bursting of the abscess, is relieved from the acute pain which the collection occasioned, yet he is seldom perfectly free from a dull kind of uneasiness, especially if he sits for a considerable length of time in one posture. The real difference between this kind of case, and that in which there is an external opening (with regard to method of cure) is very immaterial; for an external opening must be made, and then all difference ceases. In this, as in the former, no cure can reasonably be expected, until the cavity of the abscess, and that of the rectum, are made one; and the only difference is, that in the one case we have an orifice at, or near the verge of the anus, by which we are immediately enabled to perform that necessary operation; in the other we must make one.

We come now to that state of the disease, which may truly and properly be called *fistulous*. This is generally defined, *sinus angustus, callosus, profundus: acris sanie diffusus*; or, as Dionis translates it, "*Un ulcère profond, & caverneux, dont l'entrée est étroite, & le fond plus large; avec issue d'un pus acre & virulent; et accompagné de callosités.*"

Various causes may produce or concur in producing such a state of the parts concern-

ed as will constitute a fistula, in the proper sense of the word; that is, a deep, hollow sore, or sinus, all parts of which are so hardened, or so diseased, as to be absolutely incapable of being healed, while in that state; and from which a frequent, or daily discharge is made, of thin, discoloured sanies, or fluid.

These are divided into two classes, viz. those which are the effect of neglect, distempered habit, or of bad management, and which may be called, without any great impropriety, local diseases; and those which are the consequence of disorders, whose origin and seat are not in the immediate sinus or fistula, but in parts more or less distant, and which, therefore, are not local complaints.

The natures and characters of these are obviously different by description; but they are still more so in their most frequent event, the former being generally curable by proper treatment; the latter frequently not so by any means whatever.

Under the former are reckoned all such cases as were originally mere collections of matter within the coats of the intestine rectum, or in the cellular membrane surrounding the said gut; but which, by being long neglected, grossly managed, or by happening in habits which were disordered, and for which disorders no proper remedies were administered, suffer such alteration, and get into such state, as to deserve the appellation of *fistulae*.

Under the latter are comprised all those cases, in which the disease has its origin and first state in the higher and more distant parts of the pelvis, about the os sacrum, lower vertebrae of the loins, and parts adjacent thereto; and are either strumous, or the consequence of long and much distempered habits; or the effect of, or combined with, other distempers, local or general; such as a diseased neck of the bladder, or prostate gland, or urethra, &c. &c. &c.

Among the very low people, who are brought into hospitals, we frequently meet with cases of the former kind: cases, which, at first, were mere simple abscesses; but which, from uncleanness, from intemperance, negligence, and distempered constitutions, become such kind of sores, as may be called *fistulous*.

In these the art of surgery is undoubtedly, in some measure, and at some time, necessary; but it very seldom is the first or principal fountain from whence relief is to be sought: the general effects of intemperance, debauchery, and diseases of the habit are first to be corrected and removed, before surgery can with propriety, or with reasonable prospect of advantage, be made use of.

The surgery required in these cases, consists in laying open and dividing the sinus, or sinuses, in such manner that there may be no possible lodgment for matter, and that such cavities may be fairly opened lengthwise into that of the intestine rectum: if the internal parts of these hollows are hard, and do not yield good matter, which is

sometimes the case, more especially where attempts have been made to cure by injecting astringent liquors, such parts should be lightly scratched or scarified with the point of a knife or lancet, but not dressed with escharotics; and if either from the multiplicity of external orifices, or from the loose, flabby, hardened, or inverted state of the lips and edges of the wound near to the fundament, it seems very improbable that they can be got into such a state as to heal smoothly and evenly, such portion of them should be cut off as may just serve that purpose. The dressings should be soft, easy, and light; and the whole intent of them to produce such suppuration as may soften the parts, and bring them into a state fit for healing.

If a loose, fungous kind of flesh has taken possession of the inside of the sinus, (a thing much talked of, and very seldom met with) a slight touch of the lunar caustic will reduce it sooner, and with better effect on the sore, than any other escharotic whatever.

The method and medicines, by which the habit of the patient was corrected, must be continued (at least in some degree) through the whole cure; and all the excesses and irregularities, which may have contributed to injure it, must be avoided.

By these means, cases which at first have a most disagreeable and formidable aspect, are frequently brought into such state, as to give very little trouble in the healing.

If the bad state of the sore arises merely from its having been crammed, irritated, and eroded; the method of obtaining relief is so obvious, as hardly to need recital.

A patient who has been so treated, has generally some degree of fever; has a pulse which is too hard, and too quick; is thirsty, and does not get his due quantity of natural rest. A sore which has been so dressed, has generally a considerable degree of inflammatory hardness round about; the lips and edges of it are found full, inflamed, and sometimes inverted; the whole verge of the anus is swollen; the hæmorrhoidal vessels are loaded; the discharge from the sore is large, thin, and discoloured; and all the lower part of the rectum participates of the inflammatory irritation, producing pain, bearing-down, tenesmus, &c. *Contraria contrariis* is never more true than in this instance: the painful, uneasy state of the sore, and of the rectum; is the great cause of all the mischief, both general and particular; and the first intention must be to alter that state. All escharotics must be thrown out, and disused; and in lieu of them, a soft digestive should be substituted, in such manner as not to cause any distention, or to give any uneasiness from quantity: over which a poultice should be applied: these dressings should be renewed twice a day; and the patient should be enjoined absolute rest. At the same time, attention should be paid to the general disturbance, which the former treatment may

have created. Blood should be drawn off from the sanguine; the feverish heat should be calmed by proper medicines; the languid and low should be assisted with the bark and cordials; and ease in the part must, at all events, be obtained by the injection of anodyne clysters of starch and opium.

If the sinus has not yet been laid open, and the bad state of parts is occasioned by the introduction of tents imbued with escharotics, or by the injection of astringent liquors, (the one for the destruction of callosity, the other for the drying up gleet and humidity) no operation of any kind should be attempted until both the patient and the parts are easy, cool, and quiet: cataplasms, clysters, rest, and proper medicines must procure that: and when that is accomplished, the operation of dividing the sinus, and (if necessary) of removing a small portion of the ragged edges, may be executed, and will, in all probability, be attended with success. On the contrary, if such operation be performed while the parts are in a state of inflammation, the pain will be great, the sore for several days very troublesome, and the cure prolonged or retarded, instead of being expedited.

Abscesses and collections of diseased fluids, are frequently formed about the lumbar vertebræ, under the psoas muscle, and near to the os sacrum; in which cases, the said bones are sometimes carious, or otherwise diseased. These sometimes form sinuses, which run down by the side of the rectum, and burst near to the fundament.

The chirurgic treatment of such sores and sinuses can have no little influence on the remote situation, where the collection of matter is originally formed. (See *Lumbar Abscess*.)

Fistulous sores, sinuses, and indurations about the anus, which are consequences of diseases of the neck of the bladder, and urethra, called fistulæ in perinæo, require separate and particular consideration. (See *Fistula in Perinæo*.)

Pott may be considered as the source and authority of the foregoing remarks.

M. Roux has lately published a sort of critique on the preference, which English surgeons invariably give to Pott's method of operating for the fistula in ano. The chief peculiarity in the French plan, on which he bestows unqualified praise, consists in the use of a kind of director, called a gorget, which is usually made of ebony wood, and intended to be introduced within the rectum with its concavity turned towards the fistula. A steel inflexible director, slightly pointed and without a cul-de-sac, is then passed through the fistula till the point comes into contact with the wooden gorget. A long, narrow, sharp-pointed, straight bistoury is now introduced along the groove of the steel director, till its point meets the groove of the ebony gorget, by cutting upon which all the parts are divided, which lie between the internal opening of the fistula and the anus. It may be objected to this method, that it is not al-

ways easy to make a director pass at once through the fistula into the rectum. This is acknowledged by M. Richerand, who adds, that, in this circumstance, the point of the director may be forced into the rectum, without lessening the chance of the success of the operation. (*Nosogr. Chirurg. T. 3, p. 463, 464. Edit. 4.*) Why then does it matter so much, that the surgeon sometimes pierces the rectum with the point of his curved bistoury? Surely, this is as good an instrument for making the puncture as the pointed director. Besides, it appears to me, that a flexible silver director is more likely to follow the track of the fistula into the rectum, than an unbending iron instrument. I shall say nothing of the awkwardness of using the other wooden director: the finger of the surgeon can always do the office of all such contrivances, with greater safety and convenience. M. Roux also censures us for not cramming the wound with charpie; for he is not content with merely introducing into it a dossil of lint. (See *Parallèle de la Chir. Angloise, &c. p. 296, &c.*) His countryman Pouteau, however, knew better long ago: for he has expressed his decided conviction of the inutilty of cramming the wound with dressings to its very bottom after the third day, when superficial dressings, and the renewal of them as often as cleanliness requires, will be fully sufficient.

For information, relative to former opinions concerning fistula in ano, refer to *Celsus*; *Heister's Surgery*; *Le Dran's Operations*; *Sharp's Operations*; *La Faye's Notes on Dionis*. H. Bass, *De Fistula Ani feliciter curanda*, in *Hallei Disp. Chir. 4, 463*. J. L. Petit, *Traité des Mal. Chir. T. 1 and 2, p. 113*. Petit is an advocate for making an early opening, like Pott, and all the best writers on this disease. In *Kirkland's Medical Surgery, Vol. 2*, may be found an account of the opinions and practice of many former celebrated practitioners. The best modern practical remarks are contained in Pott's *Treatise on the Fistula in Ano*, in which he has offered also an excellent critique on some opinions of Le Dran, De la Foye, and Cheulden. The reader may also consult with advantage *Sabatier's Médecine Opératoire, Tom. 2*; *B. Bell's Surgery, Vol. 2*; *Latta's Surgery, Vol. 2*; *T. Whately, Cases of Polypi, &c. with an appendix, describing an improved instrument for the fistula in ano, 8vo. Lond. 1805*. J. T. Oetzmänn, *De Fistula Ani, 4to. Jenæ, 1812*. Richerand's *Nosographie Chirurgicale, T. 3, p. 446, &c. Edit. 4*. Roux, *Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, p. 396, &c. Paris, 1815*. Callisen's *Syst. Chirurgiæ Hodiernæ, T. 1, p. 470*. Schreger, *Chirurgische Versuche, B. 2, über die Unterbindung der Mastdarmfisteln, p. 1. 131. 8vo. Nürnberg, 1818*. Fr. Reisinger, *Darstellung eines neuen Verfahrens die Mastdarmfistel zu unterbinden, &c. 8vo. Augsb. 1816*. Into the consideration of these plans of curing fistula by the introduction of a ligature through them, and tying

them, I have not judged it advisable to enter, because every method of this kind is most justly exploded from the practice of surgery in this country.

ANUS, PROLAPSUS OF.

Prolapsus ani, technically called also *exomina*, or *archoptosis*. In this case, the rectum protrudes in a greater or less degree at the anus, either from mere relaxation of the internal membrane of the bowel, or from a real displacement and inversion of its upper portion, which presents itself as an external tumour. The first form of the disease is that, which is most common. The inner coat of the rectum, being connected to the muscular by a very loose elastic cellular substance, naturally forms several folds, the use of which is to let this bowel dilate sufficiently for the retention of the excrement. The swelling, occasioned by the protrusion of the inner coat of the rectum, or by the actual displacement of a greater part of this bowel, is subject to considerable variety in respect to length and thickness; when small resembling a mere ring; when large and reaching far downwards, having an oblong globular form. The tumour, sometimes, admits of reduction with ease; sometimes it cannot be returned without difficulty. The disease occurs in persons of all ages; but, it is most common in infants and elderly subjects. Such examples as are combined with thickening and relaxation of the inner coat of the rectum, internal hemorrhoids, or other tumours, are sometimes attended with a copious discharge from the anus, and from the prolapsed bowel, of a serous and mucous fluid, mixed with blood. The disease may originate from various causes:

1. From circumstances, which tend to relax and weaken the parts, which retain the rectum, or its inner membrane, in its situation.

2. From various kinds of irritation and pressure on the bowel itself, having the effect of increasing the powers, by which it is liable to be forced outward.

3. From any disease, or irritation in the adjacent parts, and affecting the rectum sympathetically.

Hence, a prolapsus ani may be caused by long habitual crying, and great exertions of the voice; violent coughing; sitting long at stool; hard dry feces, and much straining to void them; obstinate diarrhoea in infants, kept up by dentition; dysentery; chronic tenesmus; various diseases of the rectum itself; the abuse of aloetic medicines and emollient clysters; hemorrhoids; excrescences and thickenings of the inner membrane of the rectum; difficulty of making water; the efforts of parturition; the stone in the bladder; paralysis of the sphincter and levatores ani; and prolapsus vaginae.

Considering the degree of the disease, and the occasional closeness of the stric-

ture, the symptoms are sometimes mild, the rectum generally bearing pressure, exposure to the air, and other kinds of irritation, better than any other bowel. But the urgency and danger of a prolapsus ani are greater when the swelling is large, recent, and conjoined with violent pain, inflammation, and febrile symptoms. When complicated with strangulation, the consequences may be a stoppage of the feces, severe pain, swelling, inflammation, and even gangrene, within the cavity of the abdomen. In short, all the evils may arise which attend strangulated hernia. The prognosis, therefore, varies according to the different degree, species, cause, and complication of the disease. The recent, small, moveable prolapsus ani, the cause of which admits of being at once removed, may be effectually and radically cured. It should always be recollected, however, that when once the rectum has been affected with prolapsus, a tendency to protrusion from any slight occasional cause generally remains. The habitual prolapsus, which has existed for years, and comes on whenever the patient goes to stool, is the case which is most difficult of relief.

The treatment of prolapsus ani embraces three principal indications.

1. The speedy reduction of the prolapsed part.

2. The retention of the reduced bowel.

3. The removal and avoidance of the causes by which the disease is induced.

In general, when the case is recent, and the tumour not of immoderate size, the reduction may be accomplished with tolerable ease, by putting the patient in a suitable posture, with the buttocks raised, and the thorax depressed, and by making gentle and skilful pressure, either with the palm of the hand, or fingers. When difficulty is experienced, the patient, if young or robust, may be bled; and the part be fomented. The large intestines may also be emptied by means of a mild unirritating clyster, and half an ounce of the oleum ricini should be exhibited. In the habitual prolapsus ani the patient himself is generally accustomed to reduce the part, or it goes up of itself when he lies down. When, however, the inflammation and swelling are urgent, the part ought on no account to be irritated with repeated attempts at reduction. The practitioner should rather have recourse to the antiphlogistic plan, especially leeches, fomentations, or cold washes, and the exhibition of the oleum ricini, and when the swelling has been lessened, the reduction may be again attempted. When the reduction is prevented by a spasmodic resistance, the use of an anodyne poultice, or fomentations, a clyster of the same quality, the warm bath, and the internal use of opium, are the best means. Should the complaint not give way to the preceding remedies, and the symptoms become more and more pressing, the particular situation of the stricture should be examined with a probe,

and divided either with a knife and director, or with a concealed bistoury. Some writers speak of the employment of a speculum ani; but on account of the globular form of the disease, it must be difficult of application. Cases are recorded, in which the protruded part, either in the state of gangrene or of chronic hardness, thickening, and elongation, has been removed with a knife, or ligature. (See *Cheselden's Anatomy, &c.* 1741: *Kerstens, Historia Sedis prociduæ, resectione feliciter sanata*, Kilon. 1779; *Whately, in Med. Tracts and Observ.* Vol. 8, No. 16.)

However, I should apprehend, that, in the circumstance of gangrene, the measures best calculated for stopping its course, detaching the sloughs, and keeping up the patient's strength, must always be more prudent, than such an operation.

The reduction having been effected, it is proper to introduce the fore-finger up the rectum, in order to ascertain that no intussusception exists above the anus within the sphincter. The bowel is then to be kept in its place by quietude in the recumbent posture, and, if there be a great tendency to relapse, it will be proper to apply to the fundament a piece of sponge, or compresses, supported with the T bandage. But, if such means should not answer, and an habitual prolapsus ani should recur again and again, which is not unfrequent where the disease has been neglected, or its causes have long remained unremoved, the apparatus described by Mr. Gooch may be tried with more hope of success. (*Chirurgical Works, Vol. 2, p. 150, Edit. 1792.*) Others have used perforated balls of ivory. Callisen found the introduction of a piece of sponge, within the rectum, fastened to a silver probe, give effectual support. In France, instruments, made of elastic gum, have been employed with advantage for supporting the rectum. (*Richerand, Nosogr. Chir. T. 3, p. 444, Ed. 4.*)

On account of the elasticity, and unirritating quality of this substance, I conceive it is better calculated than any other material for the construction of such instruments. It cannot be denied, however, that all foreign bodies in the rectum create serious annoyance. In the female sex, a vaginal pessary, rather prominent behind, usually hinders the recurrence of a prolapsus ani.

The late Mr. Hey has published some highly interesting remarks on the cure of the procidentia ani in adults. In one gentleman, the disease took place whenever he had a stool, and continued for some hours, the gut gradually retiring, and at last disappearing, until he had occasion to go again to the vault. After each stool, he used to place himself in a chair, and obtain a little relief by making pressure on the prolapsed part; and he then was in the habit of going to bed, where the intestine by degrees regained its natural situation. While the bowel was down, there was a copious discharge from it of a thin mucous fluid, blend-

ed with blood. When the part was up, the anus was constantly surrounded by a thin, pendulous flap of integuments, generally hanging down to the extent of three-fourths of an inch. Around the anus, there were also several soft tubercles of a bluish colour, situated at the basis, and at the inner part of the pendulous flap. These were evidently formed by the extremity of the rectum. The patient, previously to the establishment of these habitual attacks of prolapsus ani, had been afflicted for several years with pain after each stool, protuberances at the extremity of the rectum, and discharge of blood and mucus. For these complaints, he applied to Mr. Sharp, who gave him an ointment to be applied after each stool, some soapy pills to be taken, and recommended the use of a clyster a little before the time of going to stool. The latter remedy, however, could not be adopted, and no material benefit was derived from the others. Some years afterwards, when Mr. Hey was consulted, the foregoing symptoms continued, in addition to which there was the grievance of the prolapsus, which came on at every time of going to stool, and lasted for several hours. This judicious surgeon, at first, advised the patient to wash the prolapsed part with a lotion composed of an infusion of oak bark, lime-water, and spirit of wine, and keeping on the tumour compresses, wet with this fluid, and supported by the T bandage. The disease, however, was too obstinate to be cured by this treatment. Nor could Mr. Hey succeed in reducing the bowel, when it came down. "Although (says he) the prolapsed part of the intestine consisted of the whole inferior extremity of the rectum, and was of considerable bulk, yet, the impediment to reduction did not arise from the stricture of the sphincter ani; for, I could introduce my finger with ease during the procidentia; but, it seemed to arise from the relaxed state of the lowest part of the intestine, and of the cellular membrane, which connects it with the surrounding parts. My attempt proved vain, as to its immediate object, yet it suggested an idea which led to a perfect cure of this obstinate disorder. The relaxed state of the part, which came down at every evacuation, and the want of sufficient stricture in the sphincter ani, satisfied me that it was impossible to afford any effectual relief to my patient, unless I could bring about a more firm adhesion to the surrounding cellular membrane, and increase the proper action of the sphincter. Nothing seemed so likely to effect these purposes, as the removal of the pendulous flap, and the other protuberances, which surrounded the anus." This operation was performed on the 13th of November. On the 15th the gut protruded, and did not gradually retire, as it used to do. Mr. Hey attempted to procure ease by means of opiates and fomentations, and avoided immediately trying to reduce the prolapsed part. However, the prolapsus

continued so long, that the appearance of the part began to alter, and, therefore, on the 16th he made an attempt at reduction, and succeeded with great ease. However, as a good deal of pain in the hypogastrium was still complained of, the patient was bled in the evening, and gently purged with the oleum ricini. These means gave relief; but, as some pain in the belly yet continued, an opiate was given. A low diet, linseed tea, lac amygdalæ, &c. were ordered, and a little of the oleum ricini every morning, or every other morning, with an opiate after a stool had been procured. "By proceeding in this manner for some days, regular stools were procured, without any permanent inconvenience. My patient recovered very well, and was freed from this distressing complaint, which had afflicted him so many years." (See *Hey's Pract. Obs.* p. 438, &c. Ed. 2.)

This, and some other cases, which this gentleman has related, convincingly exemplify the necessity of paying attention to the removal of excrescences, hemorrhoids, and other tumours, situated about the lower part of the rectum, in cases of prolapsus ani: for, unless this object be accomplished, the disease may resist every other treatment, and afflict the patient, as long as he lives, in the manner so well described in the above example. An elderly gentleman, whom I know, was troubled for many years with a prolapsus ani, which used to come on several times a week, sometimes at the vault, and sometimes at other periods. Several of the first surgeons were consulted, who failed in affording permanent benefit, because they omitted to extirpate some hemorrhoidal excrescences, situated at the lower part of the rectum; for, when these were afterwards removed, the prolapsus ani entirely disappeared.

The last indication in the treatment is the removal, and avoidance, of all such causes as are known to have a tendency to bring on the complaint. In infants, making them sit on a high close-stool, with their feet hanging freely down, will often prevent a fresh protrusion of the rectum. Every thing, tending to cause either diarrhœa, or costiveness, should be avoided. In the generality of cases, however, there is an inclination to costiveness, which must be obviated by the mildest means. For this purpose Mr. Hey used to prescribe half an ounce of the oleum ricini, which is to be taken every morning, or every other morning, as circumstances may require. The same practitioner sometimes also employed, in addition to this medicine, a clyster composed of a pint of water gruel, and a large spoonful of treacle. The tone of the relaxed intestine is to be restored by the continued use of cold clysters made with the decoction of oak bark, alum, and vinegar. In one obstinate case, under the care of the late Mr. Hey, he recommended the following lotion for washing the part affected, during the state of prolapsus, and he also advised its application to the anus in

the intervals, by means of a thick compress, supported by the T bandage. R. Aquæ calcis simplicis ℞ij. Cort. Quercus contus. ℥iv. f. infusum per hebdomadam, et colatura adde Sp. Vini rect. ℥iv. ft. lotio. (See *Hey's Pract. Obs.* p. 442, Ed. 2.)

Too much irritability of the rectum may be lessened with opium.

The intussusception of the higher part of the bowel, especially of the colon, or cœcum, causing a protrusion at the anus, is always incurable, as it is not in the power of art to rectify the displacement. Some extraordinary cases have proved, however, that large portions of the intestinal canal may, thus inverted, be separated and voided, and the patients recover. (See *Intussusception*.)

According to Mr. Travers, when an artificial anus is complicated with prolapsus, the case very rarely admits of cure. (See *Inquiry into the process of Nature in repairing Injuries of the Intestines*, p. 374.)

Surgical writers have been too much in the habit of confounding together prolapsus ani and intussusception. In the latter disease, they have even fallen into the error of supposing that the whole of the rectum becomes everted, in consequence of the relaxation of the sphincter and levatores ani, and that it then draws after it other portions of the intestinal canal. But, they ought to have been undeceived by the strangulation, which sometimes occurs under such circumstances, and which not only throws a great obstacle in the way of the reduction of the displaced part, but even sometimes brings on mortification. Besides, the connexions of the rectum with the neighbouring parts, by means of the cellular substance, which surrounds it, and the attachment of this intestine to the posterior surface of the urinary bladder, render the above origin of the complaint impossible. Such an explanation could only be admitted with regard to those protrusions of the rectum, which come on in a very slow manner. This account could not afford a satisfactory explanation of certain cases, in which the everted intestine presents itself in the form of an enormous tumour. Fabricius ab Aquapendente mentions his having seen tumours occasioned by a prolapsus of the rectum, which were as long as the fore-arm, and as large as the fist. In the *Mélanges des Curieux de la Nature*, we find an account of a tumour of this sort which was two feet long, and occurred in a woman from parturition. Nor is a more satisfactory reason assigned for these cases, by supposing, that they originate from a relaxation of the villous coat of the rectum, and its separation from the muscular one. We are not authorized to imagine, that such a separation can take place to a considerable extent, nor so suddenly, as to give rise to the phenomena, sometimes remarked in this disease.

Accurate observations long ago removed all doubt upon this subject. In the eleventh volume of the *Mémoires de l'Académie de Chirurgie*, edit. in 12mo. we read an account

of a pretended prolapsus of the rectum, which, after death, was discovered to be an eversion of the cæcum, the greater part of the colon being found at the lower end of this intestine, and most of the rectum at its upper part. This eversion began at the distance of more than eleven inches from the anus, and terminated about five or six from this opening, the tumour, formed by the disease, having been reduced some time before the child's death. It was impossible to draw back the everted part, in consequence of the adhesions, which it had contracted. Another dissection evinced the same fact. A child, having suffered very acute pain in the abdomen, after receiving a blow, had a prolapsus of intestine through the anus, about six or seven inches long. This was taken for a prolapsus of the rectum. After death, the termination of the protruded bowel was found to be the cæcum, which had passed through the colon, and rectum. (See *Intussusception*.)

ANUS, ARTIFICIAL.

This signifies an accidental opening in the parietes of the abdomen, to which opening some part of the intestinal canal tends, and through which the feces are, either wholly or in part, discharged.

An artificial anus is always preceded by an injury of the intestinal canal, either a penetrating wound of the abdomen, ulceration of the bowel, and the bursting of an abscess externally; an operation in which the preternatural opening is purposely made, with the view of saving life in particular cases of imperforate anus; and accidental wound of the gut in the operation for hernia; or, lastly, and, most commonly, mortification of the bowel, the effect of the violence and long continuance of the strangulation of the part. All these cases are further divisible into such, as are attended with a destruction of a portion of the intestinal tube, and into those, which are not accompanied with any such loss of substance. Whatever may be the kind of injury, which the bowel has sustained, one thing here invariably happens, viz. the adhesion of the two divided portions of the intestine to the edge of the opening in the parietes of the abdomen. This occurrence, which has the most salutary effect in preventing extravasation of the contents of the bowel in the cavity of

the abdomen, is produced by inflammation, which precedes gangrene, and follows wounds. (See *Œuvres Chir. de Desault, T. 2, p. 352—354.*)

When, in strangulated hernia, the case is not relieved by the usual means; or when the necessary operation has not been practised in time; the protruded bowel sloughs; the adjoining part of it adheres to the neck of the hernial sac; and the gangrenous mischief spreads from within outwards. If the patient live long enough, and an incision in the tumour be now practised, one or more openings soon form in the integuments, and, through these apertures, the feces are discharged, until the separation of the sloughs gives a freer vent to the excrement. But when an incision is made, the feces are more readily discharged, and, as Mr. Travers has related, this is sometimes the best mode of relief.

"In the ordinary situation of hernia, (as this gentleman has correctly explained,) the portions of intestine, embraced by the stricture, occupy a position nearly parallel. Their contiguous sides mutually adhere; in the remainder of their circumference, they adhere to the peritoneum, lining, or forming the stricture. The existing adhesion of the contiguous sides, strengthened by the adhesion of the parts in contact, ensures a partial continuity upon the separation of the sphacelated part. The line of separation is the line of stricture. It commences on that side of the gut, which is in direct contact with the stricture. As the separation advances, the opposite adhering sides may perhaps recede somewhat, and a little enlarge the angle of union. But, it is ever afterwards an angle; and, where the peritoneum is deficient, the canal is simply covered in by granulations from the cellular membrane of the parietes, coalescing with those of the external, or cellular surface of the peritoneum." (*On the process of Nature in repairing Injuries of the Intestines, p. 360.*) It must be confessed, that few surgeons have entertained sufficiently accurate ideas of the changes, which happen around the wounded, or mortified portion of intestine, when an artificial anus is produced; and though Desault's account was excellent, as far as it went, it was not until the year 1809, when Scarpa published his valuable work on Hernia, that the whole process of nature on such occasions was completely elucidated. The hernial sac, (says he) does not always partake of gangrene with the viscera contained in a hernia, and even when it does slough, since the separation of the dead parts happens on the outside of the abdominal ring, there almost always remains in this situation a portion of the neck of the hernial sac perfectly sound. It may be said therefore, that, in all cases, immediately after the detachment of the mortified intestine, whether it happen within, or on the outside of the ring, the two orifices of the gut are enveloped in the neck of the hernial sac, which, soon becoming adherent to them by the effect of in-

inflammation, serves for a certain time to direct the feces towards the external wound, and to prevent their effusion in the abdomen. In proportion as the outer wound diminishes, the external portion of the neck of the hernial sac also contracts; but, *that part, which embraces the orifices of the intestine, gradually becomes larger, and at length forms a kind of membranous funnel-shaped, intermediate cavity, which makes the communication between the two parts of the bowel.* However, according to Scarpa's investigation, this adhesion of the neck of the hernial sac, round the two orifices of the gut, does not hinder the latter from gradually quitting the ring, and becoming more and more deeply placed in the cavity of the abdomen. The base of the above described funnel-shaped membranous cavity corresponds to the bowel, and its apex tends towards the wound, or fistula.

But, in relation to this part of the subject, there are some other circumstances which every surgeon should well understand, and his ignorance of them would not be excusable, on the ground of their not having been, like the funnel-shaped membranous cavity, forming the communication between the two orifices of the bowel, only a discovery of recent date; for, they were fully explained many years ago. I here allude to the exact position of the two portions of the bowel, with respect to each other, the direction of their orifices, the angle, or ridge between them, and the difference in their diameters. The first of these circumstances, viz. the position of the two parts of the bowel, as we have seen, is pointed out by Mr. Travers, who represents them as occupying a position nearly parallel, and cites an interesting observation recorded by Pipelet. The patient was a woman, 56 years old; the loop of spoiled gut was from five to six inches long; the contents of the bowel were discharged through the wound for a considerable time, and an artificial anus was established. Some accidental obstruction occurred; a purgative was given, which operated in the natural way, and, in fifteen days, the wound was healed. She lived in perfect health to the age of 82, when she died of a disease not connected with this malady. Pipelet examined the body, and has given a figure representing the union. The line of the intestine formed an acute angle, where it adhered to the peritoneum, opposite to the crural arch. The cylinder is evidently much contracted. Pipelet particularly dwells upon the angular position and constriction of the tube at the point of union. The lower continuation of the intestinal tube was also remarked to be more contracted than the upper portion, a circumstance correctly referred by Mr. Travers, to the undilated state of the bowels, situated between the artificial and the natural anus. (See *Mém. de l'Acad. de Chir. T. 4, p. 164, and Travers on Injuries of the Intestines, p. 364.*) The two ends of the bowel, as Scarpa has observed, are always found lying in a more or less paral-

lel manner by the side of each other; the upper, with its orifice open, and directed towards the external wound by the feces, which issue from it, while the lower, which gives passage to nothing, becomes less capacious, and is retracted further into the abdomen. Hence, the breach in the intestinal canal is never repaired by the orifices of the upper and lower portions of the bowels reuniting, coalescing, and running, as it were, into each other. Indeed, they meet at a very acute angle; the axis of one does not correspond to that of the other; and their orifices never lie exactly opposite each other. It is in short by means of the funnel-shaped cavity, formed by the remains of the hernial sac, that the two parts of the bowel communicate, and the feces, in order to get from the upper into the lower continuation of the intestine, must first pass in a semicircular track through that funnel-shaped cavity, there being between the orifices of the bowel, directly opposite to the communication between the cavity of the intestine and that of the funnel-shaped membrane, *a considerable projection, or jutting angle, forming a material additional obstacle to the direct passage of the feces from the upper into the lower portion of the intestinal tube.* (Scarpa sull' *Ernie Memorie, Anat. Chirurgiche, Milano, 1809.*)

Desault, after noticing the efficiency of the adhesions between the injured part of the bowel and the edge of the opening in the parietes of the abdomen, in preventing extravasation, remarks, that, if such adhesions were entire, the abdominal parietes would form a substitute for the portion of the canal, which has been destroyed, and the contents of the bowel would continue to pass, as usual, towards the anus, if the portions of the intestine separated and adherent to the neighbouring parts, did not form such an acute angle as obstructs the passage of the intestinal matter. The more acute this angle is, the greater is the obstruction; when the two parts of the bowel lie nearly parallel, the entrance into the lower portion of the canal is completely prevented; but, if they meet at a right angle, then more or less of the contents of the upper portion may be transmitted into the lower. The first disposition chiefly happens when a considerable part of the intestinal canal has been destroyed, or when the tube has been completely divided; while the second posture is principally remarked in all cases where the injury has been less extensive. And it is plain, that the possibility of a cure depends materially on the kind of angle, at which the two portions of bowel meet, and that the projection of the internal frænum, or jutting membranous ridge between the two orifices, is always a greater or lesser obstacle to the cure.

With respect to the diminution, which occurs in the diameter of the part of the intestinal canal, between the artificial opening and the natural anus, Desault admits the correctness of the observation, but entirely dissents from such authors as have

spoken of the change, as sometimes proceeding so far, that an obliteration of that portion of the intestinal tube is the consequence. The mucus secreted within it suffices for preventing this obliteration; a secretion which, in these cases, is copious, and is partly voided from the rectum, in the form of white flakes. And, if any further proof were needed, that the bowels between the artificial and natural ani remain pervious, it is furnished by the fact, that, in cases of artificial anus, the lower continuation of the tube frequently becomes inverted, and protrudes. On the other hand, the kind of obliteration, above spoken of, has never been demonstrated by dissection: it was not observed by Lecat, in the examination of the body of a person who died twelve years after the entire cessation of the passage of feces *per anum*; nor was it found to exist by Desault, when he opened a patient who died of marasmus in the Hotel-Dieu, in consequence of an artificial anus, which communicated with the ileum, and had lasted two years. (*Œuvr. de Desault, T. 2, p. 354-56.*)

However proper the formation of an artificial anus may be, in many cases, in which the patient's life depends upon the event, it must be confessed, that the consequence is a most afflicting and disgusting infirmity. This truth cannot be denied, though the feces which are discharged, from not having been so long retained in the bowels, may not be so fetid as those which are evacuated in the ordinary way. As the opening, which gives vent to the excrement, is not endued with the same organization as the lower end of the rectum, and as, in particular, it is not furnished with any sphincter capable of contracting and relaxing itself, as occasion requires, the feces are continually escaping without any knowledge of the circumstance on the part of the patient. Hence the uncleanly state of the parts around the external opening; and their frequently excoriated fungous state. Some persons in this state, among the number of those whose histories are on record, have made use of a metal box, in which their excrement has been received. Schenckius relates the case of an officer who was wounded in the belly, and who allowed his feces to escape into a vessel made for the purpose. Dionis makes mention of a similar case. What occurred to an invalid soldier, says this eminent writer, is too singular to serve as an example in practice, since nature alone preserved him, by making the wound of the abdomen serve as an opening for the discharge of his feces. The intestine has become adherent to it, and he daily evacuates his excrement through this opening. The matter coming away involuntarily, necessitates him to have a tin box for its reception.

Moscatti also communicated to the Academy of Surgery, the history of a wounded man, in whom an artificial anus took place, in consequence of a wound in the abdomen

below the right hypochondrium. His excrement used to be received in a tin box, fastened to him by a belt. The above surgeon very properly remarks, as rather a singular circumstance in this wound, that it admitted of a leaden cannula being introduced, to which cannula the tin box was accommodated.

Uncleanliness is not the only inconvenience of an artificial anus. Persons have been known to be quite debilitated by the affliction, and even ultimately to die in consequence of it. This is liable to happen, whenever the intestinal canal is opened very high up, so that the aliment escapes before chyfication is completed, and the nutritious part of the food has been taken up by the lacteals. In this circumstance, the patient becomes emaciated, and sometimes perishes, as Desault had an opportunity of observing, and examples of which are also recorded by Hoin and Le Blanc. In cases of this description, the matter voided has little fetor, and is frequently sourish. In all instances, the matter is evacuated involuntarily, because there is nothing like a sphincter. But, when the opening only interests the lower convolutions of the ileum, or, what is more frequent, when it has occurred in the large intestines, the danger is less serious, and patients, in this state, are often noticed performing all their functions very well, and, with the exception of colic, to which they are subject, enjoying as good health as they did previously to their having the present disease. In such examples, the matter voided is more fetid, its discharge does not follow so quickly its introduction into the stomach, and it is retained for a longer time.

Many patients, afflicted with an artificial anus, void no feces at all from the rectum; but they occasionally go to the vault, for the purpose of voiding a thick whitish substance, which is the mucous secretion of the portion of the large intestines nearest to the anus. Under certain circumstances, the quantity of this mucus discharged is more copious. (*Desault, Vol. cit. p. 359.*)

The most grievous occurrence, to which persons with an artificial anus are exposed, is a prolapsus of the bowel, similar to what sometimes happens through the anus, with respect to the rectum. The descent of the bowel is sometimes simple, only affecting a portion of the intestinal canal just above or below the opening. On other occasions, the complaint is double, the bowel both above and below the opening being prolapsed. This descent of the intestine forms a tumour, the dimensions of which vary considerably in the different subjects in whom it is observed. When the protrusion is caused by the upper part of the intestinal canal, the feces are voided at the extremity of the tumour, and, when the swelling consists of the lower portion of the bowel, the excrement is evacuated at the base of the prolapsed part. By observing this evacuation, when the tumour is double,

it is easy to know to which end of the intestinal canal each protruded portion belongs. This consequence of an artificial anus is very serious, because it greatly increases the inconvenience which the patient suffers. Sometimes, the tumour is exquisitely sensible; and, occasionally, when the eversion of the intestine is considerable, a strangulation is produced, which puts the patient's life in danger.

I apprehend no well-informed surgeon of the present day can doubt, that formerly the frequency of artificial ani after hernia, was seriously increased by the absurd measures sometimes adopted for the express purpose of preventing them: and, as Mr. Travers has rightly observed, the cases reported by the old surgeons, if they prove any thing, prove this: "that the canal has been very generally restored, when the artificial anus was reckoned upon as inevitable, and that where an officious solicitude had been at work to prevent it, showing itself in an active interference with the arrangements of nature, the case has terminated in artificial anus; so that the event, either way, has been a matter of surprise to the surgeon. The fear of doing too little, or too much, applies only to the pernicious customs of dilating the stricture, displacing, amputating, and sewing the intestine; the general adoption of which practice fully accounts to my mind for the number of artificial ani, which are the sequelæ of hernia." (*Op. cit.* p. 367.)

The treatment of an artificial anus, is either palliative, or radical. The first consists in obviating the habitual uncleanness, produced by the involuntary discharge of the intestinal matter, and in relieving such bad symptoms, as may arise from the disorder.

The first indication is fulfilled by the employment of silver, or tin machines, which are either kept applied to the external opening by means of a spring, or form receptacles placed more or less off the artificial anus, from which the intestinal matter is transmitted through a tube, kept constantly in the opening. In general, says Desault, as elastic gum is supple, light, and capable of taking any shape, it is the best material for the construction of such instruments, which, however, rarely answer their purpose completely, and always give the patient a great deal of trouble.

As for the second indication, Richter, with the view of hindering the too quick escape of the intestinal matter, and the death of the patient from this cause, proposed covering the opening for a certain time with a piece of sponge, supported by an elastic bandage, or truss. But Loeffler found this method objectionable, as it was apt to bring on colic, constipation, and inflammation, and excoriation of the skin.

When the outer opening is disposed to contract too much, and inconveniences arise from this change, Sabatier is an advocate for preventing such closure by means of a tent, or skein of silk, introduced into

the aperture, and changed very often for the sake of cleanliness; while others prefer a ring of ivory for the purpose. But the irritation produced by the matter imbibed by this sort of tent, and in particular the liability of the bowel to protrude, and be strangulated in the opening of the ivory ring, are found strong objections to these practices; and, according to Desault, the sponge, employed by Richter, also occasions a great deal of excoriation by the irritation of the fluid which is lodged in it.

For the purposes of hindering a protrusion of the gut, of keeping the opening sufficiently pervious, of relieving any uneasiness and tenesmus, of hindering the intestinal matter from escaping in the intervals of dressing, and confining it long enough for the adequate nourishment of the patient, Desault preferred a linen tent, or stopper, covered by a pad of charpie, compresses, and a tight bandage. At first, says he, the patient feels some uneasiness from this plan, and slight colics may be the consequence of it; but, by degrees, the parts become habituated to their new state, and every thing goes on well. With respect to the employment of tents and plugs, with the views above indicated, I am disposed to think the practice can rarely be advisable, and that any necessity for it may be obviated by attention to diet, and the occasional exhibition of laxative medicines and clysters, as will be hereafter noticed. When the gut protrudes, its reduction is to be effected in the same way, as a common prolapsus ani; but considerable difficulty will occur when the protruded part is inflamed, thickened, and of considerable size. Surgeons, indeed, have usually regarded the reduction as being impracticable in these circumstances; but, according to Desault, this is not the case, as compression with a bandage, kept up for some days, will succeed. Care must be taken, however, to leave a sufficient opening for the passage of the feces. Whatever may be the size of the protrusion, Desault argues, that it should be the invariable rule of the surgeon to endeavour to return the part by the means here suggested. (*See Œuvres Chir. de Desault, T. 2, p. 361, &c.*)

The radical cure is what is next to be considered. The business of the surgeon is to prevent, if possible, the formation of an artificial anus; but, when the event has occurred, and, particularly, when the whole, or the greater part, of the stools is discharged in this way, no attempt must be made to stop up the opening, without a great deal of consideration; for, any effort of this kind, made under circumstances which do not justify it, may be the means of exposing the patient's life to the most alarming danger. Sometimes, indeed, without any interference of the surgeon, the outward opening contracts, and, the issue of the intestinal matter being obstructed, pain and tenesmus are excited; and the same consequences may be produced by any swelling and enlargement of the

projecting ridge, situated between the two portions of the bowel. In two cases, Puy found this swelling take place in such a degree, that the patients fell victims to the complete stoppage of the intestinal contents. The symptoms which arise, are then similar to those which happen in strangulated hernia. Hoin, Le Blanc, and Sabatier, also cite instances, in which the patients lost their lives by gangrene being brought on by this species of strangulation. (*Desault, Vol. cit. p. 360.*)

There is a period (says Mr. Travers,) at which the function of the lower portion of the canal, with a little assistance, may be restored. The natural order of events, connected with this recovery, has been mistaken and inverted. Practitioners have closed the wound, instead of conducting the matter by purgatives and clysters into the large intestines. Now, the wound will never fail to heal, when the matter recovers its accustomed route; but, this condition cannot be reversed. The restoration is safest, when most gradual; when there is evidence of an existing sympathy between the repair of structure, and the return of function. According to the same gentleman, there is reason to believe, that the well-timed exhibition of a single purgative might often prove effectual. "If the food is rapid, and little changed, in its passage, it should be pultaceous and nutritive, and given in moderate quantity at short intervals; while injections of the same kind should be administered at least twice in twenty-four hours, and retained as long as possible." He states, that, by such means, patients may be nourished for many weeks. If the discharge is sparing, and does not readily escape, he recommends an occasional purgative in less than ordinary quantity. He disapproves of other medicines, especially stimulants, and all such food as is difficult of digestion, giving a general preference to animal food in a gelatinous form. He bestows just praise on strict attention to cleanliness, and in opposition to Desault and Sabatier, condemns the employment of tents and sponges. (*Op. cit. p. 371, 373.*)

Numerous cases on record furnish abundance of proof, that the feces, after being voided for several months from the wound, produced by the operation for hernia, frequently resume their natural course. Facts of this kind, which in general may be said to be common where the intestine is without loss of substance, are not very rare even where more or less of the bowel has been destroyed by gangrene; and many illustrations of this remark may be found in the writings of Petit, Pott, Le Dran, &c. The greater number of these instances of success, as already stated, were the result of the most simple, unofficious treatment, or rather of the undisturbed, and very little assisted, efforts of nature.

In the radical cure of an artificial anus, the following are the general indications laid down by Desault: 1. To reduce the

gut when it protrudes, and is everted. 2. To prevent the issue of the feces from the wound, so that they may be obliged to pass on towards the rectum, at the same time that the healing of the external opening is to be promoted. 3. To obviate any internal impediments to the passage of the matter into the lower part of the intestinal canal.

How the first of these objects is to be accomplished in the case of greatest difficulty, that is, when the parietes of the bowel are thickened, has been already explained. Experience proves, says Desault, that the second indication cannot be fulfilled by means of sutures. The best thing for this purpose he represents to be the linen stopper, above spoken of as a means for preventing the protrusion of the bowel. Here it answers the double object of hindering such a protrusion, and filling up the fistulous opening, so as to make the contents of the bowel tend towards the anus. Desault argues, that the surgeon need not be apprehensive of the tent doing harm by keeping the wound from healing. The first aim, he says, should be to determine the feces to take their natural route; and when this has been done by closing the external opening, the tent may be removed, and this opening will spontaneously close.

However, when the internal impediment is too great, it must be overcome, ere such treatment can be successful. According to Desault, the most frequent impediment, here alluded to, is the angle formed by the two portions of the intestine, and it must be enlarged, and rendered less acute, in order that the feces may continue their route. This desirable change he recommends to be effected by introducing long dossils of charpie into the two ends of the bowel, and gradually altering their direction so as to bring it into one same straight line. When the dilatation is sufficient, and the inner angle, or ridge, is effaced, the long dossils need not be continued. The linen tent, with the precaution of not introducing it too deeply, lest it obstruct the course of the feces itself, will then suffice. When this plan is skilfully managed, Desault says, there will be a great chance of its succeeding, and its beneficial effect will be denoted by a rumbling in the bowels, and frequently by slight colics. At first, wind is discharged from the rectum, and, soon afterwards, the feces begin to come away. On the contrary, if they should not pass with facility, the colic should become violent, and an accumulation happen in the upper portion of the intestinal canal, the tent must be withdrawn, and the other cause of obstruction be considered, and, if possible, removed. (*Vol. cit. p. 365, &c.*)

In the preceding columns, I have given a full explanation of the impediment, made to the passage of the feces into the lower orifice of the intestinal canal, by the projecting septum, or ridge between the two parts of the bowel, and the matter having to traverse the funnel-shaped membranous

cavity in quite a semicircular track. A representation of this septum may be seen in Scarpa's work. Tab. 9, Fig. 1. and also in the sixth plate of Mr. Travers's Inquiry. In one example, in which this septum was plainly visible in the wound, Dupuytren passed into the orifice of the upper part of the bowel a curved needle, and, passing it through the projecting septum, brought it out again through the orifice of the lower portion of the gut. Thus, he included a considerable part of the septum in a ligature, which was daily made thicker, with a view of first exciting inflammation in the two layers of this septum, and thus ensuring their adhesion together, and his next plan consisted in making a division through the part embraced by the ligature, whereby, the passage of the feces into the lower portion of the bowel was made quite free. But, as the section, made by the ligature, was too superficial, Dupuytren completed the division of the septum with a knife; but peritonitis and the death of the patient ensued. In another case, this eminent surgeon tried to render the layers of the septum adherent by compressing them between the blades of a pair of forceps of particular construction, and afterwards he effected the division of the part by augmenting the compression, by means of a screw, traversing the handles of the instrument. In a case which followed the operation for the bubonocoele, attended with mortification of the bowel, Dupuytren began with dilating the outer opening with a bistoury, and, after ascertaining the position of the septum between the two orifices of the bowel, he introduced one of the blades of the forceps into each portion of the gut, and closed the instrument with the screw. The part of the instrument, situated externally to the ridge, or septum, he covered with charpie and a compress. The constriction was soon followed by colic pains, and tendency to vomit, which symptoms, however, were quickly removed by fomenting the belly. They recurred, however, the instrument became loose, and some discharge ensued. On examination, the septum was found to be partially divided. After the breadth of the instrument had been lessened, it was applied again; but when the screw was turned, the patient began to suffer such violent pain over the whole of the abdomen, that it was necessary to diminish the pressure; and, as the instrument was afterwards separated from the parts in a fit of vomiting, it was withdrawn. A trial was now made to determine the feces towards the rectum by pressure on the external opening; but the plan could not be endured, and the hinderance to the egress of the intestinal matter was so oppressive, that it was discontinued. As the forceps used on the foregoing occasion, did not take sufficient hold of the septum, nor divide it properly, the instrument was somewhat altered. Dr. Reisinger has published three cases, in which it was successfully employed by Dupuytren. In the first of these examples when the instrument had

been applied, it embraced the septum so well, that it could not be displaced from it. The colic attacks, vomiting, thirst, furred tongue, and loss of appetite, which ensued, soon gave way after the belly had been fomented; the constriction was then increased, and found to produce less and less indisposition. On the 29th, very little of the feces came out of the artificial anus, and, after a short time five natural evacuations took place. The blades of the instrument were now completely closed, and, on taking it out, a slough of membrane was found between the blades; a proof, that the septum was destroyed. On the 30th, the patient's health was undisturbed. Clysters was now administered, with the view of promoting evacuations in the natural manner; and, the next day, the patient had a proper motion, without any assistance, and a very small quantity of the feces passed out of the fistulous opening. This aperture was now merely covered with charpie; but, as some high granulations were rising, the powder of colophonium was sprinkled upon them, and compresses and a bandage were applied. The use of clysters was also daily continued, though the patient voided his feces in the natural way. On discontinuing the external pressure, the quantity of discharge from the fistulous opening increased; and, therefore, on the 1st of October, the compresses were again applied, and kept on the part with a spring truss. The treatment ended in a perfect cure.

In another case, Dupuytren enlarged the lower angle of the outer opening with a bistoury, and, after feeling with his finger, that both orifices of the bowel were close to that opening, he applied the forceps. In the evening, the constriction was increased, which was followed by severe colic pains over the whole abdomen. They subsided, however, the following day. From the outer opening, a great deal of slimy excrement was discharged. The constriction was not augmented. On the 5th day, the patient was attacked in the night, with pain and vomiting. The following night was also very restless. Though the belly was not tense, it could not bear to be touched. On the 11th and 12th days, the patient was nearly free from pain; and, by means of clysters, two natural motions were procured; and, on the 13th, as the patient was easy, Dupuytren began to make pressure on the fistulous opening. On the 26th, the edges of the aperture were touched with lunar caustic; and, on the 28th, a compress, supported by a spring truss, was applied. The patient was kept constantly in the horizontal posture; the feces began to be voided the natural way regularly, and the opening contracted in the most favourable manner.

I think the generality of surgeons will agree with Dr. Reisinger, that the foregoing treatment cannot be indiscriminately adopted, in all descriptions of patients, without danger. It should never be tried too soon after the formation of an artificial anus; but time should be allowed for the irritability

and sensibility of the gut, and especially of the septum, to be lessened by the effect of the air and the pressure of the feces. Nor should the trial ever be made ere it has been fully ascertained, that nature cannot herself bring about the cure. Many other interesting observations on this new proposal may be perused in Dr. Reisinger's tract, the title of which is given in the list of works at the end of the present article. In order not to incur the risk of extravasation of the feces in the abdomen, the constriction of the septum should never be increased with imprudent haste, before the adhesive inflammation has had time to be produced between the layers, of which that part is composed.

I shall conclude with the relation of an interesting case of artificial anus, complicated with prolapsus, as recorded by my friend Mr. Lawrence.

"If the complaint (a mortified hernia) terminates in the formation of an artificial anus, we must endeavour to alleviate those distressing inconveniences, which arise from the involuntary discharge of wind and feces through the new opening, by supplying the patient with an apparatus, in which these may be received as they pass off. An instrument of this kind, the construction of which appears very perfect, is described by Richter (*Anfangsgr. der Wundarzn.* vol. 5.) from the *Traité des Bandages* of Juville. The patient will be best enabled to adapt any contrivance of this sort to the particular circumstances of his own case. It has been found, in some instances, that a common elastic truss, with a compress of lint under the pad, has been more serviceable than any complicated instrument (*Parisian Journal*, vol. 1. p. 193.) in preventing the continual flow of feculent matter from the artificial opening." (*Treatise on Hernia*, p. 206.)

"I know," says Mr. Lawrence, "a patient with an artificial anus, in whom the gut often protrudes to the length of eight or ten inches, at the same time bleeding from its surface. This is attended with pain, and compels him to lie down; in which position the intestine recedes. The patient has now discharged all his feces at the groin for fifteen years; and has enjoyed tolerable health and strength during that time. His evacuations are generally fluid; but sometimes of the natural consistence. Whenever he retains his urine, after feeling an inclination to void it, a quantity of clear, inoffensive mucus, like the white of an egg, amounting to about four ounces, is expelled from the anus; and this may occur two or three times in the day." (P. 208.)

When the protruded intestine is strangulated, an operation may become necessary for the removal of the stricture. (*Schmucker, Vermischte Chirurgische Schriften*, t. 2.) Two cases which terminated fatally from this cause, are mentioned by Sabatier, in a memoir in the 5 tom. de l'Acad. de Chir. Mr. Lawrence also refers to Le Blanc *Précis d'Opérations de Chir.* tom. 2. p. 445. We should always endeavour to prevent such protrusions, when a disposition to their for-

mation seems to exist by the use of a steel truss, which should, indeed, be worn by the patient, independently of this circumstance. If the tumour has become irreducible by the hand, an attempt may be made to replace it by keeping up a constant pressure on the part, the patient being at the same time confined to bed. By these means, as we have already noticed, Desault, (*Parisian Journal*, vol. 1. p. 178.) returned a very large prolapsus, and, by pressure on the opening, the feces were made to pass entirely by the anus, although, for four years, they had been voided only through the wound. (*Lawrence*, p. 209, 210.)

In cases of mortified hernia, the wound sometimes closes, except a small fistulous opening, which discharges a thin fluid, and cannot be healed. Mr. Lawrence has related, in his excellent treatise on hernia, a case, in which the feces came from the wound some time after an operation, although the bowel did not appear gangrenous when this proceeding was adopted. (P. 211.)

In the appendix to this work, the author adds some further account of the case of artificial anus, which he has related. (P. 208.) The man is sixty years of age, and appears to be healthy, active, and even younger than he really is. He had had a scrotal hernia, which ended in mortification, and involved the testicle of the same side, and a large portion of the integuments, in the destruction. It is now nearly seventeen years since this event, and the feces have, during all this time, been discharged from the groin. He has never made use of a truss, nor taken any step, except that of always keeping a quantity of tow in his breeches.

The prolapsed portion of intestine varies in length and size at different times. It was four inches long when Mr. Lawrence saw it, and the basis, which is the largest part, measured nearly six inches in circumference. The prolapsus never recedes entirely, and it has occasionally protruded to the length of eight or ten inches, being as large as the forearm, and emitting blood. This occurrence is painful, and only comes on when the bowels are out of order. Warm fomentations, and a recumbent position, afford relief, and accomplish a reduction of the bowel.

The projecting part is of an uniform red colour, similar to that of florid and healthy granulations. The surface, although wrinkled and irregular, is smooth and lubricated by a mucous secretion. It feels firm and fleshy, and can be squeezed and handled without exciting pain. The man has not the least power of retaining his stools. When these are fluid, they come away repeatedly in the course of the day, and with considerable force. When of a firmer consistence, there is only one stool every one or two days, and the evacuation requires much straining. Such feces are not broader than the little finger. When the patient is purged, the food is often voided very little

changed. This is particularly the case with cucumber. In this state, he is always very weak. Ale is sometimes discharged five minutes after taken, being scarcely at all altered. The bowels are strongly affected by slight doses of purgatives.

Consult Sabatier, in *Mém. de l'Acad. de Chirurgie*, t. 5. 4to. and in *Médecine Opératoire*, t. 2. *L'Encyclopédie Méthodique*, Partie Chirurg. Richter's *Anfangsgr. der Wundarzn.* Band 5. J. R. Tieffenbach, *Vulnerrum in intestinis lethalis occasione casus rarissimi, quo colon vulneratum, inversum per 14 annos ex abdomine propendens exhibetur*; Haller's *Disp. Chir.* 5. 61. *Parisian Surgical Journal*, v. 1. *Œuvres Chirurg. de Desault* par Bichat, t. 2. p. 352, &c. Schmucker's *Chirurgische Schriften*, vol. 2. Lawrence's *Treatise on Hernia*. Callisen's *Systema Chirurgiæ Hodiernæ*, t. 2. p. 710, &c. Travers, *Inquiry into the Process of Nature in repairing Injuries of the Intestines*, chap. 8. 8vo. Lond. 1812. Scarpa sull' *Ernie Memorie Anatomico-Chirurgiche*, fol. Milano, 1800. *Anzeige einer von dem H. Professor Dupuytren erfundenen, und mit dem glücklichsten Erfolge ausgeführten Operationsweise zur Heilung des Anus Artificialis, nebst Bemerkungen von Franz Reisinger*; Augsburg, 1817. Hennen's *Military Surgery*, p. 407, &c. ed. 2. 8vo. Edinb. 1820. Three cases from gunshot wounds; the cure effected by aiding nature with the exhibition of occasional laxatives and clysters. All irritating plans were avoided. Scarpa represents the artificial ani, which follow wounds, as far more difficult of cure, than those, which are the consequence of hernia, with mortification; yet I have known many of the first description of cases cured.

*AORTA. Aneurisms of this vessel have already been treated of; but there are a few other particulars, relating to this important artery, which seem to merit notice in a dictionary of surgery.

WOUND OF THE AORTA NOT ALWAYS FOLLOWED BY INSTANTANEOUS DEATH.

A case exemplifying this fact, was some time ago recorded by M. Pelletan. In the month of May, 1802, a young military man, of middling strength, applied at the Hotel-Dieu. In a duel, he had been run through with a foil, which penetrated above the right nipple, and came out at the left loin. The most alarming symptoms were apprehended; but several days elapsed without any serious complaints taking place. The patient was bled twice, and kept on a very low regimen. Every thing went on quietly for a fortnight. He now complained of severe pains in his loins, and he was relieved by the warm bath. He seemed to be recovering, got up, and went to walk in the garden allotted for the sick; but the pain in his loins quickly returned, attended with difficulty of breathing, constipation, and wakefulness. He now became very impatient, and out of temper with the surgeons for not relieving him.

On the 15th of July, two months after the accident, a deformity of the spine was remarked, about the eighth dorsal vertebra. The patient grew rapidly worse, and died in the utmost agony, saying that he felt suffocated, and tearing of the shirt, that his chest might be free from the pressure of all kinds of clothing.

On the body being opened, the right side of the chest was found full of blood, coagulated in various degrees, and an opening, the diameter of which was equal to that of a writing pen, was detected in the aorta above the crura of the diaphragm. All the adjacent cellular substance was injected with blood, and three of the dorsal vertebrae were found carious. No mark of injury was perceptible in any of the thoracic or abdominal viscera. (See *Pelletan's Clinique Chirurgicale*, t. 1. p. 92—94.)

THICKENING AND CONSTRICTION OF THE AORTA.

Meckel met with two cases, in which the aorta was thickened and considerably constricted, just below its arch; yet, in both subjects, there was every reason to believe, that the abdominal viscera and lower extremities had been duly supplied with blood.

This fluid, which could only pass from the heart with great difficulty, and in small quantities, had, by regurgitating, lacerated the semilunar valves. (*Mém. de l'Acad. Royal de Berlin*, 1756. Obs. 17 and 18.) A similar example is recorded by Stoerk. (*Ann. Med.* 11. p. 171.) An instance, in which a stricture was met with in the aorta, opposite to the termination of the canalis arteriosus, is described by Mr. A. Cooper. The little finger could hardly pass through the constriction, which impeded the course of the blood through the heart and lungs, and was attended with a considerable dilatation of the right ventricle. (*Surgical Essays*, vol. 1. p. 103, 8vo. Lond. 1818.)

OBSTRUCTION OF THE CAVITY OF THE AORTA.

It is observed by Professor Scarpa, that the whole body may be regarded as an anastomosis of vessels, a vascular circle, and he contends, that this remark is so true, that even an obliteration of the aorta itself, immediately below its arch, may take place, without the general circulation of the blood in the body being stopped. Such a disease of the aorta was seen by Paris in the body of a woman. While she lived, the blood, which was expelled from the heart, was transmitted into the trunk of the aorta, below the constriction, and it got there by passing through the subclavian, axillary, and cervical arteries, into the mammary, intercostal, diaphragmatic, and epigastric arteries. From these latter arteries, the blood passed into the vessels of the thoracic and abdominal viscera, and those of the lower extremities. (See *Desault's Journal*, t. 2.

167. *Brasdor, in Recueil Périodique de la Soc. de Med. t. 3. No. 18.*)

Dr. Graham, of Glasgow, publishes another example, in which the aorta was completely obstructed, just below the *canalis arteriosus*. The particulars are detailed in the *Med. Chir. Trans.* vol. 5. p. 267.

Dr. Goodison, of Wicklow, in examining the dead body of a woman, in the Hospice de la Pitié at Paris, and endeavouring to trace the origin of the inferior mesenteric artery, discovered a hard tumour, placed upon the aorta, and accompanied with an obliteration of that vessel from the origin of the inferior mesenteric artery downwards the remainder of its length; the left iliac being also rendered impervious down to its bifurcation, and the right for more than one half of its length. The corpora sesamoidea of the semilunar valves of the aorta were considerably enlarged, and the mitral and tricuspid valves presented the appearances termed by Corvisart "vegetations." The arch of the aorta was greatly enlarged, and internally was studded with patches of bone. The vessels given off from the trunk, and especially the lumbar arteries, were all noticed to be considerably increased in size. At the obliterated part of the abdominal aorta, there was a firm bony sheath, covering the vessel for about two inches, and filled with a hard fleshy substance, which extended further upwards, and was firmly adherent to the coat of the artery. It was the inner coat itself which was ossified. For a particular account of the vessels, which were chiefly enlarged for the purpose of continuing the circulation, I must refer to Dr. Goodison's description. The general appearance of the body was not unhealthy; and the lower extremities, which were not emaciated, must have been well supplied with blood. The history of the case could not be traced. Mr. Crampton having carefully compared Dr. Goodison's narrative with the preparation taken from this subject, refers the obliteration of the aorta to the effects of the process, by which an aneurism had been spontaneously cured; in which particular, this case is quite different from those reported by M. Paris, and Dr. Graham. (See *Dublin Hospital Reports*, vol. 2. p. 293, &c. *Svo.* 1818.)

The next case which I shall notice, is one of the most memorable in the annals of surgery, since it was nothing less than an operation, in which a ligature was applied to the aorta of a living subject, under circumstances which, as far as my judgment extends, warranted even this desperate attempt to preserve life. Mr. A. Cooper had often placed ligatures round the aorta in dogs, and found that the blood was readily carried by the anastomoses to their posterior extremities. (See *Med. Chir. Trans.* vol. 2. p. 158.) A porter, aged thirty-eight, was admitted into Guy's Hospital, April 9, 1817, for an aneurism in the left groin, situated partly above, and partly below, Poupart's ligament. The swelling was considerably diffused, and pressure upon it gave a great deal of pain.

On the third day from his entrance into the hospital, the tumour increased to double its former size, and the pulsation became less distinct. The blood could be felt in a fluid state within the sac, which was so large that no operation was practicable, without opening the peritoneum. Mr. A. Cooper therefore waited, in order to let the man have the chance of a spontaneous cure. Notwithstanding the practice of venesection and compression, the swelling continued to increase, and, on the 20th of June, a bleeding took place from a point of the tumour, where a slough had formed. The bleeding recurred from time to time, and on the 25th he was so much exhausted by loss of blood that his feces passed involuntarily, and his immediate death was only prevented by pressure on the opening. At nine o'clock in the evening, this experienced surgeon made a small incision into the sac above Poupart's ligament, and introducing his finger, tried if it were practicable to pass a ligature round the external iliac artery, within the cavity; but the thing was found impossible, as, instead of the vessel, "only a chaos of broken coagula" could be perceived. At the moment of withdrawing the finger, two students compressed the aorta against the spine, and the incision was then closed with a dossil of lint; Mr. A. Cooper now determined to apply a ligature to the aorta itself. "I made (says he) an incision three inches long, into the linea alba, giving it a slight curve, to avoid the umbilicus. One inch and a half was above, and the remainder below, the navel," the cut being inclined towards the left side. "Having divided the linea alba, I made a small aperture into the peritoneum, and introduced my finger into the abdomen; and then, with a probe-pointed bistoury, enlarged the opening into the peritoneum to nearly the same extent as that of the external wound. Neither the omentum nor the intestines protruded; and, during the progress of the operation, only one small convulsion projected beyond the wound." With his finger nail he scratched through the peritoneum, on the left side of the aorta, and then gently moving his finger from side to side, he gradually passed it between the aorta and spine, and again penetrated the peritoneum on the right side of the aorta. A blunt aneurismal-needle, armed with a single ligature, was next conveyed under that vessel, and tied, with the precaution of excluding the intestines from the noose. The wound was then closed, by means of the quilled suture and adhesive plaster. During the operation, the feces were discharged involuntarily, and the pulse both immediately, and for an hour after the operation, was 144. An opiate was given, and the involuntary passage of feces soon ceased. The sensibility of the right leg was very imperfect. In the night, the patient complained of heat in the abdomen; but he felt no pain upon pressure; and the lower extremities, which had been cold a little while after the operation, were regaining their heat, but

their sensibility was very indistinct. At six o'clock the following morning, the sensibility of the limbs was still imperfect; but at eight o'clock the right one was warmer than the left, and its sensibility returning. At noon, the temperature of the right limb was ninety-four; that of the left, or aneurismal one, eighty-seven and a half. At three o'clock, an enema was ordered. The heat of the right leg was now ninety-six; that of the left, or diseased limb, eighty-seven and a half. It is unnecessary, here, to detail all the various circumstances which preceded the patient's death. Vomiting, pain in the abdomen and loins, involuntary discharge of urine and feces; a weak pulse, cold sweats, &c. were some of the most remarkable symptoms. At eight o'clock on the second morning after the operation, the aneurismal limb appeared livid and cold, more particularly round the aneurism; but the right leg was warm; and between one and two o'clock, the same day, the patient died. On opening the abdomen, there was not the least appearance of peritoneal inflammation, except at the edges of the wound; and the omentum and intestines were of their natural colour. The ligature, which included no portion of intestine or omentum, was placed round the aorta, about three quarters of an inch above its bifurcation. When the vessel was opened, a clot, of more than an inch in extent, filled it above the ligature; and below the bifurcation, another clot, an inch in extent, occupied the right iliac artery, while the left contained a third, which extended as far as the aneurism. The neck of the thigh-bone was also found broken within the capsular ligament, and not united; an accidental complication. As there were no appearances of inflammation of the viscera, Mr. A. Cooper refers the cause of the man's death to the want of circulation in the aneurismal limb, which never recovered its natural heat, nor any degree of sensibility, though the right leg was not prevented from doing so; hence, says this experienced surgeon, "in an aneurism similarly situated, the ligature must be applied before the swelling has acquired any very considerable magnitude." (*Surgical Essays*, vol. 1. p. 114, &c.)

Indeed, the most important conclusions from this case are—First, that, where no other impediments exist, the circulation will continue in the lower extremities, though the abdominal aorta be tied, or suddenly obstructed. Secondly, that suffering aneurismal swellings to become very large, before the operation is done, exposes the patient to considerable disadvantage, on account of the pressure of the disease upon the surrounding anastomoses, whereby the continuance of the circulation is rendered less certain than it would be, were the operation done at an earlier period.

RUPTURE OF THE AORTA WITHIN THE PERICARDIUM.

The surgical writings of Scarpa, in rela-

tion to the formation of aneurisms, have now gained extensive celebrity in the world. It is well known, that this author maintains the doctrine, that, in all aneurisms, the internal and muscular coats of the artery are ruptured, and that the aneurismal sac is not formed of these tunics, but of the dilated cellular sheath, which surrounds the vessel. When a large aneurism bursts, there is always a double rupture; one of the artery; another of the aneurismal sac. The last is that, which is the immediate cause of the patient's destruction, by altering the *circumscribed* state of the aneurism into the *diffused*.

There are some exceptions, however, to the foregoing statement, and Scarpa has not failed to point them out. When the internal and muscular coats of the aorta are ruptured in a situation, where the outside of the vessel is only covered by a thin, tense, closely adherent membrane, such membrane may be ruptured at the same time with the proper coats of the artery, and sudden death be occasioned by the effusion of blood in the cavity of the thorax. These events are liable to happen, whenever the proper coats of the aorta are ruptured, within the pericardium, where the vessel is only covered by a thin layer reflected from this membranous bag. Walter has recorded one example of this kind, and Morgagni several others. A similar case is related by Scarpa. (*See Haller Disput. Chir. Tom. 5. Acta Medic. Berlin. Vol. 8, p. 86. Morgagni de Sed. et Causis Morb. Epist. 26, art. 7. 17. 21. Epist. 27, Art. 28. Scarpa on Aneurism, trans. by Wishart, p. 81. Also Hodgson on the Diseases of Arteries and Veins.*)

STEATOMATOUS TUMOURS OF THE AORTA.

Two steatomatous tumours were noticed by Stenzel in the body of a male subject. They were situated in the substance of the membranes of the aorta, immediately below its arch. Notwithstanding these swellings rendered the vessel almost impervious, the man had the appearance of strength, and of having been well nourished. *Hæc corpora fere cor magnitudine æquabant ut omnem propemodum exeunti e sinistri cordis thalamo sanguini spatium præcluderent.* De Steatomatibus in principio arteriæ aortæ, &c. Wittemb. 1723.

This is another striking fact, illustrating the great power of the inosculation to carry on the circulation.

APHÆRESIS. (from *ἀφαιρέω*, to remove.) This term was formerly used in the schools of surgery, to signify that part of the art, which consists in taking off any diseased, or preternatural portion of the body.

APONEUROSIS. The expression *νεύρον* was applied by Hippocrates and other ancient writers to tendons and ligaments as well as nerves, all which parts seemed to resemble each other in having a white fibrous texture.

Matter often collects under aponeuroses in different situations of the body, parti-

cularly under the tendinous expansion, which cover the muscles of the thigh, the leg, and the fore-arm. Abscesses are also sometimes met with under the temporal, the palmar, and the plantar fasciæ; in the tendinous thecæ, which include the flexor tendons of the fingers; and, occasionally, also, in the aponeurotic sheath, in which the rectus abdominis muscle is situated.

One particular effect of an aponeurosis, or any kind of tendinous expansion, lying between a collection of matter and the skin, is materially to retard the progress of the pus towards the surface of the body. Hence if the case be allowed to take its own course, the quantity of matter increases, the pus spreads extensively under the aponeurosis in every possible direction, separates the muscles from such fascia, and the muscles from each other, and the abscess does not burst till a vast deal of mischief has been produced, together with more or less sloughing of the fascia, tendons, &c. These circumstances cannot happen, without a considerable degree of constitutional disturbance, and a permanent loss of the use of certain muscles. Even when a spontaneous opening is formed, and some of the matter escapes, it is often only a very imperfect discharge; for, the aperture generally occurs, not in a depending situation, nor over the main collection of pus, but, at a part, where the aponeurosis is most thin, and consequently, where the matter had the least resistance to overcome in getting to the surface of the body.

In all such cases, the chief indication is to make an early and a depending opening with a lancet, so as to prevent the extension of the abscess, and to let the matter escape as fast as it is formed. If a spontaneous opening should have occurred in an unfavourable place, a new aperture must be made in a proper situation; or if the former should be sufficiently depending, and near the principal accumulation of matter, but too small, it must be rendered larger with a curved bistoury and a director. Whenever any black dead pieces of fascia, or tendons, present themselves at the opening, they must be taken hold of with a pair of forceps, and extracted.

APOSTEME, or APOSTUME. An abscess.

APPARATUS. This implies the preparation, and arrangement of every thing necessary in the performance of an operation, or in the application of dressings. The apparatus varies according to circumstances. Instruments, machines, bandages, tapes, compresses, pledgets, dossils of lint, sponges, basins of water, towels, &c. &c. are parts of the apparatus, as well as any medicinal substances used.

It is a rule in surgery to have the apparatus ready before an operation is begun. All preparations of this kind should be made, if possible, out of the patient's room and presence, as they might agitate and render him timid.

We have been lately censured by a French

surgeon, for our too common neglect of what has been here recommended. "In France (observes M. Roux) we are careful not to let a patient, who is to undergo a serious operation, see any of the requisite preparations for it. We hasten as much as possible the immediate preparatory measures, in order not to prolong unnecessarily the restlessness and moral agitation, which the expectation of an operation, and sometimes of the slightest one, always produces. These precautions are neglected by the English surgeons, at least, by most of those whom I saw operate. They even neglect them in private practice, where, more commonly than in hospitals, we have to deal with pusillanimous individuals, who are easily alarmed, and whose extreme susceptibility it is of importance to spare. It was in the very room, where the patient lay, of course under his eyes, that the table, and all the necessary instruments for lithotomy, were arranged, at an operation, which I saw done in London, during my stay in that capital, by a gentleman at the head of his profession." (See *Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, p. 105.)

M. Roux, in his visit to London, had also too good reason to complain of the slovenly objectionable practice of leaving the application of the tourniquet, and the dressing of the wound after a surgical operation, to mere novices and students. I entirely coincide with him, that, in respect to the dressings in particular, a surgeon is bound to extend his attention and solicitude a little beyond the moment, when the operation terminates.

APPARATUS MINOR; APPARATUS MAJOR; APPARATUS ALTUS. Three ways of cutting for the stone. (See *Lithotomy*.)

AQUA PICIS LIQUIDÆ. *Dubl.* Take of tar two pints; water a gallon. Mix them with a wooden rod for a quarter of an hour, and after the tar has subsided, let the liquor be strained, and kept in well-corked bottles. This lotion is often used in cases of porrigo. Ulcers on the legs, are sometimes extensively surrounded with a scorbutic redness, and pimples. In such instances, the aqua picis, used as an application round the limb, over the dressings, is of great service. (See *Liquor*.)

ARGENTI NITRAS. (*Nitrate of silver, lunar caustic.*) Is the best of the mildest caustics. Its utility for stimulating indolent ulcers, and keeping granulations from rising too high, is well known to every surgeon.

Mr. Hunter sanctions the use of the argentum nitratum, on the first appearance of a chancre, before absorption can be supposed to have taken place. He directs the caustic to be scraped to a point, like a blacklead pencil; so that, when it is applied, every part of the surface of the chancre may be touched with it; and he advises the repetition of this process, till the last slough, which is thrown off, leaves the sore florid and healthy.

This treatment when the sore is very small, may sometimes be advisable, as a means of lessening the chance of the constitution being infected by absorption. In general, surgeons combine with the plan the moderate use of mercury.

The important use of the *argentum nitratum*, in the cure of numerous diseases, we shall have occasion to remark in various places of this work; particularly when we come to the article *Cornea, ulcers of; Iris, prolapsus of; Uleers; Urethra, strictures of, &c.*

The *argentum nitratum* is often used in the form of a solution, in the proportion of a dram of the caustic to an ounce of distilled water. In general this application ought to be at first more or less diluted with distilled water. Cancerous ulcers; and sores about the nose and neighbouring parts of the face, being examples of *lupus*, or *noli me tangere*, are often considerably benefited by the *argentum nitratum*, both in the solid and fluid state. The solution agrees also very well with certain sores, which occur round the roots of the nails of the fingers and toes. The lotion is sometimes applied with a camel-hair pencil; but in general, by dipping little soft bits of lint in the fluid, laying them on the part, and covering them with a pledget.

ARNICA. *Leopardsbane.* Amaurosis is the principal surgical case, in which this medicine is now ever employed. Its repute in the cure of that disease also chiefly prevails abroad; for, I believe, in this country, surgeons have no confidence in it, as a remedy for amaurotic disorders.

ARSENIC is the chief ingredient in a secret remedy, which has long possessed very great celebrity in Ireland for the cure of cancer, and is now well known among surgeons, by the name of Plunket's caustic. This application consists of the *ranunculus acris*, the greater crow-foot, the *flammula vulgaris*, and the lesser crow-foot, in the proportion of an ounce of each, bruised and mixed with a drachm of the white oxide of arsenic, and five scruples of sulphur. The whole is to be beaten into a paste, formed into balls, and dried in the sun. When required for use, these balls are beaten up with yolk of egg, and spread upon a piece of pig's bladder. The use of the *ranunculus* is to destroy the cuticle, upon which the arsenic would have no effect; for it is to be observed, that Plunket's caustic was employed for the dispersion of tumours, as well as for the relief of ulcerated cancers. The application is to remain on the part twenty-four hours, at the end of which time, the slough is to be dressed with any simple unirritating ointment. When arsenic was first recommended as an application for cancers, it used generally to be blended with opium. When Plunket's caustic is employed, so as to form an eschar over a scirrhus tumour, I conjecture, that if it ever do good, it is not by any specific effect of this arsenical application, but simply as a slough, or issue, formed near the disease in any other manner. It is

highly probable, also, that the swellings, which have been thus dispersed, have never been complicated with the structure characteristic of true scirrhi. With respect to cancerous ulcers, Plunket's caustic sometimes evidently produces a degree of amendment, which, however, rarely lasts for any considerable time; but, there are many inveterate ulcerations, and anomalous sores, which derive permanent benefit from the application, and are even completely cured by it. Some examples of lupus, ulcerations about the roots of the nails, and reputed carcinomatous sores of the lips, are of this description.

At Paris, an arsenical paste is often used by Dubois, and other surgeons of that capital, for cancerous sores of the penis, and other malignant ulcers. It is composed of 70 parts of cinnabar, 22 of sanguis draconis, and 8 of the white oxide of arsenic, formed into paste with saliva at the time when it is to be employed. "The pain and inflammation that succeed the use of it (says Mr. Cross,) cannot be equalled by the severest operation with the knife." (*Sketches of the Medical Schools of Paris*, p. 45, 8vo. 1815.) Even death may be occasioned by the absorption of the poison, as appears from the two annexed facts, the first of which is recorded by M. Roux, in his *Medecine Operatoire*. "The day after the paste was applied, the patient complained of colic and severe vomiting, and in two days perished in convulsions, *et les plus vives angoisses*. The body went quickly into putrefaction. The internal coat of the stomach and a great part of the intestinal canal, were inflamed, and marked here and there with dark spots. Just before I visited Paris, (adds Mr. Cross,) I dissected in London a woman, who died under similar circumstances, and where the same morbid appearances were presented, &c." (*Op. cit.*)

Mr. Justamond's applications to cancer, originally suggested by a receipt, said to be preserved in the Earl of Arundel's family, were somewhat varied. They were generally combinations of arsenic and sulphur. The above receipt directs an ounce of yellow arsenic, with half that quantity of armenian bole, and sometimes as much red precipitate. Mr. Justamond also employed a sulphuret of arsenic, and a combination of this sulphuret with crude antimony. The arsenical preparation, selected for use, was scraped, and laid on the middle of the sore, the edges of which were moistened with a combination of the muriate of iron and muriate of ammonia. In some instances, we learn, that the effects of the treatment were the correction of the fetid smell, melioration of the appearance of the sore, and separation of the cancerous part.

In the *Pharmacopœia Chirurgica*, Mr. Justamond's arsenical caustic is directed to be made in the following manner. *R. Antimonii pulverizati ℥j. Arsenici pulverizati ℥ij.* These are to be melted together in a crucible. The application may be reduced to any degree of muddiness by blending with

this pulverized caustic a quantity of opium in the form of powder, which was also supposed to act specifically in diminishing pain.

The powder of white oxide of arsenic, unmixed with other substances, has sometimes been sprinkled upon cancerous and other inveterate ulcers; but, the practice is now abandoned by every judicious surgeon, on account of the violent pain resulting from it, and the not unfrequent fatal consequences of its absorption. Could I suppose a man, so rash and ignorant as to revive this murderous practice, yet existed in the profession, I should feel disposed to lengthen these remarks: but I am persuaded, that, in this country, at least, more judgment and knowledge every where prevail. The white oxide of arsenic, however, may be applied with more prudence in other forms; either in one of those already specified; or, as a lotion composed of eight grains of the oxide, and the same quantity of subcarbonate of potash, dissolved in four ounces of distilled water: or, as an ointment formed by rubbing together one drachm of the oxide, and twelve drachms of spermaceti ointment. (See *A. T. Thomson's Dispensatory*, p. 51.)

Febure's celebrated remedy consisted of ten grains of the white oxide of arsenic, dissolved in a pint of distilled water, to which were then added an ounce of the extractum conii, three ounces of the liquor plumbi subacetatis, and a drachm of laudanum. With this fluid, the cancer was washed every morning. M. Febure likewise gave arsenic internally; and his prescription was two grains of the white oxide, a pint of distilled water, syrup of chichory q. s. and half an ounce of rhubarb. Of this mixture, a table spoonful was given every night and morning, with half a drachm of the syrup of poppies. Each dose contained about one-twelfth of a grain of arsenic; but, in proportion as the patient was able to bear an increased quantity, the dose was gradually augmented to six table spoonfuls of the solution.

The arseniate, or rather superarseniate, of potash, is an excellent preparation for internal exhibition. The Dublin Pharmacopœia directs it to be made as follows: take of white oxide of arsenic, nitrate of potassa, each an ounce. Reduce them separately to powder; then, having mixed them, put them into a glass retort, and place it in a sand-bath, exposed to a gradually raised heat, until the bottom of the retort becomes obscurely red. The vapours, arising from the retort, should be transmitted through distilled water, by means of a proper apparatus, in order that the nitrous acid, extricated by the heat, may be disengaged. Dissolve the residue in four pounds of boiling distilled water, and after due evaporation, set it apart, in order that crystals may form. This preparation has long been known under the name of Macquer's arsenical neutral salt. It may be given in the following way: *R. Potassæ Superarseniatæ gr. ij. Aq. Menthæ Sativæ Spirit. ℥iv. Vinosi tenuioris ℥j. M. et cola.*

Dosis drachmæ duæ ter quotidie.

The kali arsenicatum, or, as it ought to be called, the superarseniate of potash, may also be given in the form of the pills, made up with crumb of bread, each of which may contain from one-sixteenth to one-eighth of a grain of the arsenical salt.

The following is Dr. Fowler's method of preparing arsenic for internal use: take of the white oxide of arsenic, and pure subcarbonate of potash, each sixty-four grains. Boil them gently in a Florentine flask, or other glass vessel, with half a pound of distilled water, until the arsenic is dissolved. To this solution, when cold, add half an ounce of the compound spirit of lavender, and as much water as will make the whole equal to a pint, or fifteen ounces and a half in weight. The dose of this solution, of which the liquor arsenicalis L. P. is a near imitation, is as follows: from two years old to four M. ij. or iij to v; from five to seven M. v. to vij; from eight to twelve M. vij to x; from thirteen to eighteen M. x to xii; from eighteen upwards M. xii. These doses may be repeated every eight, or twelve hours, the medicine being diluted with thick gruel, or barley water. As the preparation is decomposed by the infusion and decoction of cinchona, it should never be ordered with either of these medicines.

The white oxide of arsenic may be given in the form of pills, made by mixing one grain of it with ten of sugar, and then beating up the mixture with a sufficient quantity of the crumb of bread to form ten pills, one of which is a dose. It will only be in my power to specify here a few of the numerous surgical cases, in which the internal employment of arsenic has been proposed. The following are particularly worthy of attention; tetanic affections; cancer; lupus; elephantiasis; inert cases of lepra; (See *Bateman's Pract. Synopsis of Cutaneous Diseases*, p. 33, Ed. 3.) various unnamed malignant ulcers; certain forms, or sequelæ of the venereal disease, or other unintelligible diseases, which cannot be subdued by mercury; different cutaneous affections, &c. A longer list of diseases, for which a trial of arsenic is suggested, may be seen in some papers published by Mr. Hill. (*Edinb. Med. and Surg. Journ. Vol. 5, 6.*)

Arsenic has also been recommended by Dr. J. Hunter, for the prevention of hydrophobia. (See *Trans. of a Society for the Improvement of Med. and Chir. Knowledge*, Vol. 1.) Later trials of the medicine, however, in this particular case, do not appear to entitle it to any confidence. Dr. Marcet found it quite unavailing, though not less than three drops of Fowler's solution were taken every other hour, in two drachms of peppermint, or sweetened water. (See *Med. Chir. Trans. Vol. 1, p. 141, 156.*) After the symptoms of hydrophobia have once begun, arsenic is decidedly useless.

But, although it fails in hydrophobia, some facts published by Mr. Ireland, surgeon to the 60th regiment, make it appear a truly valuable and efficacious remedy for

counteracting the poison of serpents. (See *Med. Chir. Trans. Vol. 2. p. 393.*)

ARTERIOTOMY. (from *αρτηρία*, an artery, and *τομή*, to cut.) The operation of opening an artery, for the purpose of taking away blood for the relief of diseases. (See *Bleeding.*)

ARTERIES. The process, by which a divided, or punctured artery is healed, is particularly considered under the word *Hemorrhage*; while the general principles, which ought to be observed in the application of the means for the stoppage of bleeding, may be collected partly from the remarks, contained in that part of the work, and partly from what is stated in the articles, *Amputation*, *Aneurism*, and *Ligature*. As the condition of a bleeding patient admits of no delay, and the preservation of his life entirely depends upon proper measures being immediately taken, no man ought to be suffered to profess surgery, who is not competent to the treatment of wounded arteries, whether injured by accident, or in a surgical operation. As Langenbeck observes, an ignorant practitioner, when called to a case of serious hemorrhage, is thrown into such consternation, as actually deprives him of the power of rendering prompt assistance. Pale as a corpse, and trembling, he beholds the jet of blood; and for the sake of appearing to do something, perhaps, he applies spirit of wine, or a very tight bandage, and cries out for further aid; while simple pressure with the thumb upon a certain point in the vicinity of the injury, would prevent all this confusion, and a dangerous loss of blood. No part of surgery, in fact, is of higher importance, than the treatment of wounded arteries, and it deserves, therefore, to be earnestly studied by every practitioner, whether he move in the higher, or the lower sphere of the profession. And, as a proof of the necessity of country surgeons making themselves acquainted with the subject, he recites the case of a turf-cutter, who let the instrument with which he worked fall against the lower part of his leg, whereby the posterior tibial artery was wounded. The blood gushed out profusely, and the surgeon who was sent for, applied a tourniquet to the popliteal artery, and thus stopped the bleeding for a time; but, unfortunately, the tourniquet was kept so long on the limb, that the foot mortified, and sloughed away. (*Bibl. für die Chir. B. 1. p. 231, 232, Gott. 1806.*) From the explanations, delivered in the article *Hemorrhage*, it will be seen, that, in all bleedings from considerable arteries, nothing is equal to the ligature, as a means for preventing the further loss of blood; and it may be laid down as a standing rule, that each extremity of the wounded vessel should be tied as near as possible to the wound in its coats. As Mr. Hodgson has remarked, "the necessity of tying both ends of a wounded artery is evident from the fact, that the anastomoses in all parts of the body, are so extensive, as to furnish a supply of blood, which may pass through

the lower extremity of the wounded vessel in a sufficient stream to produce an alarming, and, in some instances, a fatal hemorrhage" (*On Diseases of Arteries, &c. p. 469.*) This correct observation is followed by a case, in which the bleeding from the lower end of a divided brachial artery caused the patient's death. Of course, the inference is, that both extremities of the vessel ought to have been tied directly after the receipt of the wound. With regard to tying the trunk of an artery in a part of the limb, where it can be exposed with facility, when it is difficult to secure its bleeding extremities, as Mr. Hodgson remarks, the practice "was falsely deduced from a knowledge of the fact, that the ligature of an artery at a distance from the disease will effect the cure of an aneurism. But, a more intimate acquaintance with the condition of a limb after such an operation, and the processes, by which the cure of an aneurism is effected after the modern operation, afford a complete illustration of the inefficacy and danger of this mode of treating a wounded artery; for it is now fully proved, that, when an artery is tied, a stream of blood continues to pass through it below the ligature. (p. 471.) This well-informed surgeon is aware, however, that instances do occur, in which only the upper end of a wounded artery is tied, and yet the patient recovers without hemorrhage from the lower orifice, which is closed by the natural processes.

In the year 1814, in Holland, I took up the femoral artery, in the middle of the thigh, in a case, in which the popliteal artery had given way, ten days after the passage of a musket-ball through the ham. I employed only one smallish ligature, which was applied with the precaution of not detaching the artery from its natural connexions. The hemorrhage was effectually stopped, and the wound healed in the most favourable manner. Here, no doubt, the inflammation in the ham had obliterated the portion of the artery immediately below the point at which it had sloughed, or ulcerated, and there might even have been from the same cause some deposition of lymph within the upper portion of the popliteal artery, contributing to the success of the operation. But, no doubt, it was the diminution of the impulse of the circulation by the ligature of the femoral artery, which enabled nature to complete the obliteration of the wounded part of the vessel. Sometimes, says Mr. Hodgson, when hemorrhage takes place, a few days after the bleeding from a wounded artery has been stopped by compression, one extremity of the vessel will be pervious, whilst the other will have closed by the natural processes. Cases have even occurred, in which the upper end of the artery has been closed by the natural processes, whilst those processes failed in effecting the obliteration of the lower extremity of the vessel, from which a serious hemorrhage took place. (*Hodgson, Op. cit. 475; and Guthrie in New Med.*

and *Phys. Journ.* Vol. 4, p. 177.) Indeed, in the example in which I took up the femoral artery myself, it was impossible to say positively, whether the blood came from the part of the popliteal artery above, or below the slough in it, as no incision was made into the ham.

The principle, respecting the application of a ligature to each end of every large divided artery, is to be extended also to punctured arteries, one ligature being placed above, and the other below, the opening in the vessel.

From some observations, introduced in the article *Aneurism*, p. 150, it will be seen, that, when the impulse of the circulation has been lessened by the ligature of the main trunk of an artery, some distance above the wound, the hemorrhage from the more remote portion of the vessel, may sometimes be effectually restrained by pressure, which, previously to the stoppage of one great current of blood to the part, had proved unavailing. This fact is worth remembering in cases, in which the arteries of the hand, or foot, are wounded.

Mortification is observed to be more frequent after the ligature of an artery for a wound, than for an aneurism. In wounds, Mr. Hodgson very correctly, I think, refers the difference to the frequent injury of the surrounding parts, and particularly of the veins and nerves, and to the loss of blood, and want of quietude, and proper care after the accident. The principal anastomosing vessels are also sometimes divided. (P. 479.)

Having given in the article *Aneurism*, the necessary directions, how to cut down to and tie many of the principal arteries, I shall conclude the present subject with a few instructions how to take up the arteries of the fore-arm and leg, as explained by Scarpa, Mr. C. Bell, Mr. Hodgson, and others. Some directions how to act in a case of wounded axillary artery are likewise subjoined.

In order to lay bare the radial artery at the upper third of the fore-arm, a finger is to be put on the insertion of the tendon of the biceps. A little below this insertion, an incision, about two inches and a half in length, is to be made in the integuments, in the oblique direction, denoted by the inner edge of the supinator radii longus. The subjacent fascia is then to be divided, and the inner edge of the supinator muscle drawn a little from the outer side of the arm: in the space, between that muscle and the flexor carpi radialis, the radial artery immediately presents itself, passing over the tendon of the pronator radii teres, and the flexor longus pollicis, and it then runs down between the latter named tendon and the flexor carpi radialis. (See *Camper's Anat. Demonstr. Pathol. Lib. 1, Tab. 1, fig. 2.*) A branch of the musculo-spiral nerve lies on the radial side of the artery.

At the wrist, the radial artery may be taken up by making an incision a little way from the radial margin of the flexor carpi

ulnaris. Here the artery is covered by a fascia, over which a small branch of the external cutaneous nerve runs; but the vessel is now unaccompanied with the musculo-spiral nerve, which quits it, and passes under the supinator radii longus, a little below the middle of the fore-arm.

After the radial artery leaves the fore part of the wrist, it may be taken up by making an incision "on the outside of the insertion of the extensor primi internodii pollicis, and the inside of the extensor tertii internodii pollicis. Betwixt these tendons, the artery lies very deep, and over it is the extreme branch of the muscular spiral nerve. We find the artery going close to the notch, betwixt the os scaphoides and trapezium." (C. Bell, *Op. Surgery*, V. 2, p. 373.)

For bringing into view the ulnar artery at the upper third of the fore-arm, the situation and breadth of the flexor carpi ulnaris muscle must first be ascertained. An incision is then to be made from above downwards, beginning two inches below the inner condyle of the humerus, and following the course of the inner margin of the above muscle to the extent of two inches and a half. The fascia is then to be divided: the flexor carpi ulnaris is to be drawn a little away from the flexor digitorum sublimis. In this opening, rather under the margin of the latter muscle, the ulnar artery will be felt with the finger, continuing its course over the flexor profundus. The ulnar nerve is situated on the ulnar side of the artery.

Below the middle of the fore-arm, the ulnar artery is more superficial, and may easily be taken up by making an incision upon the radial side of the flexor carpi ulnaris, between the tendon of which muscle, and that of the flexor profundus digitorum, the vessel is situated. The artery, however, will not be reached until a thin aponeurosis under the fascia of the fore-arm has been divided. The nerve is rather more under the tendon of the flexor carpi ulnaris, than the artery. When the ulnar artery arises from the brachial above the elbow, it runs above the fascia, and is easily taken up at any part of its course.

The anterior tibial artery passes forward between the bones of the leg, about an inch below the upper head of the fibula. In order to take up the vessel in this situation, a free cut must be made through the fascia, extended between the heads of the tibia and fibula. The incision is then to be continued more deeply at the edge of the peroneus longus, following the fascia between this muscle and the origin of the extensor digitorum communis. The artery will be met with on the interosseous ligament. (C. Bell, V. 2, p. 376.)

In order to lay bare the anterior tibial artery, a little above the middle of the leg, the finger is to be passed along the outer side of the spine of the tibia, and the breadth of the tibialis anticus muscle is to be ascertained. Along the outer margin of this muscle, an incision is to be made

through the integuments and fascia, two inches and a half in length. The knife is then to be introduced between the outer margin of the *tibialis anticus* muscle, and the *extensor longus* of the great toe. In this space, at the depth of about an inch, the anterior tibial artery is situated. (See *Haller's Icon. Anat. Fasc. 5, Tab. 4.*) Cutting down to this artery, near the tarsus, where the vessel passes out between the tendons of the *tibialis anticus* and *extensor* muscle of the toes, is an easy operation.

The laying bare of the posterior tibial artery, behind the malleolus internus, is also quite easy: an incision, about two inches long, is to be made between the internal malleolus, and the tendo Achillis, down to the posterior surface of the tuberosity of the tibia. At this depth, the tendon of the *tibialis posticus* muscle, and that of the *flexor communis digitorum pedis*, run, as in a furrow. Along with these two tendons, but a little nearer to the os calcis, the posterior tibial artery descends to the sole of the foot.

On the contrary, the depth of the posterior tibial artery at the middle, or in the upper third of the leg, makes it very difficult to take up the vessel in these situations. And the difficulties are increased by the spasmodic contractions of the *gastrocnemius* and *soleus* muscles. When necessary, however, the artery may be exposed and tied above and below the wound in it, by proceeding as follows: an incision is to be made, three or four inches in length, along the inner side of the crest of the tibia; and the origins of the *soleus* muscle are to be detached from it to the same extent, and reflected. Under the *soleus* muscle is found the *aponeurosis*, which separates the muscles of the calf of the leg into superficial and deep seated. When this fascia has also been divided, the posterior tibial artery may be seen, or felt deeply situated, running on the *tibialis posticus* and *flexor* muscle of the toes. (See *Haller, Icon. Anat. Fasc. 5, Tab. 5.*)

In taking up the axillary artery, when it is wounded, Scarpa believes, that nothing tends more to embarrass the surgeon, than an injudicious smallness of the first incision through the skin and such other parts as conceal the wound in the artery. An assistant must compress the vessel, from above the clavicle, as it passes over the first rib. When the weapon has penetrated, from below upward, directly into the axilla, the surgeon is to make a free dilatation of the wound upon a director, or his finger. This must be done to a sufficient height to expose a considerable portion of the artery, and the precise situation of the wound in it.

When the weapon has pierced obliquely, or from above downwards, through a portion of the great pectoral muscle, into the axilla, Scarpa advises the surgeon to cut through the lower edge of this muscle, and enlarge the wound, on a director, or his finger, so as to bring fairly into view the injured part of the artery. The thoracic arteries, divided in this operation, must be immediately tied. The clots of blood are then to be removed, and the bottom of the wound cleaned with a sponge, by which means the opening in the axillary artery will be more clearly seen. As this vessel lies imbedded in the brachial plexus of nerves, the surgeon must take care to raise it from these latter parts with a pair of forceps, before he ties it. Two ligatures will be required: one above; the other below the wound of the artery.

ASTRINGENTS. (from *stringo*, to bind.) In medicine, are those substances which possess a power of making the living fibres become contracted, condensed, and corrugated. They are employed in the practice of surgery chiefly as external applications, either for restoring diminished tonic power, or checking various discharges. Astringent lotions are usually deemed eligible local remedies for phlegmonous inflammation.

ATHEROMA. (from *αθηρα*, pap.) An encysted tumour, so named from its pap-like contents. (See *Tumours Encysted.*)

B.

BALSAMUM COPAIVÆ. Exhibited by surgeons principally in cases of gonorrhea, gleet, and piles: The common dose is from ten to thirty drops, two or three times a day.

BALSAMUM PERUVIANUM CUM FELLE BOVINO. R. Felle Bovini ʒiij. Balsami Peruv. ʒj. M. Dr. H. Smith recommended this application to be occasionally dropped into the ear, when there is a fetid discharge from the meatus auditorius. This passage is also to be washed out every day, by throwing into it with a syringe warm water alone, or containing a little soap.

BANDAGE. (*Deligatio, Fascia.*)

The use of bandages is to keep dressings, compresses, remedies, &c. in their proper situation; to compress blood-vessels, so as to restrain hemorrhage; to rectify certain deformities by holding the deranged parts in a natural position; and to unite parts, in which there is a solution of continuity. As the application of bandages is an important branch of surgery, authors have not neglected it. Much has been written on the subject, and almost every writer has devised new bandages, perhaps without much benefit to the art. Unfortunately, it is next to impossible to give very clear ideas of the numerous sorts of bandages by a printed descrip-

tion of them. The surgeon can only acquire all the necessary instruction and information from the experience and habit resulting from practice. Hence, we shall confine ourselves to a general account of the subject.

Bandages should be made of such materials, as possess sufficient strength to fulfil the end proposed in applying them, and at the same time, they should be supple enough to admit of being accommodated to the parts, to which they are applied.

Bandages are made of linen, cotton, or flannel. If possible, they should be without a seam, or selvage, which sometimes causes unequal and painful pressure.

There are cases, in which the bandage should have a degree of firmness, that does not belong to the materials usually employed. This circumstance is obvious in cases of hernia, and in all those examples, in which there is occasion for elastic bandages. As we have already observed, linen, flannel, and cotton (calico,) are the common materials. The first employment of flannel bandages is imputed to the Scotch surgeons, who preferred them to linen ones, in consequence of their being better calculated for absorbing moisture, while, being more elastic, they yield in a greater degree in cases requiring this property; as in the swelling subsequent to dislocations, fractures, &c. It has been asserted, that linen is better than flannel, because more cleanly; but neither one nor the other will continue clean, unless care be taken to change it often enough. Where the indication is to keep the parts warm, flannel is of course preferable to linen or calico.

The employment of cotton or calico bandages is a more recent method, and many advantages are attributed to the softness and elasticity of this material.

In applying a bandage, care must be taken, that it be put on tight enough to fulfil the object in view, without running any risk of stopping the circulation, or doing harm in any other way. If it be not sufficiently tight to support the parts in a proper manner, it is useless; if it be too tense, it will produce swelling, inflammation, and even mortification.

In order to apply a roller skilfully, the part which is to be covered, must be put in its proper situation; the head of the roller held in the surgeon's hand, and only so much unrolled, as is necessary for the commencement of the application.

In general, the bandage should be applied in such a manner, as will admit of its being removed with the most ease, and allow the state of the subjacent parts to be examined, as often as occasion may require.

For this reason, in fractures of the leg and thigh, the eighteen-tailed bandage is generally preferred to a simple roller. The former may be loosened and tightened, at pleasure, without occasioning the smallest disturbance of the affected limb; a thing

which could not be done, were a common roller to be employed.

As soon as a bandage has fulfilled the object for which it is applied, and it has become useless, its employment should be discontinued; for, by remaining too long on parts, it may obstruct the circulation, diminish the tone of the compressed fibres and vessels, and thus do harm.

Bandages are either *simple* or *compound*. They are also sometimes divided into *general* and *particular*. The latter often derive their names from the parts to which they are usually applied.

A simple bandage is a long piece of linen or cotton, of an indefinite length, and from three to six inches in breadth. When about to be applied, it is commonly rolled up, and the rolled part is termed its *head*. When rolled up from each end, it is called a *double-headed roller* or *bandage*.

The chief of the simple bandages are the *circular*, the *spiral*, the *uniting*, the *retaining*, the *expellent*, and the *creeping*.

The *circular* bandage is the simplest; consisting merely of a few circles of a roller covering, or overlapping each other.

The *spiral* bandage is the most frequently used of all; for, it is this, which is seen in such common employment on the limbs, in cases of ulcers, varices, &c. In applying a common roller to the whole of a limb, the bandage must be carried round the part spirally; for otherwise the whole member cannot be covered. When the leg is the part, the surgeon is to begin by surrounding the foot with a few turns. Then carrying the head of the bandage over the instep, he is to convey it backward, so as to make the bandage unroll, and apply itself just above the heel. The roller may next be brought over the inner ankle; thence again over the instep, and under the sole; and the surgeon then brings the bandage spirally upward once more to the outer part of the leg. After this, every circle of the roller is to be applied, so as to ascend up the limb in a gradual, spiral form, and so as to cover about one-third of the turn of the roller immediately below it. The increasing and diminishing diameter of the limb, is one great cause, which brings into view the unskilfulness of a surgeon in this common operation; for, it prevents the roller from lying smoothly although spirally applied, unless a particular artifice be dexterously adopted. The plan alluded to, is to double back the part of the roller that would not be even, were the application to be continued in the common spiral way, without this manœuvre. When the bulk of the limb increases very suddenly, it is, sometimes necessary to fold, or, as it is termed, *reverse*, every circle of the bandage in the above manner, in order to make it lie evenly on the limb. It is manifest, that the pressure of the roller will be greatest where the duplicatures are situated, and hence, when it is an object to compress any particular part, the surgeon should contrive to

reverse the turns of the bandage just over the situation where most pressure is desirable.

When a roller is to be applied to the fore-arm, it is best to make the few first turns of the bandage round the hand.

Care must be taken not to make the bandage very tight, if it be intended to wet it afterwards with any lotion; for it is always rendered still more tense by moisture.

Mr. John Bell describes the principal purposes for which a roller is employed, as follows: "Although in recent wounds, it is with plasters and sutures that we unite the parts point to point, yet it is with the bandage that we support the limb, preserve the parts in continual and perfect contact with each other, and prevent any strain upon the sutures, with which the parts are immediately joined, and we often unite parts by the bandage alone. (This is called the *Uniting Bandage*, and will be presently described.) But it is particularly to be observed, that in gun-shot wounds, and other bruised wounds, though it would be imprudent to sew the parts, since it is impossible that they should altogether unite, yet the gentle and general support which we give by a compress and bandage, prevents them from separating far from each other, unites the deep parts early, and lessens the extent of that surface, which must naturally fall into suppuration.

"In the hemorrhagy of wounds, we cannot always find the artery; we dare not always cut parts for fear of greater dangers; we are often alarmed with bleedings from uncertain vessels, &c. or from veins as well as arteries: these hemorrhages are to be suppressed by the compress; which compress, or even the sponge itself, is but an instrument of compression, serving to give the bandage its perfect effect. Frequently, in bleedings near the groin, or the arm-pit, or the angle of the jaw, wherever the bleeding is rapid, the vessels uncertain, the cavity deep, and the blood not to be commanded by a tourniquet, and where the circumstances forbid a deliberate and sure operation, we trust to compress and bandage alone.

"Bandage is very powerful in suppressing bleeding. At one period of surgery, it took place of every other method, &c. If a compress be neatly put upon the bleeding arteries, if there be a bone to resist the compress, or even if the soft parts be firm below, and the bandage be well rolled, the patient is almost secure. But such a roller must be rolled smoothly from the very extremity of the fingers or toes; the member must be thoroughly supported in all its lower parts, that it may bear the pressure above. It is partial stricture alone that does harm, creates intolerable pain and anxiety, or brings on gangrene. Hemorrhagy requires a very powerful compression, which must therefore be very general, &c. It must not be made only over the bleeding arteries, which is all that the surgeon thinks of in general, &c.

"In abscesses, where matter is working downwards along the limb, seeking out, as it were, the weak parts, undermining the skin, and wasting it, insulating and surrounding the muscles, and penetrating to the bones, the bandage does every thing. The expelling bandage, the propelling bandage, the defensive bandage, were among the names, which the older surgeons gave to the roller, when it was applied for these particular purposes; and these are properties of the roller, which should not be forgotten." (*Principles of Surgery*, Vol. 1.)

Soon after this description of some of the chief surgical uses of the roller, Mr. John Bell proceeds to explain, in what manner this most simple of all bandages may be put on a limb.

"Practice will convince you, that the firmness and neatness of a bandage depend altogether upon these two points; first, upon the turns succeeding each other in a regular proportion; and, secondly, upon making reverses, wherever you find any slackness likely to arise from the varying form of the limb. Thus, in rolling from the foot to the ankle, leg, and knee, you must take care, first, that the turns, or as the French call them, *doloires*, of the roller lie over one another by just one-third of the breadth of the bandage; and secondly, that at every difficult part, as over a joint, you turn the roller in your hand, make an angle, and lay the roller upon the limb, with the opposite flat side towards it; you must turn the bandage so as to reverse it, making, what the French call, a *renversée* of the roller at the ankle, at the calf of the leg, and at the knee. You must be careful to roll your bandage from below upwards, and support the whole limb by a general pressure. That you may be able to support the diseased part with a particular pressure, you must lay compresses upon the hollows and upon the bed of each particular abscess, and change the place of these compresses from time to time, so as now to prevent matter sinking into a particular hollow, now to press it out from a place where it is already lodged, and again to reunite the surface of an abscess already completely formed, from which the matter has been discharged." (*Principles of Surgery*, Vol. 1.)

In the article *Joints*, we have taken notice of the good effects of the pressure of the roller in the cure of some diseases of the knee. Here we shall just introduce Mr. John Bell's sentiments upon the subject: "In a diseased bursa, as in a relaxation of the knee-joint, that disease, which, with but a little indulgence, a very little encouragement of fomentations, poultices, bleeding, and low diet, would end in white-swelling of the knee, may be stopped even by so simple a matter as a well-rolled bandage. (Vol. 1, p. 127.)

The *uniting bandage*, or *spica descendens*, used in rectilinear wounds, consists of a double-headed roller, with a longitudinal slit in the middle, of three or four inches long. The roller, having one head passed

through the slit, enables the surgeon to draw the lips of the wound together. The whole must be managed, so that the bandage may act equally. When the wounds are stitched, this bandage supports the stitches, and prevents their tearing through the skin. When the wound is deep, writers advise a compress to be applied on each side, in order to press the deeper part of its sides together. When the wound is very long, two or three bandages should be employed, and great care must be taken, that the pressure is perfectly equable.

Henkel and Richter recommend an uniting bandage, which allows the surgeon to see the wound, over which only narrow tapes cross. The reader, if he should ever wish to employ this contrivance, may read a description of it in Rees's Cyclopædia, or Motherby's Medical Dictionary; though I confess I could not understand it from the description in those works, until I looked at the plate in Richter's *Anfangsgr. der Wundarzn.* Band I.

When we make use of a single-headed roller, as a *retentive bandage* only, we should always remember to begin the application of it on the side opposite the wound. The obvious reason for so doing is to prevent a farther separation of the lips of the wound, as the contrary manner of applying the roller would tend directly to divide them. (*Gooch, Vol. 1, p. 143.*)

The intention of the *expellent bandage* is to keep the discharge sufficiently near the orifice of the wound to prevent the formation of sinuses. In general, a compress of unequal thickness is necessary; the thinner part of the compress being placed next, and immediately contiguous to, the orifice of the wound; the thicker part below. Before the bandage is applied, the pus must be completely pressed out, and the rolling begin with two, or three, circular turns on the lower part of the compress. The bandage must then be carried spirally upwards, but not quite so tightly, as below. It is afterwards to be rolled downward to the place where it began.

The *creeping* is a simple bandage, every succeeding turn of which only just covers the edge of the preceding one. It is employed in cases, in which the object is merely to secure the dressings, and not to make any considerable, or equable pressure.

A bandage is termed *compound*, when several pieces of linen, cotton, or flannel, are sewed together in different directions, or when the bandage is torn or cut, so as to have several tails. Such are the T bandage, the suspensory, the capistrum, &c.

The *eighteen-tailed bandage* is one of the most compound. It is now in general use for all fractures of the leg and thigh, sometimes for those of the fore-arm, and frequently, for particular wounds. Its great recommendations are the facility with which it can be undone, so as to allow the parts to be examined, and its not creating,

on such an occasion, the smallest disturbance of the disease, or accident.

The eighteen-tailed bandage is made by a longitudinal portion of a common roller, and by a sufficient number of transverse pieces, or tails, to cover as much of the part as is requisite.

Each of the cross pieces is to be proportioned in length to the circumference of the part of the limb to which it is to be applied; so that in making this sort of bandage for the leg, or thigh, the upper tails will be twice as long as the lower ones. After laying the long part of the bandage on a table, fix the upper end of it in some way or another. Then begin laying the upper tails across it, and proceed with placing the rest. Each tail must be long enough to extend about two inches beyond the opposite one, when they are both applied. The tails, being all arranged across the longitudinal band, they are to be stitched in this position with a needle and thread. When the bandage is intended for the leg, a piece of the longitudinal part of the roller below, is to extend beyond the tails. This is usually brought under the sole of the foot, and then applied over the inner ankle in the first instance, after the bandage has been put under the limb. Then the surgeon lays down the first of the lower tails, and covers it with the next one above. In this way, he proceeds upward, till all the cross pieces are applied, the uppermost one of which he fastens with a pin. This bandage has a very neat appearance. The tails are said to lie better, when placed across the longitudinal piece a little obliquely. (*Pott.*)

The *T bandage* is, for the most part, used for covering parts of the abdomen and back, and especially, the scrotum, perineum, and parts about the anus. Its name is derived from its resemblance to the letter T, and it is, as Mr. John Bell remarks, the peculiar bandage of the body. If the breast or belly be wounded, we make the transverse piece, which encircles the body, very broad, and having split the tail-part into two portions, one of these is to be conveyed over each side of the neck, and pinned to the opposite part of the circular bandage, so as to form a suspensory for the latter, and prevent its slipping down. But, says Mr. John Bell, if we have a wound, or disease, or operation, near the groin, or private parts, the tail-part then becomes the most important part of the bandage: then the transverse piece, which is to encircle the pelvis, is smaller, while the tail-part is made very broad. When the disease is in the private parts, perineum, or anus, we often split the tail according to circumstances; but, when the disease is in one groin, we generally leave the tail-part of the bandage entire and broad.

The *linteum scissum*, or *split-cloth*, is a bandage applied occasionally to the head, and consists of a central part, and six, or eight tails, or heads, which are applied as follows:

When the cloth has six heads, the middle, or unsplit part of the cloth is applied to the top of the head. The two front tails go round the temples, and are pinned at the occiput; the two back tails go also round the temples, and are pinned over the forehead; the two middle tails are usually directed to be tied under the chin; but, as Mr. John Bell observes, this suffocates and heats the patient, and it is better to tie them over the top of the head, or obliquely, so as to make pressure upon any particular point. (*Principles of Surgery*, Vol. 1. p. 131.)

The old surgeons usually split this middle tail into two parts, a broad, and narrow one. In the broad one, they made a hole to let the ear pass through. This broad portion was tied under the chin, while the narrow ends were tied obliquely over the head. As Mr. John Bell has observed, though this gave the split-cloth the effect of eight tails, yet, the ancient surgeons did not name it the split-cloth with eight tails. When they split the cloth into eight tails, and, especially, when they tied the eight tails in the following particular manner, they called the bandage *cancer*, as resembling a crab in the number of its legs. The *cancer* or *split-cloth of eight tails*, was laid over the head, in such a manner, that four tails hung over the forehead and eyes, while the other four hung over the back of the head. They were tied as follows; first, the two outermost tails, on each side in front, were tied over the forehead, while the two middle tails in front were left hanging over the knot. Then the two outermost, or lateral tails behind, were tied round the occiput. Next the middle tails were tied, the two anterior ones being made to cross over each other, and pass round the temples to be pinned at the occiput; while the two middle tails behind, were made to cross each other, and pass round the temples, so as to be pinned over the ears, or near the forehead. (See *John Bell's Principles*, Vol. 1. p. 132.)

The *triangular bandage* is generally a handkerchief doubled in that form. It is commonly used on the head, and now and then, as a support to the testicles, when swelled. The French term it *couvre-chef en triangle*.

The *nodose bandage*, called also *scapha*, is a double-headed roller, made of a fillet four yards long, and about an inch and a half broad. It must be reversed two or three times, so as to form a knot upon the part which is to be compressed. It is employed, when a hemorrhage from a wound is to be stopped, or, for securing the compress, after bleeding in the temporal artery. The most convenient bandage in general for the forehead, face, and jaws, is the *four-tailed one*, or *single split-cloth*.

It is composed of a strip of cloth, about four inches wide, which is to be torn at each end, so as to leave only a convenient portion of the middle part entire. This unsplit middle portion is to be applied to the forehead, if the wound be there, and the two upper tails are carried backward, and

tied over the back part of the head, while the two lower ones are to be tied either over the top of the head, or under the chin, as may seem most convenient.

When the wound is on the top of the head, the middle of the undivided part is to be applied to the dressings. The two posterior tails are to be tied forward, and the two anterior ones are to be carried backward, so as to be tied behind the head. This is sometimes called *Galen's bandage*. It is curious, that writers on bandages should use the terms *head*, and *tail*, synonymously, and hence this *four-tailed bandage* is often called the *sling with four heads*. Such confusion of language is highly reprehensible, as it contributes, in a very high degree, to obstruct the comprehension of any, the most simple subject.

If the upper lip be cut, and a bandage needed, which is seldom the case, it is almost superfluous to say, that this bandage will serve the purpose. It serves also in cuts of the lower lip, though there, also, we trust rather to the twisted suture, than a bandage.

The single split-cloth is particularly useful in supporting a fractured lower jaw, and in such cases, is the only one employed in modern surgery. This bandage, when used for this particular purpose, namely, supporting the lower jaw, is named *capistrum*, or *bridle*, because it goes round the part somewhat like a horse's halter.

"In some cases, (says Mr. John Bell) the circumstances require us to support the chin particularly, and then the unsplit part of the bandage is applied upon the chin with a small hole to receive the point; but, where the jaw is broken, we pad up the jaw-bone into its right shape, with compresses pressed in under the jaw, and secured by this bandage. When we are in fear of hemorrhagy after any wound, or operation, near the angle of the jaw, we can give the sling a very remarkable degree of firmness. For this purpose, we tear the band into three tails on each side, and we stitch the bandages at the bottom of each slit, lest it should give way, when drawn firm," &c. (*Principles of Surgery*, Vol. 1.)

We have already described one way of applying a handkerchief, as a bandage to the head, when we noticed the *triangular one*, or *couvre-chef en triangle*. The other manner of applying the handkerchief, called the *grand couvre-chef*, is as follows;

You take a large handkerchief, and fold it, not in a triangular, but a square form. You let one edge project about three finger-breadths beyond the other, in order to form a general border for the bandage. You lay the handkerchief upon the head, so as to make the lower fold, to which the projecting border belongs, lie next the head; while the projecting border itself is left hanging over the eyes, till the bandage is adjusted. The two corners of the outermost fold are first to be tied under the chin; the projecting border is then to be turned back, and pinned in a circular form round the face,

while the corners of the fold next the head are to be carried backward and tied.

After the outer corners of this bandage have been tied under the chin; after the inner corners have been drawn out and carried round the occiput; and after the border has been turned back and pinned; the doubling of the handkerchief over each side of the neck hangs in a loose awkward manner. It remains, therefore, to pin this part of the handkerchief up above the ear, as neatly as can be contrived. (See *J. Bell's Principles*.)

The grand couvre-chef has certainly nothing to recommend it, either in point of utility or elegance. A common night-cap must always be infinitely preferable to it. In the event, however, of a cap not being at hand, it is proper that the surgeon should know, what contrivances may be substituted to fulfil the objects in view.

Having, in the numerous articles of this Dictionary, noticed the mode of applying bandages in particular cases, and allotted a few separate descriptions for such bandages, as are not here mentioned, but which are often spoken of in books, we shall conclude for the present, with referring the reader for further information to *Motherby's Medical Dictionary*; *Rees's Cyclopædia*; and *John Bell's Principles of Surgery*, Vol. 1. *Galen and Vidius Vidijs are reckoned the best of the old writers on the subject*; *M. Sue, Thillaye, Heister, Juville, Lombard, and Bernstein, of the modern ones. The latter are said however, to be all too prolix.* (See *Rees's Cyclopædia*, art. *Bandage*.)

BARK, Peruvian, (See *Cinchona*.)

BELLADONNA. (*Deadly Night-shade*.) Is violently narcotic. The leaves were first used externally for discussing scirrhus swellings, and they have been subsequently given internally, in scirrhus and cancerous diseases, amaurosis, &c. Five grains are reckoned a powerful dose: one is accounted enough to begin with. At present, the extract, as directed by the London College, is more commonly prescribed.

From the power, which belladonna is known to possess, of lowering the action of the whole arterial system, it seems to be a fit medicine in many surgical cases, where that object is desirable, particularly in examples of aneurism.

A very peculiar virtue, which belladonna has, is that of causing a dilatation of the pupil, when used as an external application to the eyebrow and eyelids. The late Mr. Saunders was in the habit of employing belladonna a good deal for this express purpose. A little while before undertaking the operation for the congenital cataract, he was accustomed to introduce some dissolved extract of belladonna between the eyelids, or rub the eyebrow and skin about the eye freely with the same application. The consequence was, that if there were no adhesions of the iris to other parts, a full dilatation of the pupil was produced in less than an hour, and the whole of the ca-

taract was distinctly brought into view. This was unquestionably a considerable improvement in practice, as the iris was kept out of danger, and the operation materially facilitated. I allude here more particularly to Mr. Saunders's own method, in which he introduced the needle through the cornea, in front of the iris, and then conveyed it to the cataract through the enlarged pupil. Belladonna was also externally applied by Mr. Saunders, after the operation, with the view of preventing the edge of the iris from becoming adherent to the edges of the torn capsule. Stramonium is found to have the same effect upon the iris, as belladonna. Some experiments, in which the fact is clearly proved, were detailed many years ago, by a namesake of my own in the United States. (See *A Dissertation on the Properties and Effects of the Datura Stramonium*, &c. by Samuel Cooper, Philadelphia, 1797. *C. Himly de la Paralysie de l'Iris par une application locale de Jusquiame*, &c. 2d Ed. 12mo. Altona, 1805. *J. Bailey, Observations relative to the Use of Belladonna in painful Disorders of the Head and Face*, 8vo. Lond. 1818.)

BINOCULUS. (from *binus*, double, and *oculus*, the eye.) A bandage for keeping dressings on both eyes. Its application will easily be understood by referring to *Monoculus*.

BISTOURY. (*Bistoir*, French.) Any small knife for surgical purposes.

BLADDER, Puncture of. This is an operation, to which we are obliged to have recourse, after having in vain employed all the other means indicated for preventing the bad, and even fatal consequences of a stoppage of the evacuation of the urine, and distention of the bladder. Various accidents and diseases, both acute and chronic, may occasion this dangerous state, as will be more particularly noticed in the article *Urine, retention of*.

The bladder, which can conveniently hold about a pint and a half of urine, is no sooner dilated, so as to contain two pints, than uneasy sensations are experienced. The desire of discharging the water now becomes urgent, and if the inclination be not gratified, and the bladder be suffered to be dilated beyond its natural state, it loses all power of contraction, and becomes paralytic. The desire, indeed, continues, and the efforts are renewed in painful paroxysms; but, the power is lost and the bladder becomes more and more distended. When this viscus is dilated in the utmost degree, and neither its own structure, nor the space in the abdomen, can allow a further distention; either the bladder must be lacerated, which it never is, so equally is it supported by the pressure of the surrounding parts, or its orifice must expand and the urine begin to flow. After the third day of the retention, the urine often really begins to flow, and, whatever descends from the kidneys is evacuated in small quantities from time to time, and at this period, the bladder is distended in as great a degree, as

it ever can be, however long the patient may survive. This dribbling of the urine, which begins, when the bladder is dilated to the utmost, and continues till the eighth, or tenth day, or till the bladder sloughs, has long been understood, and is named by the French, "*urine par régorgement*." To practitioners, who do not understand it, the occurrence is most deceitful. The friends felicitate themselves, that the urine begins to flow; the surgeon believes it; basins, and cloths, wet with urine, are easily produced; but, the patient lies unrelieved. The continued distention of the bladder is followed by universal inflammation of the abdomen. The insensibility, and low delirium of incipient gangrene, are mistaken for that relief, which was expected from the flow of urine, till either hiccough comes on, and the patient dies of fever, and inflammation, or the urine gets into the abdomen, through an aperture, formed by mortification. Let no surgeon, therefore, trust to the reports of nurses, and friends, but lay his hand upon the hypogastric region, and tap with his finger, in order that he may distinguish the distended bladder, and the fluctuation of urine. As the bladder suffers no further distention, after the third day, why should it burst? Not from laceration; for it is supported by the uniform pressure of the surrounding viscera; not by yielding suddenly, for it is distended to its utmost on the third day of the retention, and yet seldom gives way before the tenth; not by attenuation, for it becomes thickened. The term *laceration* was never more wrongly applied, than in this instance; for, when there is a breach in the bladder, it is found, on dissection, to be a small round hole, such as might be covered with the point of the finger. The rest of the viscus, and the adjacent bowels, are red and inflamed, while this single point is black, and mortified! Delay is more dangerous, than even the worst modes of making an opening into the bladder, and, while life exists, the patient should have his chance. (See *John Bell's Principles of Surgery*, Vol. 2, Part 1, p. 262, &c.)

That many patients die after paracentesis of the bladder is an undoubted truth, and this circumstance has rather intimidated practitioners against the operation. It appears to me, however, that death may in general be more fairly ascribed to the effects of the disease, than to the puncture of the bladder, and that, if this last measure were not deferred so long, as it often is, the recoveries would be more numerous.

Hence, when relief cannot be obtained by the treatment described in the article, *Urine, Retention of*; when no urine at all has come away, at the end of the third day; or when it only does so in a dribbling manner after this period, while the bladder continues distended, and no catheter can be introduced; the operation should not be delayed. In urgent cases, one should rather operate, as soon as forty-eight hours have elapsed.

No doubt, a man, who is exceedingly skilful in the use of the catheter, and knows how to practise with science and judgment all the other means for relieving the retention of urine, will not frequently find it necessary to have recourse to the operation of puncturing the bladder. This is said to have been so much the case with the eminent Desault, that, in the course of ten years, he had occasion only once to perform such an operation in the Hotel Dieu, where diseases of the urethra are always extremely numerous. (See *Œuvres Chir. de Desault, par Bichat, Tom. 2, p. 316.*) When, however, this superior manual dexterity with the catheter is not the acquirement of the practitioner, the timely performance of the paracentesis of the bladder should ever be observed. At the present day, the absolute necessity for puncturing the bladder is also rendered a less frequent circumstance, not only by the treatment of diseases of the urethra being better understood, than formerly, but also by the very great perfection, to which the construction of elastic gum catheters is brought, instruments, from which the most essential assistance may frequently be derived. I shall next treat of the three modes of doing the operation.

1. Puncture through the Perinæum.

The first surgeon that ever performed this operation is said to have been M. Tolet, a French surgeon, the author of a valuable treatise, entitled "*Traité de Lithotomie, ou de l'extraction de la pierre hors de la vessie, Troisième édition, Paris, 1681.*" According to Sabatier, it was customary, at the time of Dionis, to make the opening with a narrow-pointed scalpel, about four or five inches long, which was plunged into the bladder, at the place where the incision in the apparatus major terminated. (See *Lithotomy*.) The escape of the urine indicated when the surgeon had reached the bladder. A straight probe was conducted along the knife, and then a cannula was passed along the probe into the bladder, where it was allowed to remain as long as necessary, care being taken to fix it by means of tapes, put through the rings at the broad part of the instruments. The opening was then closed with a linen tent. Some practitioners, however, after introducing a staff as far into the urethra as possible, began an incision in the perineum. Having made an opening into the canal, they pushed the staff into the bladder, and along this instrument introduced a gorget. With the assistance of the gorget, a cannula was next passed into the bladder, and allowed to continue thus introduced. This complicated mode of proceeding, which Sabatier is pleased to term more methodical than that which has been first mentioned, could only answer in cases, where the obstruction about the neck of the bladder was inconsiderable, and where in fact the introduction of the catheter was not yet impracticable. At least, therefore, the me-

thod was unnecessary. The other plan of piercing the urethra in several places, and making a passage for the urine through the prostate, says Sabatier, increased the inflammation, with which this gland was affected, and rendered the disease, if not mortal, at least much more difficult of cure.

Sabatier represents Dionis as the first who suggested this method of opening the bladder on one side of the perineum, at the part, where Frère Jacques used to perform lithotomy. Dionis conceived, that in this mode of operating, the patient would suffer less pain, because neither the urethra, nor the neck of the bladder, would be injured; but at the same time, he recommended a process to be followed, which was similar to that pursued in making the puncture in the middle of the perineum; viz. that a narrow scalpel should first be introduced, so as to make a passage for the probe, along which the cannula was to be guided into the bladder. The idea of substituting for these unsuitable instruments a trocar of convenient length, was exceedingly simple, and for this improvement, which took place in 1721, surgery is indebted to Juncker, (See *Conspectus Chirurgia*, Tab. 97, p. 674,) unless the following passage be correct: "In the year 1717, or 1718, M. Peyronie showed in the King's garden a long trocar, which he had successfully employed in a similar puncture." (*Desault's Parisian Chir. Journ.* Vol. 2, p. 267.)

The patient having been placed in the same position as for lithotomy, an assistant is to press with his left hand on the region of the bladder, above the pubes, in order to propel that viscus as far downward into the lesser pelvis as possible, while, with his right hand, he supports the scrotum. The surgeon is then to introduce the trocar at the middle of a line, drawn from the tuberosity of the ischium to the raphe of the perineum, two lines more forward than the verge of the anus. The instrument is first to be pushed in a direction parallel to the axis of the body; and its point is afterwards to be turned a little inwards. Here, according to Bichat, there is no occasion to convey the cannula so far into the bladder, as is done, when the operation is performed above the pubes. The portion of this viscus, that is pierced, being incapable of changing its position, with regard to other parts in the perineum, if the cannula only project a few lines into its cavity, it will not be liable to slip out. It would be wrong, indeed, to carry it in further; for, the pressure of its end against the posterior parietes of the bladder would do harm. Lastly, the cannula is to be fixed in its place, by means of the T bandage. (See *Œuvres Chir. de Desault*, T. 3, p. 320.)

Some writers recommend the introduction of the left index finger into the rectum, in order to draw this intestine out of the way; but Sabatier thinks it better to use this finger for pressing on the part of the perineum, where the puncture is about to be made, so as to make the skin tense, and

assist in the guidance of the trocar. (*Médecine Opératoire*, T. 2, p. 126.)

The parts, divided in the puncture, are the skin, a good deal of fat, and cellular substance, the levator ani muscle, and that portion of the lower part of the bladder, which is situated on one side of its neck.

The following is the judgment, which Bichat has passed upon this method: In the track, which the trocar has to pass, there is no part, the puncture of which must of necessity give rise to bad symptoms. A surgeon, moderately exercised in the practice of this operation, is tolerably sure of piercing the bladder, which is opened in the most depending situation, and at a point, which constantly bears the same relation to the perinaeum. But, the position, in which the patient is placed for the operation, is a great deal more disagreeable, than that for the puncture above the pubes. Several assistants are required to fix him, and one is necessary for compressing the bladder in the hypogastric region. There is a possibility of wounding the vessels of the perineum, and of pricking the nerves which accompany them. If the point of the trocar be carried too much outwards, it may glide over the external side of the bladder. If it be inclined forwards, it may slip between this viscus and the pubes. If it be turned too much inwards, it may pierce the prostate gland. If directed too much backwards, it may wound the vasa deferentia, the rectum, the extremity of the ureter, and the vesiculæ seminales. Also, while the cannula is kept introduced, the patient can neither walk about, nor sit down: but must continually keep himself in bed. Lastly, this mode of operating is frequently counter-indicated, by tumours, or other common diseases, in this part of the body, in consequence of retentions of urine. (*Œuvres Chir. de Desault par Bichat*, Tom. 3, p. 321.)

The puncture of the bladder from the perineum is now almost universally abandoned by British surgeons. "We may esteem it fortunate," says Desault, "if the trocar penetrates directly into the bladder, after piercing the fat and the muscles, situated between the tuberosity of the ischium and the anus; and, as this viscus is subject to much variation in its form, the surgeon will often be defeated, unless he be perfectly clear in his ideas respecting its situation and figure. This disappointment is not without example, and there is sufficient cause to deter a practitioner from performing this operation, independently of the danger of wounding with the trocar the vasa deferentia, vesiculæ seminales, ureter, &c." (*Parisian Chir. Journ.* V. 2, p. 267.)

If there be now any practitioners, who are averse to the total relinquishment of this method, I think the following caution, given by Sabatier, may be of service to them: perhaps, the operation would be more safe, if the surgeon were to begin with making a deep incision in the perineum, as is practised in the lateral way of cutting for the stone, and if he were to direct

from plunging the trocar into the bladder, until he had assured himself of the situation of this viscus, and felt the fluctuation of the urine. This advice was given by Garengeot to Foubert, in regard to the mode of cutting for the stone practised by the latter, and it seems equally applicable in the present place. (*Médecine Opératoire*, Tom. 2. p. 127.)

As in cases of inveterate strictures, the urethra between the obstruction and the bladder is always dilated, I think with Mr. C. Bell, that it may sometimes be better practice to cut into such distended portion of the passage, than puncture the bladder. On this point, many useful remarks may be found in this gentleman's *Surgical Observations*, Part 5, &c. the tenor of which I have more particularly considered in the 2d vol. of the 4th Ed. of the First Lines of Practice of Surgery.

2. Puncture above the Pubes.

The invention of the method of tapping the bladder above the pubes was suggested by the possibility of extracting calculi from that viscus, by what is usually denominated the high operation. The first performers of the puncture above the pubes are said to have employed a straight trocar, the very same instrument as was used for tapping the abdomen in cases of dropsy. The consequence was, that when such a trocar was too long, its cannula was apt to hurt the opposite parietes of the bladder, so as to occasion inflammation and a slough, on the separation of which the urine was liable to insinuate itself either into the abdomen, or rectum, as happened in a case mentioned by Mr. Sharp, where no more urine was discharged through the cannula, and the patient died of a sort of diarrhoea. When the trocar is short, the bladder on subsiding and contracting itself, gradually quits the cannula, which becomes useless, and a necessity for making another puncture may be produced. Whatever pains may be taken to direct the trocar obliquely downwards and backwards, so that the cannula may be, in some degree, parallel to the axis of the bladder, one, or the other of these accidents, cannot always be prevented.

Their prevention, however, may be effected by merely employing, instead of a straight trocar, a curved one, which will naturally take a suitable direction. This improvement was embraced by Frère Côme, the inventor of the lithotome caché, who also devised a curved trocar, for the paracentesis of the bladder, very superior to the instrument of the same shape previously in use.

To this way of operating, Mr. Sharp was partial, and Mr. Abernethy has more recently recommended it, under certain circumstances. The former celebrated surgeon remarks, that it is an operation of no difficulty to the surgeon, and of little pain to the patient, the violence done to the bladder being at a distance from the parts

affected. It is equally applicable, whether the disorder be in the urethra, or prostate gland, and when there are strictures, the use of bougies may be continued, while the cannula remains in the bladder. (*Critical Inquiry*, p. 125, edit. 4.)

Some writers recommend making an incision, about two inches long, through the linea alba, a little way above the pubes, and then introducing a trocar into the bladder. Others deem this preliminary incision quite useless, asserting that the operation may be performed with equal safety, and less pain to the patient, by puncturing at once the skin, the linea alba, and the bladder. When the trocar has been introduced, the stilette must be withdrawn, and the cannula kept in its position by a riband, passed through two little rings, with which it should be constructed, and fastened round the body. The orifice of the cannula should be stopped up with a little plug, so as to keep the urine from dribbling away involuntarily, and taken out as often as may be necessary. (*Encyclopédie Méthodique; Part. Chirurg. Art. Paracentese de la Vesie.*)

The trocar should be introduced in a direction obliquely downward and backward; for as this corresponds with the axis of the bladder, the instrument will be less likely to injure the opposite side of that organ.

Nearly all writers advise the puncture to be made an inch, or an inch and a half above the pubes. The reasons for so doing are the following: "If the puncture be made close to the os pubis, the bladder in that part, often rising with an almost perpendicular slope, leaves a chasm between it and the abdominal muscles, or, to speak more strictly, a certain depth of membrana cellularis only, so that, if the trocar penetrate but a little way, it possibly may not enter into the bladder. If it penetrates considerably, it may pass through the bladder into the rectum, or, if not in the operation itself, some days afterwards, when by the course of the illness and confinement the patient is more wasted. For, the abdominal muscle, shrinking and falling in, occasion the extremity of the cannula to press against the lower part of the bladder, and, in a small time, to make a passage into the rectum." (*Sharp in Critical Inquiry*, p. 127.) Though the reasons here adduced seem at first as formidable as they are numerous, does not the danger of injuring the peritoneum form an objection to plunging in a trocar at the above distance from the pubes? Certain it is, peritonitis would be more apt to be induced by such practice, than by introducing the instrument immediately above the pubes. Richerand decidedly condemns the plan, principally because the higher the puncture is made, the more apt will the bladder be to quit the cannula, on the urine being discharged. (See *Nosogr. Chir. T. 3. p. 472, Ed. 2.*) In Desault's works, by Bichat, the puncture is also advised to be made immediately above the pubes. Tom. 3, p. 318. Some of Mr. Sharp's objections are done away, by taking

care to pass the trocar into the bladder in the axis of this viscus, and employing one which is somewhat curved, as Hunter, Frère Côme, Sabatier, &c. have advised. Mr. Sharp confirms the danger of using too long a cannula, by mentioning an accident, which occurred in his own practice. Though he introduced the instrument more than an inch and a half above the os pubis, yet having pushed it full two inches and a half below the surface of the skin, its extremity in six or seven days insinuated itself into the rectum. (*Critical Inquiry*, p. 127.) The instrument, says an excellent writer, should be more or less long, according as the patient is fat, or otherwise; but, the ordinary length should be about four inches and a half. The curvature should be uniform, and form the segment of a circle, about eight inches in diameter. (*Œuvres Chir. de Desault par Bichat*, T. 3, p. 317.)

A catheter left in the bladder, longer than ten days, may possibly gather such an incrustation from the urine, as not only to render the extraction of it painful, but even impracticable. Surgeons, therefore, should never leave the cannula in the bladder quite a fortnight: or, if it must be kept introduced so long, Mr. Sharp advises a second one to be introduced, made with an end, like that of a catheter. (*Critical Inquiry*, p. 129.)

Mursinna, however, has reported one example, in which a cannula was kept in for a long time without inconvenience. (*Hecker, Annales der Ges. Medicin.* 1810, Jul. p. 39.)

Mr. Abernethy makes an incision, between the pyramidal muscles, passes his fingers along the upper part of the symphysis pubis, so as to touch the distended bladder, and introduces a common trocar, of the middle size, in a direction obliquely downwards. On withdrawing the stilette, he passes a middle-sized hollow elastic catheter, through the cannula, into the bladder. The cannula is withdrawn, and the catheter left in, till the urine passes through the urethra. After a week, as the instrument begins to be stopped up with mucus, it is taken out, and a new one introduced. (*Surgical Observations*, 1804.) It might be objected to this plan of employing a hollow bougie, that, as it is smaller than the wound, the urine is not kept from passing between the instrument, and parts, into which it is introduced, as well as through the tube itself. This happened in Mr. Abernethy's case, and, though no urine in this instance got into the cellular membrane, it might probably sometimes do so, because, it is not till after inflammation has taken place that the cavities of the cellular substance are closed with coagulating lymph. After a time, however, the cannula of the trocar might be withdrawn, and the hollow bougie employed, if preferred, though it seems difficult to discover a reason for the preference.

The following is one of Sir E. Home's conclusions: "When the puncture is made above the pubes, the cannula, which incloses the trocar, is not to be removed, till

the surrounding parts have been consolidated by inflammation, so as to prevent the urine in its passage out from insinuating itself into the neighbouring parts; for wherever the urine lodges, mortification takes place. Any advantage, therefore, which may arise from a more flexible instrument remaining in the bladder, is more than counterbalanced by its not filling completely the aperture through the coats of the bladder, and allowing the urine to escape into the cellular membrane." (*Trans. of a Soc. for Med. and Chir. Knowledge*, V. 2.)

There is much truth in the following passage: The abdomen is inflamed; the preliminary incisions, which prepare for the introduction of the trocar, sometimes pass through several inches of fat, and cellular substance; the incisions must be wide in proportion to their depth; the cannula is no sooner lodged here, than it is displaced, in some degree, by the contraction of the bladder, which, when emptied, subsides under the pubes. The cannula stands so obliquely, that the urine never flows with ease, but, by running out upon the wound, and by being injected among the cellular substance, it causes the wound to inflame; the wound by its proximity to the inflamed peritonæum soon mortifies, and thus, notwithstanding the temporary relief, produced by the emptying of the bladder, the patient dies on the third or fourth day. (*John Bell's Principles of Surgery*, Vol. 2, p. 271.)

That this operation is infinitely better, than that of making the puncture in the perineum, is indisputable. There are even now some good surgeons, who seem to prefer it to the method of tapping the bladder from the rectum. In the *Œuvres Chirurgicales de Desault*, Tom. 3. p. 324, it has received the preference, and at p. 319, of the same book, a high encomium is bestowed on it, in the following terms. "This operation is easy. The little thickness of the parts which are to be wounded, renders it quick and triflingly painful. The surgeon has occasion for no assistance. The patient is neither intimidated, nor fatigued with the posture in which he is put. It is almost impossible to miss the bladder, except it were exceedingly contracted. There is no risk of piercing the cavity of the abdomen. Anatomy proves, that here the bladder is in immediate contact with the recti muscles, and that when this viscus is distended with urine, it pushes the peritonæum upwards, and backwards, under which membrane it enlarges, and thus makes the point of the trocar become more and more distant from the cavity of the abdomen. The patient may easily lie on his side, or abdomen, so as to discharge all the urine contained in the bladder. There are here no nerves, nor vessels, of which the injury can be dangerous. No difficulty is experienced in fixing the cannula, and the presence of this instrument does not hinder the patient from sitting, standing up, or even walking about in his chamber. When the cannula, also, is introduced to the lower part of the blad-

der, this viscus cannot possibly quit it. Lastly, the wound heals with more facility, than that made in any other method."

Respecting this advice to push the cannula so far into the bladder, it is highly objectionable, for the reason already explained. The writer of the preceding commendation seems to me rather too partial. He has told us of the little thickness of the wounded parts, and, yet a little before bestowing these praises, he has acknowledged, "*il est rare, que dans cette ponction, on traverse directement la ligne blanche: on passe presque toujours sur ses côtés, et l'on divise la peau, l'aponévrose des muscles larges du bas-ventre, les muscles droits, quelquefois l'un des pyramidaux, et la paroi antérieure de la vessie.*" (Tom. 3. p. 318.)

According to my own judgment, the plan which is about to be described, is the safest and best, when the circumstances of the case afford a choice, and I think, that it would be for the benefit of the afflicted, if the puncture above the pubes were only performed in cases, in which the enormous enlargement of the prostate gland, and the disease in the rectum, prevent a puncture from being safely made from the rectum.

3. Puncture from the Rectum.

This method is more generally applicable, than either of the two plans above related. It is not, like the puncture in the perinæum, liable to the objection, that the wound is made in diseased or inflamed parts, which afterwards become gangrenous. Nor is it, like the puncture above the pubes, attended with a chance of the urine diffusing itself in the cellular membrane. It has also the advantage of emptying the bladder completely. The puncture is made sufficiently far from the neck of the bladder not to increase any inflammation existing in that situation; and the operation is really attended with little pain, since there is no skin, nor muscles to be wounded, merely the coats of the bladder and rectum, at a point where these viscera lie in contact with each other. The enlargement of the prostate gland, and disease of the rectum, are, perhaps, the only solid reason against its being uniformly preferred.

When the bladder is to be tapped from the rectum, two fingers should be introduced into the intestine, instead of one, as has been directed. In this manner, the cannula can be more conveniently guided, and held in a proper position, while the trocar is introduced with the other hand. The stilette, however, must never be introduced into the cannula, except when this is properly placed, with its extremity against the part, where it is intended to make the puncture.

We read in the *Philosophical Transactions* for 1776, of a case of total retention of urine, from strictures, where the bladder was successfully punctured from the rectum. Mr. Hamilton, who did the operation, thought of the plan, in consequence

of feeling the bladder exceedingly prominent in the rectum, on introducing his finger into the anus.

The patient was placed in the same position as that for lithotomy; a trocar was passed along the finger into the anus, and pushed into the lowest and most projecting part of the swelling, in the direction of the axis of the bladder. A straight catheter was immediately introduced through the cannula, lest the bladder by contracting should quit the latter, which was taken away, and, as soon as the water was discharged, the catheter was also removed. Notwithstanding the puncture, the bladder retained the urine as usual, until a desire to make water occurred. Then the opening made by the instrument seemed to expand, and the water flowed in a full stream from the anus. The urine came away in this manner, two days, after which it passed the natural way, with the aid of a bougie, which had been passed through the urethra, into the bladder, and which was used, till all the disease in this canal was cured.

The method is said to have been originally proposed in 1750, by Mr. Fleurant, surgeon of the hospital *La Charité*, at Lyons; and Pouteau, in 1760, published an account of it, and three cases in which Fleurant had operated. It was also the feel of the bladder, on the introduction of a finger *intra anum*, which led the latter surgeon to choose making a puncture in this situation. The urine was immediately discharged, and the cannula supported in its place with the T bandage, until the natural passage was rendered pervious again. But the cannula, being allowed to remain in the rectum, became incommensurable to the patient, when he went to stool, and the inconvenience was vastly increased by the continual dribbling of the urine from the mouth of the instrument. Hamilton avoided both these inconveniences, by withdrawing the cannula at first. In another instance, however, Fleurant left the cannula in the anus and bladder, thirty-nine days, without the least inconvenience.

In order to lessen the inconvenience, attending the presence of the cannula, Fleurant suggested that it would be better to have the tube made of a flexible substance; a proposal, that seems to merit attention, though, I believe, the inconveniences of wearing the cannula are not in general very serious, and, were a case of this kind to present itself, I should have no hesitation in withdrawing the tube altogether.

In the first volume of the *Mem. of the Medical Society of London*, two cases are related, in which, after tapping the bladder from the rectum, the cannula was immediately withdrawn, without any bad effect; and a similar fact is recorded in the *Medical Communications*, Vol. 1.

A curved trocar, of sufficient length, is the best for performing the operation, and was recommended by Pouteau. As the trocar with a lancet-point may cut blood vessels, which would bleed freely, some

authors express their preference to one made with a triangular point. (*Hovship*, p. 315.) It should be introduced into the prominence made by the distended bladder, a little beyond the prostate gland, exactly in the centre of the front of the rectum; but not imprudently far up the intestine, lest the peritoneum be injured. For some useful cautions on this head, the profession are indebted to Mr. Carpue, who has very properly adverted to the very low point to which the portion of peritoneum reflected over the rectum descends. (*Hist. of the High Operation*, &c. p. 178, 8vo. Lond. 1819.) By keeping the point of the trocar in the centre of the anterior part of the rectum, and not introducing it without first distinctly feeling with the end of the finger, the exact place into which it is to enter, the vesiculæ seminales, which diverge from each other above, will not be wounded; and even were they so, perhaps no serious consequences would follow.

It is not necessary to retain the cannula in the puncture, after the inflammation has consolidated the sides of the wound, and there is no danger of the aperture closing up, till there is another passage made for the urine. Sir E. Home thinks, that, after about thirty-seven hours, the cannula may be properly taken out. (*Trans. of a Soc. for Med. and Chir. Knowledge*, Vol. 2.) Indeed, I am not acquainted with any fact, showing the ill effect of removing the cannula at once; for, here the urine has only to pass through a mere opening, without any longitudinal extent, like what remains after puncturing above the pubes. The safety and simplicity of tapping the bladder from the rectum, will always recommend this method to impartial practitioners. The wound is made at a distance from the peritoneum, passes through no thickness of parts, and is quite unattended with any chance of the urine becoming extravasated in the cellular substance. Whether the bladder be morbidly contracted and thickened; whether the neck of the bladder be inflamed; it is equally applicable; enlargement of the prostate gland, and much disease in the rectum, can alone warrant the puncture above the pubes being ever preferred.

I am happy to join the experienced and judicious Mr. Hey with the advocates for this mode of performing the operation, and as his opinion on this subject must have considerable influence, I shall quote the following passage from his valuable work, particularly as the observations confirm some other points, adverted to in the present article. "It is sometimes impossible, from various causes, to make a catheter pass through the urethra. The puncture of the bladder then becomes necessary, if the retention of urine continues. This operation may be performed, either above the pubes, or through the rectum. I have seen it performed in both these methods; but, give the preference to the latter. It is more easy to the surgeon; and less painful

to the patient. Pouteau's curved trocar is a very convenient instrument; and may be used with safety for puncturing the bladder through the rectum; but, the operator should cautiously avoid wounding an artery, which may be felt running towards the anus, where the bladder is most protuberant. The finger, which is introduced into the rectum to guide the trocar, may be conveniently placed a little on either side of this vessel. It is not always necessary to leave the cannula in the bladder, as the urine sometimes begins to flow through the penis, within a few hours after the bladder is emptied. Perhaps, this event may be the most frequent, when the introduction of the catheter has been prevented by a stricture in the urethra. If the wound becomes closed, before the power of expelling the urine is regained, recourse must be had to a repetition of the operation, which gives very little trouble to the patient: neither is he much incommoded by suffering the cannula to remain two or three days in the bladder. This is sometimes necessary, and seldom improper." (*Hey's Practical Observations in Surgery*, p. 430—431, edit. 2.)

In the foregoing columns, I have briefly adverted to the proposal of cutting into the urethra behind the obstruction, instead of puncturing the bladder. Mr. Gruinger, of Birmingham, a few years ago, also recommended cutting into the urethra, immediately in front of the prostate, and relieving the bladder by the introduction of a female catheter through the gland, or, (if that could not be accomplished) by the division of its substance with a scalpel. (*Med. and Surg. Remarks*, &c. 8vo. Lond. 1815.)

Women seldom stand in need of a paracentesis of the bladder; but, when the operation is necessary in them, it is more safely and easily performed from the vagina, than in any other way. If it should be proper to leave the cannula introduced, this must be long enough to allow its orifice to be situated on the outside of the labia, where it must be fixed with a T. bandage.

Consult particularly Sharp on the Operations, Chap. 15. and his Critical Inquiry. Ambr. Bertrandi, Trattato delle Operazioni di Chirurgia, accresciuto di note, &c. dai Chirurghi G. A. Penchionati e G. Brugnone, 8vo. Torino, 1802. Bertrandi was an approver of the puncture from the rectum: so was Le Blanc. *Operat. de Chir.* T. 1. *Mélanges de Chirurgie*, par Pouteau, Lyon, 1760, p. 500. *L'Encyclopédie Méthodique*, Partie Chirurgicale; art. Paracentèse de la Vessie. Schmeucker, *Chir. Wahrnehmungen*, 2 Th. No. 39: puncture from the rectum. Sabatier's *Médecine Opératoire*, Tom. 2. Mursinna, *Journ. für die Chirurgie*, &c. 4, p. 46, 67. Cases of puncture from the rectum, and above the pubes. In illustration of the operation of puncturing the bladder, Camper's plates are the best: See his *Demonst. Anat. Pathol.* Tab. 2. In this work, the danger of letting the end of any long instrument, when introduced press against the inside of the bladder, is pro-

ced by a case, in which that organ was perforated by the extremity of a catheter, p. 11. Klotz, *Dis. de Paracentesi Vesicæ Urinariæ per intestinum rectum*, Jen. 1791. A. Bonn, *Anat. Chir. Bemerkungen über die Harnverhaltung, und den Blasenstich*. Leipz. 1794, prefers the puncture above the pubes. J. Howship, *Pract. Obs. on Diseases of the Urinary Organs*, p. 214, 8vo. Lond. 1816, thinks the operation from the rectum superior to the other methods. Sir E. Home in *Trans. for the Improvement of Med. and Chir. Knowledge*, Vol. 2. *Abernethy's Surgical Observations*, 1804. John Bell's *Principles of Surgery*, Vol. 2. *Œuvres Chir. de Desault par Bichat*, T. 3, p. 315, &c. W. Schmid über die Krankheiten der Harnblase, &c. 8vo. Wien, 1806. Richerand's *Nosogr. Chir.* T. 3, edit. 4. Hey's *Practical Observations in Surgery*, p. 430, edit. 2. *Parisian Chirurg. Journal*, Vol. 2. p. 156, and p. 265. S. T. Sommering über die schnell und langsam tödlichen Krankheiten der Harnblase, &c. Frankfurt, 1809. The author is an advocate for the puncture above the pubes, in preference to that through the rectum, which he thinks right only in one case, viz. when the bladder is so contracted, that it does not rise out of the lesser cavity of the pelvis, and the fluctuation of the urine can be felt in the rectum, but not above the pubes. In this opinion, he is joined by Langenbeck. (*Bibliothek*, 3 B. p. 719.) Callisen's *Systema Chirurgiæ Hodiernæ*, T. 2, p. 277, &c. *Chirurgische Versuche von B. G. Schreger*, B. 1. Über den Blasenstich Oberhalb der Schoosfuge, p. 211, &c. 8vo. Nürnberg. 1811, gives the preference to the puncture above the pubes. Edward Grainger, *Med. and Surg. Remarks, &c. with Obs. on the different modes of opening the bladder in retention of urine*, &c. 8vo. Lond. 1815. C. Bell, *Surgical Obs.* 8vo. Part 5. Lond. 1818.

BLADDER, Tumour extirpated from. Mr. Warner has recorded a case, in which an excrescence, growing from the inside of a young woman's bladder, was successfully removed. The patient, on the 24th of June, 1747, strained herself in endeavouring to lift a great weight, and she was immediately seized with a pain in the small of her back, and a total retention of urine. In April, 1750, she applied to Mr. Warner, who found, upon inquiry, that she had never been able, from the moment of the accident, to void a drop of urine without the assistance of the catheter; that she was in continual pain, and had lately been much weakened, by having several times lost considerable quantities of blood, occasioned by the force made use of in introducing the instrument into the bladder.

Mr. Warner, upon examining the parts with his forefinger, which he had great difficulty in introducing into the meatus urinarius, discovered a considerable tumour, which seemed to be of a fleshy substance, and took its rise from the lower part of the bladder, near its neck. When the patient strained to make water, and the bladder was full, the excrescence protruded a little

way out of the meatus urinarius; but, upon ceasing to strain, it presently returned.

A purgative having been given the day before the operation, and the rectum emptied by means of an emollient clyster, Mr. Warner directed the patient to strain, so as to make the bladder project. He then hindered it from returning into the bladder, by passing a ligature through it, and endeavoured to draw it further out. The latter object was found impracticable, on account of the size of the tumour. Seeing this, Mr. Warner dilated the meatus urinarius on the right side, by cutting it upwards, about half way towards the neck of the bladder, when, by pulling the swelling forwards, he was enabled to tie its base, which was very large, with a ligature.

For three days after the operation, a good deal of pain was felt in the abdomen. On the sixth day, the tumour dropped off. From the first day, the urine came away without assistance, and the patient got quite well. The tumour resembled a turkey's egg in shape and size. (See *Warner's Cases in Surgery*, edit. 5, p. 303.)

Perhaps, in this example, tying the tumour was preferable to cutting it away, even though its base was large; for, had the knife been used, there would have been some danger of the bladder becoming filled with blood.

BLADDER, Hernia of. See *Hernia*.

BLADDER, Insects discharged from. The instances, in which worms are stated to have been discharged from the bladder, are very numerous. Many cases of this kind are referred to in Voigtel's *Handbuch der pathologischen Anatomie*, b. 3, p. 337—342. A few years ago, an interesting example was recorded by Mr. Lawrence. (See *Med. Chir. Trans.* V. 2. p. 382, &c.)

BLADDER, Deficiency of. Numerous examples, in which this deviation from the natural structure has occurred, are recorded by medical writers. The publications, however, which, as far as I know, contain the most ample information on the subject, are, a Gottingen inaugural Dissertation, entitled, "*De Vesicæ Urinariæ Prolapsu Nativæ*," by Dr. Roose, late professor in Brunswick, and a paper, called "*An attempt towards a systematic account of the appearances, connected with that malconformation of the Urinary Organs, in which the ureters, instead of terminating in a perfect bladder, open externally on the surface of the Abdomen*," by A. Duncan, jun. in *Edin. Med and Surg. Journal*, Vol. 1. In this last production, may be seen references to all the most noted cases on record, both male and female. (See also *Handbuch der Pathologischen Anatomie von J. F. Meckel*, 1 B. p. 650, 8vo. Leip. 1812.)

BLADDER, Wounds of. See *Gunshot Wounds*. Many cases of rupture of the bladder from blows or falls are recorded, followed by fatal extravasation of urine in the abdomen. Two such instances have been recently detailed by Dr. Cusack. (See *Dub. Hospital Reports*, Vol. 2, p. 312, &c. 8vo, 1818.)

* **BLEEDING.** By this operation is understood the taking away of blood for the relief of diseases. Bleeding is called *general*, when practised with a view of lessening the whole mass of circulating blood; *topical*, when performed in the vicinity of the disease, for the express purpose of lessening the quantity of blood in a particular part.

General Blood-letting is performed with a lancet, and is subdivided into two kinds; viz. the opening of a vein, termed *phlebotomy*, or *venesection*; and the opening of the temporal artery, or one of its branches, termed *arteriotomy*.

Topical Blood-letting is performed, either by means of a cupping-glass and scarificator, or leeches, or by dividing the visibly distended vessels with a lancet, as is frequently done in cases of ophthalmia.

PHLEBOTOMY, OR VENESECTIQN.

The mode of bleeding, most frequently practised, is that of opening a vein; and it may be done in the arm, ankle, jugular vein, frontal vein, veins under the tongue, on the back of the hand, &c. In whatever part, however, venesection is performed, it is always necessary to compress the vein, between the place where the puncture is made, and the heart. Thus the return of blood through the vein is stopped, the vessel swells, becomes conspicuous, and, when opened, bleeds much more freely than would otherwise happen. Hence, according to the situation of the part of the body where the vein is to be opened, with regard to the heart, the bandage, or other means, for making the necessary pressure, must be applied, either above or below the puncture.

All the apparatus essential for blood-letting, on the part of the patient, is a bandage, or fillet, two or more small pieces of folded linen for compresses, a basin to receive the blood, and a little clean water and a towel. The bandage ought to be about a yard in length, and near two inches broad, a common riband or garter being frequently employed. The compresses are made by doubling a bit of linen rag, about two inches square. On the part of the surgeon, it is necessary to have a good lancet, of proper shape. He should never bleed with lancets, with which he has been in the habit of opening any kind of abscesses, as very troublesome complaints have been the consequence of doing so. The shape of the instrument is also a matter of some importance. If its shoulders are too broad, it will not readily enter the vein, and when it does enter, it invariably makes a large opening, which is not always desirable. If the lancet be too spear-pointed, an incautious operator would often run a risk of transfixing the vein, and wounding the artery beneath it. More, however, certainly depends on the mode of introducing the lancet, than on its shape.

In blood-letting, the patient may lie down, sit down, or stand up, each of which posi-

tions may be chosen according to circumstances. If the patient be apt to faint from the loss of a small quantity of blood, and such fainting can answer no surgical purpose, it is best to bleed him in a recumbent posture. But, when the person is strong and vigorous, there is little occasion for this precaution, and a sitting posture is to be preferred, as the most convenient, both for surgeon and patient. This indeed, is the common position. In some cases, however, particularly those of strangulated hernia, it is frequently an object to produce fainting, in order that the bowels may be more easily reduced. In this circumstance the patient may be bled in an erect posture, and the wound made large, as a sudden evacuation of blood is particularly apt to bring on the wished-for swoon. For the same reason, if we wish to avoid making the patient faint, we should then make only a small puncture.

Every operator should be able to use the lancet with either hand, which will enable him to bleed the patient in the right or left arm, as circumstances may render most eligible.

At the bend of the arm, there are several veins in which a puncture may be made; viz. the basilic, cephalic, median basilic, and median cephalic. The median basilic vein, being usually the largest and most conspicuous, is that in which the operation is mostly performed; but surgeons should never forget, that it is under this vessel that the brachial artery runs, with the mere intervention of the aponeurosis sent off from the tendon of the biceps muscle. In very thin persons, indeed, the median basilic vein lies almost close to the artery, and nothing is then more easy than to transfix the first of these vessels and wound the last. Hence Richerand advises all beginners to prefer opening the median cephalic, or even the trunk of the cephalic itself, to puncturing even the basilic, or the median basilic, which last are internally situated, and nearer the brachial artery. (*Ne-sagrapie Chirurgicale*, t. 3. p. 383. edit. 2.)

In fat subjects, the large veins at the bend of the arm are sometimes totally imperceptible, notwithstanding the fillet is tightly applied, the limb is put in warm water, and every thing done to make those vessels as turgid as possible. In this circumstance, if the surgeon has not had much experience in the practice of venesection, he will do well to be content with opening one of the veins of the back of the hand, after putting the member for some time in warm water, and applying a ligature round the wrist. In children, a sufficient quantity of blood cannot always be obtained by venesection, and, in this event, the free application of leeches, and, occasionally, the puncture of the temporal artery, are the only effectual methods.

With respect to the choice of a vein in the arm, the most experienced operators give the preference to one which rolls least under the skin. Such a vessel, though

sometimes less superficial than another, may commonly be opened with greater facility. The surgeon, however, is always to fix the vein as much as he can, by placing the thumb of his left hand a little below the place where he intends to introduce the lancet.

In bleeding in the arm, the fillet is to be tied round the limb, a little above the elbow, with sufficient tightness to intercept the passage of the blood through all the superficial veins; but never so as to stop the flow of blood through the arteries, which would tend to prevent the veins from rising at all. The veins being thus rendered turgid, the surgeon must choose the one which seems most conveniently situated for being opened, and large enough to furnish as much blood as it may be proper to take away.

Before applying the fillet round the arm, however, the operator should always feel where the pulsation of the artery is situated, and, if equally convenient, he should not open the vein immediately over this part. It is also prudent to examine where a pulsation is situated, on account of the occasional varieties in the distribution of the arteries of the arm. The ulnar artery is sometimes given off from the brachial very high up, and, in this case, it frequently proceeds superficially over the muscles, arising from the internal condyle, instead of diving under them, in the ordinary manner.

When the external jugular vein is to be opened, the surgeon generally makes the necessary pressure with his thumb. The orifice should be made in the direction of the fibres of the platysma myoides muscle; and the vein is not so apt to glide out of the way, when the surgeon makes the puncture just where it lies over a part of the sterno-cleido-mastoideus muscle.

When blood is to be taken from the foot, the ligature is commonly applied a little above the ankle.

The fillet having been put on the arm, the operator is to take the blade of the lancet, bent to a somewhat acute angle, between the thumb and fore-finger, and, steadying his hand upon the other three fingers, he is to introduce the lancet, in an oblique direction, into the vessel, till the blood rises up at the point of the instrument. Then bringing up the front edge in as straight a line as possible, the wound in the skin will be made of just the same size as that in the vein. The operator next takes away the thumb of his left hand, with which he steadied the vessel, and allows the blood to escape freely, till the desired quantity is obtained. The arm ought to be kept in the same position while the blood is escaping, lest the skin should slip over the orifice of the vein, keep the blood from getting out, and make it insinuate itself into the cellular substance.

When the blood does not issue freely, however, most surgeons direct the patient to move his fingers, or turn something round and round in his hand. This puts the mus-

cles of the arm into action, and the pressure they then make on the veins, makes the blood circulate more briskly through these vessels.

The proper quantity of blood being discharged, the fillet is to be untied. The flow of blood now generally ceases; though sometimes, when the orifice is large, and the circulation very vigorous, it still continues. In this circumstance, the operator may immediately stop the bleeding, by placing the thumb of his left hand firmly on the vessel, a little below the puncture.

The blood is next to be all washed off the arm, the sides of the wound placed in contact, and the compresses applied, and secured with the fillet, put round the elbow in the form of a figure of 8, and regularly crossing just over the compresses.

The patient should be advised not to move his arm much till the fillet is removed, which may be done after twenty-four hours.

In order to open the external jugular vein, the patient's head is to be laid on one side, and properly supported. Then the operator is to press upon the lower part of the vein with his thumb, so as to make the part above swell, and then the lancet is to be pushed at once into the vessel, with the cautions already stated.

There is commonly no difficulty in stopping the bleeding, after the pressure is removed. Some practitioners have directed a scalpel to be used for dividing the integuments, before opening the vein itself; but this is quite unnecessary.

Blood-letting in the feet is executed on the same principle as in other parts; but the blood from the veins in this situation, in general, not flowing with much celerity, it is customary to immerse the feet in warm water, in order to promote the bleeding.

ARTERIOTOMY.

The only arteries of any size, from which blood is ever taken in practice, are the trunk and branches of the temporal artery, which lie in such a situation, that they may easily be compressed against the subjacent bones, and the bleeding stopped. When the vessel, which the surgeon chooses to open, lies very near the surface, or can be ascertained by feeling, or even seeing, its pulsation, it may be opened at once with a lancet. But, in many instances, it is so deeply situated, that it becomes necessary, in the first place, to make a cut in the skin, and then puncture the vessel.

The bleeding generally stops without any trouble; and may always be suppressed with a compress and bandage. In a very few cases, the blood bursts forth from time to time, and more is lost than is necessary. When this happens, notwithstanding pressure, it is recommended to divide the vessel completely across, which facilitates the process of nature in closing the end of the vessel. Sometimes an aneurism follows, which must be treated on the principles

explained in a foregoing article. See *Aneurism*. Cavalline cured the disease by dividing the vessel, and compression. (*Collez. di Casi Chir.* t. 2.)

TOPICAL BLEEDING.—CUPPING.

This is done by means of a scarificator, and a glass, shaped somewhat like a bell. The scarificator is an instrument containing a number of lancets, sometimes as many as twenty, which are so contrived, that when the instrument is applied to any part of the surface of the body, and a spring is pressed, they suddenly start out, and make the necessary punctures. The instrument is so constructed, that the depth, to which the lancets penetrate, may be made greater or less, at the option of the practitioner. As only small vessels can be thus opened, a very inconsiderable quantity of blood would be discharged, were not some method taken to promote the evacuation. This is commonly done with a cupping-glass, the air within the cavity of which is rarified, by the flame of a little lamp, containing spirit of wine, and furnished with a thick wick. This plan is preferable to that of setting on fire a piece of tow, dipped in this fluid, and put in the cavity of the glass; a clumsy expedient, adding unnecessarily to the sufferings of the patient, by cauterizing the skin; doing harm also by rarifying the air more than necessary within the glass, in consequence of which the edges of the cup compress the cutaneous vessels so much as to obstruct the influx of blood. The larger the glass, if properly exhausted, the less pain does the patient suffer, and the more freely does the blood flow." (See *Mapleson's Treatise on the Art of Cupping*, p. 63—65. 12mo. Lond. 1813.) When the mouth of the glass is placed over the scarifications, and the rarified air in it becomes condensed as it cools, the glass is forced down on the skin, and a considerable suction takes place.

This professor of the said art says, that when the operation is about to be done, a basin of warm water, a piece of fine sponge, and a lighted candle, should be provided. As many of the cupping-glasses as may be judged necessary are to be put in the basin. If sixteen or twenty ounces of blood are to be taken away, four glasses, of a size adapted to the surface to which they are to be applied, will generally be required. Each glass is then to be held for an instant over the flame of the spirit-lamp, and immediately placed upon the skin. Upon the quickness with which this is done, the neatness and efficacy of the operation will depend. If dry cupping be only intended, the glasses may be allowed to remain on the skin for a few moments, and be replaced five or six times, with a little variation of their position, in order to prevent the skin from being hurt by their pressure. If the intention be to scarify and take away blood, the glass ought not to remain more than a minute, when the scarificator

is to be instantly applied; for by the quickness with which the application of the scarificator succeeds the removal of the glass, the patient is saved a degree of pain, which he would otherwise suffer from the making of the punctures. When the glasses are so full as to be in danger of falling off, or the blood is coagulated in them, they should be removed, emptied, and applied again. For the sake of neatness, care should be taken to insert the nail under the upper part of the glass, and remove it so as to keep its bottom downwards, the scarifications being at the same time wiped with a sponge, wet in warm water. The glasses also previously to each application, should be rinsed in warm water, but not dried. For these, and some other useful directions, see *Mapleson's Treatise*, p. 64, &c.

Trials have been made of syringes, calculated for exhausting the air from cupping-glasses; but the plan is not found so convenient as that above described.

A common pledget, or bit of rag, is usually applied as a dressing for the punctures made with a scarificator.

If a little smarting be not minded, Mr. Mapleson prefers the application of arquebuse water, or spirits of wine, as it immediately stops the oozing of blood, and prevents subsequent itching. (P. 69.)

LEECHES.

Leeches are often preferable to cupping, which is attended with more irritation than many surfaces, under particular circumstances, can bear, especially when the topical bleeding is to be frequently repeated; and they can be used in cases in which it would not be safe or convenient to employ the lancet.

Formerly medicinal leeches were very abundant in England, but owing to their now being in greater request, and to the draining and cultivation of waste lands, it is necessary to import large supplies from the continent, chiefly from Bourdeaux and Lisbon. As much imposition prevails in this branch of commerce, it should be understood, that unless a leech be marked with yellow rings, or spots, or with variegated lines, running the whole length of the back, it will generally be found useless. (See *A Treatise on the Medicinal Leech*, by J. R. Johnson, p. 133, 8vo. Lond. 1816.)

When leeches are to be kept in any considerable quantity, this gentleman recommends them to be placed in a large vessel, provided with a false bottom, so perforated as to allow them a ready passage. This false bottom should be raised from three to six inches above the real bottom, or to such an extent as will admit of a turf, of nearly equal dimensions, being placed between them. It should fit closely to the sides, that the earth may not be disturbed by the frequent introduction of fresh water. It is necessary that the vessel be also furnished with a stop-cock, in order that the water may be drawn off as often as may be con-

sidered expedient. But previously to our placing the leeches in this vessel, they should be singly examined. If on being handled, they contract, and feel hard and firm, it affords the best indication of their being healthy; but should they feel flabby, or exhibit protuberances, or white ulcerous specks on the surface, they should be kept in jars by themselves, the water and the turf of which should be frequently renewed." (*Op. cit.* p. 138.)

Leeches, occasionally, cannot be easily made to fix on the particular part we wish; but they will do so, if the place be first cooled with a cloth dipped in cold water, or if it be moistened with cream or milk, and they be confined in the situation with a small glass.

According to Dr. Johnson, the part on which it is intended they shall fix should be as clean as possible; it should, therefore, be first washed with soap and water, and afterwards with water alone, which will be more necessary should any liniment or embrocation have been used. Leeches are often found to bite better, when removed from the water at least an hour previously to their application. In the common practice of putting as many of them as may be required into a wine-glass, and inverting it upon the part affected, there is the disadvantage, that they frequently retire to the upper part of the glass, and cannot be got down again, without some risk of displacing those which have already fastened. To remedy this inconvenience, Dr. Johnson recommends glass vessels of various sizes and figures, but none of them more than an inch deep. But, in his own practice, he prefers applying leeches with his hand. "Bring a leech towards the part whereon you intend to fix it, and as soon as it begins to extend the head, to seek an attachment, endeavour that it may affix itself to the place required." When it evinces no disposition to bite, a little puncture may be made with a lancet, when the animal will fix itself. "When the patient is fearful of the lancet, and one leech only shall have bitten, where several are required, it may be of use to remove it, which is readily done by inserting the nail of the finger between its mouth and the skin. The blood then flowing from the orifice, will induce the remainder to bite with the greatest avidity. As soon as the leeches are gorged, they drop off; this usually happens within ten or fifteen minutes. Sometimes they remain affixed a considerable time, and become indolent; but they are quickly roused from this state by sprinkling them with a few drops of cold water." (*Johnson, op. cit.* p. 141.) When they fall off, the bleeding may be promoted, if necessary, by fomenting the part. When the bleeding continues longer than is desirable, a slight compress will usually stop it; but in more troublesome cases, the compress must be dipped in brandy, or spirits of wine. In young infants, the hemorrhage from the bites of leeches has sometimes proved fatal, and

the same thing may happen in adults. An example of each fact is related by Beauchene (*Gazette de Santé*, Sept. 1815.) When the bleeding is very troublesome, Autenrieth advises pieces of charpie to be pushed into the orifices of the bites; a method which he assures us, is perfectly effectual. (*Tubingen Blatter*, B. 2. St. 1. p. 57.)

In order to make a leech disgorge, it is usual to throw a little salt upon it: in a few seconds the blood is rejected, the leech assumes a coiled form, and is seldom found fit for use again before the end of four or five days. As salt, however, frequently blisters the leech, it has been proposed to empty the animal by regular and uniform pressure; but though Dr. Johnson considers this plan better than the other, he admits that it is scarcely practicable, without injuring the internal structure of the leech. He says, the best method, and that from which the animal suffers the least inconvenience, is pouring a small quantity of vinegar upon its head. Leeches which have been recently applied should always be kept by themselves, and allowed to retain, for their nourishment, about one-third of the blood which they extract. For a great deal of valuable information respecting leeches, see Johnson's work, the title of which is above specified.

When leeches are very scarce, their tails may be snipped off, while they are sucking, and the blood will then flow, drop by drop, from the artificial opening, as fast as the animals suck it; or with the same view, an incision may be made with a lancet, close to the tail. (*Johnson, Op. cit.* p. 144.)

SCARIFICATION WITH A LANCET,

Is mostly done in cases of inflamed eyes. An assistant is to raise the upper eyelid, while the surgeon himself depresses the lower one, and makes a number of slight scarifications, where the vessels seem most turgid, trying particularly to cut the largest completely across.

ALL CONSEQUENCES SOMETIMES FOLLOWING BLEEDING IN THE ARM.

1. *Ecchymosis.*

The most common is a thrombus, or ecchymosis, a small tumour around the orifice, and occasioned by the blood insinuating itself into the adjoining cellular substance, at the time when this fluid is flowing out of the vessel. Changing the posture of the arm will frequently hinder the thrombus from increasing in size, so as to obstruct the evacuation of blood. But, in some instances, the tumour suddenly becomes so large, that it entirely interrupts the operation, and prevents it from being finished. In these cases, however, the most effectual method of preventing the tumour from becoming still larger, is to remove the bandage. By allowing the bandage to remain, a very considerable swelling may

be induced, and such as might be attended with great trouble. If more blood be required to be taken away, it ought to be drawn from another vein, and what is still better, from a vein in the other arm.

The best applications for promoting the absorption of these tumours, are those containing spirit, vinegar, or the muriate of ammonia. Compresses, wetted with any lotion of this sort, may be advantageously put on the swelling, and confined there with a slack bandage.

2. *Inflammation of the Integuments and adjacent Cellular Substance.*

According to Mr. Abernethy, the inflammation and suppuration of the cellular substance, in which the vein lies, are the most frequent occurrences. On the subsidence of this inflammation the tube of the vein is free from induration. Sometimes the inflammation is rather indolent, producing a circumscribed and slowly suppurating tumour. Sometimes it is more diffused, and partakes of the erysipelatous nature. On other occasions, the affection is of the phlegmonous kind.

When the lancet has been bad, so as rather to have lacerated than cut the parts; when the constitution is irritable, and especially when care is not taken to unite the edges of the puncture, and the arm is allowed to move about, so as to make the two sides of the wound rub against each other, inflammation will most probably ensue. The treatment of this case consists in keeping the arm perfectly at rest in a sling, applying the saturnine lotion, and giving one or two mild saline purges. When suppuration takes place, a small poultice is the best local application.

3. *Absorbents inflamed.*

Sometimes, particularly when the arm is not kept properly quiet after bleeding, swellings make their appearance about the middle of the arm, over the large vessels, and on the fore-arm, about the mid-space, between the elbow and wrist, in the integuments covering the flexor muscles. The swelling at the inner edge of the biceps is sometimes as large as an egg. Before such swellings take place, the wound in the vein often inflames, becomes painful, and suppurates, but without any perceptible induration of the venal tube, either at this time, or after the subsidence of the inflammation. Pain is felt shooting from the orifice in the vein, in lines up and down the arm, and upon pressing in the course of this pain, its degree is increased. On examining the arm attentively, indurated absorbents may be plainly felt, leading to the tumour at the side of the biceps muscle.

The pain and swelling often extend to the axilla, where the glands also sometimes enlarge. Chordlike substances, evidently absorbents, may sometimes be felt, not only leading from the puncture to the swelling in the middle of the arm, but also from this

latter situation up to the axillary glands, and from the wound in the vein down to the enlarged glands at the mid-space between the elbow and wrist, over the flexor muscles of the hand.

The enlarged glands very often proceed to suppuration, and the patient suffers febrile symptoms. It may be suspected that the foregoing consequences arise from the lancet being envenomed, and from the absorption of the virulent matter; but the frequent descent of the disease to the inferior absorbents militates against this supposition.

When the absorbents become inflamed, they quickly communicate the affection to the surrounding cellular substance. These vessels, when indurated, appear like small chords, perhaps of one eighth of an inch in diameter: this substance cannot be the slender sides of the vessels, suddenly increased in bulk, but an induration of the surrounding cellular substance.

The inflammation of the absorbents, in consequence of local injury, is deducible from two causes: one, the absorption of irritating matter; and the other, the effect of the mere irritation of the divided tube. When virulent matter is taken up by the absorbents, it is generally conveyed to the next absorbent gland, where its progress being retarded, its stimulating qualities give rise to inflammation, and, frequently, no evident disease of the vessel, through which it has passed, can be distinguished.

When inflammation of the absorbents happens in consequence of irritation, the part of the vessel nearest the irritating cause, generally suffers most, while the glands, being remotely situated, are not so much inflamed.

The treatment of the preceding case consists in keeping the arm perfectly quiet in a sling, dressing the puncture of the vein with any mild simple salve, covering the situation of the inflamed lymphatics with linen wet with the saturnine lotion, and giving some gentle purging medicine.

When the glandular swellings suppurate, poultices should be applied, and if the matter does not soon spontaneously make its way outward, the surgeon may open the abscess. (See *Abernethy's Essay on this subject.*)

4. *Inflammation of the Vein.*

When the wound does not unite, the vein itself is very likely to inflame. This affection will vary in its degree, extent, and progress. One degree of inflammation may only cause a slight thickening of the venal tube, and an adhesion of its sides. Abscesses, more or less extensive, may result from an inflammation of greater violence, and the matter may sometimes become blended with the circulating fluids, and produce dangerous consequences, or the matter may be quite circumscribed, and make its way to the surface. When the vein is extensively inflamed, a good deal of sympathetic fever is likely to ensue, not

merely from the excitement, which inflammation usually produces, but also from the irritation continued along the membranous lining of the vein towards the heart. If, however, the excited inflammation should fortunately produce an adhesion of the sides of the vein to each other, at some little distance from the wounded part, this adhesion will form a boundary to the inflammation, and prevent its spreading further. The effect of the adhesive inflammation in preventing the extension of inflammation along membranous surfaces, was originally explained by Mr. Hunter. In one case, Mr. Hunter applied a compress to the inflamed vein, above the wounded part, and he thought that he thus succeeded in producing an adhesion, as the inflammation was prevented from spreading further. When the inflammation does not continue equally in both directions, but descends along the course of the vein, its extension in the other direction is probably prevented by the adhesion of the sides of the vein to each other. (See *Obs. on the Inflammation of the internal coats of veins*, by J. Hunter, in *Trans. of a Soc. for the Improvement of Med. & Chir. Knowledge*, Vol. 1, p. 18, &c.) More information on this subject will be found under the head of *Veins*.

Mr. Abernethy mentions his having seen only three cases, in which an inflammation of the vein succeeded venesection. In neither of these did the vein suppurate. In one, about three inches of the venal tube inflamed, both above and below the puncture. The integuments over the vessel were very much swollen, red, and painful, and there was a good deal of fever, with a rapid pulse, and furred tongue. The vein did not swell, when compressed above the diseased part. In another instance, the inflammation of the vein did not extend towards the heart, but only downward, in which direction it extended as far as the wrist.

The treatment is to lessen the inflammation of the vein by the same means, which other inflammations require, and to keep the affection from spreading along the membranous lining of the vessel towards the heart, by placing a compress over the vein, a little way above the puncture, so as to make the opposite sides of the vessel adhere together.

Mr. Abernethy can conceive a case, in which the vein may even suppurate, and a total division of the vessel be proper, not merely to obviate the extension of the local disease, but to prevent the pus from becoming mixed with the circulation. Were such a proceeding deemed right, I think Mr. Brodie's method of cutting the vessel would be best. However, I have never heard of any case, in which the practice has been adopted. As for the scheme of tying the vein above the diseased part of it, the severe effects frequently following this method, must, as Mr. Dunn has reminded me, render it less eligible, than incision.

5. *Inflammation of the Fascia of the Fore-Arm.*

Sometimes, in consequence of the inflammation arising from the wound of the lancet in bleeding, the arm becomes very painful, and can hardly be moved. The puncture often remains unhealed, but without much inflammation of the surrounding integuments. The fore-arm and fingers cannot be extended without great pain. The integuments are sometimes affected with a kind of erysipelas; being not very painful, when slightly touched, but when forcibly compressed, so as to affect the inferior parts, the patient suffers a good deal. The pain frequently extends towards the axilla and acromion; no swelling, however, being perceptible in either direction. These symptoms are attended with considerable fever. After about a week, a small superficial collection of matter sometimes takes place a little below the internal condyle: this being opened, a very little pus is discharged, and there is scarcely any diminution of the swelling or pain. Perhaps, after a few days more, a fluctuation of matter is distinguished below the external condyle, and this abscess being opened, a great deal of matter gushes from the wound, the swelling greatly subsides, and the patient's future sufferings are comparatively trivial.

The last opening, however, is often inadequate to the complete discharge of the matter, which is sometimes originally formed beneath the fascia, in the course of the ulna, and its pointing at the upper part of the arm depends on the thinness of the fascia in this situation. The collection of pus descends under the lower part of the detached fascia, and a depending opening for its discharge becomes necessary. This being made, the patient soon gets well.

In these cases, neither the vein nor the absorbents appear inflamed. The integuments are not much affected, and the patient complains of a tightness of the fore-arm. Matter does not always form, and the pliability of the arm, after a good while, gradually returns again.

Mr. Watson relates a case, which was followed by a permanent contraction of the fore-arm. Mr. Abernethy is of opinion, that a similar contraction of the fore-arm, from a tense state of the fascia, may be relieved by detaching the fascia from the tendon of the biceps, to which it is naturally connected. Mr. Watson seems to have obtained success in his first case, by having cut this connexion.

The treatment of an inflamed fascia, in consequence of venesection, has in it no peculiarity. General means for the cure of inflammation should be employed. The limb should be kept quiet, and the inflamed part relaxed. As soon as the inflammation abates, the extension of the fore-arm and fingers ought to be attempted, and daily performed, to obviate the contraction, which might otherwise ensue. (*Abernethy*.)

Mr. Charles Bell objects to calling the

affection an inflammation of the fascia, because he sees no proof of this part being inflamed, and he conceives that the symptoms proceed from the inflammation spreading in the cellular membrane, and, passing down among the muscles, and under the fascia. The fascia acts as a bandage, and from the swelling of the parts beneath, it binds the arm, but is not itself inflamed, and contracted. When necessary to divide the fascia, Mr. Charles Bell thinks it would be better to begin an incision near the inner condyle of the humerus, and to continue it some inches down the arm, rather than perform the nice, if not dangerous operation, of cutting the fascia, at the point where the expansion goes off from the round tendon of the biceps.

When the elbow joint and fore-arm continue stiff after all inflammation is over, Mr. C. Bell recommends frictions with camphorated mercurial ointment, &c. and the arm to be gradually brought into an extended state by placing a splint on the forepart of the limb. (*Operative Surgery*, Vol. 1. p. 65.)

6. *Ill Consequences of a Wounded Nerve.*

Mr. Abernethy informs us, that Mr. Pott used to mention two cases, in which the patients had suffered distracting pains, followed by convulsions and other symptoms, which could only be ascribed to nervous irritation, arising from a partial division of the nerve, and he recommended its total division, as a probable remedy. Dr. Monro related similar cases, in which such treatment proved successful.

Hence, it is highly necessary to know the characteristic symptoms of the case, particularly, as all the foregoing cases would be exasperated by the treatment just now alluded to. It is to Mr. Abernethy that we are indebted for several valuable remarks elucidating this subject. He informs us, that the two cutaneous nerves are those which are exposed to injury. Most frequently all their branches pass beneath the veins, at the bend of the arm; but sometimes, although the chief rami go beneath these vessels, many small filaments are detached over them, which it is impossible to avoid wounding in phlebotomy.

Mr. Abernethy thinks the situation of the median nerve, renders any injury of it very unlikely. If, however, a doubt should be entertained on this subject, an attention to symptoms will soon dispel it. When a nerve is irritated at any part, between its origin and termination, a sensation is felt, as if some injury were done to the parts which it supplies. If, therefore, the cutaneous nerves were injured, the integuments of the fore-arm would seem to suffer pain; if the median nerve, the thumb, and two next fingers would be painfully affected.—(*Abernethy*.)

What are the ills likely to arise from a wounded nerve? If it were partially cut, would it not, like a tendon, or any other substance, unite? It seems probable that it would do so, as nerves, as large as the cu-

taneous ones of the arm, are very numerous in various situations of the body, and are partially wounded in operations, without any peculiar consequences usually ensuing. The extraordinary pain sometimes experienced in bleeding, may denote that a cutaneous nerve is injured. The situation of the nervous branches is such, that they must often be partially wounded in the operation, though they probably unite again, in almost all cases, without any ill consequences. Yet, says Mr. Abernethy, it is possible that an inflammation of the nerve may accidentally ensue, which would be aggravated, if the nerve were kept tense, in consequence of its partial division. Mr. Abernethy thinks the disorder arises from inflammation of the nerve in common with the other wounded parts. This gentleman supposes, that an inflamed nerve would be very likely to communicate dreadful irritation to the sensorium, and that a cure would be likely to arise from intercepting its communication with that organ.

The general opinion is, that the nerve is only partially divided, and that a complete division would bring relief. Mr. Pott proposed enlarging the original orifice. It is possible, however, that the injured nerve may be under the vein, and, if the nerve be inflamed, even a total division of it, at the affected part, would, perhaps, fail in relieving the general nervous irritation, which the disease has occasioned. To intercept the communication of the inflamed nerve with the sensorium, however, promises perfect relief. This object can only be accomplished by making a transverse incision above the orifice of the vein. The incision need not be large, for the injured nerve must lie within the limits of the original orifice, and it need only descend as low as the fascia of the fore-arm, above which all the filaments of the cutaneous nerves are situated. As the extent of the inflammation of the nerve is uncertain, Mr. Abernethy suggests even making a division of the cutaneous nerve still further from the wound made in bleeding.

Examples are recorded, in which not only extraordinary pain was occasioned by the prick of the lancet; but, erysipelas of the skin ending in gangrene of the whole limb, and the death of the patient. (See *Richerand's Nosog. Chir. Tom. 2, p. 390, Edit. 2.*) A case, in which the greater part of the integuments of the arm, had been destroyed by erysipelas, thus produced, lately saw under the care of Mr. Vincent, in St. Bartholomew's hospital.

In former times, it was customary to refer many of the bad symptoms occasionally following venesection, to a puncture of the tendon of the biceps; but, this doctrine is now in a great measure renounced, the experiments of Haller having completely proved, that tendons and aponeuroses are, comparatively speaking, parts endued with little or no sensibility.

In the foregoing account, the various ill consequences occasionally arising after ven-

nesection are represented separately; no doubt, in some cases, they may occur together.

BLEEDING. (See *Hemorrhage and Arteries*.)

BLÉNORRHŒA, or *Blénorrhœa*. (From *βλενν*, mucus, and *ρῆσις*, to flow.) A discharge of mucus. Swediaur, who maintains, that gonorrhœa is attended with a mucous, and not a purulent discharge, prefers the name of blénorrhœa for the disease. However, in treating of gonorrhœa, we shall find that this last appellation is itself not altogether free from objections.

BLEPHAROPTOSIS. (From *βλεφαρον*, the eyelid, and *πτωσις*, a falling down) Called also *ptosis*. An inability to raise the upper eyelid. (See *Plaxis*.)

BLEPHAROTIS. An inflammation of the eyelids.

BLINDNESS. This is an effect of many diseases of the eye. See, particularly, *Amaurosis*; *Cataract*; *Cornea*, *Opacities of*; *Gutta Serena*; *Hydrophthalmia*; *Leucoma*; *Ophthalmia*; *Pterygium*; *Pupil, closure of*; *Staphyloma*, &c.

BLISTERS. Topical applications, which, when put on the skin, raise the cuticle in the form of a vesicle, filled with a serous fluid. Various substances produce this effect on the skin; but the powder of cantharides is what operates with most certainty and expedition, and is now invariably made use of for the purpose. The blister plaster is thus composed; *R. Cantharidum* lbj. *Emplastri ceræ* lbss. *Adipis suillæ præp.* lbj. The wax plaster and lard being melted, and allowed to become nearly cold, the powdered cantharides are afterwards to be added.

When it is not wished to maintain a discharge from the blistered part, it is sufficient to make a puncture in the cuticle to let out the fluid; but when the case requires keeping up a secretion of pus, the surgeon must remove the whole of the detached cuticle with a pair of scissors, and dress the exco-

riated surface in a particular manner. Practitioners used formerly to mix powder of cantharides with an ointment, and dress the part with this composition. But such a dressing not unfrequently occasioned very painful affections of the bladder, a scalding sensation in making water, and most afflicting stranguities. An inflammation of the bladder, ending fatally, has been thus excited. The treatment of such complaints consists in removing every particle of cantharides from the blistered part, which is to be well fomented, and making the patient drink abundantly of mucilaginous drinks. Camphor is now suspected to prove more hurtful than useful.

These objections to the employment of salves, containing cantharides, for dressing blistered surfaces, led to the use of meze-reon, euphorbium, and other irritating substances, which, when incorporated with ointment, form very proper compositions for keeping blisters open, without the inconvenience of irritating the bladder, like cantharides.

The favourite application, however, for keeping open blisters, is the powder of savine, which was brought into notice by Mr. Crowther, in the first edition of his book on the White Swelling. In the last edition, this gentleman remarks, that he was led to the trial of different eschoratic applications, in the form of ointment, in consequence of the minute attention, which caustic issues demand; and among other things, he was induced to try powdered savine, from observing its effects in the removal of warts. Some of the powder was first mixed with white cerate, and applied as a dressing to the part, that had been blistered; but the ointment ran off, leaving the powder dry upon the sore, and no effect was produced. Mr. Crowther next inspissated a decoction of savine, and mixed the extract with the ointment, which succeeded better, for it produced a great and permanent discharge. At last, after various trials, he was led to prefer a preparation analogous to the *unguentum sambuci* P. L. and he now offers the following formula, as answering every desirable purpose: *R. Sabinæ recentis conturæ* lbij, *Ceræ flavæ* lbj, *Adipis suillæ* lbiv. *Adipe et cerâ liquefactâ, incoque sabinam et cola.*

The difference of this formula from that, which Mr. Crowther published in 1797, only consists in using a double proportion of the savine leaves. The ceratum sabinæ of Apothecary's Hall, he says, is admirably made: the fresh savine is bruised with half the quantity of lard, which is submitted to the force of an iron press, and the whole is added to the remainder of the lard, which is boiled until the herb begins to crisp; the ointment is then strained off, and the proportion of wax, ordered, being previously melted, is added. On the use of the savine cerate, immediately after the cuticle raised by the blister, is removed, it should be observed, says Mr. Crowther, that experience has proved the advantage of using the appli-

cation lowered by a half, or two-thirds, of the unguentum ceræ. An attention to this direction will produce less irritation and more discharge, than if the savine cerate were used in its full strength. Mr. Crowther says also, that he has found fomenting the part with flannel wrung out of warm water, a more easy, and preferable way of keeping the blistered surface clean, and fit for the impression of the ointment, than scraping the part, as has been directed by others. An occasional dressing of the unguentum resinæ flavæ, he has found, a very useful application for rendering the sore free from an appearance of slough or rather dense lymph, which has sometimes been so firm in its texture, as to be separated by the probe, with as much readiness, as the cuticle is detached after blistering. As the discharge diminishes, the strength of the savine dressing should be proportionally increased. The ceratum sabinae must be used, in a stronger, or weaker degree, in proportion to the excitement produced on the patient's skin. Some require a greater stimulus, than others, for the promotion of the discharge, and this can only be managed by the sensations, which the irritation of the cerate occasions.

Mr. Crowther had used ointments, containing the flowers of the elematis recta, the capsicum, and the leaves of the digitalis purpurea. The two first produced no effect: the last was very stimulating; and Mr. Crowther mentions his intention to take the first convenient opportunity to determine its qualities more accurately. He has also used caustic potassa, mixed with spermaceti cerate, in the proportion of one dram to an ounce: it proved very stimulating, but produced no discharge. He has tried one dram of the oxymuriate of mercury, blended with two ounces of the above cerate; but the application was so intolerably painful, that at the end of two hours, it became necessary to remove the dressing; and the patient was attacked with a most severe pytalism. (*Practical Observations on the White Swelling, &c., a new edition, by B. Crowther, 1808.*)

Instead of keeping a blister open, it is frequently a judicious plan to renew the application of the emplastrum lyttæ, after healing up the vesication first produced, and to continue, in this manner, a succession of blisters, at short intervals, as long as the circumstances of the case may demand. Where the skin is peculiarly irritable, and, particularly, in young children, where the emplastrum lyttæ sometimes acts so violently as to produce sloughing, or, in any cases, where the plaster produces strangury and irritation of the urinary organs, I am informed, that the inconvenience may be avoided, and the cuticle raised very well, if a piece of silk paper be interposed between the plaster and the integuments. Mr. A. T. Thompson recommends for the same purpose a piece of thin gauze, wet with vinegar, and applied smoothly and closely over the plaster. (*Dispensatory. p.*

717, Ed. 2.) For infants, a proportion of opium has sometimes been added to the emplastrum lyttæ, in order to render its action less violent; a proposal made I believe, by Mr. Chevalier.

BOUGIE.—Is a smooth flexible instrument, which is introduced into the urethra for the cure of diseases of that passage; (See *Urethra*) and is so named from its generally containing wax in its composition, and bearing some resemblance to a wax taper, in French, bougie. However, the kinds of bougies are various, and some of them, employed in modern surgery, so far from having any similitude to a wax taper, are formed altogether of metal. They admit of being divided into those which are solid; and others, which are hollow, and are more commonly named catheters. (See *Catheter*.)

The exact period when bougies were first used is a doubtful point in the history of surgery. By Andrew Lacuna, a Spanish physician, the invention is ascribed to a Portuguese empiric, and in 1551, the same author published what had been communicated to him upon this subject. In the year 1554, Amatus Lusitadus published a work, in which he refers to several witnesses to prove, that the empirical practitioner, above alluded to, had learned from him the use of bougies, while, on the other hand, he candidly owns, that he himself was indebted to Aldereto, of Salamanca, for a knowledge of these instruments. In 1553, however, Alph. Ferri, of Naples, endeavoured to show, that his acquaintance with the utility of bougies reached as far back as 1548, and, of course, that he had anticipated Lacuna, and perhaps even Aldereto. But, instead of representing himself as the original inventor of bougies, he mentions that they were known to Alexander of Tralles, which, if true, carries back the invention to the sixth century. A. Ferri

also, before describing bougies and escharotic ointments, mentions various means for examining the state of the urethra, and, among other things, cylinders made of flexible lead, and of different sizes. Escharotic ointments for what were termed *caruncles* of the urethra, and bougies were also described by Petronius in 1565, and afterwards by A. Paré. The oldest bougies, which were wicks of cotton, or thread, covered with wax, and escharotic plasters, were in time succeeded by those composed of linen smeared with wax. This change was made with the view of letting them have a hollow construction: an improvement, which was first noticed by Fabricius ab Aquapendente. (*Op. Chir.* 1617.)

In the middle of the 17th century, the manner of making and using bougies was well known to Scultetus, as appears from his *Armamentarium Chirurg.* tab. 13, fig. 9, 10.

The making of bougies has now become so distinct a trade, that it may be considered superfluous to treat of the subject in this dictionary. However, though a surgeon may not actually choose to take the trouble of making bougies himself, he should understand how they ought to be made. Swediaur recommends the following composition: $\mathcal{R}$ Cere flavæ lbj, Spermat. ceti ʒij. Cerussæ acetatæ ʒv. These articles are to be slowly boiled together, till the mass is of proper consistence. Mr. B. Bell's bougie plaster is thus made: $\mathcal{R}$ Emplastri lythargyri ʒiv, Cere flavæ ʒiiss, Olei Olivæ ʒij. The two last ingredients are to be melted in one vessel, and the litharge plaster in another, before they are mixed. In Wilson's *Pharmacopœia Chirurgica*, I observe this formula: $\mathcal{R}$ Olei Olivæ lbiss, Cere flavæ lbj, Minii lbiss. Boil the ingredients together over a slow fire, till the minium is dissolved, which will be in about four or six hours. The composition for bougies is now very simple, as modern surgeons place no confidence in the medicated substances, formerly extolled by Daran. The linen, which may be considered as the basis of the bougie, is to be impregnated with the composition, which is generally wax and oil, rendered somewhat firmer by a proportion of resin. Some saturnine preparation is commonly added, as the urethra is in an irritable state, and the mechanical irritation might otherwise increase it. Of whatever composition bougies are made, they must be of different sizes, from that of a knitting-needle to that of a large quill, and even larger. Having spread the composition, chosen for the purpose, on linen rag, cut this into slips, from six to ten inches long, and from half an inch, to an inch, or more in breadth. Then dexterously roll them on a glazed tile into the proper cylindrical form. As the end of the bougie, which is first introduced into the urethra, should be somewhat smaller than the rest, the slips must be rather narrower in this situation, and, when the bougies are rolled up, that

side must be outward, on which the plaster is spread.

Daran, and some of the older writers, attributed the efficacy of their bougies to the composition used in forming them. On the contrary, Mr. Sharp apprehended that it was chiefly owing to the pressure, which was made on the affected part; and Mr. Aikin adds, that as bougies of very different compositions, succeed equally well in curing the same diseases in the urethra, it is plain, that they do not act from any peculiar qualities in their composition; but by means of some common property, probably, their mechanical form.

As the healthy as well as the diseased parts are exposed to the effects of bougies made of very active materials, modern surgeons always prefer such as are made of a simple unirritating composition.

Plenck recommended bougies of catgut, which may be easily introduced into an urethra, even when it is greatly contracted, their size being small, their substance firm, and dilatable by moisture. It is objected to catgut, however, that it sometimes expands beyond the stricture, and gives great pain on being withdrawn. Formerly, catgut bougies were sometimes coated with elastic gum, a valuable material of which I shall next speak.

The invention of elastic bougies and catheters originated with Bernard, a silversmith at Paris, who, in the year 1779, presented some instruments of this kind to the Academy of Surgery, which period was prior to the claim made by Professor Pickel of Wurzburg to the discovery. (See *Journ. de Med. an.* 1785.)

For the composition of bougies, elastic resin, or gum, is thought to be very desirable, as it unites firmness and flexibility. Mr. Wilson, in his *Pharmacopœia Chirurgica*, is inclined to think that the art of making these instruments, consists in finding a suitable solvent for the indian gum. As this substance, if dissolved in æther, completely recovers its former elasticity, upon the evaporation of this fluid, it is supposed that æther, though rather too expensive, would answer.

I find it positively asserted, however, in a modern work of great repute, that the idea of elastic gum, being the substance really employed, is a mistake, as the material used is nothing more than linseed oil, boiled for a considerable time, and used as a varnish for the silk, linen, or cotton tube. (See *Dict. des Sciences Méd. art. Bougie.*)

Very cheap and good elastic gum bougies are made by Feburier, No. 51, Rue du Bac at Paris, who has twelve different sizes. His elastic gum catheters are also well made, though, for smoothness and regularity, I think they are not equal to some, which are now constructed in London, but I believe, Feburier's smallest size is rather less than any which are made in this city; an advantage which no doubt our artists will soon be able to give their productions. This ingenious mechanic does not employ

catgut in the composition of the elastic gum bougies, for which he is so celebrated. These bougies are most excellent, when you can get them to pass; for they dilate the stricture with the least possible irritation. But, sometimes, they cannot be introduced, when a wax bougie can; and from the trials which I have made of them, I conceive this arises from their elasticity and continual tendency to become straight, when they reach the perinæum, so that the point presses on the lower surface of the urethra. Hence, when the obstruction is on that side, it must be very difficult to get the end of the bougie over it.

A few years ago, Mr. Smyth discovered a metallic composition, of which he formed bougies, to which some practitioners impute very superior qualities. These bougies are flexible, have a highly polished surface, of a silver hue, and possess a sufficient degree of firmness for any force necessary in introducing them for the cure of strictures in the urethra. The advocates for the metallic bougies assert, that such instruments exceed any other bougies, which have yet been invented, and are capable of succeeding in all cases, in which the use of a bougie is proper. They are either solid, or hollow, and are said to answer extremely well as catheters; for, they not only pass into the bladder with ease, but may also be continued there for any convenient space of time, and thus produce essential benefit. (*W. Smyth, Brief Essay on the Advantages of flexible Metallic Bougies*, 8vo. Lond. 1804.) The greatest objection, which has been urged against them, is, that they are attended with a risk of breaking. I have heard of an eminent surgeon being called upon to cut into the bladder, in consequence of a metallic bougie having broken, and a piece of it got into that organ, where it became a cause of the severe symptoms which are commonly the effect of a stone in the bladder. For the particulars of an interesting case, in which a metallic bougie broke in the urethra, the reader may consult *London Med. Repository*, Vol. 9, No. 51. It has also been objected to metallic bougies, that, although they are sufficiently flexible, they are quite destitute of elasticity.

The bougie, with its application, says Mr. Hunter, is perhaps one of the greatest improvements in surgery, which these last thirty or forty years have produced. When I compare the practice of the present day, with what it was in the year 1750, I can scarcely be persuaded, that I am treating the same disease. I remember, when, about that time, I was attending the first Hospitals in the city, the common bougies were, either a piece of lead or a small wax candle, and, although the present bougie was known then, the due preference was not given to it, nor its particular merit understood, as we may see from the publications of that time.

Daran was the first, who improved the bougie, and brought it into general use.—He wrote professedly on the diseases for

which it is a cure, and also of the manner of preparing it, but, he has introduced much absurdity into his descriptions of the diseases, the modes of treatment, and the powers and composition of his bougies.

When Daran published his observations on the bougie, every surgeon set to work to discover the composition, and each conceived that he had found it out, from the bougies, which he had made, producing the effects described by Daran. It never occurred to them, that any extraneous body, of the same shape and consistence, would do the same thing. (*See a Treatise on the Venereal Disease*, p. 116. *Sharp's Critical Inquiry*, Ch. 4; *Aikin on the External Use of Lead*; *Daran Obs. Chir. Sur les Maladies de l'Urethre*, 12mo. Paris, 1748, and 1768; *Olivier, Lettre dans laquelle on démontre les avantages, que l'on peut retirer de l'usage des bougies creuses*, &c. 8vo. Paris, 1750; *Desault, Journ. de Chir.* T. 2, p. 375, and T. 3, p. 123, 1792; *Smyth's Brief Essay on flexible metallic bougies*, 8vo. Lond. 1804; *Dict. des Sciences Medicales*, T. 3, p. 265, &c. 8vo. Paris, 1812.)

Of armed bougies, as well as of some other kinds, and of the manner of using bougies in general, I shall speak in the article *Urethra, Strictures of*.

BRAIN. (For concussion, compression of, &c. see *Head, Injuries of*; for the hernia of, see *Hernia Cerebri*.)

BREAST. (See *Mammary Abscess*; *Mamma, Removal of*; *Cancer*, &c.)

* **BRONCHOCELE.** (from *βρυχη*, the windpipe, and *κελε*, a tumour.) Also called *botium*, or *bocium*. The Swiss call the disease *gotre*, or *goitre*. Some have called it, *hernia gulturis*; *guttur tumidum*; *trachelophyma*; *gossium*; *excechebronchus*; *gongrona*; *hernia bronchialis*. Heister thought it should be named *tracheocoele*. Prosser, from its frequency on the hilly parts of Derbyshire, called it the *Derbyshire neck*; and not satisfied respecting the similitude of this tumour to that observed on the necks of women on the Alps, the *English Bronchocele*. By Alibert the disease is called *Thyrophraxia*.

1. The simple bronchocele or thyrophraxia, is the most common form of the disease, and is a mere enlargement of the thyroid gland. The integuments covering the part, are quite unchanged. Women are observed to be more subject to it than men. It is also well known to be in general free from danger, the office of the thyroid gland not being of such importance in the animal economy, as to be essential to the continuance of life. Alibert assures us, however, that he has seen one example, in which the tumour became cancerous, and destroyed the mother of a family.

2. The compound bronchocele is that which presents the greatest variety, and astonishes every beholder. Sometimes a more or less voluminous cyst is formed round it, filled with a pulsatious, or purulent matter. Sometimes, in compound bronchoceles, calcareous, and other heterogeneous substances are found. In two ca-

ses, Alibert observed, on the outside of the enlarged gland, a yellow fatty mass; and, in a third instance, the gland itself formed a true sarcoma. (*Nosologie Naturelle*, T. 1, p. 464—465, folio, Paris, 1817.)

The term *bronchocele*, always signifies in this country, an enlargement of the thyroid gland, which, with the disease of the surrounding parts, sometimes not only occupies all the space from one angle of the jaw to the other, but forms a considerable projection on each side of the neck, advancing forward a good way beyond the chin, and forming an enormous mass which hangs down over the chest. The swelling, which is more or less unequal, in general has a soft spongy elastic feel, especially when the disease is not in a very advanced state; but, no fluctuation is usually perceptible, and the part is exceedingly indolent. The skin retains nearly its ordinary colour; but, when the tumour is of very long standing, and great size, the veins of the neck become more or less varicose.

According to Prosser, the tumour generally begins between the eighth and twelfth years. It enlarges slowly during a few years, till, at last, it augments rather rapidly, and forms a bulky pendulous tumour. Women are far more subject to the disease, than men, and the tumour is observed to be particularly apt to increase rapidly during their confinement in childbed. Sometimes bronchocele affects the whole of the thyroid gland, that is to say, the two lateral lobes, and the intervening portion, and it is in this kind of case, that it is not unusual to remark three distinct swellings, for the most part of unequal size. Frequently, only one lobe is affected; while, in many cases, the three portions of the thyroid gland are all enlarged, and so confounded together, that they make, as it were, only one connected globular mass. Finally, in some dissections, the thyroid gland has been found quite unchanged, the whole of the tumour having consisted of a sarcomatous disease of the adjacent lymphatic glands and cellular membrane. (*Postiglione*, p. 21.) When only one lobe of the thyroid gland is affected, it may extend in front of the carotid artery, and be lifted up by each diastole of this vessel, so as to appear to have the pulsatory motion of an aneurism. (*A. Burns's Surgical Anatomy of the Head and Neck*, p. 195, and *Parisian Chirurgical Jour.* Vol. 2, p. 292, 293.) Alibert believes, that he first made the remark, that the right lobe was more frequently enlarged than the left. (*Nosol. Nat.* T. 1, p. 465.)

The ordinary seat of bronchocele, as Flajani remarks, is in the thyroid gland; but sometimes cysts are formed in the cellular membrane. (*Collez. a' Oss.* T. 3. p. 277.) And Postiglione also observes, that the swelling is sometimes encysted, and filled with matter of various degrees of consistence, resembling honey, &c.; in some cases, it is emphysematous, or filled with air; and, in other instances, it is sarcomatous, having the consistence of a gland,

which is enlarged, but not scirrhus.—These different characters, says he, indicate, that the treatment ought not to be the same in all cases. (*Memoria sulla Natura del Gozzo*, p. 20.)

Bronchocele is common in some of the valleys of the Alps, Appenines and Pyrenees. Indeed, there are certain places, where the disease is so frequent, that hardly an individual is totally exempt from it. Larrey, in travelling through the valley of Maurenne, noticed, that almost all the inhabitants were affected with goitres of different sizes, whereby the countenance was deformed, and the features rendered hideous. (*Mém. de Chir. Mil.* T. 1, p. 123.)—And Postiglione remarks, that in Savoy, Switzerland, the Tyrol, and Carinthia, there are villages, in which all the inhabitants without exception have these swellings, the position and regularity of which are there considered as indications of beauty. (*Memoria sulla Natura del Gozzo*, p. 22.) In many, the swelling is so enormous that it is impossible to conceal it by any sort of clothing. A state of idiotism is another affliction, which is sometimes combined with the *goitre*, in countries where the latter affection is endemic. However, all, who have the disease, are not idiots, nor cretins, as they have been called, and in Switzerland, and elsewhere, it is met with in persons who possess the most perfect intellectual faculties. Where bronchocele and cretinism exist together, Foderé, and several other writers, ascribe the affection of the mind to the state of the thyroid gland. (*See Traité sur le Goitre et le Cretinisme*, 8vo. Paris, an. 8.) This opinion, however, appears to want foundation, since the mental faculties are from birth weak, and, in many, the idiotism is complete, where there is no enlargement of the thyroid gland, or where the tumour is not bigger than a walnut, so that no impediment can exist to the circulation to, or from the brain. (*Burns on the Surgical Anatomy of the Head and Neck*, p. 192.) The direct testimony of Dr. Reeve also proves, that, in the countries where cretins are numerous, many people of sound and vigorous minds have bronchocele. (*See Dr. Reeve's Paper on Cretinism*, *Edin. Med. and Surgical Journal*, Vol. 5, p. 31.) Hence, as Mr. A. Burns has remarked, the combination of bronchocele and cretinism must be considered as accidental; a truth, that seems to derive confirmation from the fact, that, in some parts of this country, bronchocele is frequent, where cretinism is seldom or never seen. In the valleys of several mountainous countries, particularly Switzerland, Savoy, the Tyrol, Carinthia, Derbyshire, &c. bronchocele is endemic; and it occurs remarkably often in young subjects, and much more frequently in the female than the male sex.

Bronchocele is a disease not confined to Europe: it is met with in almost every country on the globe. Professor Barton, in his travels among the Indians, settled at Oneida, in the state of New-York, saw

the complaint in an old woman, the wife of the chief of that tribe. From this woman Barton learned, that bronchocele were by no means uncommon among the Oneida Indians, the complaint existing in several of their villages. He found, also, that the disease resembled that seen in Europe, in respect to its varieties. He did not indeed himself see the pendulous bronchocele, which descends over the breast; but, he understood, that it was not uncommon among the women on the banks of the Mohawk river, who wore a particular dress for its concealment. In North America, bronchocele attacks persons of every age; but, it is most frequently seen in adults; a difference from what is noticed in Europe. Bronchocele is said to be frequent in Lower Canada. Bonpland, the companion of Humboldt, informed Alibert, that the disease was endemic in New Grenada, and that it prevailed in such a degree in the little towns of Hunda and Monpa, on the banks of the Magdalen river, that scarcely any of the inhabitants were free from it.—The blacks, and those who led an active laborious life, however, are reported not to have been affected. Some of the natives of the Isthmus of Darien, are said also to be terribly disfigured by this disease. (*Alibert, Nosol. Nat. T. 1, p. 469.*)

In European women, bronchocele usually makes its appearance at an early age, generally between the eighth and twelfth year, and it continues to increase gradually for three, four, or five years, and is said sometimes to enlarge more, during the last half year, than for a year, or two previously. It does not generally rise so high as the ears, as in the cases mentioned by Wiseman. Sometimes, however, this happens, as we see in the case of Clement Desenne, of whom Alibert has given an engraving. In this patient, a part of the tumour, as large as a hen's egg, projected into the mouth. (*Nosol. Nat. T. 1, p. 466.*) The swelling extended from the ears to the middle of the breast. A seton produced a partial subsidence of it; but, when it was withdrawn, the orifices closed. After two years more, the swelling became painful, suppuration took place, and fifteen pints of matter were discharged; and six ounces every day after the swelling had burst, came away with the dressings for three months, but, notwithstanding all this suppuration, and more afterwards, the tumour was only partially lessened. The disease mostly has a pendulous form, not unlike, as Albucasis says, the flap or dewlap of a turkey cock, the bottom being the largest part of the tumour. Alibert mentions a case, in which the swelling hung down to the middle of the sternum, and the large mass, which was quite a burden to the patient, used to become hard, and as it were frozen, in very cold weather. This author, however, cannot be right, when he adds, that it was an inert body, *destitute of vitality!* (*Nosol. Nat. T. 1, p. 466.*) In another curious instance, the tumour formed

a long cylinder, which reached down to the middle of the thigh, the diameter becoming gradually smaller downwards. (*p. 468.*) As a modern author has remarked, the common seat of bronchocele is in the thyroid gland; but, frequently, the surrounding cellular membrane is more or less thickened, and contributes to the swelling. Sometimes also the neighbouring lymphatic glands are affected, when its base is widened, and extends from one side of the neck to the other. In this circumstance, the swelling gradually loses itself in the surrounding parts, and is not circumscribed, as in ordinary instances. (*Postiglione Mem. sulla Natura del Gozzo, p. 20.*) It is soft, or rather flabby to the touch, and somewhat moveable, but after a few years, when it has ceased enlarging, it becomes firmer, and more fixed. When the disease is very large, it generally occasions a difficulty of breathing, which is increased on the patient's catching cold, or attempting to run. In some subjects, the tumour is so large, and effects the breathing so much, that a loud wheezing is occasioned; but, there are many exceptions to this remark. Sometimes, when the swelling is of great size, patients suffer very little inconvenience; while others are greatly incommoded, though the tumour may be small. In general, the inconvenience is trivial. The voice is sometimes rendered hoarse, and, in particular cases, the difficulty of speech is very considerable. (*See Flajani Collez. d'Os. T. 3, p. 271.*)

The difficulty of respiration, produced by the pressure of the tumour, and the enlargement of other glands, as this author remarks, is the most dangerous effect of the disease, since by disordering the pulmonary circulation, it renders the pulse irregular and intermittent, and a strong throbbing is excited in the region of the heart, followed by fatal disease of the lungs themselves: consequences, often not suspected to have any connexion with the bronchocele, though it is in reality the immediate cause of them. (*Vol. Cit. p. 278.*)

The causes of the bronchocele are little known. To the opinion that bronchocele is caused by the earthy impregnation of water used for drink, the following objections offer themselves. 1. The water of Derbyshire, in districts, where this disease is considered endemic, contains much supercarbonate of lime; but that in common use about Nottingham, where the disease is also prevalent, is impregnated with sulphate of lime. However, that the disease is not produced by water, impregnated with sulphate of lime, is evident; for, as Alibert observes, the waters of Saint-Jean, Saint-Sulpice, and St. Pierre, where bronchocele is frequent, contain much less of this earth than the waters of Upper Maurienne, where the disease is hardly ever noticed, though the houses are built upon a vast quarry of gypsum. The same fact was observed by Bonpland in New Grenada. (*Nosol. Nat.*

T. 1, p. 471.) Nor, as Foderé explained, can the cause of the disease be correctly referred to the use of any particular kind of food. Certain localities, however, seem to contribute to its frequency; for, this author observed, that the disease is not prevalent in very high places, nor in open plains; but, that it becomes more and more common, as we descend into deep valleys, made by torrents, where there is a good deal of marsh, and abundance of fruit trees. The air is here constantly humid. 2. Abstinence from water unboiled does not diminish, nor interrupt the gradual progress of the disease. 3. Patients are cured of the disease, who still continue to drink water from the same source as before, without taking any precaution, as boiling, &c. 4. The disease in this country is less frequently found among men. Any instances may be related of a swelling in the neck, sometimes very painful, and generally termed bronchocele, being produced very suddenly, by difficult parturition, violent coughing, or any other unusual exertion. (See *Edin. Med. and Surg. Journal*, Vol. 4, p. 279.) When the swelling is suddenly enlarged during a violent exertion, the distention is said to be produced by the passage of air from the trachea into the substance of the thyroid gland, and surrounding cellular membrane. But, whether this statement be a fact or not, it is unquestionably true, that, in many patients, the tumour always becomes increased in size, when they speak loud, sing, or make any effort. (*Flajani Collez. d'Oss.* &c. T. 3, p. 276, and *Postiglione*, p. 24.) The disease is sometimes seen in scrofulous subjects; but, there is every reason to believe, that it is quite independent of the other disorder, as Prosser, Wilmer, and Kortum have particularly explained. The following are some points of difference, between bronchocele and scrofula, as indicated by Dr. Postiglione. 1. The true bronchocele is simply a local disease of the neck, the constitution being unaffected.—On the contrary, scrofula extends its effects to the whole system, attacking not only the lymphatic glands, but also the muscles, the cellular membrane, the ligaments, cartilages, and bones. 2. Both diseases chiefly occur in young subjects; but, bronchocele often begins at a later age, than scrofula, and does not, like the latter, spontaneously disappear, as the patient approaches puberty, and gains strength. 3. Scrofulous glands often suppurate and ulcerate; bronchocele rarely undergoes these changes. 4. The thickening of the upper lips of scrofulous subjects, is not an attendant on bronchocele; and, while the former patients generally enjoy their mental faculties in perfection, as long as they live, the latter disease in certain countries is often joined with cretinism. Scrofula is likewise always hereditary; while bronchocele is not so; no healthy persons become scrofulous by living a long while among scrofulous patients; but many individuals contract bronchocele by going from a country where

this disease is unknown, and taking up their residence in places where it abounds. 5. Nature alone often cures scrofula, while art seldom succeeds; on the contrary, bronchocele is seldom cured by nature, but very frequently by art. 6. The muriate of lime, recommended by Fourcroy for the cure of scrofula, is always useless: but, in bronchocele, it proves a valuable remedy. (*Postiglione Memoria sulla Natura del Gozzo*, &c. p. 25.) The error of confounding bronchocele with scrofula, is now generally acknowledged. At the hospital St. Louis, says Alibert, scrofulous patients are very numerous, while those with bronchocele are very rare. (*Nosol. Nat. T. 1, p. 465*.) On the mountainous parts of Derbyshire, Genoa, and Piedmont, they attribute the bronchocele to drinking water cooled with ice. To this theory, many of the objections, concerning the earthy impregnation of water, stand in full force; with this additional reflection, that "In Greenland, where snow water is commonly used, these unsightly protuberances are never met with, nor, (says Watson,) did I ever see one of them in Westmoreland, where we have higher mountains, and more snow than they have in Derbyshire, in which county, they are very common. But what puts the matter beyond a doubt, is, that these wens are common in Sumatra, where there is no snow, during any part of the year." (*Watson's Chymical Essays*, Vol. 2, p. 157.) The above opinion was also refuted by Foderé, who remarks, that the Swiss, who reside at the bottom of the Glaciers, are the least subject to the disease. Bronchoceles are also said to be unknown in Lapland.

Respecting the influence of particular water in bringing on the disease, Dr. Odier gives credit to the opinion, because it has appeared to him, that distilled water prevented the increase of the tumour, and even tended to lessen its bulk. (See *Manuel de Médecine Pratique*, Svo. Genév. 1811.) However, without denying this power of distilled water, I think the foregoing considerations satisfactorily prove, that the disease neither proceeds from snow water, nor water impregnated with particular salts.

An observation, lately made by an intelligent writer, would lead one to conclude, that cretinism depends upon malformation of the head. Speaking of goitre, as it appears among the inhabitants of the valley of Maurienne, Baron Larrey informs us, that, in many of these people, with this frightful deformity is joined that of the cranium, of which the smallness and excessive thickness are especially remarkable. (*Mem. de Chir. Mil. T. 1, p. 123*.) Dr. Leake thinks, that tumours of this sort may be owing to the severity of the cold damp air, as they generally appear in winter, and hardly ever in the warm dry climates of Italy and Portugal. The latter part of the observation, however, is not correct, for Dr. Postiglione and other Italian writers assure us, that the disease is extremely common in some of the warmest parts of Italy. "*Qui in Napo-*

li, e per tutto il regno, si veggono molti gozzuti, ma non in numerotale, come in Casoria, ed in pochi altri villaggi." (p. 21.) Prosser is inclined to consider the bronchocele, as a kind of dropsy of the thyroid gland, similar to the dropsy of the ovary, and he mentions, that Dr. Hunter dissected one thyroid gland, which had been considerably enlarged, and contained many cysts filled with water. These, he erroneously concludes, must have been hydatids. Dr. Baillie remarks, that when a section is made of the thyroid gland, affected with this disease, the part is found to consist of a number of cells, containing a transparent viscid fluid.

In all probability, the ordinary bronchocele is entirely a local disease, patients usually finding themselves, in other respects, perfectly well. The tumour itself frequently occasions no particular inconvenience, and is only a deformity. There is no malignancy in the disease, and the swelling is not prone to inflame, or suppurate, though, as Dr. Hunter remarks, abscesses do occasionally form in it. Alibert's case of bronchocele becoming cancerous is singular. Mr. Gooch never knew life to be endangered by this sort of tumour, however large, a remark very much at variance with the observations of some other practitioners; but, he had seen great inconvenience arise from it, when combined with quinsy. In fact, the pressure of a large bronchocele may not only greatly afflict the patient by rendering perspiration difficult, but actually cause death by suffocation. (See *Obs. sur un Goitre volumineux, comprimant la Trachée-artère*; par L. Winslow, in *Bulletin de l'Athénée de Méd. &c.*) "Some persons, as Alibert remarks, have the disease all their lives without suffering any inconvenience from it; some experience a suffocating oppression of the breathing; and in others there is an impediment in the circulation, and a tendency to apoplexy, arising from the strangulation, which afflicts them. (*Nosol. Nat. T. 1, p. 446.*) Dr. Hunter says, that the bronchocele frequently appears two, or three years before, or after the commencement of menstruation, and that it sometimes spontaneously disappears, when this evacuation goes on in a regular manner. A. Burns affirms the same thing. On the contrary, according to Prosser, this change in the constitution hardly ever affects the tumour.

TREATMENT OF BRONCHOCELE.

That certain localities, perhaps not yet correctly understood, contribute to the origin of this disease, is well proved by a fact, stated by Alibert, viz. that change of air has more effect on the complaint than medicines, as he has known many Swiss ladies, who came to Paris with bronchoceles, in whom the tumour subsided after they had resided some time in that city.—(*Nosol. Nat. T. 1, p. 473.*)

A blister, kept open, has put a stop to the growth of the tumour; but, this method is not much followed at present, as a better plan of treatment has been discovered.—

The most famous mode of curing the bronchocele is by giving internally burnt sponge, and occasionally a calomel purge, at the same time, employing frictions to the tumour itself.

The efficacy of burnt sponge is said to be most conspicuous, when this medicine is exhibited in the form of a lozenge, composed of ten grains of this substance, ten of burnt cork, and the same quantity of pumice-stone. These powders are to be made into the proper form with a little syrup, and the lozenge is then to be put under the tongue and allowed to dissolve there. To the latter circumstance, much importance is attached. Other practitioners give a scruple of the burnt sponge alone, thrice every day, while some add a grain of calomel to each dose. A purge of calomel should be ordered about once a week, or fortnight, as long as the patient perseveres in the use of the calcined sponge; but, if mercury be combined with each dose of this medicine, no occasional purgative will be requisite.

External means may very materially assist the above internal remedies. Frequently rubbing the swelling with a dry towel; bathing the part with cold water; rubbing the tumour two or three times a day, with the liq. ammon. acet. or the camphor liniment; are the best steps of this kind which the surgeon can take.

"In the treatment of bronchocele," says Mr. A. Burns, "repeated topical detraction of blood from the tumour is highly beneficial. Electricity also has sometimes a marked effect; but, there is no remedy which I would more strongly advise, than regular and long-continued friction over the tumour. By perseverance in this plan, a bronchocele, treated in London, was materially reduced in the course of six weeks. Its good effects I have likewise witnessed myself; and it is a remedy highly recommended by Girard in his '*Traité des Loupes*.' It has also been much used in scrofulous tumours by Mr. Grosvenor of Oxford, and by Mr. Russel of Edinburgh." (*Surgical Anatomy of the Head and Neck, p. 204.*)

Mr. A. Burns recommends the friction to be made with flannel, covered with hair powder, and the part to be rubbed, at least, three times a day, for twenty minutes.

In two cases of bronchocele, related by Dr. Clarke, the patients were cured, by "the steady use of the compound plaster of ammoniac and mercury, conjoined with the internal exhibition of the burnt sponge, and occasional purgatives." (See *Edinb. Med. and Surgical Journal. Vol. 4, p. 280.*)

We learn from Professor Odier, that in Geneva, the bronchocele is cured by burnt sponge, exhibited in powder, or infused in wine, and combined with purgatives to prevent the cramps of the stomach, which sometimes accompany the disappearance of the swelling. Muriate of barytes has likewise been recommended. (See *Manuel de Médecine Pratique.*)

A whole volume might be written on the various remedies, and plans of treatment, of

the bronchocele. The limits of this work, however, demand more conciseness, and, having detailed the most approved practice, we shall be very brief on other proposals.

Mr. Wilmer, credulously imputing great influence to the changes of the moon, used to begin with an emetic, the day after the full moon, and to give a purge the ensuing day. The night following, and seven nights successively, he directed the above-mentioned lozenge to be put under the tongue at bed-time, and administered every noon a bitter stomachic powder. On the eighth day, the purge was repeated, and, in the wane of the succeeding moon, the whole process, except the emetic, was renewed. (*Cases in Surgery, Appendix.*) This famous Coventry plan of treatment is said to be greatly assisted, by rubbing the tumour, with an ointment, containing tartar emetic.

Prosser succeeded with his medicines, though the patient was nearly twenty-five years old, and the swelling had existed more than twelve years. It is said, that no instance of cure has been known, after the patient was twenty-five. Prosser orders one of the following powders to be taken early in the morning, an hour or two after breakfast, and at five, or six o'clock in the evening, every day, for a fortnight, or three weeks. The powder may be taken in a little syrup, or sugar and water: $\mathcal{R}$. Cinnab. ant. op. levigat. milleped. ppt. et pulv. a a gr. xv. Spong. calcin. $\mathcal{Q}$ M.

These powders should be taken for two, or three weeks, and then left off for a week or nine days, before a repetition. At bed-time, every night, during the second course of the powders, some purgative pills, composed of mercury, the extractum colocynthid. comp. and rhubarb, are to be administered; and in general it will be proper to purge the patient with manna, or salts, before beginning with the powders. Prosser puts no faith in external applications.

Some have recommended giving two scruples of calcined egg-shells, every morning, in a glass of red-wine; half a drachm of the sulphuret of potash every day, dissolved in water; or ten, or fifteen drops of the tinct. digit. purpur. twice a day, the dose to be gradually increased. Muriated barytes; cicuta; and belladonna, have also been exhibited. Postiglione commends the muriate of lime as a medicine possessing the greatest efficacy against this disease. He makes the remedy into a bolus with honey, to which he sometimes adds burnt sponge and cinnamon in powder. He employs also frictions with flannel, liniments, and sometimes purges with calomel. The bolus is placed under the tongue, and allowed to dissolve there. (*P. 59, &c.*)

Sir J. Wylie, physician to the Emperor of Russia, adopts the following treatment:—He directs 3 grains of the sub-muriate of mercury, 3 of the ammoniacal muriate of iron, 4 of burnt sponge, and 10 of the bark of laurus cassia. This powder is to be divided into twelve doses, one of which is given twice a week, with a gentle anodyne

at night. Sir J. Wylie likewise prescribes twenty-four lozenges, made by triturating an ounce of burnt sponge, with an equal quantity of the powder of gum arabic, and fifteen grains of cinnamon, first blended with a sufficient quantity of the syrup of orange peel. One of these lozenges is to be put under the tongue daily, and allowed to dissolve there. Lastly, to the tumour itself, he applies a plaster composed of half an ounce of litharge, a drachm of the submuriate of mercury, and 10 grains of antim. tartariz. (*Alibert Nosol. Nat. T. 1, p. 474.*)

Some account of iodine, as a remedy for bronchocele, may be found in the London Med. Repository for Dec. 1820.

Petit, Heister, and Schmucker, make mention of inveterate bronchoceles, which got well gradually of themselves without much inconvenience, in consequence of the tumours suppurating. Volpi states, that such ulcerations are not unfrequent. He has published two facts of this kind, which occurred after a nervous fever; and he records a third case, where the swelling inflamed in consequence of a blow, and suppurated and sloughed, so as entirely to disappear. (See *Léveillé Nouvelle Doctrine Chir. T. 4, p. 128.*) A similar fact is recorded by Zipp. (*Siebold Samml. Chir. Beob. 2 B. p. 229.*)

The disease in its inveterate form, has also been sometimes removed by the application of caustic; (*Mesny in Journ. de Médecine, T. 24, p. 75; Timæus, Cas. p. 283.*) the establishment of issues; (*Jeitteles Obs. Med.*) the making of an incision into the swelling; or the introduction of a seton through it. (*Foderé Essai sur le Goitre et le Cretinisme, p. 75; Klein in v. Siebold Sammlung Chir. Beobacht. 2 B. p. 11; Flajani, Colezione d'Osservazioni di Chirurgia, T. 3, p. 283.*)

Bronchoceles have sometimes been removed by the part having been accidentally or purposely burnt to a considerable depth. (*Motte in Blegny Zodiac ann. 2 Febr. Obs. 11; Severinus de Efficaci Medicina, p. 220.*) The disappearance of bronchoceles has also been known to follow a wound. (*Schmidt Müller über die Ausführungsgänge der Schilddrüse, p. 37; Landshut, 1805.*) A. Burns had sometimes employed blisters, and found them useful. (*Surgical Anatomy of the Head and Neck, p. 204.*) With respect to the caustic, which is spoken of by Celsus, (*Lib. 7. cap. 13.*) Flajani states, that its operation is tedious and painful, and attended with danger, and what he says about the practice of an incision, is not more encouraging. Where the disease contains a cyst, he prefers making an opening with a trocar, though he confesses, that this plan is apt to be followed by a relapse, when the cyst is very thick and hard, in which circumstance, it will be necessary to have recourse either to an incision, or the seton, for the purpose of exciting suppuration. Should the disease, however, be merely composed of one cyst of moderate size, Flajani recommends its entire removal.

"Of all these methods, (says he) proposed for the extirpation of bronchocele, the seton is the least dangerous, and by means of it a radical cure may be generally effected without any severe symptoms, as I have found by experience in many cases. On the contrary, I have been an eyewitness of the fatal consequences induced by the other plans. I was called to assist a gentleman, about forty years of age, brought to death's door by a bleeding, which arose from the application of caustic to the forepart of the neck. As tourniquets, bandages, &c. proved quite ineffectual, it was indispensable to make pressure on the part with the finger of an assistant, for twenty-four hours, ere the hemorrhage could be stopped; a copious suppuration ensued; and it was three months before the parts were healed. I was likewise present (says he) at the opening of a similar, but larger swelling in the same situation, the disease having afflicted an elderly respectable patient for several years. The incision caused the evacuation of a small quantity of serum, contained in the cellular membrane, but the following day, the tumour inflamed, the difficulty of respiration increased, and for some days, the patient was in great danger. At length suppuration was established, followed by a destruction of a great deal of the cellular membrane, and several sinuses, and, in five months, the patient lost his life. On examination of the body, the lungs were found tuberculated, an effect of the impediment to the circulation of the blood through the smaller vessels of those organs." (*Flajani Collezione a' Osserv. T. 3. p. 283, Sco. Roma, 1802.*)

The first proposer of the employment of setons for the cure of diseases of the thyroid gland, is perhaps not exactly known; but it is certain, that the method has been known, and occasionally practised ever since the middle of the last century. "Dr. Monro, senior, (as a well-informed writer has observed) mentions in his lectures, that he had seen a dropsy in the centre of the gland, complicated with bronchocele, cured by a seton although the glandular swelling still continued." (*A. Burns on the Surgical Anatomy of the Head and Neck, p. 191.*) This statement is given on the authority of some MS. notes taken by Dr. Brown, from Dr. Monro's lectures. According to Girard, many cases in his time had been communicated to the Royal Academy of Surgery at Paris, in which the disease had been got rid of either by means of a seton, drawn through the swelling, or the application of an issue. (*Lapiologie, &c. Sco. Paris, 1775.*) The occasional success of setons was also adverted to by Richter in the year 1788. (*Bibliothek, B. 9, p. 478.*) And, the plan is spoken of in another work, published in 1790, as being eligible, where the disease is conjoined with a cyst. (*Encyclopédie Méthod. Partie Chir. T. 1, p. 231.*) The practice was particularly noticed by Foderé in his valuable treatise on bronchocele; and Alibert mentions the seton as being used at

the Hospital St. Louis. (*Nosol. Nat. T. 1, p. 466, fol. Paris, 1817.*)

In November, 1817, Dr. Quadri, of Naples, tried this practice, which he erroneously supposed to be quite new. "By means of a trocar-pointed needle, six and a half inches long, I passed (says he) a seton from above downwards through the gland, at the depth of about four lines from its surface. Suppuration took place in forty-eight hours. On the 18th of November, the seton escaped, when the matter was squeezed out, and the irritation, occasioned by replacing it, produced an abscess on the right side of the neck, which was opened on the 23d, when it was found, that the suppuration had effected the destruction of nearly the whole gland." The woman, who was thirty-six years of age, was seen by Dr. Somerville, in April 1818, with the circumference of her neck lessened, from sixteen to thirteen inches, French measure. In another case, referred to, a seton was passed through each side of the thyroid gland, and the result was a removal of the tumour on the side, where the seton was maintained long enough; but, on the opposite side, the seton being withdrawn too early, the matter collected in a sac, and at the end of four months, a sinus and discharge still continued, the patient refusing to have a counter opening practised. When the seton does not prove stimulating enough, Dr. Quadri sometimes enlarges it, or attaches to it escharotic, or irritating substances. He also frequently uses two setons. In one example, in endeavouring to perforate the gland rather deeply, Dr. Quadri appears to have injured the larger branches of the thyroid arteries, as more than an ounce of blood was discharged, and the tumour swelled, as if injected with blood. The bleeding, however, ceased spontaneously. He states, that the seton has been passed through the tumour not less than sixteen times, the direction being varied in every instance, without untoward accident, and he is confident, that, unless the needle be pushed deep enough almost to touch the thyroid cartilage, the trunks of the thyroid arteries will not be exposed to injury, while any branches, in the track of the needle, will not cause any danger. He insists also upon the propriety of retaining the seton in the tumour a considerable time, and observes, that it remains to be ascertained, whether this practice will answer in every description of bronchocele? For these and several other cases and particulars, the profession are indebted to Dr. Somerville. (*See Med. Chir. Trans. Vol. 10, p. 16, &c.*)

Mr. Gunning applied a seton in a case of bronchocele in St. George's Hospital; but, in this instance, the irritation brought on a sloughing ulceration, and the patient after a time died. The particulars of this case, and of two successful examples of the practice in England, will no doubt be detailed in the 11th volume of *Med. Chir. Trans.* not yet published. One of the two successful cases was treated by my friend, Mr.

James, of Exeter, the other by Mr. A. C. Hutchinson, who has taken the trouble to collect the history of them.

Attempts have been made to extirpate the enlarged thyroid gland; but, the numerous large arteries distributed to this part, the dilated state of these vessels when the gland is much enlarged, and the vicinity of the carotid arteries, render this operation exceedingly dangerous, especially when the swelling is very large, the only instance, in which a patient would submit to this mode of cure. In doing it, one would be obliged to cut arteries large enough to pour forth a vast quantity of blood in a very short time, and so situated, that it would be difficult to tie, or effectually compress them. Mr. Gooch relates two cases, which do not encourage practitioners to have recourse to the excision of enlarged thyroid glands. In one of these instances, so copious an hemorrhage took place, that the surgeon, though equally bold and experienced, was obliged to stop in the middle of the operation. No means availed in entirely suppressing the bleeding, and the patient in a few days died. In the other example, the same event nearly took place, the patient's life only being saved by compressing the wounded vessels with the hand, day and night for a whole week, by persons who relieved each other in turn. The surgeon found this the only way of stopping the hemorrhage, after many fruitless attempts to tie the vessels.

These cases are well calculated to deter prudent men from undertaking the hazardous operation of cutting out an enlarged thyroid gland, except under the most urgent circumstances. When bronchoceles obstruct respiration, deglutition, and the return of blood from the head, in a very serious degree, an enterprising surgeon would feel greatly inclined to make any rational attempt to relieve his patient, even though it might be one of a bold description. In such pressing circumstances, a good operator, well acquainted with the anatomy of the neck, might attempt the extirpation of the swelling, (See *Thyroid Gland*), or, as I should prefer, he might tie one or both of the superior thyroid arteries. When the quantity of blood flowing into a tumour, is suddenly, and greatly lessened, the size of the swelling commonly soon undergoes a considerable diminution. This operation was practised by Sir W. Blizard, who tied the arteries of an enlarged thyroid gland, and, in a week, the tumour was reduced one-third in its size. The ligatures then sloughed off; repeated bleeding took place from the arteries, and by the extension of the hospital gangrene, the carotid itself was exposed. The patient died; yet, as Mr. A. Burns maintained, this did not militate against a repetition of the experiment; the same thing might have happened from merely opening a vein, and, in the confined air of an hospital, has actually happened. (*Surgical Anatomy of the Head and Neck*, p. 202.)

In fact, the rationality of the experiment prevented surgeons from being intimidated by the failure in question, and, with that laudable spirit for the improvement of operative surgery, every where diffusing itself through the profession, other gentlemen were soon found who had judgment enough to make further trials of the practice. In a young man, twenty-four years of age, whose breathing was much impeded by a bronchocele, and whose upper thyroid arteries were very large, and affected with strong pulsations, Walther, of Landshut, tied the left of these vessels, the left side of the gland being the largest. The operation was done on the 3d of June, 1814. An incision, an inch and an half in length, was made in the direction of the inner edge of the sterno-cleido-mastoid muscle, where the throbbing of the artery was quite distinct. By a second stroke of the knife, the platysma-myoides was divided in the same direction, and to an equal extent. The vessel was then exposed by a cautious dissection, and separated from the surrounding parts, and one arterial branch, which was divided, was immediately secured. A ligature, composed of three silk threads, was then conveyed with an aneurism needle under the left thyroid artery, and tied with two simple knots. The wound was then closed with adhesive plaster, and the end of the ligatures brought out at the angles. The ligature on the large artery came away on the 12th day; and without any febrile symptoms, or other bad consequences, the wound was perfectly healed on the 23d day. As early as the 3d day, after the application of the ligature, the left part of the tumour began to be less tense, and the throbbing feel in it soon ceased. By degrees, it dwindled away, becoming as it lessened harder, and, as it were, cartilaginous. In a fortnight, the left half of the swelling was one third smaller, than before the operation; and, at length, only one-third of it remained, while the right side also was somewhat smaller. On the 17th of June, Walther took up the right superior thyroideal artery, which was more difficult to get at, as it lay more deeply, and was much concealed under the enlarged gland, which had pushed it out of its natural situation. The operation lasted three-quarters of an hour, and several large and small arteries which were cut were tied. With respect to the thyroid artery itself, it could not be tied without including a part of the gland in the ligature. No unfavourable symptoms followed this second operation; the ligatures were detached in good time: and the wound healed up very well. The right portion of the bronchocele also now diminished; but, though it was originally smaller than the left, it did not dwindle away so completely as the latter. The remains of the tumour, however, two years afterwards, produced no inconvenience, and respiration was quite easy. (See *Neue Heilart des Kropfes*, &c. von Ph. Fr. von Walther, p. 25.

&c. 8vo. Sulzbach, 1817.) On the 29th of December, 1818, Mr. Henry Coates, of Salisbury, took up the superior thyroideal artery for the cure of a bronchocele, which, in a young woman aged seventeen, was pressing on the trachea and œsophagus, and attended with a great noise in breathing. The superior thyroideal arteries were in this instance large, and pulsated strongly. Mr. Coates cut down upon the left of these vessels, separated it from its accompanying nerve, and passed under it a small round ligature, which was drawn moderately tight, and tied. The next day, there was headach, and some swelling of the neck and side of the head, with increased difficulty of swallowing, and febrile symptoms. These complaints, however, were relieved by bleeding and antimonial medicines. The ligature came away on the ninth day, and, on the fourteenth, the wound was completely healed. On the 14th of February, the breathing being much improved, and the tumour reduced nearly to one half of its former size, the patient was well enough to be discharged from the Infirmary. (See *Med. Chir. Trans.* Vol. 10, p. 312.) My friend Mr. Rose lately mentioned to me a case, in which a similar operation done by Mr. Brodie, did not produce any material diminution of the tumour.

Dr. Parry has remarked a frequent coincidence, either as cause or effect, between enlargement of the thyroid gland and cardiac diseases (*Elements of Pathology*, &c. p. 181.) And, another modern writer mentions, that he has lately seen three cases of this complication. (*Medico Chir. Journ.* Vol. 1, p. 181.) A case is detailed by Flajani, where the disease was accompanied with extraordinary palpitations of the heart. (See *Collezione d'Osservazioni*, &c. di Chirurgia, T. 3, p. 270.) In the instance, here referred to, there was great irregularity of the pulse, and the oppression of the breathing was such, that the patient was obliged to submit to venesection at least every month, whereby he had been rendered quite emaciated.

Albucasis gave the first good account of bronchocele. BRONCHOTOMY, (from *βρογχος*, the windpipe, and *τομή*, to cut.) This is an operation, by which an opening is made into the larynx, or trachea, either for the purpose of making a passage for the air into, and out of, the lungs, when any disease prevents the patient from breathing through the mouth and nostrils; or of extracting foreign bodies, which have accidentally fallen into the trachea; or, lastly, in order to be able to inflate the lungs in cases of sudden suffocation, drowning, &c. The operation is also named *tracheotomy*. Its practicable nature and little danger, are founded on the facility, with which certain wounds of the windpipe, even of the most complicated kind, have been healed, and on the nature of the parts cut, which are not furnished with any vessel of consequence.

When the incision is made in the larynx, the operation is termed *laryngotomy*. With respect to bronchotomy, its performance cannot be regarded as either difficult, or dangerous: *dummodo*, (says Fabricius ab Aquapendente) *qui secit sit anatomæ peritus, quia sub hoc medico et artifice, omnia tutissimè et felicissimè peraguntur*.

Bronchotomy is occasionally practised in order to enable the patient to breathe, when respiration through the mouth and nostrils is impeded by disease.

Cynanche laryngea sometimes creates a necessity for the operation, and this is particularly the case, when the disease is situated in the edges of the rima glottidis, which opening becomes so contracted as scarcely to leave the smallest space. For this reason, and on account of the tension of

the ligaments of the glottis, the voice is rendered excessively acute, and hissing as it were. The suffocation is imminent; the lungs not being expanded, the blood accumulates, in these organs, and more or less impediment prevails to the return of the blood from the head. There can be little doubt, that many patients who have perished under these circumstances, might have been saved by a timely incision in the trachea. The majority of writers, who have treated of bronchotomy, as a means of preventing suffocation in inflammatory diseases of the larynx, have regarded this operation as the ultimate resource. Both the Greeks and Arabians were of this sentiment; and Avicenna only recommends bronchotomy in violent cases of cynanche, when medicines fail, and the patient must evidently die from the unrelieved state of the affection. Rhazes also advised the operation only when the patient was threatened with death.—Thus in former times, though practitioners were aware of the principle, on which bronchotomy became necessary, they generally found the operation fail, because it was delayed too long, and rarely done, ere effusion had commenced in the lungs themselves.

It was doubtless in consequence of the ill success of the operation, that Paulus Ægineta observed: *In cynanchicis quidem chirurgiam improbamus, cum inutiles sit præcisio.* Bronchotomy, says Louis, will always be done too late, when only practised as an extreme measure. In cases of inflammation about the throat, the danger of perishing by suffocation, as this author remarks, has been known from the very dawn of medicine. The advice of Hippocrates, to remedy this urgent symptom, is a proof of it, and, he observes, that the danger is evinced when the eyes are affected and prominent, as in persons who have been strangled, and when there is great heat about the face, the throat, and neck, without the appearance of any external defect. He recommends *fistulæ in fauces ad maxillas intrudendæ, quæ spiritus in pulmones trahatur.* No doubt, he would have advised more, had it not been for the doctrine of his time, that wounds of cartilages were incurable.

This method, defective as it was, continued till the time of Asclepiades, who, according to Galen, was the first proposer of bronchotomy. Since Asclepiades, this operation has always been recommended, and practised in cases of quinsy, threatening suffocation, notwithstanding the inculcation of Cælius Aurelianus, who treated it as fabulous. The mode of doing it, however, has not been well detailed by any body who put it in practice, except Paulus Ægineta, who is precise and clear. "We must (says he) make the incision in the trachea, under the larynx, about the third or fourth ring. This situation is the most eligible, because it is not covered by any muscle, and no vessels are near it. The patient's head must be kept back, in order that the trachea may project more forward. A transverse cut is to be made between two of the

rings, so as not to wound the cartilage, only the membrane." The knowledge of this method, and its advantages in cases of the *angina strangulans*, when practised in time, ought, according to Louis, to have rendered its performance a general practice.

The convulsive angina of Boerhaave, which particularly affects those, who can only breathe well in an upright posture, has also been adduced as a case demanding the prompt performance of bronchotomy.—Mead, in his *Præcepta et Monita Medica*, mentions a case, in which the patient had been bled, very copiously twice in the space of six hours, but he died notwithstanding this large evacuation. The same author took notice in Wales, especially, on the sea-coast, of an epidemic catarrhal quinsy, which carried the patients off in two or three days. In these instances, bleeding was not of much use, and bronchotomy, which was not performed, was the only means by which the patients might have been saved.

In cases of angina and croup, some modern practitioners have been less sanguine in their expectation of benefit from bronchotomy than Louis was. From the observations of Dr. Cheyne, it would appear, that in croup, the operation cannot be necessary for the purpose of admitting air into the trachea; for, in those, who have died of the disease, he has found a pervious canal of two-eighths of an inch in diameter, and through a tube of such diameter, even an adult can support respiration for a considerable time. According to the same writer, bronchotomy is equally unfitted for the removal of the membrane formed by the effusion of lymph; for, from its extent, variable tenacity, and adhesions, this is, in almost every case, totally impracticable; and even could the whole membrane be removed, still the function of respiration would be but little improved, the ramifications of the trachea and bronchial cells remaining obstructed. (See *Cheyne's Pathology of the Larynx and Bronchia*.)

No doubt, Dr. Cheyne's statement of what is found in the dead subject is correct; and yet the operation may be necessary to prevent suffocation, which might otherwise be induced partly by the diminution of the natural passage for the air by disease, and partly by the action of the muscles of the glottis; a circumstance to which Dr. Cheyne has not assigned sufficient importance. On this point, the sentiments of Mr. C. Bell are more correct: speaking of the membrane of croup, formed by the effusion of coagulable lymph, and of the cause of death in these cases, he says, "It has not appeared to me, that it was the violence of the inflammation which destroyed the patient, nor the irritation directly from the inflamed membrane; but that the presence of this secreted membrane, acting like a foreign body, at the same time occasions spasms in the glottis, obstructs the passage, and confines the mucus. But, I am bound to state, in the strongest terms, that death is ultimately a consequence of

effusion in the lungs, occasioned by the continued struggle and difficulty; for, on opening the chest, I have uniformly found, that the lungs did not collapse, and that the bronchiæ were full of mucus. This corresponds with the symptoms; for, before death, the violence of the cough and struggle has given place to coldness and insensibility, with a pale swelling of the face and neck, and *when the child has fallen into this state, giving freedom to the trachea will be of no avail.*" (*Surg. Obs.* p. 16.)

In the cases of croup, which Mr. Chevalier has examined after death, he has found the trachea obstructed with mucus, and he thinks, that it is more by this secretion, than by that of coagulable lymph, that suffocation is finally produced. At all events, he succeeded in saving a boy on the point of suffocation, by making an incision in the trachea, and letting out an ounce, or an ounce and an half, of reddish, brown, frothy mucus. And a case, of a very similar description, in which the same practice answered, I attended, about two years ago, with Mr. Lawrence, and Dr. Blicke. This case, however, was different from Mr. Chevalier's in the circumstance of a tube being required for a couple of days after the operation, when the removal of the instrument was followed by no inconvenience.

Pelletan joins several modern writers, in representing bronchotomy, as generally useless in cases of croup; the only example, in which he thinks the operation might be serviceable, is where the disease is confined to the larynx, a case which he sets down as uncommon, and difficult to be distinguished. "*En supposant enfin l'angine avec concrétion bien caractérisée, on se trouvera encore entre la crainte de pratiquer une opération inutile, si les concrétions se prolongent jusque dans les bronches, et l'impossibilité de juger si ces concrétions sont bornées au larynx. C'est en effet dans ce seul cas que l'opération peut être fructueuse; elle facilitera la respiration pendant que la nature, aidée de l'art, travaillera à dissoudre, détacher, et faire expectorer les fausses membranes qui oblitérent la glotte et le larynx.*" (*Clinique Chirurgicale.* Tom. 1, p. 28.)

Of course, the degree of success, which will attend the practice of bronchotomy in cases of this nature, must always mainly depend upon the operation being done early enough, and in cases, where the lungs are not too seriously affected; for, if the effects of pneumonia are far advanced, the patient's chance of recovery will be hopeless, whether the trachea be opened or not. In order, also, to have a reasonable chance of success, in cases, threatening suffocation, from inflammation of the parts about the fauces, as sometimes happens, the operation must not be deferred too long. We see this fact exemplified in two cases recorded by Flajani; in one, where the operation had not been allowed till a late period of the disease, the patient died; in the other, where the practice was adopted earlier, life

was preserved. (*Collezione d'Osservazioni, &c.* T. 3, p. 230—233.)

A few years ago, Dr. Baillie published three cases, in which death was produced in the adult subject, and, in a very few days, by a violent inflammation of the larynx and trachea. The disease had a strong resemblance to croup; but, yet was different from it. There was not the same kind of ringing sound of the voice as in croup, and no layer of coagulable lymph was formed upon the surface of the inner membrane of the larynx and trachea, which, according to Dr. Baillie, uniformly attends the latter disease. In one of these cases, the cavity of the glottis was found to be almost obliterated, by the thickening of the inner membrane of the larynx at that part. The inner membrane of the trachea was likewise inflamed; but in a less degree. The lungs were sound. If, in thirty hours, no relief should be derived from bleeding ad deliquium, and the exhibition of opiates, Dr. Baillie conceives, that, in this sort of case, it might be adviseable to perform the operation of bronchotomy at the upper part of the trachea, just under the thyroid gland. This operation, he thinks, would probably enable the patient to breathe, till the inflammation in the larynx, more especially, at the aperture of the glottis, had time to subside. (See *Trans. of a Society for the Improvement of Med. and Chir. Knowledge.* Vol. 3, p. 275, 289.)

An acute affection of the membrane of the glottis, proceeding rapidly to a fatal termination by suffocation, has also been lately particularly described by Drs. Farre and Percival. (See *Med. Chir. Trans.* Vol. 3, and 4.) In some bodies, which Mr. Lawrence examined after death, he found appearances analogous to those mentioned by the above physicians. "The patients died of suffocation: but the progress of the complaint was much slower, than in those cases; the symptoms were not acute, nor did the inspection of the parts disclose any evidences of active inflammation. The membrane, covering the chordæ vocales, was thickened, so as to close the glottis, and a similar thickening extended to a small distance from these parts, accompanied with an œdematous effusion into the cellular substance under the membrane. The epiglottis did not partake of the disorder. In one or two instances, this thickened state of the membrane was the only change of structure observed; but in others it was attended either with ulceration of the surface near the glottis, appearing as if it had been formed by an abscess, which had burst; or with a partial death of one or more of the cartilages of the larynx, viz. the arytenoid, thyroid, or cricoid. The rest of the air passages and the lungs were healthy." (*Med. Chir. Trans.* Vol. 6, p. 222.)

In such examples, this gentleman is a zealous advocate for the early performance of bronchotomy, and he has cited several instances, in which this operation was successfully performed, both for the relief of

quinsy and extraction of foreign bodies from the trachea.

The affections of the larynx, requiring bronchotomy, would seem, indeed, to be more numerous and diversified, than is usually supposed: thus, Mr. C. Bell mentions the case of a medical student, who was attacked with shivering, fever, and sore throat, and in three days died of suffocation. On dissection, no obstruction in the larynx was observed, but only an inflammation of its membrane, and a spot like a small pox pustule, upon the margin of the glottis. (*Surgical Obs. Part 1, p. 14.*)

2. The compression of the trachea by foreign bodies lodged in the pharynx, or by tumours, formed outwardly, and of sufficient size to compress the windpipe, is an equal reason for operating, more or less expeditiously, according to the symptoms. Mr. B. Bell mentions two instances of suffocation from bodies falling into the pharynx. Respiration was only stopped for a few minutes; but, the cases were equally fatal, notwithstanding the employment of all the usual means. This author thinks, there was every reason to believe, that bronchotomy would have been attended with the greatest success, if it had been performed in time, before the effects of the suffocation had become mortal. The operation should also be done, when the trachea is compressed by tumours. The author of the article *Bronchotomie*, in *l'Encyclopédie Méthodique*, says, that about twenty years ago, he opened a man, who had died of an emphysema, which came on instantaneously. He had had, for a long while, a bronchocele, which was of an enormous magnitude towards the end of his life. The cavity of the trachea was so obliterated, that there was scarcely room enough to admit the thickness of a small piece of money. Doubtless, bronchotomy, performed before the emphysema made its appearance, would have prolonged this man's days.

In cases of this last description, Desault would have advised the introduction of an elastic gum catheter into the trachea from the nose, in order to facilitate respiration. This practice, I believe, has not hitherto been attempted by English surgeons, though it has been repeatedly tried in France. (*See Œuvres Chir. de Desault, T. 2, p. 236, &c.*)

Habicot successfully performed this operation on a lad fourteen years old, who, having heard, that gold, when swallowed, did no harm, attempted to swallow nine pistoles wrapped up in a piece of cloth, in order to hide them from thieves. The packet, which was very large, could not pass the narrow part of the pharynx; and here it lodged, so that it could neither be extracted, nor forced down into the stomach. The boy was on the point of being suffocated by the pressure, which the foreign body made on the trachea; and his neck and face were so swollen and black, that he could not have been known. Habicot, to whose house the patient was brought, attempted in vain, by different

means, to dislodge the foreign body. At length, perceiving the patient in evident danger of being suffocated, he resolved to perform bronchotomy. This operation was no sooner done, than the swelling and lividity of the face and neck disappeared. Habicot pushed the pieces of gold down into the stomach with a leaden probe, and the pistoles were, at different times, discharged from the anus, eight or ten days afterwards. The wound of the trachea very soon got quite well. (*See Mem. de l'Acad. de Chirurgie, Tom. 12, p. 243, Edit. in 12mo.*)

In such a case, Desault would have introduced an elastic gum catheter into the larynx, instead of performing bronchotomy, which could not answer, were the foreign body low down. (*See Œuvres Chir. de Desault, Tom. 2, p. 247.*)

3. Foreign bodies in the trachea, may render it necessary to practice bronchotomy. Here I ought rather to say, perhaps, laryngotomy, which by several modern surgeons is in these cases deemed most applicable. (*Desault; C. Bell, Surg. Obs. Part 1, p. 47, &c.*)

Louis, in an excellent memoir, on extraneous substances in the trachea, has proved, more convincingly than all other preceding writers, the necessity of the operation in circumstances of this kind. The following case fell under his observation.

On Monday, the 19th of March, 1759, a little girl, seven years old, playing with some dried kidney-beans, threw one into her mouth, and thought she had swallowed it. She was immediately attacked with a difficulty of breathing, and a severe convulsive cough. The little girl said she had swallowed a bean, and such assistance as was thought proper, was given her. Want of success was the cause of several surgeons being successively sent for, who vainly employed the different means, prescribed by art, for extracting foreign bodies from the œsophagus, or forcing them into the stomach. A fine sponge, cautiously fastened to the end of a whalebone probang, was repeatedly introduced through the whole extent of the œsophagus. The little girl, who made a sign with her finger, that the foreign body was situated in the middle of the neck, thought that she felt some relief, when the sponge was conveyed below the place which she pointed out. She had, every now and then, a violent cough, the efforts attending which produced convulsions in all her limbs. Deglutition was unobstructed; and warm water and oil of sweet almonds had been swallowed without difficulty. Two whole days had been passed in sufferings, when the relations called in Louis. The little girl, with all possible fortitude and sense, was several times held in her friends' arms, ready to die of suffocation. Louis, well aware of what had happened, came into the room where the patient was. She was sitting up in her bed, suffering no other symptom than a very great difficulty of breathing. Louis

inquired where she felt pain, and she made such a sign in reply, as left no doubt concerning the nature of the accident. She put the index finger of her left hand on the trachea, between the larynx and sternum. The fruitless attempts which had been made in the œsophagus, with a view of dislodging the foreign body; the nature and the smallness of this body, which was not such as would be stopped in the passage for the food; and the facility of swallowing, were negative proofs, that the bean was not in the œsophagus. Respiration was the only function disturbed; it was attended with difficulty, and a rattling in the throat. The little girl expectorated a frothy fluid, and she pointed out so accurately the painful point where the object producing all her sufferings was situated, that Louis did not hesitate to declare to the relations, from this single inspection, that the bean was in the windpipe, and that there was only one way of saving the child's life, which was to make an incision, for the purpose of extracting the foreign body. He apprised them, that the operation was neither difficult nor dangerous, that it had succeeded as often as it had been practised, and that the very pressing danger of the case only just allowed time to take the opinion of some other well-informed surgeons, respecting the indispensable necessity for such an operation. Louis thought this precaution necessary, in order to acquire the confidence of the parents, and to shelter himself from all reproach, in case the event of the case should not correspond with his hopes. Louis went home to prepare all the requisites for bronchotomy, and, in two hours, he was informed the surgeons, who were consulted, waited for him. Since Louis went away, the child had become quiet, and was lying on its side asleep. The opinion he had delivered, had been ill-explained by the friends and attendants, and had been discussed, before his return. They, who had been rendering their assistance, on the supposition, that the foreign body was in the œsophagus, evinced surprise at the proposal of extracting, by an operation, a substance, the presence of which, in any part of this tube, was not obvious. Louis explained his advice, in regard to bronchotomy, and he did not expect a doubt to be set up against so positive a fact. The investigation of truth may authorize objections, to which those who make them, only give the value which is due; but Louis was asked concerning the possibility of the case. It was objected, that a substance as large as a bean could not insinuate itself into the trachea. He brought every one into his sentiment, by a short explanation of cases of this sort, with which he himself was acquainted. The little girl was examined; she was better than when Louis saw her before, and a very palpable emphysema was seen above the clavicle, on each side of the neck, a symptom which did not exist two hours previously. This swelling made Louis conclude, that the urgency for the

operation was still greater. The friends, whose confidence had been shaken by the opposition he had experienced in bringing about unanimity, were in the greatest embarrassment, when they were told, that the child might die of an operation, which he had represented as only a simple incision, free from all danger. Louis was repeatedly asked, if he would be responsible for the child's life during the operation, and he in vain replied, that if there were any thing to fear during the operation, it would be from the accident itself, and not from the assistance rendered. This distinction was not perceived, and Louis withdrew, at the same time refusing his consent to the exhibition of two grains of emetic tartar, the effect of which would be useless, and might be dangerous. The medicine was given in the night: the child was fatigued with its operation, and quite unbenefitted. On Tuesday morning, Louis found the little girl very quiet, and they who had paid their visits earlier, found her wonderfully well. The respiration, however, continued to be still attended with a rattling noise, which Louis had observed in the evening, when her breathing was much more laborious. The child was nearly suffocated several times in the course of the day, and died in the evening, three days after the accident.

Bordenave, who had seen the patient, informed Louis of the child's death on Friday. The body was opened, before a numerous assembly of persons. After making a longitudinal incision through the skin and fat, along the trachea, between the sternohyoidei muscles, Bordenave slit open the trachea, cutting three of its cartilages.—This very instant, every one could see the bean, and Louis took it out with a small pair of forceps. It was manifest, from the ease with which this foreign body was extracted, that the operation would have had, on the living subject, the most salutary effect. The relations had to regret having sacrificed a child, which was dear to them, to an irresolution and a timidity, which the most persuasive arguments could not remove. (*Mem. de l'Acad. Royale de Chirurgie*, Tom. 12, p. 293, &c. Edit. in 12mo.)

This case evinces, in the most decided manner, the symptoms which result from the presence of foreign bodies in the trachea, and shows the only one surgical proceeding which can be of use. But, among the phenomena, apparently difficult of explanation, is the calm, which, at different intervals, followed the afflicting cough.—Anatomy, however, has dispelled much of the doubt on this matter. It is known, that the whole canal of the trachea is much less sensible than the rima glottidis. A foreign body, like a bean, may remain a certain time in that canal without much inconvenience, the passage being only somewhat obstructed, according to the position of the substance. It may even remain several days, months, or years, without producing any symptom of its presence, except a trivial sensation of obstruction, and

this is what happens when the body lodges in one of the ventricles of the larynx.—Facts of this kind are to be found in Tulpius, Bartholine, and many other observers. But, when the extraneous substance quits its situation, and is carried into the trachea, the irritation which it produces there, and, particularly about the larynx, occasions coughing, and if, in the fits, the foreign body should become fixed between the lips of the glottis, it may cause instantaneous death, as probably has happened in many of the cases of suffocation from extraneous substances.

Another remarkable circumstance which deserves more attention, as it confirms the presence of a foreign body in the trachea, is the emphysema, which appeared about the clavicle, towards the termination of the case. Louis did not believe, that any of the persons, who saw the patient, could entertain a just idea of the origin of this symptom. The supposition, that the obstruction, which the foreign body caused for two days, to the free passage of the air, might have occasioned a forcible distention of the trachea, and a rupture of the membrane, which connects together the cartilaginous rings of this tube, was dispelled by the examination after death. The windy tumour had not originated in the circumference of the trachea: here its limits were only seen. The very substance of the lungs, and the mediastinum, were emphysematous. The air, confined by the foreign body, had ruptured the air-cells, during the violent fits of coughing, and thus insinuated itself into the interlobular cellular substance of the lungs. Thence it had passed into the cellular substance of the lungs; and afterwards into that connecting the pleura pulmonalis with the outer surface of these organs; and by the communication of the cells with each other, it had produced a prodigious swelling of the cellular substance, between the two layers of the mediastinum. The emphysema, in its progress, at length made its appearance above the clavicles. The swelling of the lungs, and circumjacent parts, in consequence of the insinuation of air into the cellular substance, is a manifest cause of suffocation. The tumefaction appears to be so natural an effect of the presence of a foreign body in the trachea, that one can hardly believe it is not an essential symptom, though, before Louis, no author has made mention of it.

Foreign bodies in the trachea, however, do not always cause death so suddenly, which may be owing to their smallness, their smoothness, or the situation in which they are fixed. An example is related in *les Ephémérides des Curieux de la Nature*, Decad. 2. Ann. 10. As a monk was swallowing a cherry precipitately, the stone of the fruit passed into the trachea. A violent cough, and excessive efforts, as it were, to vomit, were the first symptoms of the accident, and of these the patient thought he should have died. A sleep of

some hours followed this terrible agitation, and the patient afterwards did not feel the least inconvenience during a whole year. At the end of this time he was attacked by a cough, attended with fever. These symptoms became worse and worse, every day. At length the patient evacuated a stone as large as a nutmeg. It was externally composed of tartareous matter, to which the cherry stone had served as a nucleus. A copious purulent expectoration followed the discharge of the foreign body, and the patient died consumptive some time afterwards. No mention is made of the body being opened; but, from the symptoms, there is every reason to believe, that an abscess must have arisen in the substance of the lungs, from the presence of the foreign body. That foreign bodies in the trachea, even when they do not induce pressing symptoms of suffocation, may ultimately kill the patient by inducing disease of the lungs, is proved by several cases on record, and, particularly by one, which occurred to Desault; a cherry-stone was lodged in one of the ventricles of the larynx; the patient would not consent to an operation, and died after two years *d'une phthisie laryngée*. (See *Œuvres Chir. de Desault*, P. 2, p. 258.)

Some valuable observations, confirming the necessity of an early recourse to bronchotomy, in cases where foreign bodies are lodged in the trachea, have been published by Pelletan, now one of the surgeons of the Hôtel Dieu, and a practitioner of vast experience. In one case, in which a bean had fallen into a child's trachea, and in which the most urgent symptoms of suffocation had prevailed for four days, and convulsions during the last thirty-six hours of this space of time, M. Pelletan performed the operation, which a timid practitioner, under whose management the young patient was first placed, had neglected to do at an earlier period. Upon the incision being made into the trachea, the bean was immediately thrown out to the distance of two feet, and the child for a time was relieved. The little boy was so extremely weak, that it was at one time supposed he was dead. However, with some assistance, he gradually revived, even regained his senses, called his parents, and asked for such things as he wanted.

This hopeful state lasted eight or ten hours, after which, convulsions came on again, and the child died fourteen hours after the operation.

Notwithstanding the turgid appearance of all the blood vessels of the brain, as detected after death, the little boy had yet received a degree of relief at the instant of the foreign body being extracted. Pelletan deems it unnecessary to insist on the great probability of success that would have attended the operation, had it been performed at an earlier period.

Of such success, Pelletan gives us the following example.

In May, 1796, a child about three

years old, was brought to the Hôtel Dieu, who, in playing with some French beans, and putting them into its mouth, let one of them slip into the trachea. For three days the child was afflicted with a continual cough, and sometimes the symptoms of suffocation were most pressing. This time had been spent in administering emetics, introducing instruments into the œsophagus with the design of forcing the foreign body into the stomach, and in inspiring the relations with a pernicious confidence, arising from the very long intervals of repose, which the child experienced, during which, however, a rattling in the throat continued, a characteristic mark of the accident. Pelletan immediately decided to perform the operation. The child was very fat, and this circumstance, together with the small diameter of the trachea at this age, rendered the exposure of the anterior portion of this tube difficult. Pelletan was at this moment struck with the reflection, that bronchotomy should never be attempted except by men of science, coolness, and experience in operations. The rings of the trachea, however, were at length cut, and there was no sensible interval, between the incision and the expulsion of the foreign body. The bean had swelled considerably with the moisture. The child seemed restored to life; it spoke freely; it was only troubled with coughing, the effect of a small quantity of blood insinuating itself into the trachea, which fluid was instantly rejected again. This event has the appearance of convulsions, and may alarm those, who do not understand it; but according to Pelletan, it is the guarantee of the patient's life by expelling, incessantly, and without difficulty, whatever happens to get into the trachea. The wound was healed in twenty days, and the child's voice was not perceptibly altered.

In another interesting case, recorded by the same writer, a pebble was lodged in the windpipe, and the case, not being understood, was treated, for about three weeks, as a simple inflammation of the lungs. At last, bronchotomy was performed, and, by placing the child in a horizontal position, the stone was soon discharged through the incision. The patient was immediately relieved; but, the effects of the inflammation of the lungs, and injury which these organs had sustained, could never be entirely cured, and the child died phthisical eight months afterwards.

Pelletan details other cases, in which the foreign body, being fixed in the trachea, could not be forced out by the breath, as soon as the incision was made, but, required further means to disengage it. In one instance, Pelletan made a long cut in the windpipe of a child; but, nothing made its appearance. A probe, wrapped round with some oiled linen, was then introduced several times up and down the larynx, without creating a great deal of uneasiness, and the child continued to respire very well through the opening in the trachea. The foreign

substance was presently brought to the wound and extracted: it proved to be part of the jaw of a mackarel, with many sharp teeth in it. This child soon experienced a perfect recovery.

In another instance, a young man came to the Hôtel Dieu, in consequence of being afflicted, for six weeks, with a severe cough, frequently accompanied with a sense of suffocation. These complaints, on inquiry, were ascertained to arise from a button-mould having fallen into the trachea. An opening was, therefore, made in this tube; but, though the button could be felt, it could not be extracted with the finger. The cricoid cartilage was now divided, and the foreign body was then taken out of the left ventricle of the larynx. The man recovered.

In one case, related by Pelletan, a piece of tendon of veal got down the glottis, and gave rise to most dangerous symptoms. The foreign body was described as being so large, that this surgeon could not but suppose, that the complaints were owing to its lodgment in the œsophagus, as it seemed to be incapable of entering the glottis. The introduction of instruments down the pharynx, however, produced no relief; but, on dividing the thyroid cartilage, Pelletan passed his finger within the larynx, and, without knowing it, pushed the piece of tendon towards the glottis, when, with the aid of a probang, it was forced into the pharynx and swallowed. The patient experienced immediate relief, and got quite well. (See *Pelletan's Clinique Chir. T. 1.*)

With respect to bronchotomy, or laryngotomy, for cases in which extraneous substances are supposed to be lodged in the trachea, one important caution seems necessary, viz. whenever the foreign body is above a certain size, a probang should always be passed down the œsophagus before cutting into the windpipe; for, very similar symptoms to those, which proceed from extraneous substances in the trachea, may be caused by the lodgment of foreign bodies in the œsophagus. In fact, bronchotomy has actually been performed, while the extraneous substance was in the œsophagus, from which last situation no attempt was made to displace it, and the patient lost his life. (See *Œuvres Chir. de Desault, T. 2, p. 261.*) Examples, in which various extraneous bodies have been successfully extracted by means of bronchotomy, are recorded by Engel. (*Sendschreiben an Schmid, &c. Augsp. 1750; Guncourt, Journ. de Méd. Vol. 12, p. 44; Heister, Wahrnehmungen, 1, p. 1026; Wendt, Hist. Tracheotomie, &c. Uralist. 1774.*)

4. Bronchotomy has been proposed in cases, in which the tongue is so enlarged, as totally to shut up the passage through the fauces. Richter mentions an inflammation of the tongue, in which this part became four times larger than in the natural state. Valescus had made the same observation: *Ego aliquando vidi ita magnificatam linguam propter humores, ad ejus sub-*

stantiam venientes, et ipsam imbibentes, quod quasi totum os replebat, et aliquando ex ore exibat. Lib. 2, cap. 66. Such prodigious swellings of the tongue are said sometimes to occur in malignant fevers and the small-pox. They are also sometimes quite accidental, as, for instance, the cases which happen from the stings of insects, or the unskilful employment of mercury. Mr. B. Bell gives an example of the latter sort.—He says, that the patient had taken, in a very short time, so large a quantity of mercury, that the part became alarmingly swollen in a few hours, and, though all the usual remedies were tried, none had the least effect. Bronchotomy was delayed till the patient was nearly suffocated; but he was restored as soon as an opening was made in the trachea. Some have objected to this practice, alleging, that scarifying the tongue will bring relief in time. (*Encyclopédie Méthodique; Partie Chirurgicale, Art. Bronchotomie.*) Malle's observations on the swelling of the tongue, and the most effectual means of relieving it, seem to confirm the latter sentiment. (*Mém. de l'Acad. de Chirurgie, Tom. 14, p. 408, &c. Edit. in 12mo.*)

In cases of the preceding description, Desault would have advised the introduction of an elastic gum catheter, from the nose into the trachea, in order to enable the patient to breathe, until the swelling of the tongue had subsided. (*See Œuvres Chir. de Desault. T. 2, p. 246.*)

6. Bronchotomy has been proposed, when both the tonsils are so enlarged that they quite impede respiration. Here, the inflammatory swelling is not meant; this commonly soon suppurates, and the spontaneous bursting of the tumour, or the opening of it with a pharyngotomus, generally removes all necessity for so extreme a measure. But, even in acute inflammation and great enlargement of the palate, tonsils, &c. attended with imminent danger of suffocation, the practice has been sometimes deemed necessary, as the cases, cited from Flajani, in the preceding columns, are sufficient to prove. The disease, however, which I here wish particularly to specify, as sometimes rendering bronchotomy indispensable, is a chronic enlargement of the tonsils, the case mentioned in the article *Tonsils*. From the remarks on the disease, however, it will be seen, that more is to be expected from the excision of the tonsils, than from the operation now in question. Besides, before the glands are so large as to threaten suffocation, they should be cut away, in preference to performing bronchotomy, which might relieve the urgency, but could not the cause of the difficulty of breathing.—In general, there is no urgent danger of suffocation, till the swelling is such as not only to shut up the posterior aperture of the mouth, but also the posterior openings of the nostrils, which is exceedingly rare. In cases of obstructed respiration from enlargement of the tonsils, Desault preferred the introduction of the elastic catheter,

from the nose into the larynx, to the operation of bronchotomy. It is not common for a polypus to make this operation necessary. Boerhaave, however, mentions a case, in which the patient was suffocated, as the surgeon was going to extirpate a tumour of this kind: no doubt, this patient might have been saved, if bronchotomy had been previously performed. Polypi, growing in the larynx itself, are very rare; but examples are recorded, and, if such tumours happen to obstruct the glottis, the patients are instantly suffocated. Some instances of this kind are related by Bichat. The only mode of getting at such swellings, so as to extirpate them, is by performing bronchotomy. (*See Œuvres Chir. de Desault, T. 2, p. 254, 255.*)

6. Lastly, bronchotomy has been recommended to be done on persons recently suffocated or drowned. Detharding is the first author, who has treated of the necessity of this operation, in the latter case, in a letter addressed to Schroeck, entitled, *De Methodo subveniendi submersis per laryngotomiam. Hactenus rectè*, says Haller, *si spuma quæ pulmo in submersis offeritur ea administratione repelli quiret.* This writer maintains, that drowned persons have no water in their chests, or air-vessels of the lungs, and that they perish suffocated, for want of air and respiration, and that, while the person is under water, the epiglottis applies itself so closely over the glottis, that not one drop of water can pass. But, these assertions are quite contrary to the numerous experiments made by Louis, who drowned animals in coloured fluids, and proved that they who are drowned, inspire water, with which the air vessels and cells are quite filled. Louis has also opened men, who have perished under water, but, in them, he never found the epiglottis applied to the glottis, as Detharding says it is; indeed, anatomy proves the impossibility of its being so. Detharding's theories were wrong, and, as he did not use any power to distend the lungs with air, his mere practice of bronchotomy must have been useless.—When there is a free communication between the cells of the lungs and the atmosphere, the air will not expand these organs, if the inspiratory muscles can no longer act. Hence, after opening the trachea, and letting as much water run out of this tube as possible, the pipe of a pair of bellows should be introduced, and the air forcibly introduced into the lungs.

Detharding was right in his opinion, that drowning is a species of suffocation, and that the privation of oxygen gas is the cause of death. Hence, the propriety of introducing this air into the lungs, as speedily as possible, whenever animation has not been so long suspended, that every hope of restoration is over. Indeed, it is proper to distend the lungs with air, in all cases in which animation has been recently suspended by suffocation, immersion under water, or by noxious vapours and gases.—This measure is highly proper, in conjunc-

tion with electricity, the communication of warmth to the body, the application of strong volatiles to the nostrils, rubbing the body with warm flannels, and the injection of any fluid, like warm wine and water, into the stomach, through a hollow bougie. However, tobacco clysters, which have had the sanction of the Royal Humane Society, should be reprobated, as the qualities of this plant are peculiarly destructive of the vital principle, and not simply stimulating. I am sorry to find this last means commended by so respectable a surgeon as Baron Larrey, who joins the rest of the French surgeons in condemning electricity and bronchotomy. He speaks in favour of opening the jugular vein, exposing the body to the fire, friction, &c. On dissecting the bodies of some drowned persons, Larrey found, as Louis had done long since, that the air tubes of the lungs were filled with water, instead of air, and that the epiglottis was raised and applied to the os hyoides. (See *Mémoires de Chir. Militaire*, T. 1, p. 83-85.)

There are many modern practitioners, who consider bronchotomy, as needless in cases of suspended animation, because it is contended, that, as the patient is always destitute of sensation, a tube may easily be passed into the trachea from the nose or mouth, for the purpose of inflating the lungs. Either the curved pipe of a pair of bellows may be introduced into the glottis through the mouth, or an elastic gum catheter may be passed into the trachea from the nose.—*“On peut mettre ce moyen à exécution (says Pelletan) chez les asphixiés, ou les enfans, nouveaux nés, qui ne respirent pas; parce, dans ces différens cas, non seulement il n’y a pas d’inflammation, mais même toute sensibilité est suspendue, et la canule est commode pour souffler de l’air dans les poumons, en même temps qu’elle peut causer une irritation salutaire. M. Baudelocque, mon célèbre confrère, m’a témoigné se servir habituellement, et avec succès de ce moyen pour appeler à la vie les nouveaux nés dont la respiration ne s’établit pas.”* (*Clinique Chirurgicale*, Tom. 1, p. 29.) Desault likewise conceived, that the lungs might be easily inflated, without performing bronchotomy. (*Œuvres Chir.* Tom. 2, p. 239.) Mr. A. Burns adopts the same sentiment. (*Surgical Anatomy of the Head and Neck*, p. 384.) My own individual opinion upon this subject is, that, if a surgeon knows, that he can inflate the lungs as completely and expeditiously, without performing bronchotomy, as he could by making an incision in the trachea, he is right in dispensing with the latter operation. But, in the generality of cases of suspended animation, (that of new-born infants excepted, where bronchotomy would be an objectionable undertaking,) I much doubt, whether in actual practice bronchotomy will not be found the best and most speedy means of enabling the surgeon to distend the lungs with air. If you follow Desault’s suggestion, I contend, that you are likely to be some minutes longer in

getting the elastic catheter from the right nostril into the larynx, than you would be in cutting into the trachea, and introducing into the incision the muzzle of a pair of bellows. Supposing the elastic catheter introduced, will you now be able to distend the lungs with air, in an adequate degree, an object of the highest moment? A pair of bellows seems to me almost essential to this purpose. I shall say nothing on the probability of many practitioners coming to the patient unprovided with the requisite sort of tube.

If a pair of bellows, with a curved pipe, be employed, many surgeons would be a considerable time in getting the muzzle into the glottis, and, in the meanwhile every spark of life might be extinguished. On the other hand, bronchotomy (performed by a man of ordinary care and skill) is an operation free from danger. It may be executed with a penknife, if no better instrument be at hand; and when the incision has been made, a pair of common bellows will suffice for the inflation of the lungs. Did I conceive, that bronchotomy were a perilous operation; that the lungs could be effectually distended without the employment of bellows; that the object could generally be accomplished as expeditiously without cutting into the trachea; I should be as ready to join in the condemnation of this last proceeding, as any contemporary writer. Greatly, however, as I respect most of the authors, who differ from me on this point, the reasons I have assigned, prevent me from subscribing to their sentiment. Desault, who may be regarded as the founder of the doctrine, concerning the inutility of bronchotomy, it is also to be observed, spoke only from theory, and not actual practice, in these cases.

With respect to the performance of the operation, no preparation is necessary, as delay only increases the danger. The patient being seated in an arm-chair, or, what is better, laid on a bed with his head hanging backward, an incision is to be made, which is to begin below the cricoid cartilage, and to be continued downward, about two inches, along the space between the sternothyroid muscles. Care should be taken not to cut the lobes of the thyroid gland, lest a troublesome and dangerous bleeding be occasioned, and, as the left subclavian vein lies a little below the upper part of the first bone of the sternum, the incision should never extend so low as this point. The knife must not be carried either to the right or left, in order to avoid all risk of injuring the large blood-vessels situated at the sides of the trachea. The incision in the integuments having been made, the sternothyroid muscles are to be pushed a little towards the side of the neck, so as to bring the trachea fairly into view. Most authors recommend the point of the knife to be then introduced between the third and fourth cartilage of the trachea, and the opening to be enlarged transversely. It is true, that, in this way, an opening may be safely

made large enough to allow a small cannula to be introduced. It is safer, however, in all cases, to enlarge the opening in the perpendicular direction, by cutting from within outward. There is no advantage in avoiding a wound of the cartilages of the trachea, the only reason assigned for cutting the membrane between them, in a transverse direction; while a sufficiently large opening cannot be thus safely obtained, in cases in which it is necessary to introduce the muzzle of a pair of bellows, in order to inflate the lungs. In short, it is safer and better, in every instance, to make the wound in the trachea in a perpendicular manner.

I have stated, that bronchotomy may be performed by a man of ordinary skill, without hazard. It is far otherwise with a careless practitioner. We read in Desault's work, that in one instance, the carotid artery was wounded. The following cautions, given by Mr. A. Burns, seem entitled to notice. "The arteria innominata is in risk in some subjects. I have seen it mounting so high on the forepart of the trachea, as to reach the lower border of the thyroid gland. Even the right carotid artery is not always safe. I am in possession of a cast, taken from a boy of twelve years of age, which shows the right carotid artery crossing the trachea in an oblique direction. In this subject, that vessel did not reach the lateral part of the trachea till it had ascended two inches and a quarter above the top of the sternum.

"Where both carotid arteries originate from the arteria innominata, there is considerable danger in performing the operation of tracheotomy, for in such cases, the left carotid crosses the trachea pretty high in the neck. Professor Scarpa has seen a specimen of this distribution in a male subject, and I have met with five.

"These varieties in the course of the arteries are worthy of being known, and remembered; they will teach the operator to be on his guard, since he can never, *a priori*, ascertain the arrangement of the vessels with any degree of certainty. It will impress on his mind the impropriety of using the knife further, than merely to divide the integuments and fasciæ. If he then clear the trachea with the fingers, he will never injure any of the large arteries. When, with the finger, he has fairly brought the trachea into view, he ought to examine carefully, whether any of the large arteries lie in front of it, and if he find one, he ought to depress it toward the chest, before he penetrates into the windpipe.

"In cutting into the trachea, the preferable plan is to cut the rings from below upward, avoiding injury of the thyroid gland." (See *A. Burns on the Surgical Anatomy of the Head and Neck*, p. 393, 394.)

When bronchotomy is performed for the purpose of inflating the lungs, the cut in the windpipe must be made somewhat larger, than when an opening is required merely to enable the patient to breathe through a

small cannula. The larger size of the pipe of the bellows, is the reason of this circumstance.

When a cannula is introduced, care must be taken not to pass it too far into the wound, lest it should injure the opposite side of the trachea. This is a caution, on which Fabricius ab Aquapendente dwells very strongly, and with good reason.

Small as the vessels may be, which are divided in bronchotomy, they occasionally bleed so much, as to create apprehension, and even prevent the continuance of the operation. There is a case in Van Swieten's Commentaries, confirming this remark. A Spanish soldier, aged twenty-three, was in the most urgent danger from an inflammation of his throat. It was thought nothing could save him, except bronchotomy. After the longitudinal cut in the skin, and the separation of the muscles, the trachea was opened between two of the cartilages; but the blood insinuated itself into this canal, and excited so violent a cough, that the cannula could not be kept in by any means, though it was replaced several times. Louis remarks, that in this instance, the patient's head should have been turned downward, in order to keep the blood from flowing backward into the trachea. It is asserted, that the opening of this tube was not always opposite the external wound, in consequence of the convulsive action of the muscles, and that the patient on this account could hardly breathe. Hence, Vigili was induced to slit open the trachea, down to the sixth cartilaginous ring; and it was only then that he inclined the patient's head forward. The bleeding now ceased, the patient breathed with ease, and, on the second day, the inflammation was so much better, that respiration went on without the aid of the opening in the trachea.

In order to obviate the preceding accident, a proposal has been made to adapt a cutting blade to a cannula, of a suitable size, calculated for remaining in the wound, and sufficiently compressing the orifices of such vessels as may be opened. In Richter's *Observationes Chirurgicæ*, a description of some instruments of this kind may be seen. Mr. B. Bell has described one, somewhat like a flattened trocar, only not quite so long. The patient's head being inclined backward, as far as possible, the point of the instrument is to be introduced between two of the cartilages: between the lower margin of the thyroid, and the upper edge of the cricoid, is said to be the best situation, being more extensive, less vascular, and, after the division of the skin, only the crico-thyroid ligament requires to be divided. When the instrument has entered, the lancet is to be withdrawn, and the cannula fixed, by means of a ribbon, which is tied to each of the wings of the instrument, and must be fastened at the back of the patient's neck. Should the instrument be too long, it must be passed through two or three little compresses, before being put into the wind-

pipe, which artifice will make it answer as well as if it were shorter. A piece of gauze is then to be tied over the orifice of the cannula.

A more simple and natural mode, however, of obviating all trouble from the entrance of blood into the trachea, is to tie any bleeding branch of the thyroid artery, or vein, before the windpipe is opened.

Sometimes, though very seldom, the cannula becomes obstructed with mucus, or clots of blood. Such an accident nearly suffocated a patient at Edinburgh. An ingenious person happening to be at hand, suggested the introduction of a second cannula into the first; the second one being taken out, and cleaned, as often as necessary, and then replaced.

The use of the cannula must be continued as long as the causes obstructing respiration remain. Thus, in one very interesting case of cynanche, detailed in a modern publication, the patient, thirteen months after the operation, had not been able to discontinue the tube. (*See Med. Chir. Journ. Vol. 5, p. 7.*) This example was attended in its progress with a singular circumstance, viz: the expulsion through the cannula of several portions of calcareous matter, or bone.

When respiration is suspended by the presence of a foreign body in the trachea, and the extraneous substance does not make its appearance at the opening, a trial may be made to discover its situation by means of a bent probe. When it lies downward, which it hardly ever does, the wound in the trachea may be enlarged in this direction, and the body extracted with a pair of curved forceps. The extraneous substance is mostly forced out by the air, as soon as the incision in the trachea is opened. When it cannot be immediately found, some practitioners (Heister and Raw,) have succeeded by keeping the lips of the wound asunder with a leaden cannula, by which means, the force of the air in expiration has, in a few hours, expelled the foreign body.

Richter gave the preference to a curved cannula; and since his time many surgeons have chosen to use such an instrument, though if it be double, the inner tube cannot be so easily introduced as that of a straight cannula, and, no doubt the chief disadvantage of the latter has often proceeded from its having been made of too great length.

In some instances, like that referred to above, a cannula has been borne quietly in the trachea, while in others, it has produced so much irritation, cough, and sense of choking, as to render its immediate removal necessary. Mr. Lawrence, in speaking of the obstruction of the glottis from the disease already adverted to in this article, observes, that when the cannula causes inconvenience, he should advise a longitudinal incision, of about half an inch, in the middle of the trachea, and the removal of a

thin slip of the tube, which would leave an artificial opening for respiration equal in size to the natural one. (*See Med. Chir. Trans. Vol. 6, p. 249.*)

On the continent, the operation of laryngotomy, which was first advised, by Vicq d'Azyr, and was recommended by Desault, is frequently preferred to tracheotomy. The surgeon makes an incision over the anterior part of the thyroid cartilage, punctures the crico-thyroid membrane, and, if it be necessary, introduces a director, and slits the thyroid cartilage upwards. A single opening in the crico-thyroid membrane, would suffice for the introduction of a cannula for the purpose of enabling the patient to breathe; but for the extraction of foreign bodies, it would be necessary also to cut the thyroid cartilage. The fact, that extraneous substances, when they are loose, are almost always lodged at the upper part of the larynx, proves, that laryngotomy, in such cases, must commonly be most advantageous; and, according to Desault, even when the foreign bodies are lower down in the trachea, they may in general be most easily extracted with the aid of a pair of curved forceps. In this country, laryngotomy has been less commonly practised, though commended a few years since, by Mr. Coleman, and more recently by Mr. C. Bell.

"Of the three situations (says Mr. Lawrence,) in which it has been proposed to make the opening, viz. in the thyroid cartilage, between that and the cricoid, or in the trachea, I consider the first as the least eligible. Besides the objections from the ossification of the cartilage, and the danger of wounding, or otherwise injuring, the chordæ vocales, there is the inconvenience in the case of angina laryngea, arising from the swollen and thickened state of the membrane, which may actually impede the passage of the air. I am not aware of any objection to a transverse opening between the thyroid and cricoid cartilages. The prominence of the former in the neck, serves as a guide to the part, which should be opened. Whether bronchotomy, or laryngotomy ought to be selected, must of course depend upon the nature of the case: in cases of cynanche, the proximity of the inflamed parts would be an objection to laryngotomy; while in examples of foreign bodies within the glottis, this operation may generally be most advisable, for reasons already explained. It is absurd to think of confining one mode of operating to different cases. (*See Medico-Chir. Trans. Vol. 6, p. 248.*)

Of the operation, performed in the membranous space, Mr. C. Bell entertains a favourable opinion. He directs us to slit up the membrane, and open the incision with the handle of the knife, when the patient will immediately breathe with ease. Here, says he, there is nothing to alarm the most timid operator. No great turgid veins are opened; the cut is made above the thyroid

gland; and above the anastomosing branch of the thyroid arteries. The part is strongly marked by the prominence of the thyroid cartilage above, and the ring of the cricoid cartilage below. "If the occasion be temporary, a simple slit of the membrane will be found sufficient. If necessary, a transverse cut will afford any degree of opening. If a round hole be desired, the four corners, left by the incisions, may be snipped off," or the edges of the opening may be kept asunder by means of the doubled wire of a catheter, the middle part of which lies on the wound, while the ends are bent round the neck, and tied by a ligature behind. In Mr. C. Bell's cases, less annoyance was caused by this contrivance, than by a tube.

The reader may collect the most valuable information on the foregoing subject from the following sources; *Hevin sur les corps Etrangers qui sont arrêtés dans les premières Voies, et qu'il faut tirer par incision, in Mém. de l'Acad. BUBO. (*Buba*, the groin.) Modern surgeons mean, by this term, a swelling of the lymphatic glands, particularly of those in the groin, and axilla.

The disease may arise from the mere irritation of a local disorder; from the absorption of some irritating matter, such as the venereal poison; or from constitutional causes.

Of the first kind of bubo, that, which is named the *sympathetic*, is an instance. Of the second, the venereal bubo is a remarkable specimen. (See *Venereal Disease*.)

The *pestilential bubo*, which is a symptom of the plague, and *scrofulous swellings* of the inguinal and axillary glands; may be regarded as examples of buboes from constitutional causes. (See *Scrofula*.)

The inguinal glands often become affected with simple phlegmonous inflammation, in consequence of irritation in parts, from which the absorbent vessels, passing to such glands, proceed. These swellings ought to be carefully discriminated from others, which arise from the absorption of venereal matter. The first cases are simple inflammations, and only demand the application of leeches, the cold saturnine lotion, and the exhibition of a few saline purges; but the latter diseases render the administration of mercury indispensable. *Sympathetic* is the epithet usually given to inflammation of glands from mere irritation; and, we shall adopt it, without entering into the question of its propriety.

The sympathetic bubo is mostly occasioned by the irritation of a virulent gonorrhœa. The pain, which such a swelling gives, is trifling, compared with that of a true venereal bubo, arising from the absorption of matter, and it seldom suppurates. However, it has been contended, that the glands in the groin do sometimes swell and inflame from the actual absorption of venereal matter from the urethra, in cases of gonorrhœa, and which swellings must con-

sequently be venereal. (*Hunter on the Venereal*, p. 57.)

The manner, in which buboes form from mere irritation, will be better understood by referring to the occasional consequences of venesection, in the article *Bleeding*.

The distinguishing characters of the venereal bubo are noticed in the article *Venereal Disease*.

BUBONOCELE. (from *bubon*, the groin, and *ocele*, a tumour.) A species of hernia, in which the bowels protrude at the abdominal ring. The case is often called an *inguinal hernia*, because the tumour takes place in the groin. (See *Hernia*.)

BURNS are usually divided into three kinds. 1st. Into such as produce an inflammation of the cutaneous texture, but an inflammation, which, if it be not improperly treated, almost always manifests a tendency to resolution. 2dly. Into burns, which injure the vital powers of the cutis, occasion the separation of the cuticle, and produce suppuration on the surface of the cutaneous texture. 3dly. Into burns, in which the vitality and organization of a greater or less portion of the cutis are either immediately or subsequently destroyed, and a soft slough or hard eschar produced. (See *Thomson's Lectures on Inflammation*, p. 585, 586.)

Suppuration is not always an unavoidable consequence of the vesications in burns; but it is a common and a troublesome one. "In severe cases, it may take place by the second, or third day; often not till a later period. It often occurs without any appearance of ulceration; continues for a longer, or shorter time; and is at last stopped by the formation of a new cuticle. In other instances, small ulcerations appear on the surface or edges of the burn. These spreading form extensive sores, which are in general long in healing, even where the granulations, which form upon them, have a healthy appearance." (*Op. cit.* p. 595.)

Burns present different appearances, according to the degree of violence, with which the causes producing them have operated, and according to the kind of cause, of which they are the effect. Burns, which only irritate the surface of the skin, are essentially different from those, which destroy it; and these latter have a very different aspect from what others present, which have attacked parts more deeply situated, such as the muscles, tendons, ligaments, &c. Scalds, which are the effect of heated fluids, do not exactly resemble burns, occasioned by the direct contact of very hot metallic bodies, or some combustible substance on fire. As fluids are not capable of acquiring so high a temperature, as many solid things, scalds are generally less violent than burns, in the injury which they produce; but, in consequence of liquids often flowing about with great rapidity, and being suddenly thrown in large quantities over the patient, scalds are frequently dangerous on account of their extent. It is well worthy of remark, that the

danger of the effects of fire is not less proportioned to the size, than the degree and depth of the injury. A burn, that is so violent, as to kill parts at once, may not be in the least dangerous, if not extensive; while, a scald, which perhaps only raises the cuticle, may prove fatal, if very large. The degree of danger, however, is to be rated from a consideration both of the size and violence of the injury. The worst burns, which occur in practice, arise from explosions of gunpowder, or inflammable gases, from ladies's dresses catching fire, and from the boiling over of hot fluids, in laboratories, manufactories, &c.

Burns, which only destroy the cuticle, and irritate the skin, are very similar to the effects, produced by cantharides and rubefacients. The irritation, which such injuries excite, increases the action of the arteries of the part affected, and they effuse a fluid under the cuticle, which becomes elevated and detached. Hence, the skin becomes covered with vesicles, or bladders, which are more or less numerous, and large, according to the manner, in which the cause has operated. But, when the skin, or subjacent parts, are destroyed, no vesicles make their appearance. In this circumstance, a black eschar is seen; and when the dead parts are detached, there remains a sore, more or less deep, according to the depth, to which the destructive effects of the fire have extended.

The parts may either be killed, at the moment of the injury, by the immediate effect of the fire, or they may first inflame, and then mortify.

In all cases of burns, the quantity of injury depends on the degree of heat in the burning substance; on the duration and extent of its application; and on the sensibility of the burnt part.

When a large surface is burnt, mortification sometimes makes its appearance with great violence, and very quickly after the accident; but, in general, the symptom, the most to be dreaded, in such cases, is inflammation. The pain and irritation often run to such a pitch, that, notwithstanding every means, there is frequently immense trouble in keeping down the inflammation. When the burnt surface is very large, the effects of the inflammation are not confined to the part, which was first injured; but, even cause a great deal of fever; and, in certain cases, a comatose state, which may end in death.

It has been observed, that persons, who die of severe burns, seem to experience a remarkable difficulty of breathing, and oppression of the lungs. These organs, and the skin, are both concerned in separating a large quantity of water from the circulation, and their participating in this function may, perhaps, afford a reason for respiration being often much affected, when a large surface of skin is burnt. However, the kidneys perform the same office, and they are not particularly affected in burnt patients; so that the asthmatic symptoms, frequently

noticed in cases of burns, are probably owing to a sympathy between the lungs and skin, or else to causes not at present understood.

TREATMENT OF BURNS.

Two general methods of treating burns have at all times been followed. One consists in the application of substances, which produce a cooling or refrigerant effect; the other in the employment of calefacient or stimulating substances. Dr. Thomson is satisfied, that each of these different modes may have its advantages in particular cases. (*Lect. on Inflammation*, p. 588.)

The practice mostly resorted to in this country some years since, is explained by Mr. B. Bell. When the skin is not destroyed, but seems to suffer merely from irritation, relief may be obtained by dipping the part affected in very cold water, and keeping it for some time immersed. This author states, that plunging the injured part suddenly into boiling water would also procure ease; an assertion, however, much to be doubted, and a practice not likely to be imitated. In some cases, emollients afford immediate relief; but, in general, astringent applications are best. Strong brandy or alcohol is particularly praised. At first the pain is increased by this remedy; but an agreeable soothing sensation soon follows. The parts should be immersed in the spirit, and, when this cannot be done, soft old linen, soaked in the application, should be kept constantly on the burn.—The liquor plumbi superacetatis dilutus is recommended. It is said to prove useful, however, only by being astringent, as equal benefit may be derived from a strong solution of alum, &c. Such applications were frequently made with the view of preventing the formation of vesicles; but, Mr. B. Bell always remarked, that there was less pain, when the blisters had already appeared, than when prevented from rising, by remedies applied immediately after the occurrence of the injury.

The applications should be continued as long as the pain remains; and in extensive burns, creating great irritation, opium should be prescribed. The stupor, with which patients, so situated, are often attacked, receives more relief from opium, than any thing else.

Some recommend opening the vesications immediately; others assert, that they should not be meddled with. Mr. B. Bell thinks they should not be opened till the pain arising from the burn is entirely gone. At this period, he says, they should always be punctured; for, when the serum is allowed to rest long upon the skin beneath, it has a bad effect, and even induces some degree of ulceration. Small punctures, not large incisions, should be made. All the fluid having been discharged, a liniment of wax and oil, with a small proportion of the superacetate of lead, is to be applied.

On the subject of opening the vesications

in burns, Dr. Thomson believes, that the diversity of opinion arises from the different effects resulting from the particular manner in which the opening is made. "If a portion of the cuticle be removed, so as to permit the air to come into contact with the inflamed surface of the cutis, pain, and a considerable degree of general irritation, will necessarily be induced; but if the vesications be opened cautiously with the point of a needle, so as to allow the serum to drain off slowly, without, at the same time, allowing the air to enter between the cuticle and cutis, the early opening of the vesications will not only not occasion pain, but will give considerable relief, by diminishing the state of tension, with which the vesications are almost always, in a greater or less degree, accompanied. When opened in this manner, the vesications often fill again with serum; but the punctures may be repeated as often as is necessary, without any hazard of aggravating the inflammation. Great care should be taken, in every instance, to preserve the raised portion of cuticle as entire as possible," &c. (*See Lectures on Inflammation*, p. 595.)

When there is much irritation and fever, blood-letting, and such remedies, as the particular symptoms demand, must be advised. On account of the pulse being frequently small, quick and vibratory, bleeding is at present not often employed. As Dr. Thomson remarks, however, it may become necessary in patients of a strong robust constitution, in whom the symptomatic fever assumes an inflammatory type.—He has often seen a single bleeding procure great relief in these cases; and he does not remember a case where bleeding was followed by injurious effects. (P. 594.) When the skin ulcerates, the treatment does not differ from what will be described in speaking of *Ulcers*.

When burns are produced by gunpowder, or less destroyed, cooling emollient applications were formerly thought most effectual, and a liniment, composed of equal proportions of lime-water and linseed oil, gained the greatest celebrity. Even at this day, the application is very often employed. Mr. B. Bell advises it to be put on the parts, by means of a soft hair pencil, as the application and removal of the softest covering, are often productive of much pain. The same author admits, however, that there are some cases in which Goulard's cerate, and a weak solution of the superacetate of lead, more quickly procure ease, than the above liniment.

The sloughs having come away, the sores are to be dressed according to common principles. (*See Ulcers*.)

When burns are produced by gunpowder, some of the grains may be forced into the skin: these should be picked out with the point of a needle, and an emollient poultice applied, which will dissolve and bring away any particles of gunpowder yet remaining.

Burnt parts, which are contiguous, frequently grow together in the progress of the cure. The fingers, toes, sides of the nostrils, and the eye-lids are particularly liable to this occurrence which is to be prevented by keeping dressings always interposed between the parts likely to become adherent, until they are perfectly healed.

The sores, resulting from burns, are, perhaps, more disposed, than any other ulcers, to form large granulations, which rise considerably above the level of the surrounding skin. No poultices should now be used. The sores should be dressed with any moderately stimulating, astringent ointment: the ung. lapid. calaminaris, or the unguentum resinæ with the pulv. hydrarg. nitr. rub. is now generally preferred: and, if the part will allow of the application of a roller, the pressure of this will be of immense service in keeping down the granulations, and rendering them more healthy. When these methods fail, the sores should be gently rubbed with the argentum nitratum.

In the dry and hot state of the skin, Dr. Thomson is an advocate for diaphoretics. "Laxatives (says he) are often necessary; but, it is in general best to employ only the gentler sort, on account of the trouble and pain, which moving always gives the patient. Anodynes are often required, not only to procure sleep, but even a temporary alleviation of the pungency of the pain, which the burn occasions. A mild vegetable and farinaceous diet should be used during the period of the symptomatic fever. Animal food, wine, and other cordials, may be required in the progress of a suppurating burn; but, they are not necessary at first, and when given in this stage, are almost always injurious. (See *Lectures on Inflammation*, p. 594.)

With respect to the topical applications recommended by this gentleman, he generally prefers in cases of superficial burns cooling and refrigerant remedies. When there are vesications, and suppuration takes place without ulceration, he advises us, after refrigerants have ceased to produce beneficial effects, to use the linimentum aquæ calcis. However, where the progress of cicatrization is slow, he recommends, instead of this liniment, ointments containing lead, or zinc, particularly the unguentum lapid. calaminaris.

In the ulcerating state of suppurating burns, he prefers emollient cataplasms.—But, when the discharge continues, or becomes more profuse under the use of poultices, they are to be left off, and astringent washes employed, such as lime-water, the compound decoction of oak bark; a weak solution of sulphate of copper, &c.

Where the parts are destroyed and converted into sloughs, Dr. Thomson does not think it matters much whether vinegar, oily liniments, turpentine, spirits of wine, or emollient poultices, be at first employed. He acknowledges, however, that the poultice is the remedy, under the applica-

tion of which, the separation of the dead parts is most easily and agreeably accomplished. "The question (says he) at present most deserving the attention of medical practitioners, with regard to the use of the warm emollient poultice in burns, is, whether we should apply it immediately after the burn has been received, or interpose for some hours, as has been so strongly recommended, dressings with vinegar, spirits of wine, or oil of turpentine. My own experience has not been sufficient to enable me to determine this point to my entire satisfaction. Yet, I think it right to state to you, that, in a number of trials made at different times, I have had occasion to see burns, to which common emollient poultices had been from the first applied, slough and granulate faster, and in a more kindly manner, than similar burns in the same persons, to which in some instances the Carron oil (lin. aq. calcis.) and, in others again oil of turpentine, were applied at the same time with the poultices." (See *Lectures on Inflammation*, p. 609.)

MR. CLEGHORN'S PLAN.

This gentleman, who was a brewer at Edinburgh, was induced to pay great attention to the effects of various modes of treating burns, on account of the frequency of these accidents among his own workmen. His observations led him to prefer the immediate application of vinegar, which was to be continued for some hours, by any of the most convenient means, until the pain abated; and when this returned, the vinegar was repeated. If the burn had been so severe as to have produced a destruction of parts, these, as soon as the pain had ceased, were covered with a poultice, the application of which was continued about six, or, at most, eight hours, and after its removal the parts were entirely covered with very finely powdered chalk, so as to take away every appearance of moisture on the surface of the sore. This being done, the whole burnt surface was again covered with the poultice. The same mode was pursued every night and morning, until the cure was complete. If the use of poultices relaxed the ulcers too much, a plaster, or ointment, containing sub-carbonate of lead, was applied; but the chalk was still sprinkled upon the sore.

With respect to general remedies, Mr. Cleghorn allowed his patients to eat boiled, or roasted fowl, or in short, any plainly dressed meat, which they liked. He did not object to their taking moderate quantities of wine, spirits and water, ale, or porter. He never had occasion to order bark, or any internal medicines whatever, and he only once thought it necessary to let blood. When the patient was costive, Mr. Cleghorn ordered boiled pot-barley and prunes, or some other laxative nourishing food, and sometimes an injection, but never any purgative, as he remarked that the disturbance of frequently going to stool was

distressing to a patient with bad sores. Besides, he thought that a hurtful weakness and languor were always (more or less) brought on by purgatives. From the effects, too, which he felt them have upon himself, and observed them to have upon others, they did not seem to have so much tendency to remove heat and feverish symptoms as is generally supposed, and he believed, that they more frequently carried off *useful* humours than *hurtful* ones.

Diluted sulphuric acid was not found to answer so well as vinegar, and the latter produced most benefit, when it was fresh and lively to the taste.

In cold weather, Mr. Cleghorn sometimes warmed the vinegar a little, placed the patients near the fire, gave them something warm internally, and kept them, in every respect, in a comfortable situation. His object, in so doing, was to prevent the occurrence of tremblings, and chiliness, which, in two instances, after employing cold vinegar, took place in an alarming degree.

The account of Mr. Cleghorn's plan was published by Mr. Hunter. (See *Med. Facts and Observations*, Vol. 2.)

SIR JAMES EARLE'S PLAN.

This gentleman was an advocate for the use of cold water, or rather ice; and published several cases of extensive burns, in which this method was employed with the best effect. Cold water was enumerated by Mr. B. Bell, among the applications to burns, and it was not uncommonly used long before Sir James Earle communicated the result of his experience to the public. The method, indeed, is very ancient.—“Cold is a remedy (says Dr. J. Thomson) which has long been employed to diminish the inflammation of superficial burns.—Rhazes directs, that, in recent burns, cloths dipt in cold water, or in rose-water cooled with snow, be applied as soon as possible to the parts which have been injured, and that these cloths be renewed from time to time; and Avicenna says, that this practice often prevents the formation of blisters.” (*Lectures on Inflammation*, p. 589.) Sir James Earle's publication, however, had the good effect of drawing considerable attention to the subject, and of leading surgeons to try the method in a great number of instances, in which other more hurtful modes of treatment might otherwise have been employed.—The burnt parts may either be plunged in cold water, or they may be covered with linen dipped in the same, and renewed as often as it acquires warmth from the part. The application should be continued as long as the heat and pain remain, which they will often do for a great many hours. (See *Essay on the Means of lessening the Effects of Fire on the Human Body*. 8vo. Lond. 1803.)

Some caution, however, in the application of cold becomes necessary, when a scald is of very large size, or situated upon

the trunk of the body. In extensive burns, superficial as they may be, the patient is liable to be affected with cold shiverings; and these shiverings may be greatly aggravated by exposure, and by the application of cold. Perhaps, therefore, in these examples, warm applications ought to be preferred. (*Dr. J. Thomson's Lectures on Inflammation*, p. 591.)

BARON LARREY'S PLAN.

It seems to me, that, on the subject of burns, there is, even at the present day as much contrariety of sentiment, as in any part of surgery whatsoever. After all the praises, which we have of late years heard of vinegar, cold applications, oil of turpentine, &c. a French surgeon, whose talents and opportunities of observation, entitle his opinion to the highest attention, has recently censured the employment of all such remedies. Larrey, though a military surgeon, has had occasion to see numerous burns, in consequence of explosions. He declares, that he has been long struck with the bad effects of repellents, such as fresh water with the muriate of ammonia, oxycerate, the aqua vegeto-mineralis, and the solution of opium in ice-water, applications, which are extolled in some modern books, and used in cases of deep burns, by a great number of practitioners; and he expresses his belief, that such injuries frequently prove mortal, for want of more judicious treatment. He recommends dressing all deep burns, with fine old linen, spread with saffron ointment, which, he says, has the quality of diminishing the pain, and preventing irritation by keeping the nervous papillæ from coming into contact with the air, or being pressed by the linen and clothes. The employment of this ointment, (or in case good oil cannot be procured for its composition, honey, instead of it) is to be continued till suppuration takes place. When this is established, Larrey employs the ointment of styrax, for the purpose of supporting the systaltic power of the subjacent vessels, promoting the detachment of the eschars, and checking the extension of the sloughing. As soon as the dead parts have separated, Larrey again has recourse to the saffron ointment, for which he gradually substitutes dry lint, with strips of linen spread with cerate.—When the vessels exceed the level of the edge of the sore, he touches them with the argenti nitratum; and he occasionally applies a weak solution of the oxy-muriate of mercury, or of the sulphate of copper.

Larrey prescribes emollient and antispasmodic beverages, which are to be taken warm, such as milk of almonds, containing nitre, and properly sweetened; hydromel; rice ptisan, &c. His patients were never deprived of light nourishment, such as broths, jellies, eggs, soups, &c. His experience had taught him, that soldiers (who it is to be observed were his patients) cannot bear low diet, so well as persons leading an

inactive life. Besides, he remarks, that as these injuries, with loss of substance, are a long time in healing, it would be acting contrary to the precept of Hippocrates to put burnt patients on low diet. Larrey assures us, that he has found this simple treatment, which he calls soothing and gently tonic, almost always successful. (See *Mémoires de Chirurgie Militaire*, Tom. 1, p. 93.)

DR. KENTISH'S PLAN.

From what has been stated, it appears, that in cases of burns, cold and hot, irritating and soothing, astringent and emollient applications, have all been outwardly employed without much discrimination. But, the internal treatment has always been of one kind, and both the ancients and moderns agree in advising blood-letting, cooling purges, and, in short, the whole of the antiphlogistic plan. If we except Mr. Cleg-horn, who condemned purges, and allowed stimulants internally. Dr. Kentish has been almost the only advocate for the latter means.

The fanciful theories advanced by Dr. Kentish, lead him to believe, that as burns are injuries, attended with increased action, there are two indications, for restoring what he terms *the unity of action*; viz. the excitement, or action, of the part, is first to be gradually diminished; secondly, the action of the system is to be increased to meet the increased action of the part, holding this law as the system in view: *That any part of the system, having its action increased to a very high degree, must continue to be excited, though in a less degree, either by the stimulus, which caused the increased action, or some other having the nearest similarity to it, until by degrees the extraordinary action subsides into the healthy action of the part.*

With this view, holding the part to the fire seems to Dr. Kentish, the best mode of relief; but, as parts of the body are injured, to which this cannot be done, the most stimulant applications must be used; for, in this class, there is little fear of any of them being greater, than that which originally caused the accident. The strongest rectified spirits, made still stronger by essential oils, are proper, and may also be heated as much as the sound parts can bear.—These, and many more applications of the same class, says Dr. Kentish, will give the most speedy and effectual relief. These are to be continued only for a certain time, lest they cause the very ill which they are given to cure. They are then to be succeeded by less stimulant applications, until the parts act by common natural stimuli.

The internal mode of relief is to give those substances, which soonest excite the system to great action, such as æther, ardent spirits, opium, wine, &c. by which means, the solution of continuity of action is allowed to last the shortest time possible, and the unity of action is restored, which constitutes the cure.

Suppose, for instance, as a local application, we at first apply the strongest alco-

hol, heated to the degree which the sound part would bear without injury: it should afterwards be gradually diluted until it becomes proof spirit, and the heat should be diminished, although gradually, as cold is always pernicious, bringing on that tendency to shiver, which should ever be continually guarded against, as being a most hurtful symptom, and the forerunner of a violent sympathetic fever. To prevent this, the external heat should be kept at a high temperature, and the action of the whole system raised in as great a degree as may be safe. By this means, the action of the whole is made to meet the increased action of the part, by which the lessening of the increased action of the part to join the action of the whole, is rendered more easy. Thus, there is, says Dr. Kentish, an unity of intention by both the external and internal means, leading to the restoration of the unity of action, and the cure is performed.

It may be said, these circumstances can only take place when there is an increased action, and, when the parts are destroyed, other means should be used, such as emollients, &c. In replying to this remark, Dr. Kentish distinguishes burns into two kinds; one, in which the action of the part is only increased; and, another, in which some parts have increased action, while other parts are destroyed. It is of little consequence, says Dr. Kentish, what is applied to the dead part, as the detachment of an eschar depends upon the action of parts, which remain alive, and not upon what is applied to those which are dead. Dr. Kentish remarks however, that he never saw an instance of a burn, in which, though some parts were totally destroyed, there were not always other parts, in which there was only increased action. Now as our duty is always to save living parts, our mode of cure in the first instance, will always be the same, viz. to cure the parts which have only an increased action, in the doing of which the dead parts will not be the worse, as their separation is a process of the system, which requires time, and, if the injury is to any extent, draws forth the joint efforts of the system, and even, says Dr. Kentish, calls up all the energy of its powers, to violent fever. This state should be supported by every artificial aid, in order to bring the parts to suppuration, otherwise the subject falls in the contest: for, if the living parts have not the power to throw off the dead, the dead will assimilate the living to themselves, and a mortification ensue.

When the living parts have been preserved, (continues Dr. Kentish) which according to this treatment, will be in the course of two or three days, the dead parts will be more plainly observed, and the beginning of the process to throw them off will be commencing. This process must be assisted by keeping up the powers of the system, by stimulant medicines and a generous diet. The separation of the eschars will be greatly promoted by the application of

the stimulus of heat, by means of cataplasms frequently renewed. These may be made of milk and bread, and some camphorated spirit, or any essential oils, sprinkled upon the surface. Such means need only be continued, until the suppuration is established, as then a different mode must be pursued.

After Dr. Kentish had supported this system to a suppuration, he then found that, gradually desisting from his stimulant plan, diminished the secretion of pus, and wonderfully quickened the healing process.

Thus we see, observes Dr. Kentish, the whole of the former treatment inverted.—The most gentle soothing means were used externally and internally; these were continued until suppuration took place; and then the system was excited under an idea of supporting it, which not unfrequently so fatigued the constitution, as to induce a hectic fever. The present mode is the reverse of this. When a part of the frame has been much excited this part is not allowed to cease to act for want of stimulus, but, is kept in action by an adequate stimulus, which is gradually diminished, until the ordinary action returns. With the same view, the internal means are highly stimulant to the whole system, which must be supposed to be in a natural state at the time of the accident.

Thus increasing the action of the whole by strong stimuli, and decreasing the action of the part, by lessening the stimuli, the desired end will be more readily obtained: that is, an equilibrium of action will be restored.

When some parts are destroyed, there must be others with increased action; and, in this case, according to Dr. Kentish, the foregoing mode will be the best for restoring the living parts, and promoting the separation of the dead ones. Suppuration having taken place, the exciting of the system by any thing stimulant, either by food or medicine, should be cautiously avoided.—Should the secretion of pus continue too great, gentle laxatives, and a spare diet, are indicated. If any part, as the eyes, for instance, remain weak, with a tendency to inflammation, topical bleedings, or small quantities of blood taken from the arm, are useful. For the purpose of defending the new skin, camphorated oil, or camphorated oil and lime water in equal parts, are good applications.—Wounds of this kind heal very fast, when the diminution of pus is prevented, by attention to diet: if necessary to keep up the patients' strength, small doses of bark, taken two or three times a day, in some milk, will answer that purpose, and will not excite a quickening circulation, as wine, ale, or spirits, are apt to do. By attention to these principles, (continues Dr. Kentish) I can truly assert, that I have cured very many extensive and dangerous burns and scalds, in one, two, three, and four weeks, which in the former method would have taken as many months; and some, which I believe to have been incurable by the former method.

After explaining his principles, Dr. Kentish takes notice of the several substances,

which have commonly been employed.—Of these he would chiefly rely on alcohol, liquor ammoniæ subcarbonatis, æther, (so applied as to avoid the cooling process of evaporation) and spirit of turpentine.

In applying these, we are directed to proceed as follows: the injured parts are to be bathed, two, or three times over, with spirits of wine, spirits of wine with camphor, or spirit of turpentine, heated by standing in hot water. After this, a liniment, composed of the common yellow basilicon, softened with spirit of turpentine, is to be spread on soft cloth, and applied. This liniment is to be renewed only once in twenty-four hours, and, at the second dressing, the parts are to be washed with proof spirit, or laudanum, made warm.—When a secretion of pus takes place, milder applications must be made, till the cure is effected.

The yellow ointment stops the pores of the cloth, impedes evaporation, and thus confines the effect of the alcohol to the burnt surface. The first dressings are to remain on four and twenty hours. Dr. Kentish thinks it of importance, that the injured surface should be left uncovered as little as possible. It is, therefore, recommended, to have plasters, ready spread, before removing the old ones, and then only to take off one piece at a time.

It will seldom be necessary to repeat the application of alcohol a second time, or that of oleum terebinthinæ. The inflammatory action will be found diminished, and according to Dr. Kentish's principles, the exciting means should therefore be diminished. Warm proof-spirits, or laudanum, may be substituted for the alcohol, and the unguentum resinæ flavæ is to be mixed with oleum camph. instead of turpentine. If this should be found too irritating, Dr. Kentish recommends ung. saturn. or cer. lap. calaminaris. Powdered chalk is to be used to repress the growth of exuberant granulations, and to absorb the pus. In the cavities of separated eschars, and in the furrows, between sloughs and living parts, he introduces powdered chalk. Then a plaster is applied, and, in tedious cases, a poultice over the plaster.

With respect to the internal treatment, the author observes, that great derangement of the system arises in certain persons, from causes, which, in others, produce no effect; and that this depends on a difference in the degree of strength. Hence he concludes, that as strength resists the sympathetic irritative actions of parts, and weakness induces them, we should, in all cases, make the system as strong as we can, immediately upon the receipt of the injury. In considerable burns, he supposes a disproportion of action to take place, between the injured parts, and the system at large, or what he styles, a solution of the continuity of action; and that by a law of the system, a considerable commotion arises, for the purpose of restoring the equilibrium, or enabling the constitution to take on the action of the part. Hence, Dr. Kentish is of opinion, that the indication is to restore

the unity of action of the whole system, as soon as possible, by throwing it into such a state as to absorb the diseased action, and then gradually bring down the whole to the natural standard of action by nicely diminishing the exciting powers. Æther and alcohol, or other stimulants, are to be immediately given in proportion to the degree of injury; and repeated, once or twice, within the first twelve hours, and afterwards, wine or ale is to be ordered, till suppuration takes place, when it will be no longer necessary to excite the system.

In a second essay, Dr. Kentish remarks, that, in the first species of burns, in which the action of the part is only increased, he has not found any thing better for the first application, than the heated oleum terebinthinæ and the basilicon ointment, thinned with the same. In superficial burns, when the pain has ceased, he considers it advisable to desist from this application in about four and twenty hours, and use at the second dressing, a digestive, sufficiently thinned with common oil, beginning on the third day, with the ceratum lap. calaminaris. This author has frequently seen secondary inflammation excited by the remedy. The most certain remedy, for this unpleasant symptom, is a digestive ointment, thinned with oil or a plaster of cerate, and over that a large warm poultice. The cerate will finish the cure. Should there be much uneasiness of the system, an anodyne, proportioned to the age of the patient, should be given.

The growth of fungus, and the profuse discharge of matter, are to be repressed, as already mentioned, by sprinkling powdered chalk on the surface, and by the use of purgatives, in the latter stages. The chalk must be very finely levigated.

Dr. Kentish's theories are, as far as I can judge, visionary; they may amuse the fancy, but can never improve the judgment. They are nearly unintelligible; they are unsupported by any sort of rational evidence; and, as being only the dreams of a credulous, sportive imagination, they must soon decline into neglect, if not oblivion. However, in making these remarks, it is far from my intention to extend the same animadversion to the mode of treatment insisted upon by Dr. Kentish, which forms a question which cannot be determined by reason, but by experience. He is a man, who has had superior opportunities of observing this part of practice, and the alleged success of his plan of treatment has acquired extensive approbation, although there are still many practitioners, who prefer common methods, and the antiphlogistic principles. The cicatrix of a burn is often of great extent, and, on this account, the subsequent absorption of the granulations on which the new skin is formed, (a process by which the magnitude of the scar is afterwards lessened,) is so considerable as to draw the neighbouring parts out of their natural position, and occasion the most unpleasant kinds of deformity. Thus, burns

on the neck are apt to cause a distortion of the head, or even draw down the chin to the breast bone; and in the limbs such contractions as fix the joints in one immovable position. Simply dividing these contractions again mostly fails altogether, or only produces very partial and temporary relief, as after the cicatrization is completed, the new-formed parts are absorbed, and the contraction recurs. A proposal has been lately made by my friend Mr. Earle, to cut away the whole of the cicatrix, and then bring the edges of the skin as much towards each other as possible, in the transverse direction, with strips of adhesive plaster. In one case, in which "from the forepart of the upper arm, to within about two inches of the wrist, a firm tense cicatrix, of an almost horny consistence, extended, which kept the elbow immovably bent to a right angle," this gentleman performed such an operation. After removing the cicatrix, the flexor muscles at first made some resistance to the extension of the limb; but by degrees they yielded, and the arm was brought nearly to a right line. The whole limb was kept in this position by means of a splint and bandage. In the end, the contraction was cured, and the use of the limb restored. (See *Med. Chir. Trans.* Vol. 5, p. 96, &c.)

Probably, as this patient was a young growing subject, only six years of age, the operation would have proved equally successful, if a simple division of the contracted skin had been made, and the arm kept extended for a length of time by the use of a splint. It is hardly necessary to observe, that cutting a large cicatrix entirely away, must always be a severe, and sometimes a dangerous operation: therefore, the avoidance of it, if possible, cannot but be desirable. BURSÆ MUCOSÆ.—These are small membranous sacs, situated about the joints, particularly the large ones of the upper and lower extremities. For the most part, they lie under tendons. The celebrated Dr. A. Monro, of Edinburgh, published a very full

account of the bursæ mucosæ, and also of their diseases. These parts are naturally filled with an oily kind of fluid, the use of which is to lubricate surfaces, upon which the tendons play, in their passage over joints. In the healthy state, this fluid is so small in quantity, that it cannot be seen without opening the membrane containing it; but, occasionally, such an accumulation takes place, that very considerable swellings are the consequence. Tumours of this sort are often produced by bruises and sprains, and, now and then, by rheumatic affections. These swellings are not often attended with much pain, though, in some cases, it is very acute, when pressure is made with the fingers. The tumours yield, in a certain degree, to pressure; but, they rise again, with an appearance of elasticity, not remarked in other sorts of swellings. At first, they appear to be circumscribed, and confined to a small extent of the joint; but, sometimes, the fluid, forming them, is so abundant, that they extend over a great part of the circumference of the limb. The skin, unless inflamed, retains its usual colour.

In this morbid state of the bursæ mucosæ, they contain different kinds of fluids, according to the cause of the disease. When the tumour depends on a rheumatic affection, the contents are ordinarily very fluid. They are thicker, when the cause is of a scrophulous nature. When the disease is the consequence of a bruise, or sprain, the effused fluid often contains hard concretions, and, as it were, cartilaginous ones, which are sometimes quite loose, and, more or less, numerous. Such substances may frequently be felt, when the tumour is examined with the fingers.

In practice, such distinctions are not of much consequence. While the swellings are not very painful, an attempt may be

made to disperse them, by warm applications, friction, (particularly with camphorated mercurial ointment,) or blisters, kept open with the savin cerate. But, if these tumours should become very painful, and not yield to the above methods, Dr. Monro recommends opening them; a practice, however, which can seldom be really necessary, or proper. This author was continually alarmed at the idea of the bad effects of air admitted into cavities of the body, and, hence, in the operation, even of opening the bursæ mucosæ, he is very particular in directing the incision in the skin, not to be made immediately opposite that made in the sac. Care must also be taken to avoid cutting the tendons, near the swelling.

Dr. Monro had seen cases, in which amputation became indispensable, in consequence of the terrible symptoms following the opening of bursæ mucosæ.

On account of such evil consequences, which are imputed to the air, though they would as often arise, were the same practice pursued in a situation, in which no air could have access at all, it has been recommended to pass a seton through the swelling, and to remove the silk, after it has remained just long enough to excite inflammation of the cyst, when an attempt is to be made to unite the opposite sides of the cavity by pressure.

I have never seen any swelling of this kind, which could not be discussed by the means usually employed for promoting the absorption of other tumours. Indeed, the treatment should be very like that of Hydrops articuli. (See Joints.)

C.

CÆSAREAN OPERATION. Called also *Hysterolomia*, from *ὕστερα*, uterus, and *τομή*, sectio. Pliny, book 7, chap. 9, of his Natural History, gives us the etymology of this operation. *Auspiciatius* (says he) *enecti parente gignuntur, sicut Scipio Africanus prior natus, primusque Cæsar à cæso matris utero dictus; quâ de causâ cæsones appellati. Simili modo natus est Manlius qui Carthaginem cum exercitu intravit.*

From this passage we are to infer, that the Cæsarean operation is extremely ancient, though no description of it is to be found in the works of Hippocrates, Celsus, Paulus Ægineta, or Albucasis. The earliest account of it in any medical work, is that in the *Chirurgia Guidonis de Cauliaco*, published about the middle of the fourteenth century. Here, however, the practice is

only spoken of, as proper after the death of the mother, and is alleged to have been adopted only at such a conjuncture in the case of Julius Cæsar. (See *Cap. de Extractione Fetus.*) Vigo, who was born towards the close of the fifteenth century, takes no notice of the Cæsarean Operation; and Paré, who greatly improved the practice of midwifery, thinks this measure only allowable on women, who die undelivered. (*De Hominis Generatione, cap. 31.*) Rousset, who was contemporary with Paré, collected the histories of several cases, in which the operation is said to have been successfully performed, and after the publication of these, the subject excited more general interest.

By the *Cæsarean Operation*, is commonly understood that, in which the foetus is taken out of the uterus, by making an in-

cision into the abdomen, and through the parietes of the womb. The term, however, in its most comprehensive sense, is applied to three different proceedings. It is sometimes employed to denote the incision, which is occasionally practised in the cervix uteri, in order to facilitate delivery; but, this particular method is named the *Vaginal Cæsarean Operation*, for the purpose of distinguishing it from the former, which is frequently called, by way of contrast, the *Abdominal Cæsarean Operation*. With these cases, we have also to class the incision, which is made in the parietes of the abdomen, for the extraction of the fœtus, when, instead of being situated in the uterus, it lies in the cavity of the peritoneum, in consequence of the rupture of the womb, or in the ovary, or Fallopian tube, in consequence of an extra-uterine conception. This last operation, as Sabatier has remarked, is a species of gastrotomy. However, as it is analogous to the abdominal and vaginal Cæsarean Operations, it can be most conveniently treated of in the present article.

VAGINAL CÆSAREAN OPERATION.

Disease, malformation, or a preternatural position of the cervix uteri, may render this practice indispensable. A scirrhus hardness of the neck of the uterus is the most frequent. When the induration is such that the cervix cannot become dilated, and the patient is exhausting herself with unavailing efforts, the parts should be divided in several directions. This has been successfully done under various circumstances. Cases have been met with, in which the cervix uteri presented no opening at all, and yet the preceding operation proved quite effectual. Such is the example, which Dr. Simson has inserted in the third volume of the *Edinburgh Essays*. A woman, forty years of age, became pregnant, after recovering from a difficult labour, in which the child had remained several days in the passage. She had been in labour sixty hours; but the neck of the womb had no tendency to dilate. Dr. Simson, perceiving that its edges were adherent, and left no opening betwixt them, determined to practise an incision with the aid of a speculum uteri. The bistoury penetrated to the depth of half an inch before it got quite through the substance, which it had to divide, and which seemed as hard as cartilage. As the opening did not dilate, in the efforts which the woman made, it became necessary to introduce a narrow bistoury on the finger, in order to cut this kind of ring in various directions. There was no hemorrhage; and the only additional suffering, which the patient encountered, arose from the distention of the vagina. As the child was dead, Dr. Simson perforated the head, in order to render the delivery more easy.

Strong convulsions, at the moment of parturition, may create a necessity for the vaginal Cæsarean Operation. These some-

times subside, as soon as the membranes are ruptured, and the waters discharged, so as to lessen the distention of the womb. However, if the convulsions were to continue, and the cervix uteri were sufficiently dilated, the child should be extracted with the forceps, or by the feet, according to the kind of presentation. On this subject Baudeloque has recorded a fact, which was communicated to the Academy of Surgery, by Dubocq, professor of surgery at Toulouse. The woman was forty years of age, and had been in convulsions two days. She was so alarmingly pale, that she could scarcely be known. Her pulse was feeble, and almost extinct, and her extremities were cold, and covered with a clammy perspiration. The edges of the opening, which was about as large as a crown piece, felt, as it were, callous, and hardly had this aperture been dilated, when delivery took place spontaneously. The child was dead. The symptoms were appeased, and the woman experienced a perfect recovery. Another case, in which the indurated cervix uteri was successfully divided, is recorded by Lambron, a surgeon at Orleans. (See *Dict. des Sciences Med. T. 23, p. 297.*)

A considerable obliquity of the neck of the womb, combined with a pelvis, of small dimensions, may also be a reason for the performance of the vaginal Cæsarean Operation. Not that such obliquity always occasions that of the rest of the uterus; nor is the neck of this viscus invariably directed towards that side of the pelvis, which is opposite to its fundus, although this is sometimes the case. In the latter circumstance, as the contractions of the uterus do not produce a dilatation of its cervix, which rests upon the bones of the pelvis, the adjacent part of that organ is dilated and pushed from above downwards, so as to present itself in the form of a round smooth tumour, without any appearance of an aperture. Such a case may have fatal consequences. Baudeloque furnishes us with an instance. A woman, in her first pregnancy, not being able to have the attendance of the accoucheur, whom she wished, put herself under the care of a midwife, who let her continue in labour pains during three days. When the accoucheur came, on being sent for again, the child's head presented itself in the vagina, covered with the womb. The portion of the uterus, which included the fœtus, was in a state of inflammation. The os tincæ was situated backward, toward the sacrum, hardly dilated to the breadth of a penny piece, and the waters had been discharged a long time. The patient was bled, and emollient clysters were administered. All sorts of fomentations were employed. She was laid upon her back, with her pelvis considerably raised. The accoucheur had much difficulty in supporting the head of the child, and keeping it from protruding at the vulva, enveloped, as it was, in the uterus. Notwithstanding such assistance, the patient died.

So fatal an event, says Sabatier, might have been prevented, by making the woman lie upon the side, opposite the deviation of the uterus, and employing pressure from above. If these proceedings had failed in bringing the os tinæ toward the centre of the pelvis, this opening might have been brought into such position, by means of the finger, in the interval of the pains, and kept so, until it were sufficiently dilated for the membranes to protrude.

This is what was done by Baudeloque in one case, where the womb inclined forward and to the right. The os tinæ was situated backward. The waters escaped, and the head advanced towards the bottom of the pelvis, included in a portion of the uterus. The whole of the spherical tumour which presented itself, could be felt with the finger; but, no opening was distinguishable; and the swelling might also be seen, on separating the labia from each other, and opening the entrance of the vagina. It became necessary to keep the patient continually in bed, and to have the finger incessantly introduced; but, she was not sufficiently docile to submit to such treatment. Fortunately, the unexpected appearance of two officers of justice, forty-eight hours after the commencement of the labour, had the effect of making her more manageable. It was time for her to become so; for the uterus had now become tense, red, and painful. The abdomen was also so tender, that it could scarcely bear the contact of the clothes. Febrile symptoms had begun, and the ideas were beginning to be confused. Baudeloque made her lie down; and he pressed, with one hand, on the abdomen, for the purpose of raising the uterus, while, with the other, he pushed the head a little way back, in order that he might reach the os tinæ, which he now brought with his finger toward the centre of the pelvis, and kept there for some time. The efforts of the patient being thus encouraged, she was delivered in about a quarter of an hour.—The infant was of a thriving description, and the case had a most favourable termination.

When the obliquity of the uterus is such that the os tinæ cannot be found, and the mother and fœtus are both in danger of perishing, it is the duty of the practitioner to open the portion of the womb, that projects towards the vulva. Laverjat met with a case of this description in his practice. A woman, pregnant with her first child, suffered such extreme pain in her labour, that Laverjat was solicitous to ascertain the real state of things. He was surprised to find the vulva completely occupied by a body, which even protruded externally, and yielded to the pressure of the fingers, except during the labour pains.—In examining this tumour, he could only find at its circumference a cul-de-sac, half an inch deep, without any aperture, through which the child could pass. Other

practitioners, who were consulted about this extraordinary case, were also anxious to learn what had happened. They found in the tumour a laceration, which only affected a part of the thickness of its parietes. This laceration was deemed the proper place for making an incision. The operation having been done, the finger was passed into the cavity, in which the child was contained. A large quantity of turbid fluid was discharged. The child presented, and passed through the opening, with a trivial laceration on the right side. Laverjat, having passed his hand into the uterus, was unable to find either the os tinæ, or the cervix. No particular indisposition ensued, and the lochia were discharged through the wound, which gradually closed. In the course of two months, the os tinæ and neck of the uterus, were in their natural position again. (*Laverjat Nouvelle Méthode de pratiquer l'Operation Cæsarienne, Paris. 1788.*)

When the case is a scirrhus induration of the cervix uteri, or a laceration of the parietes of this viscus, at the place, where it projects into the vagina, the vaginal Cæsarean Operation is attended with no difficulty. It is performed with a blunt-pointed bistoury, the blade of which is wrapped round with lint to within an inch of the point. The instrument is to be introduced, under the guidance of the index finger, into the opening presented by the uterus, and the aperture is to be properly enlarged, from within outwards, in various directions. But when the scirrhus hardness of the cervix presents no opening at all, or when the part of the uterus projecting in the vagina is entire, the incision should be made from without inwards, with the same kind of knife. Too much caution cannot be used in introducing the instrument, in order that no injury may be done to the child, which lies directly beyond the substance, which is to be divided. No general direction can here be offered, except that of proceeding slowly, and of keeping the index finger extended along the back of the knife, so that it may be immediately known, when the substance of the womb is cut through, into the cavity of which the finger ought to pass as soon as the knife. If it should be necessary to extend or multiply the incisions, the cutting instrument should be regulated in a similar manner with the same finger. The cervix uteri having been divided, the expulsion of the child is either to be left to nature, or to be promoted by the ordinary means.—The operation that has been described, requires no dressings. If the bleeding should prove troublesome, we are recommended to apply to the incision a dossil of lint, wet with vinegar, or spirit of wine. (*See Sabatier's Médecine Opératoire, T. 1.*) The chief object would here be to prevent adhesions between the cervix of the uterus and the upper part of the vagina. (*Diction. des Sciences Méd. T. 23, p. 298.*)

ABDOMINAL CÆSAREAN OPERATION.

This is a far more serious operation than that of which we have just now been treating, and it is the proceeding, to which the term Cæsarean Operation is more particularly applied.

There are three cases, in which this operation may be necessary. 1. When the fœtus is alive, and the mother dead, either in labour, or the last two months of pregnancy. 2. When the fœtus is dead, but cannot be delivered in the usual way on account of the deformity of the mother, or the disproportionate size of the child. 3. When both the mother and child are living, but delivery cannot take place from the same causes as in the second example.

In many instances, both mother and child have lived after the Cæsarean Operation, and the mother even borne children afterwards. (See *Heister's Institutes of Surgery*, chap. 113. *Mem. de l'Acad. de Chirurgie*, Tom. 1, p. 623, Tom. 2, p. 308, 4to. *Edinb. Med. Essays*, Vol. 5, art. 37, 38. *Edinb. Med. and Surgical Journal*, Vol. 4, p. 179. *Med. Chir. Trans.* Vol. 9, and 11, &c.)

In England, the operation has been attended with remarkable ill success; and perhaps there is not one unequivocal example, in which the mother has here survived the true Cæsarean Operation. In the last edition of this work, indeed, I referred to the case recorded by Mr. James Barlow, of Chorley, Lancashire, who made an incision into the abdomen, extracted a dead child, and saved the mother's life.—(See *Medical Records and Researches*, p. 154, 1798.) My friend Dr. Gooch, however, having obligingly communicated to me his doubts, and those of Dr. Hull, respecting the reality of an incision having been made in this instance into the uterus, I am glad to have the opportunity of expressing my perfect conviction of the more correct view of the case taken by these physicians. "I suspected, from the first, (says Dr. Hull) that Mr. Barlow was deceived in this case, from the account he gave of the remarkable thinness of the uterus. And I had formed an opinion that the child had escaped through a laceration of the uterus, into the abdomen, enveloped in the secundines, and that he had merely divided the membranes, when he fancied he had divided the uterus." Dr. Hull then proceeds to explain the confirmation of his own sentiments by those of Mr. Howarden, a very intelligent practitioner at Blackrod, who assisted at the operation. In fact, the particulars stated by this gentleman, leave no doubt, that the fœtus had escaped through a laceration of the uterus into the cavity of the abdomen. (See *Hull's Defence of the Cæsarean Operation*, &c. p. 72.) The case also referred to by Mr. D. Stewart, (see *Edin. Med. Essays*, Vol. 5,) where the labour had endured twelve days, and the life of the mother was saved, after the dead fœtus had been extracted by a midwife, was also probably of the same nature: at

all events, the want of authentic particulars, and the circumstance of the operation having been done by a woman, leave the true nature of the case questionable.

If therefore, when we speak of the Cæsarean Operation, we mean that, in which the parietes of the abdomen and those of the uterus are divided by the surgeon, and the fœtus extracted, I believe that, as far as the history of the practice extends in this country, it cannot be said, that the mother has ever recovered after such a proceeding; though some years ago, a calculation was made, that the operation had been done not less than eighteen times in Great Britain. Ten of the children, however, are stated to have been saved. On the continent, the practice has proved infinitely more successful; for, of 231 cases of this operation, to be found in the records of medicine, 139 are said to have terminated successfully. (*Kellie, in Edin. Med. and Surgical Journal*, Vol. 8, p. 17.) No doubt, the ill success of the Cæsarean Operation in England was correctly explained by Dr. Hull: "In France, and some other nations upon the European Continent, the Cæsarean Operation has been, and continues to be performed, where British practitioners do not think it indicated; it is also had recourse to early, before the strength of the mother has been exhausted by the long continuance and frequent repetition of tormenting, though unavailing pains, and before her life is endangered by the accession of inflammation of the abdominal cavity. From this view of the matter, we may reasonably expect, that recoveries will be more frequent in France, than in England and Scotland, where the reverse practice obtains. And, it is from such cases as these, in which it is employed in France, that the value of the operation ought to be appreciated. Who would be sanguine in his expectation of a recovery under such circumstances, as it has generally been resorted to in this country, namely, where the female has laboured for years under *malacosteon*, (*mollities osium*) a disease hitherto in itself incurable; where she has been brought into imminent danger by previous inflammation of the intestines; or other contents of the abdominal cavity; or been exhausted by a labour of a week's continuance, or even longer." Dr. Hull thus refutes the opinion of Mr. W. Simmons, that our ill success was owing to climate, or some peculiarity in the constitutions of the females of this island.—(See *Hull's Defence of the Cæsarean Operation*, p. 10.)

When the fœtus is contained in the womb, and cannot be expelled, by reason of the invincible obstacles to which I have already referred, the Cæsarean Operation should be practised before the mother and fœtus both perish from the violence of the pains, hemorrhage, convulsions, &c.

For this purpose it is necessary to make an extensive incision in the integuments of the abdomen, and in the uterus. Some

have thought, that cutting the parietes of the belly would be mortal, while others have believed a wound of the uterus equally dangerous. Hence, such persons have condemned the operation on the principle, that religious reasons do not authorize taking one life to save another. All the opponents of the Cæsarean Operation fear the hemorrhage, which, they say, must follow. Indeed, if the uterus were not to contract sufficiently, when the fœtus and after birth had come away, the bleeding would really be perilous. But when, by means of the Cæsarean Operation, the fœtus is extracted, together with the placenta and membranes, the uterus contracts, just as it does after a natural labour. Besides, even when the mother is alive, the operation is not commonly done, till the uterus evinces a propensity to deliver itself, and begins to contract. The womb being delivered of its contents, the incision becomes closed, the vessels obliterated, and there is no fear of hemorrhage. The wound must also make so irritable an organ more disposed to contract: but, whatever arguments may be adduced, it is enough to say in this case: *Artem experientia fecit, exemplo monstrante viam*. Rousset, in 1581, published a work in French, entitled *Hystérotomie, ou l'Accouchement Césarien*. This book, in 1601, was translated into Latin, and enlarged with an appendix by the celebrated Bauhin. Even then, the practice of the Cæsarean Operation on the living mother had its defenders. Bauhin relates that, in the year 1500, a sow-gelder performed the Cæsarean Operation on his wife, *tam feliciter, ut ea postea gemellos et quatuor adhuc infantes enixa fuerit*. This is said to be the first instance, in which the operation was ever done on the living mother with success. Many other cases were afterwards collected and published.

The possibility of operating successfully on the living mother, was proved with great perspicuity and accuracy, by Simon, in the *Memoires de l'Acad. de Chirurgie*, T. 1, 4to. Here we are presented with a collection of sixty-four Cæsarean Operations, more than a half of which had been done on thirteen women. Some of these had undergone the operation once or twice; others five or six times. There was one woman in particular, who had undergone it seven times, and always with success. This seems to prove, notwithstanding all assertions to the contrary, that the operation for the most part succeeds. But, if the life of the mother should not invariably be preserved, the Cæsarean Operation ought not to be rejected on this account: it ought always to be done, when relief cannot be obtained by other means; just as amputation and lythotomy are practised, though they are not constantly followed by success. Would any thing be more cruel, than to abandon a mother and her child, and leave them to perish, while there is any hope of saving them both? It is true, that when a pregnant woman dies

of any inward disorder, and not from the pains and efforts of labour, the fœtus is sometimes still alive in the uterus; but, in cases of death after difficult labours, and the great efforts made by the uterus to overcome the obstacles to parturition, the fœtus is generally dead; and the operation therefore is less likely to be availing. (See *Bertrandi Traité des Opérations de Chirurgie*, chap. 5.)

It is the opinion of the best writers upon this subject, that whenever a woman dies, at all advanced in pregnancy, the performance of the Cæsarean Operation is highly proper. The propriety of this practice, in such circumstances, was known to the ancient Romans; for, by a decree of Numa Pompilius, no woman, who died pregnant, was suffered to be buried, ere her body had been opened, with the view of preserving the infant for the use of the state. (*Sprengel Geschichte der Chir. Th. 1, p. 371*.) Experience has proved, that when the fœtus has not attained the period, at which parturition commonly happens, it will sometimes survive the operation a considerable time, and that, when it is full grown, its life may be most happily preserved.—Although instances are cited, in which the fœtus in utero has been found alive upwards of four and twenty hours after the death of the mother, little stress should be laid on such prodigies. The operation ought to be done without any delay. Even then, we are not certain of saving the infant's life. In the greater number of instances, the fœtus perishes at the same time with the mother, and from the same causes. The cases which are recorded of the fœtus being extracted alive, after the death of the mother, are numerous: I shall here only refer to three, two of which rest on the unimpeachable authority of Flajani, who was himself the operator. (*Collezione di Osservazioni, &c. di Chirurgia*, T. 3, p. 144—146.) In one of these instances, the operation was done on a woman killed by violence in the ninth month of pregnancy: the child lived six hours; in the other, a fœtus was extracted from a woman who had died of typhus fever, in the seventh month, and though the operation was not done till she had been dead about an hour, the child was taken out alive, and continued to live full ten minutes. A living child was also taken out of its mother by Vesling, after her death from typhus. (*Welsch. Obs. Med. Episagm. No 74, p. 47*: *Sprengel Geschichte der Chir. Th. 1, p. 374*.) With respect to the statements of Cangiamila, a Sicilian practitioner. I join Sprengel in considering them as incredible exaggerations; five instances are given, in which the fœtus was taken out of the mother from fifteen to twenty-four hours after her death, and yet continued to live. Cangiamila says, that at Syracuse, in the course of eighteen years, the operation had been practised twenty times under the same circumstances; that at Girgenti, thirteen children were saved out of twenty-two

women, who had died pregnant; and that, in twenty-four years at Montereali, twenty-one children were preserved in the same manner. (*Embryologia Sacra. Venet. 1763. fol.*) As Sprengel remarks, one might almost suppose, from this account, that in Sicily pregnancy was generally fatal. If the mother should happen to die in labour, and the neck of the uterus were sufficiently dilated, or disposed to be so, an attempt should be made to accomplish delivery in the ordinary way; for, examples have occurred, in which women, supposed to be dead in this circumstance, were in reality alive. Hence, we find, that the senate of Venice in 1608 enacted a law, by which practitioners were liable to punishment, in case they neglected to operate with as much caution on a pregnant woman, supposed to be dead, as on the living subject; and rules to be observed were again issued by the same government, in 1720. (*Seb. Melli La Com-mare levatrice, p. 108, 4to Venez 1721; Personè Diss. sopra l'Operaz. Cesar p. 15, 8vo. Venez. 1778.*) A law to the same effect was likewise made in 1749, by the king of Sicily, who decreed the punishment of death to those medical men, who omitted to perform the Cæsarean Operation on such women as died in the advanced stages of pregnancy. In the *Journal de Savans de Janvier, 1749*, the following case, confirming the propriety of such caution, was inserted by Rigaudeau, surgeon to the Military Hospital at Douay. This practitioner, having been sent for to a woman, to whose residence he was unable to proceed, till two hours after her apparent death, he had the sheet, with which she was covered, removed, and perceiving that the body retained its suppleness and warmth, he tried whether the foetus could not be extracted in the ordinary way, which was easily effected as soon as the feet were got hold of. The first endeavours to save the child were very unpromising; but, after a few hours, they had the desired effect. As the woman continued in the same state five hours afterwards, Rigaudeau recommended that she might not be buried before her limbs were quite cold and stiff. He afterwards had the satisfaction to learn, that she was also restored to life. This remarkable case happened on the 8th of June, 1745, and both the mother and child were living at the period, when Rigaudeau published the observation.

Supposing, however, delivery in the ordinary manner, to be impracticable, at all events, the Cæsarean Operation ought to be performed, with the same cautions, as if the mother were alive, only one incision being made for the purpose of opening the uterus.

Almost all the insurmountable obstacles to delivery originate from the bad conformation of the pelvis, depending upon rachitis; though they are not an invariable consequence of it, since there are women, extremely deformed, in whom no imperfec-

tion of the pelvis exists, while it prevails in others, whose shape is but trivially disfigured. An examination of the dimensions of the pelvis is the right mode of ascertaining, whether there is really such an impediment to parturition. In order that the dimensions may not be an obstacle to delivery, the distance, between the upper edge of the sacrum and the os pubis, ought to be three inches and a half; and the distances between the tuberosities of the ischium, and between each of these protuberances and the point of the os coccygis, three inches. Women have indeed been known to be delivered, without assistance, although the first of the above distances was only two inches and a half; but, then the heads of the children were so elongated, that the great diameter was nearly eight inches, while that which extends from one parietal protuberance to the other, was reduced to two inches five or six lines, and the infants were lifeless. If they are to be born alive, they must be taken out of the womb by the Cæsarean Operation; but, the latter proceeding should never be adopted, without a certainty, that they are actually living; for, when dead, they may be extracted in a way, that is attended with much less risk to the mother.

It is not always an easy matter to ascertain with certainty, whether a foetus in utero, be living or dead. If it has entirely ceased to move, after being affected with a violent motion, the probability is, that it is no longer alive. But, to be certain, manual examination is necessary, which may be practised in two ways. One consists in pressing upon the uterus, through the parietes of the abdomen. If the child lives, such pressure makes it move, and the motion can be plainly felt, and distinguished. In the other method, one hand is employed in pressing upon the uterus externally, while, with the fingers of the other hand, passed up the vagina, corresponding pressure is also to be made. The uterus is likewise to be allowed to descend as far as possible, in order to induce the foetus to move. When no decisive indications can be thus obtained, it becomes necessary to rupture the membranes, if they have not already given way, introduce the hand into the uterus, and put a finger into the child's mouth, for the purpose of making it move its tongue. The finger may also be applied to the region of the heart, so as to examine whether this organ is beating; and the umbilical cord may be touched, in order to ascertain whether there is still a pulsation in it. When none of these proceedings furnish unequivocal information, the conclusion is, that the child is dead, and its extraction is indicated, unless the narrowness of the parts be such, that the hand cannot be passed into the uterus, in which case, the Cæsarean Operation is indispensable.

But, how are we to form a judgment respecting the dimensions of the pelvis? And how can we know, whether that diameter, which extends from the upper edge of the

sacrum to the os pubis, is long enough to allow the passage of the child? The proper confirmation of this part is known, by the roundness and equality of the hips, both in the transverse and perpendicular direction; by the projection of the pubes; by the moderate depression of the sacrum; by an extent of four or five inches from the middle of this depression to the bottom of the os coccygis; by an extent of seven or eight inches from the spinous process of the last lumbar vertebra to the highest part of the mons veneris, in a woman moderately fat; and by there being an interspace of eight or nine inches, between the two anterior superior spinous processes of the ossa ilium.

These general calculations, however, are insufficient. In order to acquire more correct opinions, double compasses have been employed. The branches of the first being applied to the top of the sacrum, and middle of the mons veneris, three inches are to be deducted from the dimensions, indicated by the instrument; viz. two inches and a half for the thickness of the upper part of the sacrum, (which is said to be constant in subjects of every size,) and half an inch for that of the os pubis. In women, who are exceedingly fat, some lines must also be deducted on this account. Hence, when the total thickness of the pelvis, measured in this direction, is seven inches, there will remain four for the distance from the upper part of the sacrum to the os pubis, or for the extent of the lesser diameter of the upper aperture of the pelvis.

For taking the measurement internally, a kind of sector was invented by Coutouly. It bears a considerable resemblance to the instruments employed by shoemakers for measuring the feet. It is passed into the vagina, with its two branches approximated, until one arrives opposite the anterior and upper part of the sacrum, when the other is to be drawn outward, so as to be applied to the pubes. The distance between the branches, is judged of by the graduations on the instrument. This was named by its inventor a pelvimeter. According to Sabatier, it is not always easy to place it with accuracy; its employment is attended with some pain; and there are particular cases in which it cannot be used.

Instead of this contrivance, the celebrated Baudeloque recommended a means, which seems to be very safe and simple. The index finger of one hand is to be introduced into the vagina to the upper part of the projection of the sacrum. The finger, having the radial edge turned forwards, is then to be inclined anteriorly till it touches the arch of the pubes. The point of contact being then marked with the opposite hand, the length from the point in question to the end of the finger is to be measured. This length, which indicates the distance between the sacrum and the bottom of the symphysis pubis, usually exceeds that of the lesser diameter of the pelvis by about six lines. Baudeloque acknowledges, that this measurement is not exactly accurate;

but, he believes, it will do very well, because, unless the narrowness of the pelvis be extreme, two, or three lines hardly make any difference in the facility of parturition.

The following is the description of the pelvis of the woman, twice operated upon by Dr. Locher: the ossa pubis, which should be on the same level with the promontory of the sacrum, were found perpendicularly under it; so that the child necessarily extended the abdominal integuments by its own weight, into a pendulous bag overhanging the thighs. For the same reason, nothing could be felt of the child by examination per vaginam. The sacrum, instead of closing the pelvis behind, by a semi-circular curve, which forms a kind of conductor for the child in parturition, stretched nearly horizontally backwards. A representation of this pelvis, with a few other particulars, may be seen in a modern publication. (*Med. Chir. Trans. Vol. 11, p. 199.*)

The pelvis may be every where well formed, and yet present an insurmountable obstacle to delivery, in case an exostosis, lessening its dimensions, should exist on one of the bones, which compose this part of the skeleton. Pineau met with a case of this description in a woman, who died undelivered. The tumour originated from one of the ossa pubis. A steatomatous swelling situated with the head of the child in the upper aperture of the pelvis, might produce the same effect, unless it were detected, and could be pushed out of the way, so as to make room for the fœtus to pass. Baudeloque mentions a swelling of this kind. It was six or seven inches long, and an inch and a half in width. The extremity of it, which was as large as half an hen's egg, had a bony feel, and contained nine well-formed teeth, the rest of the mass being steatomatous. It had descended into the lesser pelvis, below the projection of the sacrum, and a little to one side. It might have been taken for an exostosis of this last bone. The labour pains continued sixty hours, and the propriety of performing the Cæsarean Operation was under consideration. Baudeloque was averse to this proceeding. He recommended turning the child, and extracting it by the feet, because he thought, that the pelvis was sufficiently capacious to admit of delivery. The event proved, that it was three inches nine lines, from before backward, and four inches nine lines transversely. The fœtus was soon easily extracted. The assistance of the forceps was necessary to get out the head. The child was stillborn. The mother, exhausted with numerous unavailing efforts, only survived between 50 and 60 hours. Baudeloque was of opinion, that a defective regimen also tended to occasion her death.

Among the insurmountable obstacles to delivery may be reckoned such a displacement of the uterus, that this viscus protrudes from the abdomen, and forms a hernia. The records of surgery have preserved some examples of this extraordinary occurrence. Twice has the Cæsarean Operation

been performed, and, in one of the cases, the woman survived so long, that hopes were entertained of her recovery. Indeed, as Sabatier observes, why should not the operation succeed in such a case, where the uterus is only covered by the integuments, and there is no occasion to cut into the abdomen, just as well as other instances, in which it is indispensable to divide the muscles, and open the cavity of the belly? In the other case on record, delivery was effected in the ordinary way, either by raising the abdomen, and keeping it in this position with towels skilfully placed, or by making pressure on the uterus, which had the beneficial effect of making this organ resume its proper situation.

Having shown the absolute necessity for the Cæsarean Operation, under certain circumstances, it remains to consider the proper time for performing it, the requisite preparatory means, and the method of operating.

With regard to the time of operating, practitioners do not agree upon this point; some advising the operation to be done, before the membranes have burst, and the waters been discharged; others, not till afterwards. The arguments, in favour of the first plan, are, the facility with which the uterus may be opened without any risk of injuring the fœtus, and the hope that the viscus will contract with sufficient force to prevent hemorrhage. The advocates for the second mode believe, that, in operating after the discharge of the waters, there is less danger of the uterus falling into a state of relaxation, in consequence of becoming suddenly empty after being fully distended, and that this method does not demand so extensive an incision. Hence, they recommend, as a preliminary step, to open the membranes. Whatever conduct be adopted, it is essential, that the labour should be urgent and unequivocal, that the cervix uteri should be effaced, and that the os tincæ should be sufficiently dilated to allow the lochia to be discharged; but, at the same time, says Sabatier, if the operation is not to be done till after the escape of the waters, there ought not to be too much delay, lest the patient's strength should be exhausted, and the violent efforts of labour should bring on an inflammatory state of the parietes of the uterus.

The propriety of emptying the rectum and bladder is so evident, that it is unnecessary to insist upon it. This precaution is more particularly requisite in regard to the latter of these viscera, which has been known to rise so much over the uterus, as to conceal the greater part of it. Baudeloque had occasion to remark this circumstance, in a woman, upon whom he was operating. The bladder ascended above the navel, and presented itself through the whole extent of the opening made in the parietes of the abdomen.

The instruments, dressings, &c. which may be wanted, are two bistouries, one with a convex edge, the other having

probe-point; sponges; basins of cold water acidulated with a little vinegar; long strips of adhesive plaster; needles and ligatures; lint; long and square compresses; a bandage to be applied round the body, with a scapulary, &c.

For the purpose of undergoing the operation, the patient should be placed at the edge of her bed, well supported; her chest and head should be moderately raised; her knees should be somewhat bent, and held by assistants, one of whom ought to be expressly appointed to fix the uterus by making pressure laterally, and from above downward, so as to circumscribe, in some degree, the swelling of the uterus, and prevent the protrusion of the bowels. These things being attended to, the integuments are to be divided with the convex-edged bistoury to the extent of at least six inches. The place, and direction of this incision, differ with different operators.

In the most ancient method, it was customary to make the incision between the outer edge of the rectus muscle, and a line, drawn from the anterior superior spinous process of the ilium, to the junction of the bone of the first rib with its cartilage. This cut was begun a little below the umbilicus, and was continued downward as far as an inch above the pubes. After the integuments had been divided, the muscles, aponeuroses, and peritoneum were cut, and the uterus, cautiously opened. The left index finger was then introduced into this viscus, the wound of which was dilated by means of the probe-pointed bistoury.

This manner of operating is subject to great inconveniences. The place, where the incision is made, is the situation of muscles, the fibres of which have a different direction; and, on contracting, separate the edges of the wound, and make it gape. The considerable blood vessels, which ramify there, may be the source of perilous bleeding. The bowels can protrude in that situation more readily, than any where else. When the position of the uterus is oblique, and when, consequently, the edges of this viscus are turned forward and backward, and its surfaces to the right and left, the incision will be made in one of the lateral portions of the uterus, where the trunks of its blood-vessels are known to be situated, and sometimes even the Follapian tube and ovary may be cut. The fibres of the uterus are cut transversely, so that the edges of the incision are apt to gape, instead of being in contact. This last circumstance may the more readily permit the lochia to escape into the abdomen, inasmuch as the uterus is cut nearly through its whole length, and there is no cavity, in which they can accumulate, in order to be discharged through the cervix of that organ.

The linea alba has been frequently considered the most eligible place for making the incision. As Sabatier informs us, it was the method adopted by Soleyres and Dealeurye, and it has the recommendation of

Baudeloque, because there are fewer parts to be cut, and, when the uterus is exposed, an incision, parallel to its principal fibres, may be made in its middle part. Soleyres thought that this plan of operating originated with Platner and Guérin, a surgeon at Crepi en Valois, Platner says; *Incidantur juxta lineam albam, plagâ majore quæ ab umbilico ad ossa pubis ferè descendit, tum abdominis muscoli, tum peritonæum, ubi tandem vitandum ne violetur arteria epigastrica.* Guérin, in his case, made an incision, six inches long, which began a little above the umbilicus, and extended to within an inch and a half of the pubes. He afterwards divided the fat, muscles, and peritoneum, in order to get at the uterus, the anterior part of which was opened, the wound being made rather in the body, than the fundus of that viscus. Deleurye will not admit, that these writers actually divided the linea alba, because they speak of having cut muscles, which in reality do not exist in that situation; and he attributes the honour of the invention to Varoquier, a surgeon of Lisle, in Flanders; but, the method was known to Mauriceau, as we may be convinced of by the following passage, extracted from the chapter in which he treats of the Cæsarean Operation, "*La plupart veulent qu'on incise au côté gauche du ventre; mais l'ouverture sera mieux au milieu entre les muscles droits, car il n'y a en ce lieu, que les tégumens et les muscles à couper.*" Lauverjat, who has made this remark, and cited the Latin edition of Mauriceau, page 247, also observes, that the incision in the linea alba was practised by a contemporary of La Motte, a circumstance which Sabatier has not been able to ascertain. (*Médecine Opératoire, Tom. 1.*) The following would be the proper manner of operating in the linea alba. The operator should first divide the integuments perpendicularly, so as to expose the linea alba, making the wound about six inches long. An opening should then be carefully made through the aponeurosis, into the abdomen, either at the upper, or lower part, of the linea alba in view. A curved bistoury is then to be introduced into the opening, and the tendon and peritoneum cut from within outward, as far as the extent of the wound in the integuments. The latter cut should be cautiously made, with the crooked bistoury, guided by the forefinger of the left hand, lest any of the intestines be accidentally injured. The uterus must next be carefully opened, making an incision in it, of the same length, as the preceding wound. The foetus is to be taken out through the wound, and then the placenta and membranes. In this way, M. Artiste lately operated, so as to save both mother and child. (See *Edinb. Med. & Surg. Journ. Vol. 4, p. 178.*)

This mode of operating, as Sabatier observes, gives more hopes of success, than the plan first described; but he argues, that such hopes have not been realized by experience. Though the operation may have been more easy, he contends that the

edges of the wound in the skin, and those of the incision in the uterus, have had no tendency to remain in a state of proximity to each other, because the linea alba is the point, on which all the large muscles of the abdomen principally act, and because the contraction of the uterus invariably takes place from above downwards. Sabatier alleges, that the wound in this viscus has been found to incline to one of its sides for the same reasons, as occur, in operating at one of the sides of the abdomen. He also states, that the incision has been concealed under the integuments of the upper part of the pubes, and that the presence of the bladder hinders the wound from being carried sufficiently far down. Perhaps, says he, a part of these inconveniences which depend upon the contraction of the uterus, and the return of this organ to its natural state, might be avoided, by extending the incision to its highest part. Baudeloque has advised this plan, with a view of preventing the fatal extravasations in the abdomen, which frequently follow this operation. Sabatier, however, has doubts, whether, in operating in the linea alba, the wound can be carried high enough. Besides, he maintains, that this precaution would not prevent the wound from gaping, nor the greater tendency of the lochia to be extravasated in the abdomen, than to accumulate in the uterus, and be discharged through the os tincæ. (*Médecine Opératoire, Tom. 1, p. 274, 275.*)

In this country, (where, indeed, the Cæsarean Operation has proved most unsuccessful) the linea alba is preferred, I believe, by the majority of practitioners. That the method is not always attended with the formidable objections, urged against it by Sabatier, is quite certain: the case, lately published by Dr. Chisholm, is a decisive proof of this assertion. (See *Edinb. Med. and Surgical Journ. Vol. 4, p. 178, 179.*)

There is a third method of performing the abdominal Cæsarean Operation. It consists in making a transverse incision, five inches in length, through the parietes of the abdomen, between the rectus muscle and the spine, and in a situation more or less high, according to the more or less elevated position of the uterus. This plan was recommended by Lauverjat, in a publication entitled, "*Nouvelle Méthode de Pratiquer l'Operation Césarienne, Paris, 8vo. 1788.*" Lauverjat acknowledges, that the method had been successfully practised by different persons before himself, and, especially, in one instance, which was particularly remarkable, as, in consequence of the first incision having been made too high up, it became necessary to make a second one, which extended obliquely from the other. However, according to Sabatier, Lauverjat has as much merit, as if he had invented the plan, since he has given a better explanation of its advantages, than any of his predecessors.

The side, on which the operation is to be done, is in itself a matter of indifference.

But, if the liver or spleen were to project, one ought to avoid it. Also, if the uterus were to incline more towards one side, than the other, it would be proper to operate on that side, where this viscus could be most conveniently exposed. The patient being put in a proper position, and held by assistants, and her abdomen kept steady by an attendant, who must apply the palms of his hands to the sides of the uterus, the integuments, muscles, and peritoneum are to be divided, with the usual precautions. The uterus is then to be opened, and the wound in it enlarged in the requisite degree, by means of a probe-pointed bistoury. Should the placenta present itself, care must be taken not to injure it for fear of opening one of the arteries of this mass, which communicate with the umbilical arteries of the child, or of leaving a portion of it in the uterus; but, it should be separated, in order to facilitate breaking the membranes at its circumference. The child is next to be extracted. This part of the operation is subject to no general rule. Delivery being accomplished, we are recommended to introduce through the vagina anodyne injections, in order to lessen spasm, and wash out the coagula. This method is preferable to that of clearing out the uterus with the hand. Sabatier most properly condemns the plan, formerly advised by Rousset and Ruleau, of passing up the neck of this viscus, a catheter, for the purpose of washing out the lochia, as well as the absurd proposal of employing a seton to promote their escape. Should the lochia not pass readily outward, we are recommended to introduce the finger occasionally into the cervix uteri, so as to free it from the coagula, which may obstruct it.

Sabatier observes, that nearly all authors, who have spoken of the Cæsarean Operation, whether performed at the sides of the abdomen, or in the linea alba, have advised keeping the edges of the wound in the skin, muscles, and peritoneum together, by means of the interrupted, or twisted suture, care being taken to place at the lower part of the incision a tent, in order to prevent adhesion, and leave a free issue for whatever discharge may take place from the abdomen. Others have been content with recommending the use of adhesive plasters and the uniting bandage.

Sabatier condemns sutures as painful and irritating, and he states, that the other means only act upon the skin, without fulfilling the object in view, because the integuments have no fixed point, and the divided muscles tend to contract. He assures us, that, in the last mode of operating, the edges of the wound may be brought into contact by merely laying the patient upon her side. Besides, he remarks, that there are not many muscular fibres cut, those of the transversalis being only separated from each other. He affirms, that this manner of operating also favours the approximation of the edges of the wound in the uterus, in consequence of this organ contracting

most extensively in the perpendicular direction. It is likewise asserted, that, as the uterus has only been opened at its upper part, it affords in its middle and lower portions a large cavity, which does not communicate with the abdomen, and in which the lochia may easily accumulate, and afterwards be discharged by the natural way. The only dressings, advised by Sabatier, are a large pledget, compresses, and a moderately tight bandage round the body. These are to be changed, when soiled with the matter or discharge. In this country, practitioners would not neglect to bring the edges of the wound, as much as possible together, by means of strips of adhesive plaster; for, though they may not act with so much effect in this situation as many others, they undoubtedly assist in promoting the main aim of the surgeon, which is to heal at least all the upper part of the incision, if possible, by the first intention. I have no doubt, there are many, who would be advocates for sutures. In this country, the last method of operating has also been tried.

Mr. Wood, of Manchester, performed the Cæsarean Operation, in a case, in which parturition was prevented by deformity of the pelvis. The incision was made nearly in a transverse direction, on the left side of the abdomen, about five inches in length, beginning at the umbilicus. This part was fixed upon, because the nates of the child could be felt there, and it was evident, that no intestine was interposed betwixt the abdominal parietes and the uterus. There was scarcely any effusion of blood, either from the external wound, or from that of the uterus, though the latter was made directly upon the placenta. Instead of dividing the placenta, Mr. Wood introduced his hand betwixt it and the uterus, and, laying hold of one of the child's knees, extracted the fœtus with ease. His hand readily passed betwixt the placenta and uterus; this produced a hemorrhage, but, not in any considerable degree; for, the whole quantity of blood lost did not exceed seven or eight ounces. After the uterus was emptied, the intestines and omentum protruded at the wound. These having been reduced, the integuments were brought into contact with sutures and adhesive plaster. This operation, however, did not save the woman's life; she died on the fourth day after its performance. (See *Med. and Physical Journ.* Vol. 6.) As I have already explained, the ill success of the Cæsarean Operation in England has been such, that not a single case has yet happened, in which the life of the mother has been preserved after the child was truly extracted from the womb by incision. The probable reason of this circumstance I have also noticed. Abroad, however, the success of the practice forms quite a contrast, to what has occurred in this country, the operation having been often done so as to save the lives both of the mother and child, of which an interesting example was re-

cently published by Dr. Locher, of Zurich. (See *Med. Chir. Trans.* Vol. 9. p. 11.) And, in Vol. 11 of the same work, may be read a case, in which Dr. Meyer, of Minden, lately saved a woman, by the operation, but the foetus was dead. Likewise an example, in which Dr. Spitzbarth, in 1819, preserved the lives both of the infant and mother; and another interesting relation of two Cæsaean Operations performed by Lorinser on a woman still living at Nimes, in Bohemia. (See also *Siebold's Journ. für Geburtshulfe, &c.* Vol. 3, Part 1, Frankf. 1819.) In 1801, Dr. Schlegel, of Merseburg, likewise operated on a woman, who recovered, notwithstanding the bowels became strangulated, and she is still living, with a hernia in the situation of the wound. (*Schweighäuser Archiv. des Accouchemens*, p. 135, 8vo. Paris, 1797.)

OF OPERATING, WHEN THE FÆTUS IS
EXTRA-UTERINE.

Delivery cannot possibly happen in the ordinary way, when the foetus is situated in the ovaries, or Fallopian tube, or in the cavity of the peritoneum. However, there are many instances recorded of ventral pregnancies, which the mothers survived, the dead putrified foetus having been discharged, either out of an abscess, or through the rectum.

Practitioners are occasionally called upon to do a very similar operation to the Cæsaean, when the child has passed into the cavity of the peritoneum, in consequence of the rupture of the uterus. Unfortunately, such an accident is not uncommon, and though the causes of it may not be obvious, nothing is more certain, than that the foetus itself is entirely passive, and has no share in producing the misfortune. The symptoms, by which the event can be known, are not always easy of comprehension. When, however, the pains have been violent; when the last, after being excessively severe, has been followed by a kind of calm; when the countenance loses its colour, the pulse grows weak, and the extremities become cold and covered with a cold sweat; when the abdomen is generally flat and only partially affected with a swelling, occasioned by the foetus, which either continues to move, or is dead and motionless; when the patient complains of a moderate degree of heat about the belly; and, lastly, when the child shrinks from the touch of the accoucheur; it is manifest that the uterus is lacerated. If the child has passed completely into the abdomen, gastrotomy is the only resource. Should a part of it, however, yet remain in the uterus, it may be extracted, with the aid of the forceps, if the head presents, or by the feet, provided only the upper part of the body be in the abdomen.

Baudeloque quotes three instances of gastrotomy, performed on account of the rupture of the uterus. The first is that inserted by Thibaud Dubois in the *Journal de Médecine* for May, 1760. Every preparation was

made for a natural labour, when, after excessively violent pains about the upper and left part of the uterus, the child disappeared. Thibaud opened the abdomen, though not till some hours after the accident. The infant was dead; but, the mother experienced no ill effects after the operation, except such as are usual after the ordinary labours.

The second and third cases were communicated to the French Academy of Surgery in 1775, by Lambron, a surgeon of Orleans. He practised the operation twice, on the same woman, with success. In the first instance, he operated eighteen hours after the rupture of the uterus. The child was dead. An ill-conditioned abscess formed near the wound; but, the patient got quite well in the course of six weeks. She was pregnant again the following year, and the uterus was once more ruptured. Lambron now had recourse to the operation without delay. The child betrayed some signs of life; but soon died. The mother not only survived, but, afterwards became pregnant again, and had a favourable delivery.

In the foregoing column, I have adverted to the case, in which Dr. Locher, of Zurich, saved both the mother and child by the Cæsaean operation, performed in the linea alba. After her recovery, a small point of the wound, not exceeding two or three lines in length and breadth, required a long time to be quite healed, though no particular inconvenience was experienced from it. Some time afterwards, the cicatrix gave way again, and a portion of omentum protruded, which was reduced, when a piece of bowel came out, and was also returned. The edges of the wound were then brought together; but a small superficial ulcer continued open, in spite of every effort to close it. In 1818, the year following that in which the Cæsaean Operation had been performed upon her, she became pregnant again, and the chief particularity, which happened during gestation, was an increase in the size of the preceding ulcer, which became three inches in width. The sore, however, was covered with charpie, and the integuments well supported with adhesive plaster. On the 23d of May, she was seized with labour-pains; and about seven in the evening, she complained all at once of a very acute pain, and at the same moment voided a considerable quantity of blood from the vagina. On examining by this passage, nothing was discovered; but, when the hand was applied below the navel, in the line of the old wound, and under the ulcer, a circumscribed firm swelling was felt, caused by the child's head, of which the sutures were plainly discernible. Dr. Locher naturally concluded, that the uterus had burst, so as to allow the child to escape, and the hemorrhage was thus easily explained. A repetition of the Cæsaean Operation was deemed indispensable. The place of the incision was determined by the round swelling, caused by the child's head. An incision, six inches in length, was made into the abdomen, where a quantity of coag-

gulated blood was found. When this had been removed, the membranes presented themselves, exhibiting a bluish hue, and, after they had been opened, the head of the child immediately appeared. The navel-string passed round the neck, which was also compressed in the opening of the uterus. The child evinced no signs of life. The placenta came away during the attempts to reanimate the child. The uterus contracted, and there was little bleeding. This patient, after a good deal of indisposition, and occasional approaches to a perfect recovery, was at length attacked with inflammation of the stomach and bowels, and died on the 9th of July. The uterus was found contracted to a small size, with an opening, of about the size of an almond, on its anterior surface, with a rounded callous edge. This aperture, Dr. Locher thinks, had remained ever since the first operation, and had allowed the escape of the child in the second labour; a circumstance, which may be doubted, as the hemorrhage indicated the period, when the uterus had been lacerated, as this gentleman indeed has in one place particularly noticed himself. (See *Med. Chir. Trans. Vol. 11, p. 182, &c.*) An almost incredible case is related of, what may be called, a Cæsarean birth, effected solely by the powers of nature, and, as would appear, by a sudden rupture of the uterus and parietes of the abdomen, after the patient had been in labour three days. (See *Essays and Obs. Physical and Literary, Vol. 2.*)

A laceration in the uterus, or the wound, made in this viscus in the Cæsarean operation, may give rise to dangerous and even fatal symptoms of strangulation, if any of the intestines insinuate themselves into the preternatural opening. When such an occurrence happens in the performance of the preceding operation, the intestine must be directly withdrawn and replaced. If the accident were to happen, when the child is extracted in the natural way, the bowel is to be pushed back into the abdomen from the uterus. Were the occurrence to take place several days after the operation, Sabatier inquires what ought to be done? A surgeon is said to have pushed back the intestine from the uterus as late as the third day. Sabatier thinks, that later it could not be done. In this circumstance, Baudeloque advises the operation, suggested by Pignatelli, namely, that of opening the abdomen and withdrawing the bowel from the place, in which it is incarcerated. But, there are serious objections to this proceeding. There is no certainty that the intestine is strangulated, and, if it were so, the adhesions, which are soon formed, would frustrate the design of the operator.

Gastrotomy has not only been recommended for cases, where the child has passed into the abdomen through a rupture of the uterus; it has likewise been advised for instances, in which the fœtus has grown in the Fallopian tube, ovary, or cavity of the abdomen. Here, indeed, the operation de-

serves to be called Cæsarean; for, in addition to the incision in the skin and muscles of the abdomen, it is necessary to open the pouch, in which the child is contained. The instances of conceptions in the Fallopian tube are not uncommon. Those in the ovary, and cavity of the peritoneum, are more rare. Sabatier conjectures, that most of the cases, reported to be of the latter kind, if attentively examined, would have been found to be in reality conceptions in the Fallopian tube.

Extra-uterine conceptions hardly ever arrive at maturity. However, the fœtus, formed in the Fallopian tube, has sometimes been known to attain the term of nine months, and then die, either from the impossibility of its expulsion, or from the insufficiency of the nourishment afforded it. The pouch in which it was contained, and the neighbouring parts, have then inflamed, and after becoming connected together by numerous adhesions, have suppurated. The abscess has burst, partly at some point of the circumference of the belly, and, partly, into the rectum; and the dead fœtus has been discharged piecemeal with the matter.

In other examples, the fœtus, instead of giving rise to abscesses, has become ossified, with the enveloping membranes, and continued in this state many years, without any other inconvenience to the patient, than what depended on the size and weight of the tumour within the abdomen.

Most frequently, however, the pouch containing the fœtus, bursts, about the middle of the ordinary period of gestation, and the child passes into the cavity of the peritoneum. At the same moment, the blood-vessels, ramifying on the parietes of the containing parts, usually pour forth into the abdomen so much blood, that the patients generally die in the space of a few hours. (See a case by Dr. Clark in *Trans. of a Society for the Improvement of Medical and Chirurgical Knowledge. Also another adverted to by Mr. C. Bell, in Medico-Chirurg. Trans Vol 4, p. 340.*)

Sabatier acquaints us, that two facts of this kind fell under his observation. The women were in the end of the fourth month of pregnancy. Excepting a swelling, which affected only one side of the abdomen, and frequent dragging pains in this cavity, there was no indication of any thing extraordinary. In other respects, the patients were well. They were both, all on a sudden, attacked with extremely acute pains, which lasted two or three hours. A more violent suffering, than the rest, was followed by entire ease. The abdomen subsided, and became as it were flat. An equal moderate warmth diffused itself over this part of the body. The skin lost its colour. Almost continual syncope occurred. The pulse was feeble and concentrated. The whole body was covered with a cold sweat, and the women died. The rapid course of these symptoms rendered it impossible for Sabatier to be of any assistance. The patients were actually dying, when he

was called to them. The examination of their bodies evinced, that the abdomen contained a large quantity of blood: that the children lay on the intestines, connected with the lacerated Fallopian tube by means of the umbilical cord; and that the tube itself, which was strongly contracted, presented no other tumour, except that which depended on the after-birth.

There is nothing that announces an extra-uterine pregnancy, with sufficient certainty, to justify any positive conclusion, respecting the nature of the case, before the ordinary time of parturition. In many women, the gravid uterus inclines to one side, and numerous pregnant females have dragging pains, which may depend upon other causes. Things, however, are different when the fœtus has lived to the ordinary period of parturition, and the woman is attacked with labour-pains; because, besides the unequivocal signs of the presence of a child in the abdomen, the womb is empty, and is little changed from its common state. Should we now, asks Sabatier, have recourse to the Cæsarean Operation, just as if the fœtus were in the womb? Can we be sure, that the pouch, which contains the child, will contract itself, like the uterus, and that the incision, which is in contemplation, will not give rise to a fatal hemorrhage? Would it be easy to separate, and remove the whole of the placenta? How could the discharge, analogous to the lochia, find an outlet, and would not its extravasation in the abdomen, be likely to prove fatal? Sabatier thinks, that the risk, which is to be encountered, is much less when things are left to nature. The child, indeed, must inevitably perish. It will either give rise to abscesses, with which it will be discharged in fragments, or it will remain for a length of time in the abdomen, without any urgent symptoms. Sabatier also calls our attention to the great precariousness of an infant's life, and expresses his opinion, that there can be no difficulty in deciding what conduct ought to be adopted. Happily, practitioners are not often placed in circumstances so delicate, and extra-uterine conceptions mostly perish before the end of the common period of gestation. We have then only to second the efforts of nature; either by promoting suppuration, if it should seem likely to occur; by making a suitable opening, or enlarging one that may have formed spontaneously; by extracting such fragments of the fœtus as present themselves; by breaking the bones, when their large size confines them in the abscess, as Littre did in an instance, where the abscess burst into the rectum; and, lastly, by employing suitable injections. (See *Sabatier's Médecine Opératoire*, Tom. 1.)

An extremely uncommon case of extra-uterine conception, was related a few years ago by Josephi: the fœtus having at length passed into the bladder by ulceration, and caused such affliction, as rendered an incision into that receptacle indispensable with the view of extracting the parts of the

fœtus lodged in it. The operation was done above the pubes; but, the internal mischief already existing was so great, that the patient did not recover. (*Ueber die Schwangerschaft ausserhalb der Gebärmutter*; Rostock, 1803. 8vo.)

Govei, p. 401, relates a case of ventral conception, in which instance the Cæsarean Operation was done, and the child preserved. A lady, aged 21, had a tumour in the groin, which was at first supposed to be an epiplocele, but an arterial pulsation was perceptible in it. In about ten weeks, the swelling had become as large as a pound of bread. Govei, solicited by the lady, opened the tumour. He first discovered a sort of membranous sac, whence issued a gallon of a limpid fluid. The sac was dilated, and a male fœtus found, about half a foot long, and large in proportion. It was perfectly alive, and was baptized.—After tying the umbilical cord, the placenta was found to be attached to the parts just behind, and near the abdominal ring; but it was easily separated. Govei does not mention whether the mother survived; but the thing would not be very astonishing, considering the situation of the fœtus. Bertrandi says he was unacquainted with any other example of the Cæsarean Operation being done in cases of extra-uterine fœtuses, so as to save both the mother and infant. This eminent man condemned operating, in ventral cases, on the ground that the placenta could not be separated from the viscera, to which it might adhere, or, if left behind, it could not be detached, without such inflammation and suppuration as would be mortal. But if, in addition to such objections, says Bertrandi, the operation has been proposed by many, and practised by none, we may conclude, that this depends on the difficulty of judging of such pregnancies, and of the time when the operation should be attempted. He puts out of the question the dilatations, which have been indicated for extracting dead portions of the fœtus, and also Govei's case, who operated without expecting to meet with a fœtus at all. (*Bertrandi Traité des Opérations de Chirurgie*, Chap. 5.)

Whenever the Cæsarean Operation, or gastrotomy, has been performed, the practitioner is not merely to endeavour to prevent inflammation, heal the wound, and appease any untoward symptoms, which may arise; he should also prevail upon the mother to suckle the child, in order that the lochia may not be too copious, and, after the wound is healed, she should be advised to wear a bandage, for the purpose of hindering the formation of a ventral hernia, of which, according to surgical writers, there is a considerable risk.

CALCULUS. Calculi form in the ducts of the salivary glands; in the kidneys, bladder, urethra, gall-bladder, &c. A paper on calculi formed in the lachrymal sac,

has just been published in Græfe's new Journal. (*Journ. für die Chir. No. 1, Berlin, 1820.*) For an account of what are commonly called stones in the bladder, refer to *Urinary Calculi*.

CALCULUS IN THE INTERIOR OF THE EYE. See Eye, &c.

CALLUS, *New bone*, or the substance which serves to join together the ends of a fracture, and for the restoration of destroyed portions of bone.

1. The old surgeons believed callus to be a mere inorganic concrete, a fluid poured out from the extremities of the ruptured vessels, which was soon hardened into bone. They always described it as an "exudation of the bony juice, and imagined that it oozed from the ends of broken bones, as gum from trees, sometimes too profusely, sometimes too sparingly. The reunion of broken bones, and the hardening of callus, they compared with the glueing together of two pieces of wood, or the soldering of a broken pot. (*A. Part.*) The old surgeons also conceived, that callus sometimes flowed into the joints, so as to form a clumsy, prominent protuberance.—They imagined that callus was a juice, which congealed at a determinate period of time, and they therefore had fixed days for undoing the bandages of each particular fracture. They supposed that its exuberance might be suppressed by a firm and well-rolled bandage, and its knobby deformities corrected by pillows and compresses; that it might be softened by frictions and oils, so as to allow the bone to be set anew. All their notions were mechanical; and their absurd doctrines have been the apology for all the contrivers of machines, from Hildanus down to Dr. Aitken and Mr. Gooch.

2. By Galen and Duhamel, however, a second doctrine was entertained, which imputed the formation of callus altogether to the periosteum and medullary texture, which were supposed to produce two solid rings round the fracture, the interspace between them being afterwards effaced.

3. A third opinion, maintained by Bordenave, and the best modern observers, is, that the process of nature, in the production of callus, bears a great resemblance to the changes which take place for the reunion of wounds of the soft parts.

A bone is a well-organized part of the living body; that matter, which keeps its earthy parts together, is of a gelatinous nature. The phosphate of lime, to which a bone owes its firmness, is deposited in the interstices of the gluten, undergoing a continual change and renovation. It is incessantly taken up by the absorbents, and secreted again by the arteries. It is this continual absorption and deposition of earthy matter, which forms the bone at first, and enables it to grow with the growth of the body. It is this unceasing activity of the vessels of a bone which enables it to renew itself when it is broken or diseased. In short, it is by various forms of one secret-

ing process, that bone is formed at first, is supported during health, and is renewed on all necessary occasions. Bone is a secretion, originally deposited by the arteries of the bone, which arteries are continually employed in renewing it. Callus is not a concrete juice, deposited merely for filling up the interstices betwixt fractured bones, but it is a regeneration of new and perfect bone, furnished with arteries, veins, and absorbents, by which its earthy matter is continually changed, like that of the contiguous bone. Indeed, there could be no connexion between the original bone and callus, were the latter only the inorganic concrete, which it was formerly supposed to be.

Notwithstanding the more accurate opinions now entertained, concerning callus, the supposition is still very common, that the slightest motion will destroy a callus, which is about to form. But, says Mr. John Bell, it is an ignorant fear, proceeding merely from the state of the parts not having been observed; for, when callus forms, the perfect constitution of the bone is restored; the arteries pour out from each end of a broken bone a gelatinous matter; the vessels, by which that gluten is secreted, expand and multiply in it, till they form, betwixt the broken ends, a well-organized and animated mass, ready to begin anew the secretion of bone. Thus, the ends of the bone, when the bony secretion commences, are nearly in the same condition, as soft parts which have recently adhered; and it is only when there is a want of continuity in the vessels, or when a want of energetic action incapacitates them from renewing their secretion, that callus is imperfectly formed. This is the reason, why in scorbutic constitutions, in patients infected with syphilis, in pregnancy, in fever, or in any great disorder of the system, or while the wound of a compound fracture is open, no callus is generated. (*John Bell's Principles of Surgery, Vol. 1, p. 500, 501.*) How far some of the latter statement is correct, or not, will be seen in the article *Fractures*.

For some time, the secretion of earthy matter is imperfect; the young bone is soft, flexible, and of an organization suited for all the purposes of bone; but, hitherto delicate and unconfirmed; not a mere concrete, like a crystallization of a salt, which, if interrupted in the moment of forming, will never form; not liable to be discomposed by a slight accident, nor to be entirely destroyed by being even roughly moved or shaken. Incipient callus is soft, fleshy, and yielding; it is ligamentous in its consistence, so that it is not very easily injured; and, in its organization, it is so perfect, that when it is hurt, or the bony secretion interrupted, the breach soon heals, just as soft parts adhere, and thus the callus becomes again entire, and the process is immediately renewed.

In consequence of the above circumstances, if a limb be broken a second time,

when the first fracture is nearly cured, the bone unites more easily than after the first accident; and Mr. J. Bell even asserts, that when it is broken a third, and a fourth time, the union is still quicker. In these cases, the limb yields, it bends under the weight of the body, which it cannot support; but, without any snapping or splintering of the bone, and, generally, without any overshooting of the ends of the part, and without any crepitation.

Callus is found to be more vascular, than the old bone. Mr. John Bell mentions an instance of a bone, which had been broken twelve years before he injected it, yet the callus was rendered singularly red. When a recently formed callus is broken, many of its vessels are ruptured, but some are only elongated, and it rarely happens that its whole substance is torn. It is easy to conceive, how readily the continuity of the vessels will be renewed in a broken callus, when we reflect on its great vascularity; and the vigorous circulation, excited by the accident in vessels already accustomed to the secretion of bone. These reasons show, why a broken or bent callus, is more speedily united, than a fractured bone.

When bones granulate, says Mr. Wilson, the granulations at first appear exactly similar to those of the soft parts, and, as in the soft parts, take place to restore any loss, which the bones may have suffered. This process is very similar to that of the first formation of bone. In the skull, membrane was first formed; and here also, in the process of restoration, the granulations change into membrane, and then into bone. In cylindrical bones, the granulations first produce a species of cartilage, and this is afterwards converted into bone. Thus, in the restoration of bone, nature is guided by the same laws, which prevail in its first formation. If the granulations, thrown out on the surface of a bone, be viewed in a microscope, they appear to form a number of small points, like villi, the bases of which first become similar to cartilage, and then to bone. "The preparations from the surface of granulating stumps, show the extreme delicacy of the first bony threads, and also their mode of uniting laterally with each other." (*J. Wilson's Lectures on the Structure, Physiology, and Diseases of the Bones, &c. p. 197, Sco. Lond. 1820.*)

And, in another place, he repeats, "I have examined several skulls on the death of the persons, at different periods, from days to years after pieces of bone had been removed, and before the vacancies had been completely filled up; but, I never could, in any of them, discover the least appearance of cartilage." A membrane here always precedes the formation of bone. (p. 210.) For additional observations on callus, see *Fracture. N. M. Muller, De Callo Ossium; 4to. Norimb. 1707; Duhamel in Mém. de l'Acad. Royale des Sciences an. 1741. p. 92, et 222; Boehmer, de Callo Ossium è rubia tinctorum radice pastu insectorum, 4to. Lips. 1752; Dethleef, Diss. exhibens Ossium Calli*

CALOMEL. (Submuriate of mercury; hydrargyri submuriatis. L. P.) Its extensive utility, in numerous surgical diseases, will be conspicuous in a large proportion of the articles in this work. When prescribed, as an alterative, the common dose is a grain once or twice a day; when ordered as a purgative, from three to eight grains may be given, and when directed, with the view of exciting salivation, one or two grains, conjoined with opium, are usually administered night and morning. This medicine, combined with opium, is frequently given, for the relief of what is usually termed *spasmodic stricture*, which is an attendant on severe cases of gonorrhœa.

CALX CUM POTASSA. This is a strong kind of caustic, chiefly used for making the eschars, when issues are formed in cases of diseased vertebrae, white swellings, morbid hip-joints, &c. (See *Vertebrae*.) This caustic is also sometimes used, though not so often as it was formerly, for opening buboes and other abscesses. Some are in the habit of making it into a paste with soft soap; they cover the part affected with adhesive plaster, in which there is a hole of the size of the eschar intended to be made; and into this aperture they press the paste till it touches the skin. A bandage is then applied to secure the caustic substance in its situation, till the intended effect is produced.

The action of calx cum potassa, in this way, however, is more inert and tedious, and, perhaps, on this account, more painful. Hence, many of the best modern surgeons never adopt this method; but, after covering the surrounding parts with sticking plaster, rub the caustic on the situation, where it is desired to produce an eschar, till the skin turns brown. The end of the caustic must first be a little moistened.

The calx cum potassa, is sometimes employed also for destroying fungous excrescences.

Before the port-wine injection was found to answer best for the radical cure of hydrocele, this caustic was often used as a means of cure. (See *Hydrocele*.) Mr. Else, a chief advocate for the latter method, used to mix the caustic with powdered opium, by which contrivance, it is said, though not with much appearance of truth, that the sloughs were made with little, or no pain to the patient.

Some assert that the potassa alone, acts more quickly, than when mixed with quicklime. I have not found this to be the fact, and, after trying both, give the preference to the calx cum potassa.

CAMPHOR, is used externally, chiefly as a means of exciting the action of the absorbents, and thus dispersing many kinds of swellings, extravasations, indurations, &c. Hence, it is a common ingredient in liniments. It has also the property of rousing the action of the nerves, and quickening the circulation in parts, on which it is rubbed. For this reason, in paralytic affections, it is sometimes employed. Perhaps, there is no composition, that has greater power in exciting the absorption of any tumour, or hardness, than camphorated mercurial ointment.

In cases of delirium, depending on the irritation of local surgical diseases, and in some descriptions of mortification, camphor is occasionally prescribed. It has also been recommended, as singularly useful for the relief of stranguries, even those depending on the operation of cantharides. But, although it may occasionally have succeeded, when given with this view, it not only does not always do so, but, it has been known to cause an opposite effect, sometimes producing great scalding in voiding the urine, and sometimes pains like those of labour. (*Medical Transactions*, Vol. 1, p. 470.) In chordee, its utility is generally acknowledged.

CANCER. (derived from *cancer*, a crab, to which, a part, affected with cancer, and surrounded with varicose veins, was anciently thought to have some resemblance.) *Carcinoma*.

The disease has two principal forms; one named *scirrhus*, or *occult cancer*; the other, *ulcerated*, or *open cancer*. According to the usual definition, as Mr. Pearson observes, an indolent scirrhus is a hard and almost insensible tumour, commonly situated in a glandular part, and accompanied with little, or no discolouration of the surface of the skin. But, when the disease has proceeded from the indolent to the malignant state, the tumour is unequal in its figure, it becomes painful, the skin acquires a purple, or livid hue, and the cutaneous veins are often varicose. (*Principles of Surgery*, § 331, 343.) The pain is remarked to be acute and lancinating, and its attacks recur with more or less frequency. At length, the tumour breaks, and is converted into cancer, strictly so called, or the disease in the state of ulceration.

The female breast, and the uterus, are particularly subject to the disease. The breasts of men are but rarely affected. The testes, lips, (especially the lower one of male subjects) the penis, the lachrymal gland and eye, the tongue, the skin, (particularly that of the face) the tonsils, the pylorus, the bladder, rectum, prostate, and a variety of other parts, are recorded by surgical writers as having frequently been the seat of scirrhus and cancer. They seem, however, to have comprehended an immense number of different malignant diseases under one common name, and, in many of the cases called cancerous, there are no vestiges of the true scirrhus structure.

OF SCIIRRHUS, OR CANCER, NOT IN THE UL-
CERATED STATE.

Mr. Abernethy has given a matchless history of this affection, as it appears in the female breast, where it most frequently occurs, and can be best investigated. Sometimes, says this valuable writer, it condenses the surrounding substance, so as to acquire a capsule; and then it appears, like many sarcomatous tumours, to be a part of new formation. In other cases, the mammary gland seems to be the nidus for the diseased action. In the latter case, the boundaries of the disease cannot be accurately ascertained, as the carcinomatous structure, having no distinguishable investment, is confused with the rest of the gland. Sir Everard Home also remarks, that when the disease originates by a small portion of the glandular structure of the breast becoming hard, which is very commonly the case, it is readily distinguished by the hard part never having been perfectly circumscribed, and giving more the feel of a knot in the gland itself, than of a substance distinct from it. In each of these instances, carcinoma begins at a small spot, and extends from it in all directions, like rays from a centre. This is one feature distinguishing this disease from many others, which, at their first attack, involve a considerable portion, if not the whole, of the part, in which they occur. The progress of carcinoma is more or less quick in different instances. When slow, it is in general unremitting. Mr. Abernethy thinks, that though the disease may be checked, it cannot be made to recede by the treatment, which lessens other swellings. On this point, however, he is not positive; for, surgeons have informed him, that diseases, which eventually proved to be carcinomatous, have been considerably diminished by local treatment. With great deference to Mr. Abernethy, we may be allowed to remark in this place, that every tumour, which ends in cancer, is not from the first of this nature, though it has in the end become so; consequently, it may at first yield to local applications, but will not do so after the cancerous action has commenced. Hence, Mr. Abernethy's opinion, that a true carcinomatous tumour cannot be partially dispersed, at least, remains unweakened by the fact, that some tumours have at first been lessened by remedies, though they at last ended in cancer. Sir E. Home's observations tend to prove, that any sort of tumour may ultimately become cancerous.

Without risk of inaccuracy, we may set down the backwardness of a scirrhus swelling to be dispersed, or diminished, as one of its most confirmed features. This obdurate and destructive disease excites the contiguous parts, whatever their nature may be, to enter into the same diseased action. The skin, the cellular substance, the muscles, and the periosteum, all become affected, if they are in the vicinity of cancer. This very striking circumstance distinguishes carcinoma, says Mr. Aber-

nethy, from several other diseases. In what this author calls *medullary sarcoma*, the disease is propagated along the absorbing system; but the parts immediately in contact with the enlarged glands do not assume the same diseased actions. Neither in the *tuberculated* species does the ulceration spread along the skin, but destroys that part only which covers the diseased glands. According to Mr. Abernethy, a disposition to cancer existing in the surrounding parts, before the actual occurrence of the diseased action, was a circumstance noticed by Mr. Hunter. Hence arose the following rule in practice: *That a surgeon ought not to be contented with removing merely the indurated, or actually diseased part, but that he should also take away some portion of the surrounding substance, in which a diseased disposition may probably have been excited.* In consequence of this communication of disease to the contiguous parts, the skin soon becomes indurated, and attached to a carcinomatous tumour, which, in like manner, is fixed to the muscles, or other part, over which it was formed.

As a carcinomatous tumour increases, it generally, though not constantly, becomes unequal upon its surface, so that this inequality has been considered as characteristic of the disease. A lancinating pain is common; but it is not experienced in every case, without exception. It is also a symptom, attending other tumours, which are unlike carcinoma in structure, and it cannot, therefore, be deemed an infallible criterion of the nature of the disease. (*Abernethy's Surgical Works, Vol. 2, p. 69, &c.*)

A hard and painful glandular swelling, having a disposition to become cancer, says Richter, is the common, but, inadequate and erroneous definition of scirrhus. The disease is not regularly attended with swelling; sometimes scirrhus parts diminish in size and shrink. Hardness is not a characteristic property; for many tumours, which are not scirrhus, are exceedingly indurated. The disease is not always situated in the gland: it frequently attacks structures, which cannot be called glandular; and hard glandular swellings are often seen, which do not partake of scirrhus.—The disposition to cancer cannot be enumerated among the marks of scirrhus, since it is not discoverable, till carcinoma has actually commenced. Its termination in open cancer, is not an invariable occurrence; and other tumours become cancerous, to which no one would apply the term scirrhus. (*Anfangsgr. der Wundarzn. B. 1.*)

Scientific surgeons ought undoubtedly to have a definite meaning when they employ the term scirrhus; the word is generally used most vaguely; and, perhaps, influenced by its etymology, surgeons call an immense number of various morbid indurations scirrhus, which are not at all of a malignant or dangerous character.

I have always considered scirrhus as a diseased hardness, in which there is a propensity to cancerous ulceration, and a

greater backwardness to recede, than exists in any other kind of diseased hardness, although the skin may occasionally not break during life, and a few scirrhus indurations may have been lessened.

Though Richter states, that this disposition cannot be discovered, till carcinoma has actually taken place; though Mr J. Buras and Sir E. Home confirm, that other indurations and tumours may terminate in cancer; though Mr Abernethy shows, that sarcomatous and encysted tumours may end in most malignant diseases, and such as from their severity merit the name of cancer; (*Chir. Works*, p. 83.) yet, it is now well ascertained, that, in all these instances, the changes, which precede cancerous ulceration, bear no resemblance to those of a true malignant scirrhus.

The puckering of the skin, the dull leaden colour of the integuments, the knotted and uneven feel of the disease, the occasional darting pains in the part, its fixed attachment to the skin above, and muscles beneath, form so striking an assemblage of symptoms, that, when they are all present, there cannot be the smallest doubt, that the tumour is a scirrhus, and that the disease is about to acquire, if it have not already acquired, the power of contaminating the surrounding parts, and the lymphatic glands, to which the absorbents of the diseased part tends.

As Sir Everard Home has observed, the truly scirrhus tumour, which is known to be capable of changing into the true open cancer, when allowed to increase in size is known to be hard, heavy, and connected with the gland of the breast; and, when moved, the whole gland moves along with it. The structure of a scirrhus tumour in the breast, is different in the various stages of the disease; and a description of the appearances, exhibited in the three principal ones, may give a tolerable idea of what the changes are, which it goes through, previous to its breaking, or becoming, what is termed, an open cancer.

When a section is made of such a tumour, in an early stage, provided the structure can be seen to advantage, it puts on the following appearance: the centre is more compact, harder to the feel, and has a more uniform texture, than the rest of the tumour; and is nearly of the consistence of cartilage. This middle part does not exceed the size of a silver penny; and from this, in every direction, like rays, are seen ligamentous bands, of a white colour, and very narrow, looking, in the section, like so many extremely irregular lines, passing to the circumference of the tumour, which is blended with the substance of the surrounding gland. In the interstices, between these bands, the substance is different, and becomes less compact towards the outer edge. On a more minute examination, transverse ligamentous bands of a fainter appearance, form a kind of network, in the meshes of which the new-formed substance is enclosed. This structure accords with what Dr. Baillie describes

to be the case in cancerous diseases of the stomach and uterus.

In a more advanced stage of the tumour, the whole of the diseased part has a more uniform structure; no central point can be distinguished; the external edge is more defined, and distinct from the surrounding gland; and the ligamentous bands, in different directions, are very apparent, but do not follow any course, that can be traced.

When the tumour has advanced to what may be called cancerous suppuration, which, however, does not always happen in the centre, before it has approached the skin, and formed an external sore; it then exhibits an appearance totally different from what has been described. In the centre is a small irregular cavity, filled with a bloody fluid, the edges of which are ulcerated, jagged, and spongy. Beyond these there is a radiated appearance of ligamentous bands, diverging towards the circumference; but the tumour near the circumference is more compact, and is made up of distinct portions, each of which has a centre, surrounded by ligamentous bands, in concentric circles.

In some instances, scirrhus has no appearance of suppuration, or ulceration, in the centre, but consists of a cyst, filled with a transparent fluid, and a fungous excrescence, projecting into this cavity, the lining of which is smooth and polished.—When a large hydatid of this kind occurs, a number of very small ones have been found, in different parts of the same tumour; and, in other cases, there are many very small ones, of the size of pins' heads, without a large one. These hydatids are, by no means, sufficiently frequent in their occurrence to admit of their forming any part of the character of a cancerous tumour.—(*Home's Observations on Cancer*, p. 156, &c. 8vo. Lond. 1805.)

In the fourth chapter of this work, the author relates two cases of hydatids found in the breast. In the first, the contents of the cyst were bloody serum; in the second, a clear fluid. These two cases of simple hydatids in the breast, unconnected with any other diseased alteration of structure, led Sir E. Home to consider more particularly the nature of such hydatids, as are sometimes found in cancerous breasts; and, he believes, that they form no real part of the cancerous disease, but are accidental complaints superadded to it; and it is this gentleman's belief, that, as they occur in the natural state of the gland, they are much more likely to do so in disease. (*Op. cit.* p. 108, 159.)

Sir E. Home defines what he means by cancer, as follows: "As cancer is a term too indiscriminately applied to many local diseases for which we have no remedy, though they differ very much among themselves, it becomes necessary to state what the complaints are which I include under this denomination. The present observations respecting cancer, apply only to those diseased appearances, which are capable of

contaminating other parts, either by direct communication, or through the medium of the absorbents; and when they approach the skin, produce in it small tumours of their own nature, by a mode of contamination, with which we are at present unacquainted.

"There is a disease, by which parts of a glandular structure are very frequently attacked, particularly the os tincæ, the alæ of the nose, the lips, and the glans penis. This has been called cancer, but differs from the species, of which we are now treating, in not contaminating the neighbouring parts with which it is in contact; and neither affecting the absorbent glands, nor the skin at a distance from it. It is, properly speaking, an eating sore, which is uniformly progressive; whereas, in cancer, after the sore has made some progress, a ridge is formed upon the margin, and the ulceration no longer takes that direction. It also differs from a cancer, in admitting of a cure in many instances, and under different modes of treatment.

"From the facts which have been stated, (*See the cases detailed in this gentleman's work,*) it appears that cancer is a disease which is local in its origin. In this respect the cases (alluded to) only confirm an opinion very generally received among medical practitioners; but, in favour of which no series of facts had been laid before the public, of sufficient force entirely to establish the opinion." (P. 145, &c.)

Sir E. Home endeavours to establish a second point, that cancer is not a disease which immediately takes place in a healthy part of the body; but one, for the production of which it is necessary, that the part should have undergone some previous change, connected with the disease. In proof of this, Sir E. Home adduces the two first cases in his work, and the innumerable instances in which a pimple, small tumour, or wart upon the nose, cheek, or prepuce, may remain for ten, fifteen, or thirty years, without producing the smallest inconvenience; but, at the age of sixty or seventy, upon being cut in shaving, bruised by any accidental violence, or otherwise injured, assumes a cancerous disposition.

All the cases of induration of the gland of the breast, or of indolent tumours in it, which have continued for years without producing any symptom, and, after being irritated by accidental violence, have assumed a new disposition, and become cancerous, admit of the same explanation; and are adduced as so many proofs of the truth of this latter position. (P. 147, &c.)

However, the doctrine that certain tumours may change their nature, and change into cancer, is one which is sometimes looked upon with suspicion. "Improper treatment may without doubt exasperate diseases, and render a complaint, which appeared to be mild and tractable, dangerous or destructive; but, to aggravate the symptoms, and to change the form of the disease, are things, that ought not to be

confounded. I do not affirm (says Mr. Pearson) that a breast, which has been the seat of a mammary abscess, or a gland that has been affected by scrofula, may not become cancerous; for they might have suffered from this disease, had no previous complaint existed; but, these morbid alterations generate no greater propensity to cancer, than if the parts had always retained their natural condition. There is no necessary connexion between cancer and any other disease; nor has it ever been clearly proved, that one is convertible into the other." (*Pract. Obs. on Cancerous Complaints*, p. 8.) To the latter way of thinking, Mr. Abernethy also inclines; for, in speaking of the occurrence of cancer in parts previously diseased in another manner, he confesses, that his own observations have not led him to believe, that this change is common. "Cases of tumours, which have remained indolent for twenty or more years, becoming cancerous at an advanced period of life, are not unfrequently met with;" but, (says Mr. Abernethy,) the patients "might have been liable to the formation of a cancerous disease, even if no diseased structure had previously existed." A degree of indecision, however, appears to be thrown upon this statement by the admission, that cancer is more likely to begin in parts previously diseased. (*Surg. Works*, Vol. 2, on Tumours, p. 87.)

The following are some of the most distinguishing characters of scirrhus. A scirrhous induration seldom acquires the magnitude, to which almost all other tumours are liable to grow, when no steps are taken to retard their growth. Many scirrhi are attended even with a diminution, or shrunk state, of the part affected.

Scirrhi are generally more fixed, and less moveable, than other sorts of tumours; especially, when the latter have never been in a state of inflammation.

With the exception of the fungus hæmatoides, other diseases do not involve in their ravages indiscriminately every kind of structure, skin, muscle, cellular substance, &c. and the integuments seldom become affected before the distention, produced by the size of such swellings, becomes very considerable. In scirrhous cases, the skin soon becomes contaminated, discoloured, and puckered.

Some few tumours may be harder, and heavier, than a few scirrhi; but, the reverse, is commonly the case.

As other indurations, and tumours, may assume the cancerous action, and even end in cancerous ulceration; and, as some true scirrhi, when not irritated by improper treatment may continue stationary for years; the occurrence of actual carcinoma cannot prove, that the preceding state was that of scirrhus. The only criterion of the latter disease is deduced from the assemblage of characters already specified; for, except the peculiar puckering, and speedy leaden discolouration of the skin, no other appear-

ances, considered separately, form any line of discrimination.

The white ligamentous bands, around a scirrhus, form a very characteristic mark of the complaint, at least as it presents itself in the female breast; but, these cannot be detected, till the disease has been removed. Hence, how manifestly prudent it must be to take away a considerable portion of the substance surrounding a scirrhus tumour! Were any of these white bands left, the disease would inevitably recur.

Mr. Pearson has never yet met with an unequivocal proof of a primary scirrhus in an absorbent gland, and, (says he) "if a larger experience shall confirm this observation, and establish it, as a general rule, it will afford material assistance in forming the diagnosis of this disease. (*Pract. Obs. on Cancerous Complaints*, p. 5.) Sir E. Home, however, has given the particulars of one case, which seemed to him to have commenced in one of the lymphatic glands, situated between the nipple and the axilla. (*Obs. on Cancer*, p. 161.) The position laid down by Mr. Pearson, that when the disease originates in those glands, it will rarely be found to be of a cancerous nature, may yet be very generally correct.

OF CANCER IN THE STATE OF ULCERATION.

According to the observations of Mr. Abernethy, the diseased skin, covering a carcinomatous tumour of the breast, generally ulcerates, before the swelling has attained any great magnitude; a large chasm is then produced in its substance, partly by a sloughing, and partly by an ulcerating process. Sometimes, when cells, contained in the tumour, are by this means laid open, their contents, which are a pulpy matter of different degrees of consistence, and various colours, fall out, and an excoriating ichor issues from their sides. This discharge takes place with a celerity, which would almost induce belief, that it can hardly result from the process of secretion. When the diseased actions have, as it were, exhausted themselves, an attempt at reparation appears to take place, similar to that which occurs in healthy parts. New flesh is formed, constituting a fungus of peculiar hardness, as it partakes of the diseased actions, by which it was produced. This diseased fungus occasionally even cicatrizes. But, though the actions of the disease are thus mitigated; though they may be for some time indolent and stationary; they never cease, nor does the part ever become healthy.

In the mean while, the disease extends through the medium of the absorbing vessels. Their glands become affected, at a considerable distance from the original tumour. The progress of carcinoma in an absorbent gland, is the same as that, which has been already described. The disease is communicated from one gland to another, so that after all the axillary glands are affected, those which lie under the collar

bone, at the lower part of the neck, and upper part of the chest, become disordered. Occasionally, a gland, or two, become diseased higher up in the neck, and apparently out of the course which the absorbed fluids would take. As the disease continues, the absorbent glands, in the course of the internal mammary vessels, become affected. In the advanced stage of carcinoma, a number of small tumours, similar in structure to the original disease, form at some distance, so as to make a kind of irregular circle round it.

The strongest constitutions now sink under the pain and irritation, which the disease creates, aggravated by the obstruction, which it occasions to the function of absorption, in those parts, to which the vessels leading to the diseased glands belong. Towards the conclusion of the disease, the patient is generally affected with difficulty of breathing, and a cough. (See *Abernethy's Surgical Works*, Vol. 2, p. 72, &c.)

In the above species of carcinoma, described by Mr. Abernethy, the part is peculiarly hard, and rarely attains considerable magnitude. He admits, however, that there are varieties, and speaks of another case, in which the integuments sometimes remain pale and pliant; "and a surgeon, who first sees the breast in this state, may doubt whether the disease be actual cancer, or common sarcoma. The substance of the tumour is also much less hard, than in the specimen first described; yet, it is more compact and weighty, than most other diseases of the same bulk, which are not carcinomatous. If the history of the disease accords with that of carcinoma; that is to say, if it began in a small district, and regularly and unabatingly attained its present magnitude; if the surface of the tumour be unequal, having produced in various parts roundish projecting knobs, the disease will almost invariably be found to be carcinoma. The skin will soon adhere to one, or more of these prominences; it will ulcerate and expose the subjacent parts; and the future progress of the disease will accord to that of the harder and smaller specimen," except that the absorbents are much less liable to be affected. (*Vol. cit.* 85.)

The edges of a cancerous ulcer are hard, ragged, and unequal, very painful, and reversed in different ways, being sometimes turned upwards and backwards, and, on other occasions inwards. The whole surface of the sore is commonly unequal: in some parts, there are considerable risings, whilst, in others, there are deep excavations. The discharge, for the most part, is a thin, dark coloured, fetid ichor; and is often possessed of such a degree of acrimony, as to excoriate, and even destroy, the neighbouring parts. In the more advanced stages of the disease, a good deal of blood is often lost from the ulcerated vessels. A burning heat is universally felt over the ulcerated surface; and, this is the most tormenting symptom, that attends the disorder. Those shooting, lancinating pains, which

are generally very distressing in the occult state of the complaint, became now a great deal more so. Notwithstanding cancerous diseases are not always situated in glandular parts, the situation of such sores affords some assistance in the diagnosis; for, six times as many cancerous affections occur in the lips, and female breasts, as in all the rest of the body together. (*B. Bell.*)

By some of the old writers, the causes of cancer were referred to the presence of worms, which destroyed the parts, and produced all the local mischief. Strange as this doctrine may appear, one very analogous to it was adopted by the late Dr. Adams. (*Observations on Morbid Poisons.*) When hydatids found their way into a solid substance, he supposed, that the effect would be cancer; and he conjectured, that the success of an operation would depend, in a great measure, upon these animals being confined in a common cyst, for then they could be entirely removed; whereas, if they were unconnected, some of the smaller ones would be likely to remain. The absurdity of this doctrine, and the eccentric reasoning, by which it is supported, make it quite unnecessary here to fatigue the reader with an explanation of it. Concerning the manner, in which these animals produce the symptoms of cancer, we are told, that "this enlargement of a foreign body in a solid substance, and so extremely sensible, as the breast, cannot but be attended with intense pain, and frequent inflammation:" a doctrine not far removed, says Mr. J. Burns, from that taught in the humoral schools, which maintained, that the coagulation, and inspissation of the fluids, distended the follicles of the glands, producing many cavities, and much pain. (*J. Burns on Inflammation, Vol. 2.*) Though hydatids are occasionally found in cancerous tumours, they are not found often enough to make any part of the character of the disease; and they are met with in cases in which there is not the least vestige of such disorder.

After cancer had continued some time, it was believed, that the matter was absorbed into the blood, and that all the humours were speedily assimilated. Hence was explained the fatal and rapid progress of relapses, after an apparent cure. The only effect of absorption, however, is on the lymphatic glands, which intervene betwixt the sore and the heart; for, beyond these, the absorbed matter is changed in its nature and properties. (*Burns.*)

In many instances, cancer is evidently produced by the same causes, which are capable of producing simple inflammation. It is, however, a general opinion, that cancer arises frequently from some unknown and mysterious cause, which we cannot detect, and which, therefore, has been resolved into a constitutional taint. But, as far as we know, the constitution is perfectly healthy in the commencement of this disease; nor is there the smallest proof, that resembles scrofula, in depending on any

peculiarity of constitution, before the causes operate. Blows, bruises, &c. may give rise to cancer; but, in many instances, there is no evident local cause acting directly on the part. In the breast, cancer frequently commences, without the interference of any topical agent. In these cases, however, there is always an irregularity, or disappearance of the menses; and the affection of the mamma may be supposed to depend on sympathy between it and the uterus. Certain it is, that cancer is very frequent about the time of life, when the menstrual discharge ceases.

It is a commonly received opinion, that cancer is an hereditary disease, or observed to prevail a good deal in particular families. Sir Everard Home has endeavoured to reconcile this sentiment to the doctrine of the disease being at first entirely of a local nature; circumstances, which seem incompatible: "It is now universally admitted (says he) that children take after their parents in the general structure of their bodies, and therefore will be more or less liable to have the different solids, of which they are composed, disturbed by the same causes; and when a violence of any kind is committed upon them, it may be productive of the same diseases.—In some families, the venereal disease shall always appear in the form of gonorrhœa [?]; in others again, rarely or never in that form, but, in that of chancre. [?] Strictures in the urethra are common in some families: they have taken place in a father, and all his sons from very slight causes; such indeed as would not have produced the disease in others. Yet, stricture cannot be called hereditary, because it is a local complaint, arising from a local inflammation differing in different people, according to the natural irritability of the parts, which are affected. In this way, and this only, can cancer run in families, and be an hereditary disease, &c." (*Obs. on Cancer, p. 150.*) The observations, which this gentleman has published respecting cancer, are unquestionably some of the most valuable which have yet been collected; but, I am doubtful about the correctness of one term, which is frequently met with in his work, viz. *cancerous poison*. At all events, I am not at present acquainted with any facts, which satisfactorily demonstrate the existence of such virus; and, from some circumstances briefly mentioned in vol. I of the 4th edition of the *First Lines of the Practice of Surgery*, the reality of a poison of this nature would seem at least questionable. In support of the belief in the existence of a cancerous virus, it has been observed, however, "that we scarcely ever see glands diseased out of the course, which the absorbed matter would naturally take, though they are affected in this manner in diseases, which can be propagated by irritation." (*Abernethy's Surg. Works, Vol. 2, on Tumours, p. 75.*)

Undoubtedly, cancer is most common in elderly persons; but no age is exempt from the disease. Mr. J. Burns has seen it dis-

tinctly marked, and attended with a fatal event, in children of five years old; he mentions two instances of the eye being affected in such subjects, though from the late observations of Mr. Wardrop, we may now reasonably suspect, that these examples were really cases of the fungus hæmatodes. An instance, in which a cancerous disease of the breast began at the age of fifteen, is related by Sir E. Home. (*Obs. on Cancer, &c. p. 50.*)

TREATMENT OF CANCER.

Cancers have sometimes been supposed to be a general disorder of the system; sometimes merely local affections. This is a point of much importance in practice; for, if cancers are originally only local affections, no objection can be made to extirpating them. They who think, that cancer is a constitutional disease, regard the operation as useless, perhaps hurtful, inasmuch as it may convert a scirrhus into an open cancer, or make the affection occur in some other part.

Some of the best practitioners of the present day, however, reject the doctrine of cancer depending on constitutional causes; and, we have stated Sir E. Home's sentiments, in opposition to the opinion. When cancer breaks out again, in the same part, after the performance of an operation, it is often owing to some portion of the disease having been blameably left behind, or to the operation having been put off too long. How likely it is, that some of the cancerous disease may be left unremoved by the operator, is obvious on considering the manner, in which the white bands, resembling ligament, shoot into the surrounding fat; and that, even the fibres of the muscles, beneath a cancerous disease, are frequently affected. At the same time, it must be allowed, that the disease is sometimes, to all appearances, so freely and completely removed, that its recurrence may be imputed, perhaps with equal probability, to the continued operation of the same unknown cause, which originally produced the first cancerous mischief.

Until late years, the accounts given of the results of operations for cancers were so unpromising, that they deterred many patients from undergoing a timely operation; which, for cancerous complaints, is the only remedy to be depended on, with which we are as yet acquainted. As Mr. B. Bell remarks, the great authority of Dr. Alexander Monro must have had no inconsiderable influence even with practitioners, in making them much more backward in undertaking the extirpation of cancers, than they otherwise would have been. "Of near sixty cancers," says he, "which I have been present at the extirpation of, only four patients remained free of the disease, at the end of two years: three of these lucky people had occult cancers in the breast, and the fourth had an ulcerated cancer on the lip." (*Edinb. Med. Essays, Vol. 5.*) Dr. Monro also observes, that, in

those, in whom he saw the disease relapse, it was always more violent, and made a quicker progress, than it commonly did in others, on whom no operation had been performed. Hence he questions, "whether ought cancerous tumours to be extirpated, or ought the palliative method only to be followed?" and, upon the whole, he concludes against their extirpation, except in such as are of the occult kind, in young healthy people, and have been occasioned by bruises, or other external causes.

More modern experience, however, has afforded a very different result, and given ample encouragement to the early performance of an operation, and even to making an attempt to cut away the disease, in every instance, both of the occult and ulcerated kind, when such a measure can be so executed, as not to leave a particle of the cancerous mischief behind.

Mr. Hill, in 1772, published some valuable remarks on the present subject. At this period, he had extirpated from different parts of the body eighty-eight genuine cancers, which were all ulcerated, except four; and all the patients, except two, recovered of the operation. Of the first forty-five cases, only one proved unsuccessful; in three more, the cancer broke out again in different parts; and, in a fifth, there were threatenings of some tumours, at a distance from the original disease. These tumours, however, did not appear, till three years after the operation; and the woman was carried off by a fever, before they had made any progress. All the rest of the forty-five continued well, as long as they lived: or are so, says Mr. Hill, at this day. One of them survived the operation above thirty years; and, fifteen were then alive, although the last of them was cured in March, 1761.

Of the next thirty-three, one lived only four months; and, in five more, the disease broke out afresh, after having been once healed. The reason why, out of forty-five cases, only four or five proved unsuccessful, and six, out of thirty-three, was as follows: "The extraordinary success I met with, (says Mr. Hill,) made cancerous patients resort to me from all corners of the country, several of whom, after delaying till there was little probability of a cure by extirpation, or any other means, forced me to perform the operation, contrary both to my judgment and inclination."

Upon a survey in April, 1764, made with a view to publication, the numbers stood thus: Total cured, of different ages from eighty downwards, sixty-three; of whom there were then living thirty-nine. In twenty-eight of that number, the operation had been performed more than two years before; and, in eleven, it had been done in the course of the last two years. So that, upon the whole, after thirty years' practice, thirty-nine, of sixty-three patients, were alive and sound; which gives Mr. Hill occasion to observe, that the different patients lived as long after the extirpation of the cancers, as according to the bills of morta-

lity, they would have done, had they never had any cancers, or undergone any operation.

The remaining twenty-five, which complete the eighty-eight, were cured since the year 1764. Twenty-two of these had been cured, at least, two years; and some of them, it may be remarked, were seventy, and one ninety years old.

In the year 1770, the sum of the whole stood thus: Of eighty-eight cancers, extirpated at least two years before; not cured, two; broke out afresh, nine; threatened with a relapse, one; in all, twelve, which is less than a seventh part of the whole number. At that time, there were about forty patients alive and sound, whose cancers had been extirpated above two years before.

Mr. B. Bell, who was present at many of these cases, bears witness to Mr. Hill's accuracy; and the former very judiciously states, that, "from these and many other authenticated facts, which, if necessary, might be adduced, of the success attending the extirpation of cancers, there is, it is presumed, very great reason, for considering the disease, in general, as a local complaint, not originally connected with any disorder of the system." With respect to Mr. Bell's opinion, that a general cancerous taint seldom, or perhaps never, occurs, but in consequence of the cancerous virus being absorbed into the constitution from some local affection, much doubt attends even this supposition, though the practical inference from it is what cannot be found fault with: viz. in every case of real cancer, or rather in such scirrhusities, as from their nature, are known generally to terminate in cancer, we should have recourse to extirpation as early as possible; "and if this were done soon after the appearance of such affections, or before the formation of matter takes place, their return would probably be a very rare occurrence." (*System of Surgery*, Vol. 7.)

After comparing the different accounts of success given by Monro and Hill, well might Richter say: "*Jure sane dixeris, de uno eodemque morbo hos viros loqui, dubitari fere potest.*" (*Obs. Chir. Fasc. 3.*)

MEDICINES AND PLANS, WHICH HAVE BEEN TRIED FOR THE CURE OF SCIRRHUS AND CANCER.

It is a contested point, whether a truly cancerous disease is susceptible of any process, by which a spontaneous cure can be effected. It appears certain, however, that a violent inflammation, ending in sloughing, may sometimes accomplish an entire separation of a cancerous affection, and that the sore, left behind, may then heal. Facts, confirming this observation, are occasionally exemplified in cases, where caustic is used, and accidental inflammations have led to the same fortunate result, as we may be convinced of by examples recorded by Sir Everard Home, Richerand, &c. The latter writer, adverting to the effort, which nature sometimes makes to rid herself

of the disease, on the inflammation and bursting of the tumour, takes the opportunity to relate the following case. A woman, aged forty-eight, of a strong constitution, was admitted into the hospital of St. Louis, with a cancerous tumour of the right breast. The swelling, after becoming softer, and affected with lancinating pains, was attacked with an inflammation, which extended to the skin of the part, and all the adjacent cellular membrane. The whole of the swelling mortified, and was detached. A large sore, of healthy appearance, remained after this loss of substance, and healed in two months. (*Nosographie Chir. T. 1, p. 381, Edit. 2.*)

In general, however, it must be confessed, that inflammation, attacking a cancerous disease, renders things worse instead of better, and by converting occult cancers into ulcerated ones, hastens the patient's death, or, at all events, renders his cure more difficult, and forbids any attempts, which, on such a principle, might be made for his relief.

Of the general remedies, narcotics, such as cicuta, opium, nightshade, &c. have been employed with most confidence.

Cicuta owed its reputation to the experimenting talent of Storck, who has written several libelli on this plant. According to him, cicuta possesses very evident powers over cancer, and has cured a great many cases; but, in less prejudiced hands, it has been found much less successful; and even in many of the instances, adduced by Baron Storck, of its utility, it is by no means proved, that the disease was really cancer. The public have now, with great reason, very little reliance on this medicine. Mr. J. Burns declares, that, in cancerous ulceration, he never knew cicuta to produce even temporary melioration.

The common way of exhibiting hemlock is to begin with small doses, and increase them gradually, until they produce vertigo. We may begin with two grains of the extract, or four of the powder, recently prepared, twice, or thrice a day, and the quantity is to be gradually increased. In this way, some patients have at last been able to take an ounce of the extract daily; but, says Mr. Burns, if a much less quantity, than this, produce no good effect, we may consider it as useless to continue a remedy, which, in this dose, must injure the constitution every day that it is continued. On the continent, hemlock has been used in the form of a bath; but, this method is so disagreeable, that few will submit to it.

Belladonna was highly recommended by Lambergen. During its use, he kept the bowels open with clysters, administered every second day. The dose should be, at first, a grain of the dried leaves, made into a pill. This, in the beginning, is to be given in the morning and evening, and afterwards more frequently. The reputation of belladonna has not been supported by much success.

Hyosciamus has often been tried in can-

cerous cases, and was held in great estimation by the ancients. Mr. J. Burns says, he has employed it occasionally, but with little effect. The common dose at first is three grains of the extract.

Aconitum has also been given; and, as it is a very powerful and dangerous narcotic, a patient usually begins with only half of a grain of the extract night and morning. *Solanum dulcamara*, *Paris quadrifolia*, *phytolacca*, &c. have been recommended; but, they are now hardly ever employed; which is a sufficient proof of their inefficacy. Mr. J. Burns tried the hydro-sulphuret of ammonia, without any benefit. Richter prescribed the laurus cerasus, but with very little success. The dose of the distilled water being uncertain, four or five grains of the fresh leaves may be infused in a little water, as a dose.

The digitalis diminishes vascular action, and may act on scirrhi, like abstinence, bleeding, &c. It has, however, no specific virtue in curing cancerous diseases.

Opium is seldom employed, with an intention of curing cancer, although it probably has just as much power of this kind, as other narcotics, which have been more frequently used. For the purpose of lessening the pain of cancerous diseases, opium is very freely employed.

Tonics may sometimes improve the general health; but, as they never produce any effect on the local disease, they are now seldom exhibited.

Justamond thought arsenic a specific for cancers. Future experience has not, however, confirmed the truth of this opinion, though there are many practitioners, who continue to think highly of the efficacy of this mineral in certain forms of disease, which have sometimes been classed with cancer, and in many cases of lupus, and malignant ulcers of the tongue, and other parts, it may really possess greater claims to further trial, than perhaps any other medicine, yet suggested. It unquestionably cures numerous ill-looking sores, on the face, lips, and tongue, and is one of the best remedies for lupus. Mr. Hill observes: "Experience has furnished me with some substantial reasons for considering arsenic as a medicine of considerable merit, both with regard to actual cancer and scirrhus, which may one day terminate in that horrible species of ulcer; and although I cannot as yet say it will remove the one, or cure the other, as certainly and safely as mercury commonly does a syphilitic swelling, or open sore, yet, it will, in a great majority of cases, retard the progress of the true scirrhus tumour, and often prevent its becoming cancer. In some, it has appeared, to dissipate such swellings completely." (See *Edinb. Med. and Surgical Journ.* Vol. 6. p. 58.)

Mercury, in conjunction with decoctions of guaiacum, sarsaparilla, &c. has been recommended; but, as Mr. J. Burns remarks, no fact is more certainly ascertained, than that mercury always exasperates the dis-

ease, especially, when in the ulcerated state.

Sulphate of copper has been tried; but, at present, it retains no character, as a remedy for cancer. The same may be said of muriated barytes.

The carbonate (rust) of iron was particularly recommended by Mr. Carmichael. Besides the carbonate of iron, he sometimes prescribed the tartrate of iron and potass, and the phosphate, oxyphosphate, and suboxyphosphate of the metal. Some constitutions can bear these preparations only in small quantities; they affect most patients with constipation, and many with headach and dyspnea. These circumstances, therefore, must be attended to in regulating the dose. The above gentleman has seldom given less than thirty grains, in divided doses, in a day, or exceeded sixty. He prefers the suboxyphosphate for internal use, and states, that it answers best in small doses, frequently repeated. It should be blended with white of egg, have a little pure fixed alkali added, and then be made into pills with powdered liquorice. Aloes is recommended for the removal of costiveness. When half a grain is combined with a pill, containing four grains of carbonate of iron, and taken thrice a day, the constipation will be obviated. When the internal use of iron brings on headach, difficult respiration, a quick, sometimes full pulse, which is also generally hard and wiry, excessive languor, lassitude, &c. and such symptoms become alarming, the iron is to be left off, and four grains of camphor given every fifth hour.

At the same time, that preparations of iron were internally administered, Mr. Carmichael employed externally, for ulcerated cancers, the carbonate, phosphate, oxyphosphate, and arseniate of iron, blended with water, to the consistence of a thin paste, which was applied once every twenty-four hours. To occult cancers, the same gentlemen applied a solution of the sulphate of iron, $\mathfrak{zj}$ to lbj of water. The acetate of iron, diluted with eight or ten times its weight of water, was also used. These lotions were put on the part affected by means of folded linen, wet in them, and covered with a piece of oiled silk to prevent injury of the clothes. (See *An Essay on the effects of the Carbonate and other preparations of iron upon Cancer, &c.* by R. Carmichael, 2d Ed. 8vo. Dublin, 1808.)

Many remedies have acquired celebrity in cases of cancer, because very bad and malignant diseases, only supposed to be cancers, have got well, under their use. Such is probably the case with the carbonate of iron.

The only mode of treatment, which Mr. Pearson has ever seen to do any particular benefit to cancer, is that of keeping the patient on a diet, barely sufficient for the support of life, such as barley-water alone, tea, &c. Patients, with cancers, receive considerable benefit from being kept strictly on a milk diet.

The old surgeons commonly dressed can-

cerous sores, with narcotic applications. Vesalius used cloths, dipped in the juice of the solanum; whilst others employed it mixed with oil of roses, and preparations of lead, and antimony. Others had recourse to the hyosciamus; but, of late, cicuta poultices have superseded most other narcotic applications; and, in many cases, as Mr. J. Burns observes, they have undoubtedly abated pain, and diminished fetor; but this is all which can reasonably be expected; and even this expectation will not always be realized. This gentleman thinks carrot poultices better than those of hemlock, as they produce as much ease, and more powerfully diminish the fetor.

The fetor of cancers having been thought to resemble that of the sulphuret of potash, (liver of sulphur) and the oxygenated muriatic acid being the best agent for decomposing and destroying such smell, it has been recommended, as an application to cancerous sores. It may correct the fetor; but, it will never accomplish a cure. Carbonic acid has been said not only to correct the fetor, but, in some instances, completely to cure the disease. It was long ago proposed, says Mr. J. Burns, by Peyrille, and was again brought forward by Dr. Ewart. Experience, however, has not shown, that the efficacy of carbonic acid, in cases of cancer, is very great. Fourcroy remarks: "After the first applications, the cancerous sore appears to assume a more favourable aspect; the sanies, which flows from it, becomes whiter, thicker, and purer, and the flesh has a redder and fresher colour; but, these flattering appearances are deceitful, nor do they continue long, for the sore speedily returns to its former state, and its progress goes on, as before the application." The best method of applying carbonic acid is, by means of a bladder, the mouth of which is fastened round the sore with adhesive plaster. The air is introduced by a pipe, inserted at the other end.

Sometimes the fermenting poultice is employed.

Digitalis, as a local application, is entitled to about as much confidence as cicuta.

Tar ointment, gastric juice, absorbent powders, &c. have been tried; but, without any evident good. (See *J. Burns on Inflammation*, Vol. 2.)

Mr. Fearon rejected all internal remedies, as inefficient in the treatment of cancer, and in the early stages of the complaint, recommended a method of practice, founded on his idea of the inflammatory nature of the disease. "In the beginning of scirrhus affections of the breast and testis, the mode I have adopted of taking away blood, is by leeches repeatedly applied to the parts. In this course, however, I have often been interrupted by the topical inflammation, produced by these animals, around the parts where they fastened. In delicate female habits, I have often lost a week, before I could proceed to the re-application of them. When the symptoms lead me to suspect the

stomach, uterus, or any of the viscera, to be so affected, that the complaint either is, or, most probably, soon will become cancerous, I then have recourse to general bleedings. But, whether topical or general, perseverance for a sufficient length of time is necessary. Though the pulse never indicated such practice, yet the patients have not suffered by repeated bleedings; on the contrary, when they passed a certain time without losing blood, they felt a return of their symptoms, and of their own accord, desired to be bled again. To this plan of repeated bleedings, I joined a milk and vegetable diet, avoiding wine, spirits, and fermented liquors." Mr. Fearon used also to keep the belly open, and employ saturnine applications.

Of the method of treating cancer by pressure, I have spoken in another work. (*First Lines of the Practice of Surgery*, Vol. 1.) and therefore, in this place, I need merely repeat, that it is a practice, which none of the best modern surgeons think entitled to approbation.

From the preceding accounts, we may infer, that scarcely any reliance is to be placed on any known remedy, or plan, in cases of real scirrhi, and ulcerated cancers.

The operation is the only rational means of getting rid of the disease; and, to waste time, so as to allow the disorder to increase in a serious degree, merely for the sake of trying a train of unpromising medicines, is conduct, which is unworthy of a wise surgeon's imitation.

Perhaps, in early cases, it may be right to make trial of arsenic, cicuta, or preparations of iron. But, the practitioner should beware of devoting too much time to medicines, which will in all probability prove inadequate to the object for which they are exhibited. Mr. Fearon's method seems also warrantable, together with diet merely enough to support life; but the punishment, attending a resignation to this last regimen, would be greater, than that of having the disease cut away, while the chance of efficacy would be much less. Upon the whole, therefore, the operation is what we should generally adopt, as the surest, and the safest means of getting rid of cancerous diseases. As I have before remarked, the operation is always admissible, when every particle of the disease can be removed by it. Even large open cancers, if they can be entirely cut away, are often capable of being effectually cured.

The removal of cancerous disorders even in the slightest and most trivial cases, should always be effected with the scalpel, in preference to caustic; the use of which, though sometimes it may succeed by producing a complete destruction of the diseased parts, causes severe agony, and, in the event of its not acting sufficiently on all the diseased parts, often renders the complaint more aggravated, and kills the patient, and this in a very short space of time.

In cases of cancer, the irritation generally

occasioned by every application of the caustic kind, together with the pain and inflammation, which commonly ensue, are strong objections. Plunket's remedy, which is chiefly arsenic, is equally objectionable. Nor can you, at once, so certainly extirpate every atom of cancerous mischief with any caustic, as you can with the knife: for, with this, you immediately gain an ocular inspection of the surface surrounding the disease, so as to see and feel whether the disordered parts are completely removed, or whether any portion of the disorder requires a further employment of the instrument. With respect to the pain, that of caustics is infinitely greater, more intolerable, and more tedious, than that occasioned by the knife. When caustic also fails in destroying every particle of the disease at once, it almost always tends to enlarge, in a very rapid way, the original boundaries of the mischief. For an account of the method of removing scirrhi and ulcerated cancers, see *Mamma, Removal of*. Much additional information, respecting cancers, is contained in the 4th Ed. of the *First Lines of the Practice of Surgery*, Vol. 1, 8vo. 1819. *Le Dran's Operations in Surgery*, p. 87, &c. CANCER SCROTI.—CHIMNEY-SWEEPER'S CANCER. (See *Scrotum*.)

CANCER CRUM ORIS. A deep, foul, irregular, fetid ulcer, with jagged edges, which appears upon the inside of the lips and cheeks, and is attended with a copious flow of offensive saliva. According to Mr. Pearson, this disease is seldom seen in adults; but, most commonly, in children from the age of eighteen months to that of six or seven years. The gums, as well as the lips and cheeks, are sometimes affected, in which circumstance, the teeth are generally carious and loose. The ulceration is occasionally attended with abscesses, which burst either through the cheek, lip, or just below the jaw. Exfoliations are not unfrequent, and, when the disease is neglected, extensive sloughing sometimes happens.

Living in a marshy situation; unwholesome food; and inattention to cleanliness; are suspected to be conducive to this disorder. The causes of the affliction seem not to be understood; but it is remarked, that the disease prevails most in houses, where children are crowded together. It is uncertain whether the complaint is contagious.

Though children are the usual subjects of this disease, grown-up persons do not always escape its attacks.

The treatment recommended consists in extracting diseased teeth and loose pieces of bone, directing a milk vegetable diet, with a prudent quantity of fermented liquors; and prescribing bark, sarsaparilla, and elm bark, with sulphuric acid.

The best external applications are, diluted mineral acids; burnt alum; the decoction of cinchona, with sulphate of zinc; tincture of myrrh; lime-water, with spirit of wine, &c. (See *Pearson's Principles of Surgery*, Edit. 2, p. 287.)

CANTHARIDES. (*Lytæ*.) Spanish or French flies, with which the common blistering-plaster is made. In surgery, they are also prescribed in incontinence of urine, gleet, &c. The tincture is sometimes used as a liniment for stimulating parts.

CAPELINA. (from *capeline*, a woman's hat, or bandage, French.) A double-headed roller, above twenty-four feet long, and four inches broad. The middle is applied to the occiput, and, after two or three circular rounds, the rollers intersect each other upon the forehead and occiput; then one roller being reflected over the vertex to the forehead, the other is continued in a circular track. They next cross each other upon the forehead, after which the first head is carried back obliquely towards the occiput, and reflected by the side of the other.

The last is continued in a circular direction; but the first is brought again over the sagittal suture, backward and forward, and so continued, till the whole head is covered.

By the ancients, this bandage was some-

times applied in cases of hydrocephalus: it has no advantage, however, and is now hardly ever used.

CAPILLARY FISSURE. A very minute crack in the skull. The term came into use from the resemblance of such a fracture to a hair.

CAPISTRUM. (See *Bandage*.)

***CARBUNCLE.** (from *carbo*, a burning coal.) *Anthrax*. This is a very common symptom in the plague; but comes on also sometimes as a primary disease. The first symptoms are great heat and violent pain in some part of the body, on which arises a kind of pimple, attended with great itching; below which a circumscribed, but very deep-seated, and extremely hard tumour may be felt with the fingers. This tumour soon assumes a dark red, or purple colour, about the centre, but is considerably paler towards the edges. A blister frequently appears on the apex, which, as it occasions an intolerable itching, is often scratched by the patient. The blister being thus broken, a brown sanies is discharged, and an eschar makes its appearance. Many such pimples are sometimes produced upon one tumour, in consequence of the patient's scratching the part. (*Bromfield's Obs.* Vol. 1.)

Carbuncles have been distinguished into the *benign* and *malignant* kinds; but as far as the disease can be judged of at present in this country, the distinctions are only founded upon the different degrees of violence, with which the disease makes its attack. Some carbuncles are said to be *pestilential*; while others are not at all infectious. Fortunately, all cases, which are met with in this island are of the last sort; for no opportunities of remarking the pestilential anthrax have occurred in England since the deplorable periods of 1665, and 1666.

The carbuncle sometimes appears in persons affected with typhoid fevers, in which case, it is attended with great weight and stiffness of the adjacent parts; the patient is restless and pale, the tongue white, or of a deep red, and moist; the pulse low, urine sometimes pale, sometimes very turbid, with all the other symptoms in an exaggerated degree, which attend typhoid fevers. The patient often complains much of his head, either from pain or giddiness. Sometimes he is drowsy; at other times, he cannot get the least sleep. Occasionally, he is delirious. The case is also apt to be attended with chilliness, or rigours, and profuse perspirations. The patient is sometimes costive, sometimes afflicted with a profusion of stools; he generally complains of loss of appetite, nausea, and vomiting, takes but little nourishment, complains of difficulty of breathing, and is extremely low, with palpitations of the heart, and sometimes faintings. (See *Bromfield's Observations*, Vol. 1, p. 122.)

Sometimes a little slough, of a black colour, appears in the middle of the tumour. This was supposed by the ancients to be a part of the body burnt to a cinder, or hard crust, by the violence of the disease. By some authors, the carbuncle is considered

as a sort of gangrenous affection of the cellular substance. (*Latta*.) The progress of carbuncles to the gangrenous state is generally quick. Their size is very various; they have been known to be as large as a plate. Considerable local pain and induration always attend the disease. The skin, indeed, has a peculiar feel, like that of brawn. As the complaint advances, several apertures generally form in the tumour. Through these openings, there is discharged a greenish, bloody, fetid, irritating matter. The internal sloughing is often very extensive, even when no sign of mortification can be outwardly discovered.

If attention is paid to the skin in this case, we shall frequently find some miliary eruptions about the clavicles, the breasts, or other parts of the body; and, towards the latter end of the disorder, a different collection of large pimples will sometimes be thrown out, like the small-pox, and suppurate. Some of these, indeed, are occasionally converted into actual carbuncles. It was this species of anthrax, which was called *malignant*, and certainly, if any cases, seen in this country, demand this epithet more strongly than others, it is the instance, the description of which we have just quitted.

The constitution is often so low and exhausted, that death follows. The carbuncle, indeed, is most frequent in old persons, whose constitutions have been injured by voluptuous living, and, hence, we cannot be surprised, that the local disease, influenced by the general disorder of the system, should assume a dangerous aspect.

The degree of peril may generally be estimated by the magnitude and situation of the tumour, the number of such swellings at the same time, the age of the patient, and the state of his constitution.

In cases of anthrax, the duty of a surgeon may be described in a few words.—With regard to the local treatment, the grand thing is to make an early, and free incision into the tumour, so as to allow the sloughs and matter to escape readily. As much of the contents as possible is to be at once pressed out, and then the part is to be covered with an emollient poultice. Indeed, until the tumour is opened, no applications are more proper than emollient poultices, and, when an incision has been made, they are far preferable to any detersive antiseptic injections, made with bark, tincture of myrrh, &c. or to any lotions made with the sulphates of copper, and zinc, nitrate of silver, &c.; fomentations will also be found to afford considerable relief, both before and after an opening has been made. As the discharge is exceedingly fetid and irritating, it will be necessary to put on a fresh poultice two or three times a day. The use of the poultice is to be continued till all the sloughs have separated, and the surface of the cavity appears red, and in a granulating state, when soft lint and a pledget of some unirritating ointment, should be applied, together with a compress and bandage. The manner in

which the disease is protracted, by not making a proper opening in due time, cannot be too strongly impressed upon the mind of every practitioner, and it may justly be regarded as a frequent reason of the fatal terminations of numerous cases. Mr. Bromfield forcibly inculcates the necessity of making a timely opening for the discharge of the sloughs; for, says he, in case you rely on the opening, made by nature, the thin matter only will be discharged; the sloughy membranes will remain, and the orifice close up. (See *Vol. 1, p. 128*.)

It was formerly not an uncommon custom to extirpate carbuncles with the knife, or to destroy them with the actual and potential cauteries. The French were very fond of burning the swelling with a hot iron, the employment of which is sanctioned by Porteau. (See his *Œuvres Posthumes*.) These methods, having been found cruelly painful, and, in no manner advantageous, have long been branded with the reproaches of all English surgeons. With respect to the constitutional treatment, we should remember that the disease is for the most part met with in bad constitutions, and in persons who are weak and irritable.—Hence, it is only when there is a full strong pulse, and the complaint is just beginning, that bleeding is allowable. Bark and camphor are the internal medicines most commonly needed. The diluted sulphuric acid is also highly proper, as well as wine and aromatics. As the pain is very severe, opium is generally an essential remedy.—The constitutional treatment is very analogous to that of mortification, and, for this reason, I do not deem it necessary to enlarge the present article, by expatiating on this part of the subject. (See *Mortification*.)

In many of the southern parts of Europe, a malignant species of carbuncle, appears to be endemic, contagious, and very often fatal. For an account of this form of the disease, I would particularly advise the reader to consult *Richerand's Nosogr. Chir. T. 1, p. ccx, &c. Edit. 4.* and *Larrey's Mémoires de Chirurgie Militaire, Tom. 1, p. 104, &c.* A description of it was likewise introduced into the 4th edition of the *First Lines of Surgery*. Bromfield's *Chirurgical Cases and Observations, Vol. 1. L'Encyclopédie Méthodique, Partie Chirurg. art. Anthrax.* Pearson's *Principles*. Richter's *Anfangsgr. der Wundarzn. B. I. Boyer's Traité des Maladies Chirurgicales, T. 2, p. 50, &c.*

CARCINOMA. (from *καρκος*, a crab.) See *Cancer*.

CARIES. (from *καρπαιω*, to abrade.) Caries is a disease of the bones, supposed to be very analogous to ulceration of the soft parts; and this comparison is one of great antiquity, having been made by Galen. However, by the generality of the ancients, caries was not discriminated from necrosis.

It was from the surgeons of the eighteenth century, that more correct opinions were derived respecting caries. Until this period, writers had done little more, than mention the complaint and the methods of treating it. Some new light was thrown upon the

subject by J. L. Petit, in his remarks upon exostosis and caries. (*Mal des Os*. T. 2, Chap. 16. p. 27.) But, as he only spoke of the disorder, as one of the terminations of exostosis, he has not entered far into the consideration of it. The best observations on caries were first made by Dr. A. Monro, *primus*. (*Edinb. Med. Essays*, T. 5, art. 25.) This memoir contains the earliest correct ideas of *dry caries*, or *necrosis*, which is rightly compared to mortification of the soft parts, and named *gangrenous caries*.

The bones, like other parts of the body, are composed of arteries, veins, absorbent vessels, nerves, and a cellular texture; they are endued with vitality; they are nourished, grow, waste, are repaired, and undergo various mutations, according to the age of the individual; and they are subject to diseases analogous to those of the soft parts. To the phosphate of lime, which is more or less abundantly distributed in their texture, they owe all their solidity, and, perhaps, it is to the same earthy substance, that the difference in their vital properties, and in their diseases, from those of the rest of the body, is to be referred. In fact, this particular organization, and inferior vitality of the bones, are generally supposed to account for the small number peculiar character, and slow progress of their diseases. (*Dict. des Sciences Med.* T. 4, p. 80.)

All the bones are liable to caries; but those of a spongy texture are more frequently attacked, than such as are compact. Hence, the vertebrae; astragalus, and other bones of the tarsus; those of the carpus; the sternum; the bones of the pelvis, and the heads of the long bones, are often affected; and the bones of young persons are unquestionably more frequently the seat of caries, than those of old subjects.

In necrosis, the bone is entirely deprived of life; in caries, the vital principle exists, but a morbid action is going on, whereby the texture of the bone is altered, and rendered softer and lighter than natural.

In the most common species of caries, a loose, fungous flesh grows out of the interstices, formed on the surface of the diseased bone, and bleeds from the slightest causes. There is generally a sinus in the soft parts, which leads down to the caries, and emits a very fetid, dark-coloured sanies. These symptoms, however, as well as the tendency in the accompanying ulcer or sinus, to produce large fungous granulations, are more constant in cases of necrosis, than in those of caries, some of which may remain a very considerable time unattended with any outward sore, abscess, or sinus, as we see illustrated in the caries produced by various diseases of the joints. And, indeed, particular forms of caries, (if they deserve that name) are rarely accompanied with suppuration: a fact, to which I shall again advert.

"The absorption of bone, like that of soft parts (says Dr. Thomson,) may be distinguished into interstitial, progressive, and ulcerative. We have ample proofs of the interstitial absorption, or that which is daily,

hourly, and unceasingly taking place from every part of the substance of bone, in the deposition and removal of phosphate of lime, that has been tinged with madder. If too much earth be removed, the quantity of animal matter will be relatively increased, and a disposition given to softness of the bones—a state, which exists in the bones of children in the disease called the rickets, and in the bones of older people in that denominated *mollities ossium*, or the rickets of grown people.

"I have already had occasion to mention the effects of the progressive absorption of bone, as manifested in the progress of aneurisms and other tumours to the skin; but, the formation of pus is by no means a necessary, constant, or even frequent attendant on the progress of progressive absorption in bone. Hydatids in the brains of sheep, tumours growing from the pia or dura mater in the human body (see *Dura Mater*), or aneurism seated over the cranium, or within the cavity of the chest, are often the cause of the whole substance of a bone being removed, layer after layer, by progressive absorption, without the formation of a single particle of pus. (See *Aneurism*.) This state of the bone has often been confounded, but improperly, with that state of the bone, which arises from ulcerative absorption, the state, which is properly denominated caries, and in which, one or more solutions of continuity may be produced upon the surface, or in the substance of the bones. The ulcerations occasioned in bones by the venereal disease, afford by far the best marked examples of the effects and appearances of ulcerative absorption, or caries in bones, &c." (See *Thomson's Lectures on Inflammation*, p. 389.)

Caries has been divided into three kinds, according to the nature of its causes: 1, Caries from external causes; 2, from an internal local cause, where no outward injury of the bone, and no internal constitutional disease, can be suspected to have produced the disorder, and where the affection can be removed by local means. The caries of the finger bones from whitlows, is quoted as a specimen of this form of the disease. Perhaps, however, the case is generally rather an instance of necrosis; 3, from a general internal cause, or constitutional disease, in which cases, besides local remedies, it is necessary to employ such medicines, as are calculated to obviate the particular affection of the system, whence the diseased state of the bone has originated.

But, in addition to these general divisions of the subject, there are many circumstances, in relation to the varieties of caries, which may be said yet to lie in obscurity. If, as a modern writer remarks, the situation of the bones, the nature of their organization, and the slowness of their diseases, would let an attentive observer trace the formation, developement, and progress of caries, no doubt, there would be noticed a diversity in its symptoms, corresponding to its different species; and, probably, it

would be found, that a venereal, or scrophulous caries would vary in its origin and progress, as much from a caries, from a purely local cause, as a venereal or scrophulous ulcer differs from the kind of ulceration, which follows a common abscess. (*Dict. des Sciences Méd. T. 4, p. 84.*) The *worm-eaten* caries, as it has been termed, which penetrates the whole substance of a bone, and gives it an appearance as if it had been bored in hundreds of places, is a very different affection from some other forms of the disease, whether superficial, or extended to the deeper texture of the bone affected.

Abscesses situated in the vicinity of bones, are frequently thought to be the cause both of necrosis and caries. Hence, the rule to open such abscesses at an early period, in order to prevent the bone from being affected. If some abscesses, like those which form over the anterior surface of the tibia, and mastoid process of the temporal bone, be frequently attended either with caries or necrosis, the latter is mostly the cause, and not the effect of the suppuration. Pus, which is a bland, unctuous, inodorous fluid, never attacks the soft parts, with which it is in contact, until its qualities are changed by exposure to the air. When an abscess forms in the anterior part of the parietes of the abdomen, the peritoneum of that part, naturally a thin membrane, instead of being destroyed, becomes thick and strong enough to resist the extension of the abscess towards the cavity of the abdomen. So also, when an abscess is formed over a bone, not originally diseased, or hurt by the same causes, which produced the abscess, and not injured by being kept exposed, or by astringent escharotic applications, neither caries, nor necrosis, is likely to happen. On the contrary, the periosteum, like the peritoneum, becomes thickened, and granulations are formed over it.

The venereal disease is sometimes a cause of caries; sometimes of necrosis; and in other instances, of exostosis. When it attacks the bones of the nose, it generally renders them carious, and the face sadly disfigured. The bones of the palate are sometimes altered in the same manner; but, on other occasions, the effect is necrosis.

In cases of cancer of the breast, the sternum and ribs are sometimes found carious. I believe, that, in such cases, the disease of the bones has nothing in its own nature, entitling it to be regarded as cancerous. It is a mere effect of the original disorder, and if the carious bone could be removed together with every particle of the disease of the soft parts, a cure would probably follow. Or, supposing the carious bone were the only portion of the disease left, it is conceivable, that the case might yet end in a cure.

Caries, arising from syphilis, most commonly affects the tibia, cranium, ossa nasi, ossa palati, and sternum.

A caries of the vertebræ is known by pe-

culiar symptoms, among which a paralysis of the inferior extremities, and lumbar abscesses, are the most remarkable.

Caries from an external, or from a local internal cause, is less dangerous than that, which proceeds from a constitutional disease, particularly, when the latter is difficult of cure.

A caries of the spongy part of bones is more difficult to cure, than a similar affection of their compact parts. Caries of the carpal and tarsal bones is particularly obstinate. These bones being in close contact, the affection cannot easily be prevented from spreading from one to the other. Amputation is often the only means of cure. The same is frequently the case, when the spongy heads of the long bones forming the large joints, become carious. Even this mode of relief is not practicable when the head of the bone lies very deep, like that of the os femoris.

Caries of the ossa ilium, is also observed to be particularly difficult of removal.

Caries from scrophula is more difficult of cure, than that from syphilis, and scurvy; for, some efficacious remedies against the latter diseases are known; but scrophula cannot be said to be within the reach of medicine. The prognosis is less favourable in old, than young subjects, and much depends on the extent of the disease, the patient's strength, and the state of the soft parts.

When caries arises from constitutional disease, internal remedies are of course indicated. Thus mercurial and sudorific medicines put a stop to caries from syphilis; while, vegetable diet, and acids, cure both the scurvy, and the caries dependent on it.

According to writers, the indications in the treatment of caries are; either to produce a change in the action of the diseased portion of bone, whereby it may regain a healthy state; or to destroy it altogether.

In the caries from constitutional causes, the first object seems to be brought about by the operation of such remedies as remove the original disease; and I should much doubt, whether, in these cases, any very active local treatment is necessary, or free from objection. Of course, this remark is meant to apply only to examples, in which we possess some medicine, or plan, which is known to be a tolerably sure remedy for the general disease. This is not the case in caries from scrophula, and here issues, blisters, and other local means are unquestionably advantageous (*See Joints and Vertebræ*.) But, surgeons have proceeded further, and, not content with issues, blisters, fomentations, &c. as means for quickening the action of the diseased bone, they have commonly recommended applying directly upon it the strongest stimulants, as the tincture of aloes or myrrh, a solution of the argentum nitratum, or diluted muriatic acid.

For the destruction of caries, the actual and potential cauteries, and cutting instruments, have been employed.

* On the continent, and particularly in France, they still adhere to the plan of touching carious parts of bones with the actual cautery, after bringing them fairly into view by the previous use of the knife. It is thought, that the burning iron acts, by changing the caries into a necrosis, irritating the subjacent sound parts, and exciting that action of the vessels, by which the dead or diseased part of the bones must be thrown off. Such is the doctrine inculcated by Boyer.

Mr. Hey succeeded in cutting away a carious part of the tibia. He began the operation by dissecting off the granulations of flesh, which had arisen from the bone, and then sawed out, by means of a circular headed saw, a wedge of the tibia, two inches in length. The removal of this portion brought into view a caries of the cancelli, almost as extensive as the piece already removed. With different trephines, suited to the breadth of the caries, Mr. Hey removed the diseased cancelli of the bone, quite through to the opposite lamella. As the caries extended in various directions, it was not possible to remove the whole of it with a trephine, without removing also a large portion of the sound part of the bone, which Mr. Hey wished to avoid. By the assistance, therefore, of a strong sharp-pointed knife, he pursued the caries in every direction until every part was taken away, which had an unsound appearance. The wound was simply dressed with dry lint; the whole surface was speedily covered with good granulations; and a complete cure was obtained, without any exfoliation.

Mr. Hey concludes this subject, as follows: "I have treated some other cases of caries of the tibia in the same manner, and with equal success. Where the extent of the caries is not so great as to prevent a complete removal of the morbid part, this method is extremely useful, and far superior to the use of the potential or actual cautery.

"The trephine is not wanted, where the cancelli of the bone are not affected with the caries. The diseased parts of the lamella may be removed with gouges or small chisels. Granulations of flesh will then arise from the sound parts of the bone, and become united with the integuments, which ought to be preserved as far as is possible." (*Pract. Obs. on Surgery.*)

If surgeons are often censurable for inert measures in a variety of diseases, I believe, they cannot be blamed for the same kind of inactivity in the treatment of caries, where they run, perhaps, into the opposite extreme, and, too confident in their knowledge of the causes and nature of the disease, they often make themselves too officious, and rather disturb, than promote the salutary processes of nature. (See *J. L. Petit, Traité des Mal. des Os. Paris, 1741. A. Monro, in Edinb. Med. Essays, Vol. 5. Weidmann de Necrosi Ossium, Francof. 1793. Callisen's Systema Chirurgiæ Hodiernæ, Vol. 1, p. 493. Boyer's Traité des Maladies Chir. T. 3. p.*

453, et seq. Paris, 1814. Richerand's Nosogr. Chir. T. 3, p. 134, edit. 4. Paris, 1815. Dict. des Sciences Med. T. 4, p. 78, &c. J. Wilson on the Structure, Physiology, and Diseases of the Bones, &c. p. 263, 8vo. Lond. 1820. A good description of the different kinds of caries is yet a desideratum.)

CASTRATION. The operation of removing a testicle. For an account of the cases rendering this measure necessary, see *Testicle, Diseases of*. The manner of operating is as follows: The patient being laid on a table of convenient height, the integuments covering the spermatic vessels in the groin, are to be divided. This incision should begin as nearly as possible, opposite to the opening in the abdominal muscle, and should be continued a good way down the scrotum.

The manner of beginning this incision is differently described by writers; some of them advising that the skin be held up by an assistant; others that the knife be used perpendicularly in this as in other parts. The latter mode is generally preferred by English surgeons. The length of the division is a more important consideration. A small wound will indeed serve to lay bare the spermatic chord; but it will not permit the operator to do what is necessary afterwards with dexterity, or facility; and as the scrotum must, first or last, be divided nearly to the bottom, it had better be done at first. The spermatic chord, thus laid bare, is to be freed from its surrounding membranous connexions; and then the operator, with his finger and thumb, separating the blood-vessels from the vas deferens, must pass a ligature between them, and having tied the former only, must cut through the whole chord, at a quarter or half an inch distance from the said ligature, according as the state of the process and testicle will admit. This done; he is then, with the same knife, with which he has performed the former part of the operation, to dissect the testicle out from its connexion with the scrotum: the loose texture of the connecting cellular substance, the previous separation of the testicle from the spermatic chord, and the help of an assistant to hold up the lips of the wound, will enable him to do this with very little pain to the patient and great facility to himself. If any considerable artery bleeds in the scrotum, it is to be tied. (*Polt.*)

Mr. S. Sharp once castrated a man, whose testicle weighed above three pounds, and some of the vessels were so exceedingly varicous and dilated, as nearly to equal the size of the humeral artery. (*Operations of Surgery, chap. 10.*)

Desault first divides the chord, and, holding its upper end between the index finger and thumb of his left hand, he then takes up the arteries with a pair of forceps, and they are immediately tied by an assistant. (*Œuvres Chir. par Bichat, T. 2.*)

The spermatic artery, and any scrotal vessels, which require to be taken up, should be tied with fine silk ligatures, as re-

commended by my friend Mr. Lawrence. (See *Med. Chir. Trans.* Vol. 6, p. 197.)

Pott used to fill the cavity of the wound with lint; but Desault, and all the modern surgeons of this country, bring the edges of the wound together, and endeavour to heal as much of it as possible by the first intention. Some, with this view, use sutures and sticking plaster; others, only the latter, aided with compresses and a T bandage; which means, in my humble opinion, are quiet enough.

The operation of the compresses and bandages cannot be too carefully attended to, as it is the surest means of preventing hemorrhage from any small arteries in the scrotum, while it conduces to the union of the parts. Care must be taken, however, not to let the pressure hurt the sound testicle.

The plan of dressing adopted by Mr. Lawrence, consists in retaining the edges of the skin in apposition with two or three sutures, and then applying a narrow strip of simple dressing. A folded cloth, kept constantly damp, is also laid over the wound. (*Med. Chir. Trans.* Vol. 6, loc. cit.) With respect to sutures, some doubt may be entertained of their utility after this operation, and I have remarked, that considerable irritation and an extensive erysipelas sometimes follow their employment. Roux also noticed their bad effects in a case, which occurred during his visit to this country. (See *Parallèle de la Chirurgie Anglaise avec la Chirurgie Française*, p. 121.)

It is somewhat extraordinary, that Larrey should condemn the plan of uniting the wound, though, indeed, we cannot be surprised at his delivering this advice, when we recollect, that he disapproves of healing the stump, after amputation, by the first intention. The passage, relative to dressing the wound after castration, seems to be a contrast to the sensible observations which generally prevail in this author's publication: "*Il ne faut pas réunir les bords de la plaie, comme l'ont conseillé quelques praticiens, parce qu'ils doivent suppurer, et que la suppuration est nécessaire!*" (*Mem. de Chirurgie Militaire*, Tom. 3, p. 426.)

Larrey is joined by Roux and the rest of the French surgeons on this point. The main reasons, stated by the latter writer, for not bringing the wound together, are, that secondary hemorrhage cannot be well guarded against, except by filling the part with charpie; that the redundancy and looseness of the skin render it difficult to keep its edges in exact contact, without removing a portion of it, and using sutures, which are objectionable; and that suppuration cannot commonly be prevented because there is a large quantity of loose cellular substance in the wound, which substance readily suppurates. (*Parallèle de la Chirurgie Anglaise avec la Chirurgie Française*, &c. p. 119, &c.) By applying cold water, and gentle compression to the part, I believe, however, such hemorrhage may generally be averted, and the union of the

wound materially expedited. As a judicious writer observes: "In the London hospitals, complete union by the first intention is seldom, or never accomplished; yet, by attempting it, the wound is much diminished, and the cure of it rarely delayed later, than three or four weeks; whereas the wound, when stuffed with lint, is usually not healed in less than seven or eight weeks." (See *Sketches of the Medical Schools of Paris* by J. Cross, p. 144.)

Sometimes, one or more vessels begin to bleed soon after the patient is in bed, although they effused no blood just after the removal of the testicle. Keeping the dressings and scrotum continually wet with the cold saturnine lotion very often suffices for the prevention and suppression of such hemorrhage: if not, the wound must be opened again, and the vessels tied.

J. L. Petit made some useful remarks on this operation. The vessels of the scrotum, says he, are not the only ones, which may be the source of hemorrhage. Anatomists know, that the septum, which divides this part into two cavities, is furnished with an artery, that is not considerable, but, which becomes materially enlarged, in the case of a sarcocele, or other tumour. It is sometimes so considerable, that it causes a bleeding, which makes a surgeon, who has had no previous opportunity of seeing the occurrence, exceedingly uneasy. Such hemorrhage, says Petit, may be easily suppressed with a ligature; and, he assures us, that he has seen a surgeon dress the patient three times, without ever suspecting, that the bleeding, for which the applications were a third time removed, proceeded from this artery. (*Petit, Traité des Maladies Chir.* T. 2, p. 524—525.)

The same experienced and able surgeon also acquaints us, that he has more than once extricated from trouble, persons who knew not how to stop the bleeding after the operation. He has seen some of them take off the dressings several times, without discovering the wounded vessel. As they imagined, that the only hemorrhage, which could follow castration, must be from the spermatic artery, they contented themselves with examining the ligature on the chord, and increasing the compression, in order to stop the bleeding; but, finding their attempts fail, they were compelled to seek assistance. On being sent for, M. Petit found, that the blood did not issue from the cord, but from a small artery under the skin, at the inferior angle of the wound. He easily stopped the hemorrhage, and explained, not only, that the cord had no share in the accident, but, that it is generally suspected without foundation. Indeed, says he, the least constriction will stop the bleeding from the spermatic artery; it is not essential to tie it;—"I myself am content with cutting the cord, so as to leave it rather longer than usual, and apply no ligature; I press it against the os pubis, near the ring of the external oblique; I lay over it a linen compress, half as thick as

the finger, two inches in length, sufficiently broad to cover the part, and yet narrow enough to be placed entirely within the wound. Over this compress, I put dossils of lint; I fill the scrotum with plain lint, and then cover the whole with compresses, observing to put one, which is thicker than the rest, above the pubes, immediately over that which I have laid upon the cord, so that the bandage may make moderate pressure on this last part, yet sufficient to prevent bleeding." (*Op. cit.* p. 526, 527.)

This quotation is not made with a view of inducing any modern operator to imitate the preceding practice, which, indeed, the advantages of the present mode of dressing the wound entirely forbid, as well as the greater security of the ligature; but, the passage is cited, for the express purpose of impressing on the mind of the young surgeon, that, in general, after the removal of a diseased testis, there is more risk of bleeding from the vessels of the scrotum, than those of the cord. I have never seen hemorrhage from the spermatic artery give trouble after the operation, but, have often known surgeons obliged to take off the dressings on account of bleeding in the scrotum.

In every operation, in which a considerable portion of skin is to be divided, and particularly in this, and in the amputation of women's breasts, it should always be remembered, that, as the division of the skin (the general organ of sensation) is the most acute and painful part of what is done by the knife, it cannot be done too quickly, and should always be done at once: the scrotum should constantly be divided to the bottom, and the circular incision in the skin of a breast always made quite round, before any thing else be thought of. If this be not executed properly, and perfectly, the operation will be attended with a great deal of pain which might be avoided, and the operator will be justly blameable. (*Pott.*)

When the diseased testicle is exceedingly large, or a part of the scrotum is diseased, the surgeon should take care to remove the redundant, or morbid portion of the skin, by including the piece, which he designs to take away, within two long elliptical incisions, which are to meet at the upper and lower part of the swelling. In this manner, as Mr Samuel Sharp has observed, the hemorrhage will be much less, the operation greatly shortened, the sloughing of the distended skin prevented, and the recurrence of cancerous disease rendered less likely. (See *Treatise of the Operations*, chap. 10.)

Mr. Lawrence concurs with M. de la Faye in thinking it best in this operation always to remove a large piece of the scrotum with the testicle, by which means the surface of the wound is lessened. (See *Med. Chir. Trans.* Vol. 6, p. 196.)

If the tumour be of a pyriform figure, perfectly smooth, and equal in its surface, and free from pain, notwithstanding the degree of hardness may be great, and the surgeon may in his own opinion, be clear that the tumour is not produced by water, but is a

true scirrhus, let him, immediately previous to the operation, pierce the anterior part with a trocar, in order to be certain "My reason for giving this advice is, that I was once so deceived by every apparent circumstance of a true, equal indolent scirrhus, that I removed a testicle, which proved upon examination to be so little diseased, that, had I pierced it with a trocar previous to the operation, I could, and certainly should have preserved it." (*Pott.*)

It is well known, that the agony of tying the cord is immensely increased by including the vas deferens, and, as no good results from so doing, the practice deserves the severest reprobation, notwithstanding the opposite opinion of Mr. Pearson, (*Pract. Obs. on Cancer*, p. 74.) and the writer of the article *Castration* in Rees's Cyclopædia.

Cases are even recorded, in which the inclusion of the whole of the spermatic cord appears to have occasioned severe and perilous consequences, and these in so great a degree, that it has been found necessary to cut and remove the ligature. Sometimes, says Petit, patients on whom castration has been performed, suffer more or less acute pain in the kidneys. The suffering often becomes insupportable and highly dangerous, the belly being swelled, tense, and painful; the patient being affected with syncope, and affections of the heart, sometimes with vomiting, and retention of urine; lastly, an universal inflammation of the belly, and a violent fever, accompanied with delirium, are occasionally the fatal consequences of this operation. Petit was required to visit a patient, who had been in this deplorable state for twenty-four hours, after having suffered castration, and this distinguished surgeon could impute the sudden and violent symptoms to nothing, except the ligature on the spermatic cord; consequently, he advised the ligature to be removed. The patient received some slight relief from this step, and, after having been bled twice within a short space of time, he found himself a great deal better; but, as the dressings became wet with blood, apprehension of bleeding began to be entertained. Petit, therefore, had recourse to moderate compression of the cord, in the manner above related. No hemorrhage ensued; the case afterwards went on well; and the patient recovered sooner than was expected. (*Traité des Maladies Chir.* Tom. 2, p. 527, 528.)

In the operation of removing a testicle, one caution seems particularly necessary, viz. if the cord should be at all enlarged, the surgeon ought carefully to examine, whether the augmentation of its size may not be owing to a portion of intestine, or omentum, that is contained within it. (See *Sabatier's Médecine Opératoire*, Tom. 1, p. 332, *Édit.* 1.) In one case of extirpation of the testicle, "after the operation was completed, and the wound dressed, the patient being seized with a fit of coughing, to the astonishment and dismay of the surgeon, the dressings were forced off by a protrusion of several convolutions of small intestines."

tines; from this, it was proved, that the patient had had a hernia; but, the diseased enlargement of the testicle had acted as a truss, and prevented the rupture from coming down. (See *Operative Surgery*, by C. Bell, Vol. 1, p. 226, also p. 224.)

There is another circumstance, which merits attention in the performance of this operation: when there are reasons, which oblige us to divide the cord high up, and this part has not been tied before such division is made, it may be drawn up by the cremaster within the abdominal ring, and some difficulty may be experienced in securing the spermatic arteries. Mr. B. Bell saw this happen twice, and the patients lost their lives from hemorrhage. Hence, when it is necessary to cut through the cord near the ring, perhaps it may be best always to apply the ligature first, observing not to include the vas deferens. However, were the cord, previously to the application of ligatures to its arteries, to happen in any instance to be drawn up within the ring, a surgeon would be guilty of most supine neglect to let the patient die of bleeding; for, as Mr. C. Bell has remarked, we may follow the cord with perfect safety, even to the origin of the cremaster, which pulls it up, if attention be paid to the course of the cord, obliquely upward and outward, within the inguinal canal.

It sometimes happens, that abscesses form in the remains of the spermatic cord, after the operation of castration. Such suppuration may frequently be prevented by the employment of bleeding directly after the operation, and repeating the evacuation on the first access of the inflammation of the part concerned. Besides venesection, low diet, neutral salts, diluents, &c. are indicated, and the part should be covered with an emollient poultice. When pus is completely formed, the abscess should be opened.

When the symptoms subside, says Petit, they, who are little versed in practice, are apt to fancy the abscess cured; but, they are sometimes mistaken. The matter is not always sufficiently near the surface to be felt, and, in this circumstance, the aponeurosis of the external oblique muscle is so tense, that it hinders the fluctuation from being distinctly felt. Indeed as the matter finds a lodgment under this aponeurosis, following the course of the sheath of the vessels, there is reason to fear, that it may lead to additional inflammation and suppuration, and extend up the duplicature of the peritoneum to the loins. In these cases, the abscess occasionally makes its way outward, and the dressings are inundated with matter; but, if this should not happen quickly, the sooner the tumour is opened the better. The opening ought unquestionably to be made wherever the fluctuation is plainly distinguishable; but, as Petit has remarked, the tension of the aponeurosis of the external oblique muscle makes the undulation of the matter less readily and plainly perceptible, than if the abscess were only in the fat. Therefore, in order to avoid mistake, this

surgeon advises us to feel at the abdominal ring, as, in general, the pus can be more readily felt here, than in other situations. If matter is felt, and no resistance is experienced, Petit advises the finger to be passed into this opening, and in case the seat of the abscess should be found to be under the aponeurosis, we are recommended to divide, with a probe-pointed bistoury, the skin and fat immediately covering the ring, then to separate the fibres of this aperture, as it were, without cutting them. (See *Traité des Maladies Chirurgicales*, Tom. 2, p. 529—530.) No doubt, this surgeon meant, that the division of the tendon ought to be made in the direction of its fibres.

A long account of the particular sentiments of several eminent surgeons is to be found in *Rees's Cyclopædia*, art. *Castration*. *Roux, Parallèle de la Chirurgie Angloise avec la Chirurgie Française*, p. 119. &c. *Laurence in Med. Chir. Trans.* Vol. 6, p. 196—197. *Sketches of the Medical Schools of Paris*, by J. Cross, p. 139, &c.

CATAPLASMA ACETI. Made by mixing a sufficient quantity of vinegar with either oatmeal, linseed meal, or bread crum. When linseed is employed, it is best to add a little oatmeal, or bread crum, in order to keep the poultice from becoming hard. The vinegar poultice is generally applied cold, and is principally used in cases of bruises and sprains.

CATAPLASMA ACETOSÆ. *Sorrel Poultice.* $\mathcal{R}$ *Acetosæ* lbj. To be beaten in a mortar into a pulp.

CATAPLASMA ALUMINIS. Made by stirring the whites of two eggs with a bit of alum, till they are coagulated. In cases of chronic and purulent ophthalmy, it has been applied to the eye, between two bits of rag, and it has been praised as a good application to chilblains, which are not broken.

CATAPLASMA BYNES. (Malt.) $\mathcal{R}$ *Farinæ Bynes*, *Spumæ Cerevisiæ*, q. s. This is applied to cases of gangrene and ill conditioned extending sores. It is used in instances similar to those, in which the cataplasma fermenti is employed, and, by giving out carbonic acid gas, is supposed to operate as a gentle stimulus, and as a corrector of fetid effluvia.

CATAPLASMA CARBONIS. Made by mixing powdered charcoal with linseed meal and warm water, and is applied to improve the condition of several kinds of unhealthy sores.

CATAPLASMA CEREVISIÆ. Made

by stirring some oatmeal, or linseed meal, in strong beer grounds. It is used in the same cases, as the Cataplasma Fermenti, and Cataplasma Bynes.

CATAPLASMA CICUTÆ. *Hemlock Poultice.* R. *Herbæ cicutæ exfoliatæ* ʒij. *Aquæ fontanæ* ℥ij. To be boiled, till only a pint remains, when as much linseed meal as necessary is to be added.

This is an excellent application to many cancerous and scrofulous ulcers, and other malignant sores; frequently producing a great diminution of the pain of such diseases, and improving their appearance. Justamond preferred the fresh herb, bruised.

CATAPLASMA DAUCI. *Carrot Poultice.* R. *Radiciſ Dauci recentis* ℥ij. Bruise it in a mortar into a pulp. Some, perhaps, with reason, recommend the carrots to be first boiled. The carrot poultice is employed as an application to ulcerated cancers, scrofulous sores of an irritable kind, and various inveterate malignant ulcers.

CATAPLASMA DIGITALIS. Made by mixing linseed meal with a decoction of the leaves of the plant. It is said to have great sedative virtues, to be adapted to the same cases as the cicuta poultice, and even to be more beneficial.

CATAPLASMA FARINACEUM. The bread and milk poultice, made by putting some slices of bread crum in milk, and letting them gently simmer over the fire in a saucepan, till they are properly softened. The mass is then to be mixed and stirred about with a spoon, and spread on linen, in order to be applied. This poultice, which is of the emollient kind, is with many persons the common one for all ordinary purposes. Most surgeons, however, employ, instead of it, the linseed poultice, which is cheaper, more readily made, not apt to turn sour, and in all common cases, quite as advantageous in every respect.

CATAPLASMA FERMENTI. *Fermenting Poultice.* R. *Farinæ Tritici* lbj. *Cerevisiæ Spumæ, Yest dictæ*; ℥ss. These are to be mixed together and exposed to a moderate heat, till the effervescence begins. In cases of sloughing and many ill-conditioned ulcers, this is an application of great repute.

CATAPLASMA LINI. *Linseed Poultice.* R. *Farinæ Lini* ℥ss. *Aq. ferventis* ℥ss. The powder is to be gradually sprinkled into the hot water, while they are quickly blended together with a spoon.

This is the best and most convenient of all the emollient poultices for common cases, and it has nearly superseded that of bread and milk, which was formerly much more frequently employed.

Mr. Hunter speaks in the following terms of the linseed poultice and its uses.

"Poultices are commonly made *too thin*; by which means, the least pressure, or their own gravity, removes them from the part; they should be thick enough to support a certain form when applied.

"They are generally made of *stale bread* and milk. This composition, in general,

makes too *brittle* an application; it breaks easily into different portions, from the least motion, and often leaves some part of the wound uncovered, which is frustrating the first intention.

"The poultice which makes the best application, and continues most nearly the same between each dressing, is that formed of the meal of linseed, it is made at once, and when applied, it keeps always in one mass.

"The kind of wound to which the above application is best adapted, is a wound made in a sound part, which we intend shall heal by granulation. The same application is equally proper when parts are deprived of life, and consequently will slough. It is therefore the very best dressing for a *gunshot* wound, and probably for most *lacerated wounds*; for *lint*, applied to a part that is to throw off a *slough*, will often be retained till that slough is separated, which will be for eight, ten, or more days."

CATAPLASMA MALI MATURI. This is made by roasting a ripe apple, removing the peel and core, and beating the pulp into a soft mass. It is sometimes applied to inflamed eyes, by means of a little muslin bag.

CATAPLASMA MURIATIS SODÆ. R. *Pulveris Lini, Micæ Panis a. a. partes æquales, Aq. Sodæ Muriatæ q. s.* This is used for diminishing scrofulous tumours and glands. When it excites too much irritation in the skin, a linseed poultice may be substituted for it, until this state has subsided.

CATAPLASMA PLUMBI SUBACETATIS.

R. *Liquoris Plumbi Subacetatis* drach. j. *Aquæ distillatæ* lib. j. *Micæ panis* q. s.—*Misce.*

Practitioners who place much confidence in the virtues of lead, externally applied, often use this poultice in cases of inflammation.

CATAPLASMA QUERCUS MARINI.

This is prepared by bruising a quantity of the marine plant commonly called *sea tang*, which is afterwards to be applied by way of a poultice.

Its chief use is in cases of scrofula, white swellings, and glandular tumours.

When this vegetable could not be obtained in its recent state, a common poultice of sea-water and oatmeal was substituted by the late Mr. Hunter and other surgeons of eminence.

CATARACT. (From *καταρασσω*, to confound or disturb; because the disease confounds or destroys vision.) *γλαυχομα, ὑπόχυμα. Gutta opaca. Suffosio. Der grane Staar.*

A cataract is usually defined to be a weakness or impediment to sight, produced by opacity of the crystalline lens, or its capsule. Professor Beer applies the term to every perceptible obstacle to vision, situated in the posterior chamber, between the vitreous humour and the uvea. (*Lehre vom*

Augenkrankheiten, B. 2, p. 279, 8vo. Wien. 1817.)

Hippocrates and the ancient Greeks described the cataract, as a disease of the crystalline lens under the name of *γλαυχμα*; but, no sooner had Galen promulgated the doctrine of the lens being the immediate organ of sight, than the correct opinion of the ancient founder of medicine began to decline, and for many ages afterwards, had no influence in practice. In fact, the seat of the cataract was entirely forgotten, till about 1656, when first Lasnier, and, afterwards, Borel, Bonnetus, Blegny, Geoffroi, &c. revived the truth which had been so long extinct; and they, and a few others, believed, that the disease was situated in the crystalline lens. The bulk of practitioners, however, remained ignorant of this fact even as late as 1713, or, in other words, until the several publications of Mery, Maitre-Jan, Brisseau, and Heister, combined to render the truth universally known.

A cataract, even in its highest degree, does not always produce complete blindness. For the most part, its formation takes place slowly; the cases in which it originates very quickly, being but few, and those in which it is suddenly produced in a complete form, still more unusual.

The characteristic symptoms, commonly remarked when a cataract is slowly formed, are the following: 1. All objects, especially white ones, seem to the patient to be covered by a thin smutty or dusty cloud, which as the late Mr. Ware observed, is generally perceptible by the patient before any opacity is visible in the pupil. 2. The decline of vision bears an exact proportion to the increasing opacity distinguishable behind the pupil. 3. In most cases, the opacity is first discerned behind the pupil, most plainly also at the central point, the instances in which it first presents itself at the edge of the pupil, being less frequent.—4. In eyes with a light-coloured iris, the more progress a cataract makes the more clearly can one perceive at the edge of the pupil a blackish ring, which partly arises from the shadow of the iris falling on the cataract, but chiefly from the dark coloured pupillary edge of the iris, which, in a clear pupil cannot be seen, but now that a grayish surface lies behind it, is very manifest. As a cataract generally begins at the central point behind the pupil, such objects as are placed directly in front of the eye, are most difficultly seen even in the early stage of the disease, but those which are laterally placed, especially when the light is not too strong, and of course the pupil a good deal dilated, can yet be seen tolerably well. 6. Hence, when the opacity, at the central point behind the pupil, is at all considerable, the patient is completely blind in a strong light, while on the contrary, in a moderately dark room, a degree of vision is yet enjoyed. When the opacity is not far advanced, the eyesight may be improved for a short time by the patient's turning

his back to the light. 7. Persons with incipient cataracts derive the greatest palliative aid from the use of convex glasses, because objects are magnified by them; but, they only answer while the opacity is inconsiderable. 8. To such patients, the flame of a candle seems to be enveloped in a whitish misty halo, which always becomes broader, the further the patient is from the light. When the cataract is far advanced, the flame of the candle cannot be seen, and the patient can only indicate the place near which the light is, or say whether it is close or at a distance. 9. Lastly, a cataract which forms slowly, produces in the course of its progress, no change in the mobility of the iris; and, if this effect sometimes takes place where the disease is very completely developed, the nature of the case is now so manifest, that no surgeon is in any danger of mistaking the complaint for amaurosis.

The characteristic appearances of amaurosis are entirely different. 1. The opacity, perceptible behind the pupil, is at a considerable distance from this opening, as may be best seen when the eye is viewed sideways. 2. The opacity is somewhat concave. 3. Its colour inclines rather to a greenish, or reddish cast, than to gray. 4. The decline of the eyesight is not at all in a ratio to the degree of opacity, the patient being almost blind. 5. The pupil is more or less dilated; the iris nearly or quite motionless, its pupillary edge being here and there thrown into an angle, and of course it is not exactly circular. 6. Even the cornea itself is not quite so clear and transparent as in the natural state. 7. The temporary increase or diminution of blindness, so common in patients with incomplete amaurosis, never depends, as in those with cataracts, upon the degree of dilatation of the pupil, or the degree of light, but upon causes, which tend either to depress, or excite the system. 8. The misty halo, which such amaurotic patients perceive around the flame of a candle, is not like a whitish cloud, but has all the hues of the rainbow: indeed, the flame itself presents these colours, and when the patient goes to some distance from it, it generally seems split.—9. At no period of the complaint are spectacles of any service in enabling the patient to see better. 10. Lastly, such objects as are situated to one side, cannot be seen more plainly than those which are directly in front of the eye. (See *Beer's Lehre von den Augenkr.* B. 2, p. 281—284.)

According to this author, the first and most important division of cataract is into the *genuine* and *spurious*; for the obstacle to vision, situated in the posterior chamber, between the vitreous humour and the uvea, and making what is termed a cataract, may be either within the limit of the capsule of the lens, or between the anterior layer of that capsule and the uvea. The first case is the *genuine*; the *second*, the *spurious* cataract.

A genuine cataract, when a primary dis-

ease, and unattended from the first with other morbid effects in the eye, is mostly a single independent affection; on the contrary, as the spurious cataract is generally the consequence of internal ophthalmia, it is almost always more or less combined with a partial opacity of the anterior layer of the capsule, and, of course, with a genuine cataract.

The first variety of genuine cataract, noticed by Beer, is that which he calls *lenticular*; it always begins in the centre, or very nucleus of the lens, mostly presenting a very dull yellowish-gray colour, which is somewhat deeper at the centre, than at the margin of the pupil; a character retained even when the disease is in its most complete stage. The lenticular cataract is always formed very slowly, and except when the iris is too dark coloured, it is more or less attended with a blackish ring at the edge of the pupil, which ring becomes plainer as the disease advances. A genuine lenticular cataract never causes any alteration in the expansion or contraction of the iris; nor does it even in its highest degree deprive the patient of all power of vision, the patient in shady places, or when the pupil is artificially dilated with hyosciamus, being often capable of distinguishing pretty well many objects, which are placed laterally with respect to the eye. A lenticular cataract also is usually at some distance from the uvea, so that the extent of the posterior chamber is manifest, while the opacity presents more or less of a convex appearance, and never that of very white cloudy specks. Frequently, as Beer observes, the lenticular cataract is unattended with any change in the capsule, or the liquor of Morgagni. In most cases of senile cataract, not preceded by inflammation, the capsule is said to remain transparent. (Travers, *Synopsis of the Diseases of the Eye*, p. 207, 8vo. Lond. 1820.)

The second species of genuine cataract, noticed by Beer, is the *capsular*, which he thinks should not be called *membranous*, as the expression may lead to mistake. The disease seldom commences in the centre of the pupil, and usually arises at its margin in the form of distinct, very white, shining points, streaks, or specks; its colour, therefore, is always very light, and never altogether uniform, even when the disease is completely formed. The dotted, or mottled appearance of this cataract, is also particularly noticed by Mr. Travers. (*Synopsis of the Diseases of the Eye*, p. 207.) The blackish ring, which when the iris is light coloured, is even more evident in this, than the lenticular cataract, is here not owing to the shadow of the iris, but to its dark border; for this cataract is too near the iris for any shadow to be formed. This observation, however, is somewhat at variance with what Mr. Travers has remarked; for when a transparent circumference can be seen on dilating the pupil with belladonna, Mr. Travers has never found the

capsule opaque; and he believes, that the black rim may be considered as the diagnostic mark of the transparency of the capsule. But, where the opacity of the lens is diffused, this sign is of course absent. (*Med. Chir. Trans. Vol. 4, p. 288*.) The disease also has some effect on the motions of the iris, at least, their quickness. A capsular cataract never remains long the only affection, but is followed by disease of the lens itself; a fact, says Beer, which cannot surprise us, when we consider, that it is through the medium of the capsule, that the particles of the lens are incessantly undergoing the changes of removal and reproduction.

The capsular cataract is subdivided by Beer into the *anterior capsular cataract*; the *posterior capsular cataract*; and the *complete capsular cataract*, in which both the front and back portions of this membrane are opaque.

The *anterior capsular cataract*, which is not at all unfrequent, does not continue long in this form after it has attained a high degree, but, according to Beer, becomes combined with an opacity, and, according to Mr. Travers, with a slow absorption of the lens itself. (*Synopsis, &c. p. 207*.) "When the capsule is completely opaque, (says Mr. Travers) we can hardly judge of the texture of the lens." But, in such examples, "the lens is commonly diminished in bulk; it undergoes a waste after the opacity of the capsule, so as in process of time to become a membranous cataract. This I conceive to be owing to the obliteration of the vessels of the capsule, from which those of the lens are derived. When the capsular opacity is congenital, it is either purely capsular, or only a very small piece of lens remains. When the capsule turns opaque from injury, the lens is soon greatly reduced in bulk, as appears from the falling in, or concavity of the iris, which loses its support, and is demonstrated in the operation. This observation renders the operation with the needle appropriate to the cataract, in which the capsule is opaque, in cases which are not very recent." (*Med. Chir. Trans. Vol. 4, p. 286*.) The anterior capsular cataract, may be known by its light gray, and in some places, completely chalk-white colour, intersected by shining, mother-of-pearl-like streaks and spots. As the capsule is at the same time thicker than natural, the posterior chamber is lessened, and the cataract is not unfrequently close to the uvea, especially when the lens has also completely lost its transparency. In this stage, the movements of the iris are likewise rendered less quick, and the shadow at the margin of the pupil is entirely absent. Hence, vision is not only hurt, but quite impeded, in regard to any correct sensation of light, whether the patient be in a light, or shady situation; and frequently a faint light is completely invisible to him.

The *posterior capsular cataract* belongs to the rarer forms of the disease of the eye, but

says Beer, when it happens, the lens always participates in the opacity, much more quickly, than occurs in the anterior capsular cataract. Hence, the disease can never be observed up to its perfect developement. Respecting the state of the lens, some difference prevails between the statement of Beer and that of Mr. Travers: the latter gentleman informs us, that where the opacity of the posterior capsule is met with, which he agrees with Beer in considering as very rare, the lens and anterior capsule are usually transparent; "and when this is not the case, and the cataract escapes with a posterior fold of opaque capsule, it is always accompanied with a considerable discharge of vitreous humour. (*Synopsis of the Diseases of the Eye*, p. 209.) And, in speaking of the opacity of the posterior capsule, in another work, he informs us, that he has not observed, that, in this case, the lens undergoes any diminution. (*Med. Chir. Trans. Vol. 4. p. 286.*) Like the anterior capsular cataract, it is denoted by a whitish-gray, unequal variegated colour; but no light-coloured, chalk-white spots and streaks are ever discernible, which while the lens retains its transparency may be owing to the distance of the cataract from the pupil. However, the opacity situated behind the pupil, always seems concave, when the eye is inspected, not from before, but from every side of it. While the posterior half of the capsule is not completely opaque, the lens is not materially affected; the eyesight is only more or less weakened; and sometimes, especially with the aid of a magnifying glass, a tolerable degree of vision is enjoyed, notwithstanding the considerable opacity behind the pupil. This species of cataract has not itself any influence over the motions of the iris, and after the lens becomes opaque, it is not softened.

Though the complete capsular cataract is not the rarest species of genuine cataract, it cannot be said to be very common. In addition to the symptoms of the anterior capsular cataract, it presents few, yet decided characters, which indicate it previously to an operation: viz. the iris is nearly motionless, the cataract lying close to that organ; the posterior chamber for the same reason is effaced; and an inexperienced surgeon might really suppose the anterior portion of the capsule were adherent to the uvea, unless he convinced himself of the contrary, by producing an artificial dilatation of the pupil with hyosciamus, or belladonna. Sometimes, the iris even seems thrust out, by this large cataract, towards the cornea in a convex form; and the patient can only perceive the strongest kinds of light.

The third species of genuine cataract is the *cataracta Morgagniana*, which some term the milk cataract, and others confound with the purulent cataract. It is one of the rarest forms of the disease; so rare indeed, that Mr. Travers regards the case as purely hypothetical. (*Synopsis of Diseases of the Eye*, p. 208.) The following is the form of disease, described by Beer, under

this name; it proceeds from a total conversion of the lens into a milky fluid, or thin jelly, frequently attended with a complete capsular cataract. Its origin is said to be always quick, and an immediate effect of chymical injuries of the eye, especially those produced by the gases formed when a metal is oxydated by a mineral acid. The following are the symptoms of the case, while it is uncomplicated with disease of the lens and capsule; a state, which can never continue long. Though the colour is milk-white, it is delicate and thin, like that of diluted milk.

The whole pupil seems cloudy, but whenever the eye-ball moves suddenly and violently, or the eyelid is rubbed over the eye, the opaque substances change their shape and position. The posterior chamber is nearly annihilated, which may be owing to the quantity of fluid, or gelatinous substance collected. While the lens and capsule are not materially changed, the sight suffers only a diminution, though it is very cloudy, and small objects cannot be distinguished at all. When, however, the lens and capsule become opaque, vision is quite abolished, a certain power of knowing light from darkness only remaining. Not unfrequently, says Beer, when the lens itself is in a dissolved state, the capsule is partially opaque, the eye is kept quiet for a few minutes, and the patient stands or sits in an upright posture, two rows of opaque matter can be plainly seen; the upper being the least white of the two; the lower presenting a chalky whiteness. However, as soon as the patient suddenly or violently moves his eye, or head, or the eyelid is rubbed over the eye, both these rows of opaque matter disappear, and the colour of the opacity behind the pupil again seems uniform.

The fourth species of genuine cataract, described by Beer, is the *capsulo-lenticular cataract*, to which he conceives the liquor of Morgagni in an altered state, may likewise often contribute, as may be inferred from the prodigious size of this cataract. It is by no means uncommon, and is attended with the following characteristic symptoms. The colour of the opacity close to the uvea, is partly chalk-white, partly like that of mother-of-pearl, and, in many places, both these colours can be evidently seen disposed one over the other, that of mother-of-pearl, however, being always most superficial. Exposure of the eye to the most vivid light scarcely causes any motion of the iris, but the pupil is circular, without any angles in it. After the application of the extract of henbane, the iris contracts again exceedingly slowly, and the pupil is long in returning to its former diameter. Besides the obliteration of the posterior chamber, the anterior one itself is mostly diminished, in consequence of the iris being pushed towards the cornea by the very large size of the cataract, and hence, the sensation of light is very indistinct.

The capsulo-lenticular cataract is not unfrequently the consequence of a slow inflam-

matory process in the iris, the lens and its capsule; and hence, several varieties of this case, and its not unfrequent combination with a spurious cataract; all which different modifications, says Beer, should be correctly understood previously to an operation, in order to form a just prognosis of its event, and to know what method of operating ought to be adopted.

Of these varieties the first is the *capsulo-lenticular cataract*, conjoined with slight depositions of new matter upon the anterior capsule of the lens. These after-formations upon the front layer of the capsule, as Beer calls them, put on very different appearances, and accordingly receive various appellations. For instance, the *marbled capsulo-lenticular cataract*, when the chalk-white new formed substances upon the anterior layer of the capsule are so arranged as to resemble the variegated appearance of marble. The *window, or lattice capsulo-lenticular cataract*, when the new-deposited substances cross each other, leaving darker coloured interspaces. The *stellated capsulo-lenticular cataract*, when the new matter runs in concentric streaks, towards the middle of the pupil. The *central-capsulo-lenticular cataract*, when a single, elevated, white, shining point is formed on the anterior capsule, while the rest of this membrane is tolerably clear, and the lens not completely opaque. The *dotted capsulo-lenticular cataract*, when the front layer of the capsule presents several distinct unconnected dispositions on its surface. The *half-cataract, or cataracta capsulo-lenticularis dimidiata*, when one half of the front layer of the capsule is covered with a white deposit. In all these, and some other examples, says Beer, the lens is found to be converted to its very nucleus into a gelatinous, or milk substance.

The second variety of the capsulo-lenticular cataract, pointed out by Beer, is the *encysted*, indicated by its snow-white colour; sometimes lying so close to the uvea, as to push the iris forward towards the cornea; and, at other times, appearing to be at a distance from the uvea. These circumstances, as Beer remarks, almost always depend upon the position of the head; for, when this is inclined forwards, the cataract readily assumes a globular form, and projects considerably towards the anterior chamber. Frequently, this variety of the capsulo-lenticular cataract constitutes the kind of case, to which the epithets, *tremulous* or *shaking* and *swimming*, or *floating*, are applied. According to Beer, the reason of such unsteadiness in the cataract is owing to the broken, or very slight connexion of the capsule of the lens with the neighbouring textures. The same author has never seen any case of this kind, which had not been preceded by a violent concussion of the eye, or adjacent part of the head. Both layers of the capsule are opaque, and sometimes considerably thickened. The third variety of the capsulo-lenticular cataract, described by Beer, is the *pyramidal, or conical*, which is one of the rarer forms of the

disease, and always brought on by violent internal inflammation of the eye, especially affecting the lens, its capsule, and the iris. It may be known by a white, almost shining, conical, more or less, projecting new-formed substance, which grows from the centre of the anterior layer of the capsule, and is almost in close contact with the pupillary margin of the iris. Hence, the iris is always quite motionless, and the pupil angular. Sometimes, this growth from the capsule extends itself so far into the anterior chamber, as nearly to touch the inner surface of the cornea, and sometimes actually to adhere firmly to it: a circumstance, says Beer, which is very constant in the conical staphyloma of the cornea, though not discoverable till the operation is performed. The power of discerning light is feeble and indistinct, and sometimes entirely abolished.

The fourth variety of the capsulo-lenticular cataract is that which is covered with a dry shell, or husk. Though principally met with in young children, it is not one of the most uncommon affections in adults, and in the former, it is often falsely regarded as a congenital complaint. When this cataract is extracted either from children, or grown-up persons, Beer says, that the dried shrivelled capsule is always found round the equally dry nucleus of the lens, like a husk, or shell. In children, however, he says, that the nucleus of the lens is often scarcely perceptible, while, in adults, it is always of considerable size, and this may be the reason, why this cataract in children does not present so bright a yellow-white colour, as it does in grown-up persons. In infants, in which it is frequently seen in the first weeks of their existence, it is manifestly produced by a slow and neglected inflammation of the lens and its capsule, arising from too strong light. In adults, the inflammation, exciting this form of cataract, is always owing to external violence; yet Beer supposes, that a considerable diminution of cohesion between the capsule and the adjacent textures must likewise have a principal share in bringing on the disease, which, in grown-up persons, is constantly preceded by a concussion of the eye-ball, from the cut of a whip, the lash of a horse's tail, &c. Professor Schmidt had never seen this kind of cataract, except in boys and girls, who in their early childhood had been afflicted with convulsions; and hence, he thought, that the cause of the disease was owing to a partial loosening of the capsule from its natural connexions by the violence of the convulsive paroxysms. *Abhandlung über Nachstaar und Iritis nach Staar. operationen, Wien. 1801, 4to.* However, Beer assures us, that he has seen infants, scarcely two months old, affected with this cataract, which had not been preceded, or followed by any convulsions; while a much larger number of children with the same kind of cataract had fallen under his notice, where more or less severe

blows on the head had been received. With respect to the convulsions, spoken of by Schmidt, he also questions, whether they and the cataract might not be owing to the same cause, viz. the preceding inflammation within the eye? In children, says Beer, this form of cataract may be known by its light gray, whitish, though seldom very white, colour, its diminutive size, and considerable distance from the uvea, and by the freedom, with which the iris moves, when no adhesions exist at any points between this organ and the cataract, as occasionally happens; a proof of the previous inflammation of the capsule, lens, and neighbouring textures. The eye-sight is never quite impeded, but only much diminished. On the contrary, in adults, as Beer has remarked, this cataract invariably presents a dazzling white hue, and only a few points of it are of a smutty yellowish white colour, whence the case has been sometimes termed the *gypsum cataract*. It is not convex, but rather flat; it does not approach the iris; and, when free from adhesions to the uvea, which are more likely to happen in adults, it has no effect on the motion of the iris. Vision is generally entirely lost, with the exception of the power of discerning the light, and, even this faculty is sometimes destroyed, in consequence of the previous violence done to the eye, whereby not merely the lens and its capsule, but also the retina, have suffered.

According to Beer, one of the rarest varieties of the *capsulo lenticular cataract* is that accompanied with a cyst of purulent matter. It is indicated by a deep lemon colour, very slow motion of the iris, manifest abolition of the posterior chamber, slight convexity of the iris, trivial perception of light, and the weak, unhealthy constitution of the patient. The purulent cyst, which sometimes contains a very fetid matter, and was therefore called by Schiferli the *putrid cataract*, (*Theoretisch-Praktische Abhandlung über den Grauen Staar*. 8vo. Jenn. and Leipz. 1797.) may sometimes be taken out, without being broken, together with the whole capsule of the lens, with the aid of the forceps, or cataract-tenaculum, as was first correctly remarked by Professor Schmidt. In one single example, Beer found the cyst of matter between the lens and the anterior portion of its capsule. Mr. Travers has likewise seen an example of suppuration within the capsule, which projected through the pupil in a globular form, and was filled with pus. The case happened in a lad, and had been preceded by a severe blow on the eye. (*Synopsis of the Diseases of the Eye*. p. 206.)

The sixth, and last variety of the *capsulo-lenticular cataract*, mentioned by Beer, is the well-known case, described by the French under the name of *cataracte barrée*, the *bar-cataract*, and by Schmidt under the appellation of the *cataract, with a girth or zone*. The case, says Beer, is one of the least frequent. The diagnosis is easy; for, behind the diminished, more or less angular pupil, the cataract can be plainly seen, to

which is attached, either in a more or less perpendicular, or horizontal direction, a chalk-white, generally very shining, and thickish kind of bar, or girth, which is closely adherent at both its extremities to the pupillary margin of the uvea, and sometimes reaches, but often only on one side, more or less towards the ciliary processes. The iris is therefore completely motionless, the uvea not being merely adherent to the substance forming what is termed the *bar*, or *girth*, but also closely connected with the whole front portion of the capsule. The perception of light is either very indistinct, or quite lost, and, not unfrequently, the globe of the eye is somewhat smaller than natural. Beer says, that he has never met with this variety of cataract, except after violent internal inflammation of the eye. He describes the substance, composing the *bar* or *girth*, as being of various consistence, and sometimes firm and almost cartilaginous. In two cataracts of this sort, which he extracted from a boy twelve years of age, he found the *bar*, strictly speaking, ossified, and the capsule, which was nearly cartilaginous, was adherent to a very small, firm nucleus of the lens, though they were yet capable of separation. In a dead subject, Beer also examined such a cataract, in which the outer end of the *bar* scarcely extended to the greater ring of the uvea, but the inner end reached over the ciliary processes to the ciliary ligament, from which latter part it was inseparable. (*Lehre von den Augenkr.* B. 2, p. 302.)

OF SPURIOUS CATARACTS.

The most frequent, according to Beer, is what he names the *lymph-cataract*. It is, without exception, the effect of an inflammation, which is chiefly situated in the iris, the lens, and its capsule. Hence, it is frequently combined with a genuine cataract. The nature of the disease may be known from the patient's account, that the present blindness has been preceded by a painful tedious affection of his eye and head; and from an examination of the eye itself, in which the pupil will be found more or less diminished and angular; the iris either perfectly motionless, or nearly so; the eyesight, and even sometimes the perception of light, more or less impeded, or lost, and this not merely in proportion to the quantity of lymph observable immediately behind the pupil, but also in proportion to other morbid effects produced in the organ by inflammation. Lastly, the surgeon may notice directly behind the pupil a plastic lymph, either in the form of a delicate kind of network, or of a thick web of a snow-white colour. Sometimes, in this variety of spurious cataract, though very little coagulating lymph appears upon the anterior portion of the capsule of the lens, and what is effused, as well as the lens itself, is almost clear and transparent, yet, the eyesight is considerably impaired; and, on more careful examination of the pupil, something of a dark-brown colour is perceived, which often pro-

jects, at several points behind the pupillary edge of the iris, a good way towards the centre of the pupil. In this substance, one may discern, with a good magnifying glass, new vessels extending from those of the uvea, and formed by the previous inflammation, by means of which vessels, this mass, and the delicate layer of lymph, are connected with the capsule of the lens. According to Beer's sentiments, it is only the real lymph-cataract, which rightly deserves the epithet *membranous*, which is sometimes wrongly applied to the *capsular cataract*; for, says he, the *lymph-cataract alone consists of an adventitious membrane, formed by inflammation of a web of plastic lymph, which may be very thin, and semi-transparent, while the lens and its capsule are nearly quite clear, though the patient may be almost or completely blind, when the effects of the inflammation have extended to the choroides and retina.*

The *spurious purulent cataract* is much less frequent, than the lymph-cataract. In neglected cases of hypopium (*see this word*), where the pupil is already quite covered with pus, the greater part of the effused matter is sometimes absorbed, and the pupil can be seen again, but, immediately behind it, a quantity of coagulating lymph can be discerned as in the lymph cataract, sometimes even projecting partly into the anterior chamber, but blended with particles of purulent matter, so as to give it a light yellowish tinge, and a clustered appearance. The pupil is always diminished, adherent to the morbid substance, and angular; the motionless iris projects towards the cornea; and not only the eye-sight, but even the perception of light are completely lost, or the latter at least much diminished.

A rare variety of spurious cataract, described by Beer, is the *blood-cataract*. Either from some considerable injury of the eye, a large quantity of blood is extravasated in the chambers, and, slowly absorbed during the ophthalmia caused by the violence, a part of it, however, remaining in the posterior chamber in the form of small clots, encysted in the lymph, which was effused during the inflammation; or else in the course of a more tedious and neglected case of hypopium, blood is effused in the chambers of the eye, and, not mixing with the pus, still continues in the same form behind the pupil, after the matter has been absorbed. In the first example, this cataract looks like a reddish web, interwoven with silvery streaks, or threads; the pupil, though angular, is seldom contracted; the iris nearly, or quite motionless; and, not only is the light clearly distinguished, but a partial degree of vision sometimes retained. On the contrary, in the second instance, the opacity behind the pupil is very dense, white, studded with reddish, or brownish points, or specks, having a clustered appearance, and frequently projecting through the pupil into the anterior chamber; while the pupil itself is very small, and angular, the iris quite incapable of motion, and ge-

nerally either no perception of light remains, or only a very confined indeterminate sensation of it. Beer says, that this cataract may easily be mistaken for lymph, and that its differences can only be made out with a good magnifying glass.

The *dendritic cataract* of Schmidt, the *arborescent cataract* of Richter, or the *choroid cataract*; as Beer observes, is not one of the least frequent of the spurious cataracts, and is invariably the consequence of a violent concussion of the globe of the eye, with, or without a wound, whereby a portion of the tapetum of the uvea is loosened and becomes placed upon the anterior layer of the capsule, more or less resembling in its appearance the arborescent form of the stone termed a dendritis. Immediately after such a concussion of the eye-ball, the patient complains of a serious diminution and confusion of vision. Whoever examines the eye only superficially, will certainly not discern the pieces of the tapetum lying upon the yet perfectly transparent capsule of the lens, for the most careful inspection will be necessary for the purpose, and sometimes the aid of a magnifying glass will be requisite. But, as the lens and its capsule are mostly at the same time loosened from their connexions, they likewise generally become deprived of their transparency, and as soon as this has happened, the displaced portion of the tapetum can be readily seen. When inflammation ensues, the flakes of the tapetum become closely adherent to the front layer of the capsule of the lens, and even the pupillary edge of the uvea acquires the same kind of connexion, so that the perception of light is diminished. But, says Beer, when inflammation follows, the pupillary margin of the uvea remains free, the iris is perfectly moveable, the light clearly distinguishable though the lens and its capsule be entirely opaque, and sometimes the flakes of the tapetum resembling the arborescent streaks of the dendritis alter in shape, size, and position, but never completely disappear, though they may not closely adhere to the capsule. (*Lehre von den Augenkr. B. 2, p. 303, 309.*)

Another classification of cataracts, which is of great importance to an operator, is that which is founded upon their consistence; for, as Beer remarks, this makes not only a great difference in the prognosis, but also in the choice of a method of operating.

When the opaque lens is either more indurated, than in the natural state, or retains a tolerable degree of firmness, the case is termed, a *firm, or hard cataract*. When the substance of the lens seems to be converted into a whitish, or other kind of fluid, lodged in the capsule, the case is denominated a *milky, or fluid cataract*. When the opaque lens is of a middling consistence, neither hard nor fluid, but, about as consistent as a thick jelly, or curds, the case is named a *soft, or caseous cataract*. When the anterior, or posterior, layer of the crystalline capsule becomes opaque, after the lens itself has been removed from this little membranous

sac, by a previous operation, the affection is named a *secondary cataract*.

The harder the cataract is, the thinner and smaller it becomes. In this case, the disease presents either an ash-coloured, a yellow, or a brownish appearance: According to Beer, its colour is very dark. The interspace, betwixt the cataract and pupil, is considerable. The patient distinctly discerns light from darkness, and when the pupil is dilated, can even plainly perceive large bright objects. In the dilated state of the pupil, a black circle surrounding the lens is very perceptible. The motions of the iris are free and prompt; and the anterior surface of the cataract appears flat, without any degree of convexity. (*Richter's Anfangsgr. der Wundarzn* p. 177. 3 B. Beer, Vol. cit p. 309.)

Beer says, that it is only the genuine lenticular cataract, which can be hard, and it is chiefly met with in thin, elderly persons; but, with respect to the opinion, that all cataracts in old persons are firm, he says, this is frequently contradicted by experience. In cataracts, extracted from thin, aged individuals, the lens is sometimes found dwindled, as hard as wood, nearly of a chesnut-brown colour, and with its two surfaces as flat as if they had been compressed. This case has sometimes been denominated the *dark-gray cataract*, and is very difficult to make out previously to an operation, being liable to be mistaken for an incipient amaurosis. Hence, in order to judge of it effectually, the pupil should always be dilated with hyosciamus.

To the firmish, consistent kind, Beer refers several capsulo-lenticular cataracts, namely, the *encysted*, and *conical* or *pyramidal cataracts*, that to which he applies the epithet *dry husked*, the *gypsum cataract*, in particular, and the *bar-cataract*, which at least is always partly firm, as well as all the varieties of *spurious cataract* (Beer, B. 2, p. 309.)

The fluid, or milky cataract, has usually a white appearance; and irregular spots and streaks, different in colour from the rest of the cataract, are often observable on it. These are apt to change their figure and situation, when frequent and sudden motions of the eyes occur, or when the eyes are rubbed and pressed; sometimes, also, these spots and streaks vanish, and then reappear. The lower portion of the pupil seems more opaque than the upper, probably because the untransparent and heavy parts of the milky fluid sink downward to the bottom of the capsule. The crystalline lens, as it loses its firmness, commonly acquires an augmented size.—Hence, the fluid cataract is thick, and the opacity close behind the pupil. Sometimes one can perceive no space between the cataract and margin of the pupil. In advanced cases, this aperture is usually very much dilated, and the iris moves slowly and inertly. This happens because the cataract touches the iris, and impedes its action. The fluid cataract is

sometimes of such a thickness, that it protrudes into the pupil, and presses the iris so much forward, as to make it assume a convex appearance. Patients, who have milky cataracts, generally distinguish light from darkness very indistinctly, and sometimes not at all; partly, because the cataract, when it is thick, lies so close to the iris, that few or no rays of light can enter between them into the eye; partly, because the fluid cataract always assumes, more or less, a globular form, and therefore has no thin edge, through which the rays of light can penetrate. (*Richter's Anfangsgr. der Wundarzn* 3 B. 174, 175.) Mr. Travers believes that fluid cataracts are rarely contained in a transparent capsule, and his experience has taught him, that this membrane is partially opaque, presenting a dotted, or mottled surface. The opaque spots are most distinguishable when viewed laterally. (See *Med. Chir. Trans.* Vol. 4, p. 284.)

According to Beer, a fluid cataract is mostly conjoined with a complete opacity of the capsule; its diagnosis therefore is commonly very difficult, and sometimes its nature cannot be known with certainty, until an operation is undertaken. When the capsule is opaque only in some places, he states, that the following circumstances may be noticed. The cataract lies close to the uvea, and when the patient inclines his head forwards, the cataract presses the iris towards the cornea, and the anterior chamber becomes evidently smaller; but, when he lies upon his back, the cataract recedes in some degree from the uvea. The power of distinguishing the light is decided. When the head is kept quiet for a long time, a thick sediment, and a thinner part can be plainly remarked in the cataract; during which state, that is, while the two substances are undisturbed, the patient can sometimes distinguish large well-lighted objects, as through a dense mist; but, when the head, or eye, is quickly moved, these two substances become confused together again, and the cataract again presents an uniform white colour. (Vol. cit. p. 312.) It cannot be denied, says Beer, that what is called the *congenital cataract*, and which presents itself in infants soon after birth, when their eyes have been exposed to immoderate light, is not unfrequently fluid; but in such cases it must not be presumed that the lens is always in this state; for, in fact, the cataract is often of that sort, which Beer describes under the name of *dry-husked*.

Sometimes the opaque lens is of a middling consistence, neither hard nor fluid, but about as consistent as thick jelly, curds, or new cheese. Cases of this description are termed soft or caseous cataracts. The consistence here spoken of, may be confined to the two surfaces of the lens, or may exist in its very centre. The first case is the most frequent. The diagnosis is not difficult; for, it always has a light gray, grayish white, or seagreen colour. When it is far advanced, it quite impedes the eyesight

and sometimes considerably interferes with the perception of light. (*Beer, B. 2, p. 310.*) As the lens softens in this manner it commonly grows thicker and larger, even acquiring a much greater size than the fluid. It is not unfrequent to meet with caseous cataracts of twice the ordinary size of a healthy crystalline lens. The motions of the iris are very sluggish. (*Richter's Anfangsgr. der Wundarzn. p. 178. 3 B.*) Indeed, Beer says, that it is sometimes requisite to use the hyosciamus, in order to ascertain that no adhesions exist between the uvea and the cataract, for, in such cases, the posterior chamber is very often completely abolished, as the more caseous the lens is, the larger it is; and hence likewise the black ring at the edge of the pupil is not at all owing to the shadow of the iris, but entirely to the dark border of the iris, at the margin of that opening. According to Beer, the colour of such cataracts is never uniform, but more or less speckled; the spots, however, either have no determinate outline, or they seem like mother-of-pearl fragments, into which the cataract crumbles when extracted, or couched, or else they assume the appearance of clouds. (*Beer, B. 2, p. 311.*) According to Mr. Travers, the caseous cataract has a heavy dense appearance, uniformly opaque, a clouded, not a fleecy whiteness, and sometimes a greenish, or dirty white tinge.—(*Med. Chir. Trans. Vol. 4, p. 285.*) He further states, that what he terms the *flocculent* or *fleecy*, and the *caseous*, or *doughy* cataracts, are most frequently met with; the *fluid*, or *milky* cases, and those called *hard*, being comparatively rare (*Op. et loc. cit.*)

As Beer observes, a cataract, which is recent, and has originated suddenly, especially in young subjects, requires much more circumspection ere an operation is determined upon, than a cataract, which has already existed a long while, and the formation of which has been only gradual, particularly in an old subject: for, the first case is more frequently owing to a concealed slow kind of inflammation, than is generally supposed. (*Vol. cit. p. 314.*)

Cataracts are also denominated *ripe*, or *unripe*; terms, which have often led to the error of supposing, that every cataract must ripen in time. A cataract is called ripe, as soon as it is in a state which will admit of no increase, whether the eyesight be completely lost, or only diminished, and whether the pupil be entirely occupied by it or not. Thus, says Beer, the *dry-husked cataract*, in its most advanced stage, never totally fills the pupil, and the patient can sometimes even discern colours; nor does the *floating capsular-lenticular cataract* fill the pupil in a greater degree; and yet both these cases are completely ripe for an operation. On the other hand, to the *unripe* cataracts belong the *central cataract of the capsule and lens*, the *posterior capsular cataract*, and the *slight degree of lymph-cataract*. Most of these unripe cataracts, after, perhaps, remaining for years in this state, not

unfrequently all on a sudden become complete, upon an accidental and slight attack of ophthalmia; but, sometimes, they remain unchanged during life. (*Beer, B. 2, p. 316.*)

Another very useful and practical division of cataracts is into those which are called *simple local*, and into others, which receive the name of *complicated*. A *simple local* cataract is so denominated by Beer, when the patient is in every other respect perfectly healthy, and no disease prevails in any other part, however distant from the eye. A cataract may be *complicated* in three ways; for, it may be attended either with other simultaneous disease in the eye itself, or its appendages, when the case is termed a *local complicated cataract*; or there is some other disease prevailing in the system, either unconnected, or connected, with the production of the cataract, which then has the epithets *general complicated* applied to it; or, lastly, both descriptions of complication exist together, the *complete complicated cataract*.

Among the *local complicated* cases, is the *adherent cataract*. The preternatural cohesion may be one of the anterior layer of the capsule with the uvea, produced by effused lymph; it may consist in a very firm connexion of the posterior layer of the capsule with the membrana hyaloidea; or it may be an unusually close cohesion of the whole of the capsule with the lens; or, says Beer, all the three species of adhesion may exist together. (*p. 318.*)

The adhesion of the capsule of the lens to the uvea (*synechia posterior*) is generally obvious enough; for, as Beer has observed, the pupillary margin of the iris is not completely circular and is more angular the stronger the light is. The cataract lies close to the uvea, and is very white. The motions of the iris are more or less obstructed, and, when the adhesion is extensive, are quite prevented. The perception of light is indistinct, often very faint, and sometimes entirely lost, for the preternatural adhesion is always the consequence of previous internal ophthalmia, which, besides occasioning opacity of the lens and its capsule, readily produces other serious effects upon the retina, the choroid coat, and vitreous humour, quite adequate to account for the loss of sight, and the incapacity of distinguishing the rays of light.—When the anterior layer of the capsule is adherent only at a single point to the uvea, the extent of the adhesion may be readily ascertained by artificially dilating the pupil with hyosciamus, or belladonna; and the information thus obtained, will have great weight in the selection of a method of operating (*Beer, loco cit.*)

Some other local complications of cataract are so obvious, that they cannot fail to be understood; as, for instance, its combination with an adhesion of the iris to the cornea (*synechia anterior*;) with closure of the pupil, unattended by any adhesion of the uvea to the anterior capsule of the lens

(*synechia posterior*;) as in watchmakers, and hysterical or hypochondriacal subjects, the complications with atrophy, hydrophthalmia, cirsophthalmia, specks and scars upon the cornea, pterygium, and various forms of ophthalmia.

According to Beer, the combination of cataract with glaucoma is also readily made out by any body who has once seen the case; for the cataract always presents a greenish, and sometimes quite a sea-green colour; it is of prodigious size, so as to project through the pupil towards the cornea; the colour of the iris is more or less changed, nearly in the same manner as after iritis; the iris is perfectly motionless; the pupil very much expanded and drawn into angles, for the most part towards the canthi; the lesser circle of the iris is nowhere visible, because it lies concealed under the far-projecting soft cataract; the light cannot be perceived, though the blinded patient is frequently conscious of false luminous appearances within the eye (*photopsia*;) and, lastly, the case is invariably accompanied with more or less of a varicose state of the blood vessels of the eye. The origin of this sort of cataract is constantly attended with severe, obstinate headach.

There are, says Beer, two other local complications, which are much more difficult to learn before an operation. The first is a cataract combined with a dissolution of the vitreous humour (*synchysis*;) the diagnosis of which, indeed, when the affection prevails in a considerable degree, is tolerably easy, as the cataract trembles, and the iris always swings backwards and forwards upon the slightest motion of the eye-ball; the globe itself is somewhat affected with atrophy; the eye is quite spoiled, and feels flaccid and unresisting; the sclerotica, immediately around the cornea, is bluish, as in infants; and, the perception of light is uncertain. On the other hand, when the *synchysis* is not far advanced, the only symptoms are a suspicious softness of the eye-ball, and a swinging of the iris, when the eye is suddenly or violently moved.

The other complication of cataract, sometimes very difficult to detect previously to an operation, is amaurosis. When, indeed, the pupil is extraordinarily large, the iris nearly or quite motionless, and the patient cannot distinguish day from night, and, of course, not the least glimmer of light, no great powers of divination are required to predict with certainty, that no operation will restore the eyesight, which is abolished not by the cataract, but by the existing amaurosis. On the other hand, when the motions of the iris are nearly as free as in the natural state, the pupil as small as it usually is in a given degree of light, the patient capable of judging accurately of the strength of the light, and yet the cataract conjoined with amaurosis, which, with the exception of the faculty of perceiving the light, completely impedes vision, it is then only by a careful inquiry into the history of

the disease, that certain circumstances, attending the origin of the cataract, and indicating in some measure the prevalence of amaurosis, can be traced; sometimes in consequence of one eye being affected with amaurosis, and not with cataract, a reasonable suspicion may be deduced, that the eye with cataract is also amaurotic; yet, says Beer, in such a case, nothing certain can be known before an operation is done.

As the same author observes, the general complications of cataract are as numerous as the diseases of the constitution itself, or as the affections of other organs, besides the eye; but the most common are scrophula, gout, syphilis, psora, old ulcers of the leg, and an unhealthy constitution.

CAUSES; PROGNOSIS; &c.

Persons, who are much exposed to strong fires as blacksmiths, locksmiths, glassmen, and those who are engaged in similar employments, are deemed to be more subject to the cataract than others. Persons above the age of forty, are reckoned more liable to cataracts than younger subjects. (*Wenzel*.) The disease, however, is by no means unfrequent in the latter; even children are often seen affected with this kind of blindness, and some are born with it. Beer assents to the general correctness of the opinion, that old age is conducive to cataracts, since the disease is most frequently observed in old persons. Yet, says he, that age, nay a very great age, cannot be deemed a regular cause of cataract, is clear from the circumstance of many very old, and even decrepit, individuals being able, with the aid of spectacles to read the smallest print; and it would seem, that other causes, besides old age, are essential to the production of cataracts; as, for instance, immoderate exertion of the eye during youth, particularly in such employments as expose the organ to a strong reflected light. (*Lehre von der Augenkr.* B. 2, p. 325.)

Among the circumstances which promote the formation of cataracts, Beer enumerates rooms illuminated only by reflected light; and all kinds of work, in which the eyes are employed upon shining, small, microscopic objects, especially when, during such labour, a determination of blood to the head and eyes is kept up by the compressed state of the abdomen, the cataract often seeming to come on more or less quickly with inflammation of the capsule, and lens. And, according to the manifold experience of the same author, one of the most important, though least noticed, causes promoting the formation of cataract, is allowing very strong light suddenly to enter the eyes of a new-born, or very young delicate infant, the consequence of which is, that cataracts form more or less quickly with inflammation of the capsule and lens, or remain for life incomplete, as is the case in the central capsular-lenticular cataract. The habitual vision of minute objects, in a

depending position of the head, by which an undue proportion of blood is said to be thrown upon the organ, frequently brings on cataracts. (See *Medico-Chir. Trans.* Vol. 4, p. 279.) In the majority of instances, a cataract seems to arise spontaneously, without any assignable cause. Sometimes the opacity of the lens is the consequence of external violence; a case, which, more frequently than any other, gets well without an operation.

Frequently (says a modern writer) the cataract "proceeds from a hereditary disposition, which has existed for several successive generations; while, in other cases, it attacks several members of the same family, without any disposition of this kind being recognizable in their progenitors. Among others, Janin mentions a whole family of six persons, who laboured under this disease. (*Obs. sur l'Oeil*, p. 149.) Richter extracted the cataract from a patient, whose father and grandfather had been affected with the same malady, and in whose son, at that period, it had begun to manifest itself. He adds, that he had seen three children, all born of the same parents, who acquired cataracts at the age of three years. (*On the different kinds of Cataract*, p. 3.) "During my apprenticeship with the late Mr. Hill, of Barnstable, I was present when he operated on two brothers, and a sister, all of whom were adults, and who stated, that three or four others of their family were affected with symptoms not unlike those which they had experienced at the commencement of the complaint. I myself recently operated on two gentlemen advanced in years, who informed me, that they had a brother, on his return from India, who was similarly affected." (See *Adams's Pract. Observations on Ectropium, Artificial Pupil, and Cataract*, p. 101. London, 1812.) Beer also speaks of families, in which the children all became afflicted with cataracts at a certain age; cases, says he, where an operation, though done by the most skilful practitioner, hardly ever succeeds. (*Lehre von der Augenkr.* B. 2, p. 331.)

Long exposure of the head and eyes to the rays of the sun, together with a bent position of the body, as in some kinds of field labour, and the drinking of new acid wines, are reckoned by Beer as causes promoting the formation of cataracts on the approach of age; also hard labour near strong fires, as near ovens and forges, in glass houses, &c.; and hence, it is not unfrequent for smiths, cooks, &c. when they are advanced in years, to be afflicted with cataracts.

Beer says, that he has also learned from repeated observation, that exposing the eye to the vapour of concentrated acids, naphtha, and alcohol, will sometimes bring on a cataract; a statement, which will be received in this country with some hesitation, where the vapour of ether has been occasionally recommended for the dispersion of opacities of the lens and its capsule. The

dust of lime is also supposed to be conducive to the disease, cataracts being said to be frequent among the workmen in lime pits and kilns.

Wounds of the eye, where the weapon has pierced the capsule and the lens, and especially violent concussions of the forepart of the globe of the eye, though no wound may exist, are in general followed by a cataract, as an immediate consequence. This is the case, says Beer, even when no inflammation arises from the injury, the cataract often occurring in a few hours, and in so considerable a degree as not to admit of being mistaken.

The cause of cataract thus rapidly produced, must depend, in Beer's opinion, upon the complete separation of the lens, from its connexions with the capsule, and not unfrequently in part upon the detachment of the capsule itself from the neighbouring textures; for, in such cases, this membrane also gradually becomes opaque.

According to Beer, cataracts frequently arise from a slow, insidious, inflammation of the lens and its capsule.

With respect to the prognosis, it must be evident from what has been premised, that there are many cataracts in which the cure is highly problematical, and others, in which the impossibility of restoring vision, even in the slightest degree, may be predicted with absolute certainty.

With the little positive information which surgeons possess concerning the causes of cataracts, scarcely any expectation can ever be entertained of curing opacities of the lens and its capsule, by means of medicine, so as to supersede all occasion for an operation. A possibility of success, as Beer remarks, can exist only when the cause of the cataract is ascertained, admits of complete removal, and the disease is in an early stage. And he has learned from manifold and repeated trials, that the attempt to cure an incipient cataract will never succeed, except when some determinate and obvious general or local affection of a curable nature has had a chief share in the production of the disease of the eye; as, for instance, scrophula in a mildish form, syphilis (?) and the sudden cure of eruptions, or old ulcers of the legs, (?) or a slow insidious inflammation of the iris and capsule of the lens. In some examples of this kind, Beer could only check the further progress of the cataract, and, even when the eye sight was improved, it was never rendered perfectly clear. And when the cataract was far advanced, and quite developed, with the exception of the general melioration of the health, and an improved state of the eye, whereby it was put in a better condition for the operation; not the slightest benefit was derived from medicine. (*Lehre, &c.* B. 2, p. 333.)

The principal external remedies that have been tried for the cure of the cataract, are, bleeding, cupping, scarifying, setons, issues, blisters, and fumigations; and the chief internal remedies are aperients, emetics, en-

charties, sudorifics, cephalics, and sternutatories. Preparations of eye-bright, millepedes, wild poppy, henbane, and hemlock, were some years ago credulously commended as specifics for the disorder.

Scultetus asserts, that he checked the progress of a cataract, by applying to the eye the gall of a pike, mixed with sugar; and Spigelius boasted of having successfully used, for this purpose, the oil of the eelpout (*mustela fluvialis*.)

Cataracts are said to have been cured in venereal patients, while under a course of mercury. Probably, however, many such cases might have been mere opacities of the cornea, which had been mistaken for cataracts. Wenzel placed no reliance whatever on the power of any remedies to dissipate a cataract, and, as he had remarked their inefficacy in numerous instances, he felt authorized in declaring, that internal remedies, either of the mercurial, or any other kind, are inadequate to the cure of this disorder; and equally so, whether the opacity be in the crystalline, or in the capsule, whether incipient, or advanced.

Although the late Mr. Ware coincided with Wenzel and Beer, in regard to the uncertainty of all known medicines to dissipate an opacity, either in the lens, or its capsule, or even to prevent the progress of such opacity, when once begun, yet according to his observations, many cases prove, that the powers of nature are often sufficient to accomplish these purposes. The opacities, in particular, which are produced by external violence, Mr. Ware had repeatedly seen dissipated in a short space of time, when no other parts of the eye had been hurt. In such cases, the crystalline lens is generally absorbed, as is proved by the benefit which is afterwards derived from very convex glasses. In some of these cases, though the crystalline had been dissolved, the greater part of the capsule remained opaque, and the light was transmitted to the retina only through a small aperture, which had become transparent in its centre. Instances are also not wanting, in which cataracts, formed without any violence, have been suddenly dissipated in consequence of an accidental blow on the eye. The remedies which Mr. Ware found more effectual than others, were the application to the eye itself of one or two drops of æther, once or twice in the course of the day, and occasionally rubbing the eye, over the lid, with the point of the finger, first moistened with a weak volatile, or mercurial liniment. But, as Beer observes, the operation is now regarded almost as the only means affording any rational hope of restoring the eyesight of patients afflicted with cataracts.

Notwithstanding also the perfection to which the operation, with all its different modifications, is really brought, its performance will not always re-establish vision; nay, says Beer, it is frequently counterindicated; and, even in favourable cases, the result of the operation is exposed to so many contingencies, that it is rather a mat-

ter of surprise, that, on the whole, so much success should attend it as is found to happen.

When an operation for a cataract is done apparently under favourable circumstances, and its event is unexpectedly very incomplete, or quite unsuccessful, surgeons in vain ascribe the failure to the method of operating, which they have hitherto adopted, and uselessly abandon it for another; because none of these methods, including that which is preferred, brought to the highest state of perfection possible, can be applicable to all cataracts. But, says Beer, the reason of the ill success is generally rather owing to the operation not having been indicated, or to a mode of operating not well calculated for the particular case having been selected. He ridicules the idea of adhering exclusively to any one plan of operating; and, whenever the question is put to him, what is his own plan? he answers, that his custom is to operate in the manner which appears to him to be best adapted to each particular case, about which he is consulted. A surgeon should be able to distinguish, first, the cases of cataract, in which an operation may be done with the best chance of success; secondly, the examples, in which the prognosis is more or less doubtful; and, lastly, the cases, in which there is a great probability, or an absolute certainty, of the operation failing, in which last circumstance the practice is prohibited.

According to Beer, the result of an operation will probably be favourable; 1. When the cataract is a genuine local complaint, perfectly free from every species of complication. 2. When the conformation of the eye and surrounding parts is such, as to allow whatever method of operating may be most advantageous for the particular case, to be done without difficulty. 3. When the patient is intelligent enough to behave himself, in a manner, which will not disturb the precision and safety of the requisite proceedings in the operation, or the subsequent treatment. 4. When the operator, not only possesses all requisite medical and surgical knowledge in general, but is capable of judging correctly, what method of operating suits the particular case; and when besides he has derived from nature and acquirements such mental and corporeal qualities, as are essential to a skilful operator on the eye; viz. an acute eyesight, a steady, but light, skilful hand, excellently qualified for mechanical artifice in general; long, pliant fingers; a delicate touch; a certain tenderness in the scientific treatment of this particular organ; complete fearlessness; invincible presence of mind; and proper circumspection. 5. When the requisite instruments are not too complicated; but well adapted to the purpose, and in right order. 6. When the domestic condition of the patient is such as not to occasion any particular disadvantages during, or after the operation. Yet, says Beer, even with this fortunate combination of circumstances, uniform success must not

be expected after operations for cataracts : for a patient, whose sight is quite prevented by this disease, and who previously to its origin, was already far-sighted, will be still more so after the removal of the diseased lens, and in order to see distinctly the most common objects which are near, he will be obliged constantly to employ suitable glasses. An individual of this description, though the operation be done with great success, is apt not to be satisfied. But, such patients as were short sighted previously to the formation of their cataracts, are more pleased with the restoration of vision ; as, before the operation, their eyesight was much less than what it is now, and, in general, they can lay aside the glasses, which they formerly made use of, without having occasion for any others. Lastly, as Beer remarks, although patients, who, before the origin of their cataracts, were neither far nor short-sighted, are sensible of the important benefit of an operation, inasmuch as they now plainly discern all objects again, yet, they are usually obliged to employ spectacles in reading, writing, or doing any kind of fine work.

On the other hand, the result of an operation Beer considers always more or less doubtful ; 1. When the cataract is only locally complicated, as, for instance, with pterygium, which may not form any absolute reason against the experiment. 2. When the conformation of the eye and surrounding parts, causes several hinderances to the operator ; as is the case, when the eye is small, and deep in the orbit, and the fissure of the eye-lids very narrow. 3. When the patient is either very stupid, and obstinate ; or rough mannered ; particularly timid ; or badly fed. 4. When the surgeon knows how to operate only in one way, in which, perhaps, he has also not had sufficient experience, and when possibly he is also deficient in the qualities specified above, as essential to a good operator on the eyes. 5. When the instruments are bad. 6. When in the patient's domestic affairs, there are any circumstances which cannot be removed, and are likely to have a bad effect upon the operation, as an unwholesome, damp room, great uncleanness, &c. 7. When the origin of the cataract was attended with repeated, or tedious headach, though this may have subsided a long while. 8. When the patient is particularly subject to catarrhal and rheumatic complaints, especially affecting the eyes. 9. When the patient has often had, or still labours under an attack of erysipelas, notwithstanding the parts inflamed be remote from the eye. 10. When the patient's skin is peculiarly irritable. 11. When in his childhood, or youth, he has been frequently afflicted with convulsions, or epileptic fits, though these complaints may have ceased many years. 12. When there is the least tendency to certain constitutional diseases, scrophula, gout, syphilis, &c. Gout, however, does not always make an operation fail, as we learn from Mr. Travers, who, in three cases, ex-

tracted the cataract from gouty subjects, and, though a smart attack of the disease followed the operation, the eyes were unaffected, and the sight was well recovered. (*Synopsis of the Diseases of the Eye*, p. 297.) 13. When the patient's habit is bad, though not affected with any definite disorder. 14. When the patient in his youth has often been troubled with attacks of ophthalmia. 15. When he cannot perceive the different degrees of light, and correctly describe them, while nothing to account for this state can be detected in the eye itself. 16. The result of an operation is always very doubtful, when there is the slightest tendency to hysteria, or hypochondriasis. 17. When the patient is subject to violent mental emotions, mania, &c. 18. When the eye to be operated upon can still discern things, however feebly, a state, which generally produces an involuntary resistance, to the necessary measures in the operation. 19. When the cataract is the consequence of a wound, though free from complication. 20. When the patient is in the state of pregnancy. 21. When one eye has been already destroyed by suppuration. 22. And lastly, when one eye has already been operated upon without success, by a man, whose professional judgment, skill, and caution, are unquestionable.

According to Beer, the result of the operation will be more or less unfavourable ; 1. When the patient is affected with gutta, or acne rosacea, not the effect of hard drinking, but rather of scurvy. 2. When evident traces of some general disease of the constitution are present. 3. When the patient has been ill, and is only yet convalescent. 4. When any other disease, though not constitutional, is present. 5. When the cataract is adherent for a considerable extent to the uvea, or an incurable, though not very severe chronic inflammatory affection of the eye-lids, or eye-ball, prevails, as, for instance, an habitual inflammation of the Meibomian glands ; ectropium of the lower eye-lid ; the remains of a pannus ; or, a strong aversion to light.

Lastly, as Beer observes, every operation must fail, when the cataract is manifestly joined with complete amaurosis, a dissolution of the vitreous humour, dropsy, or atrophy of the eye, some species of ophthalmia, glaucoma, or a general varicose affection of the blood vessels of the eye.

The capacity of distinguishing light from darkness, and, in a shady place, where the pupil is not too much contracted, of perceiving bright colours and the shadows of objects, is, as Scarpa has particularly noticed, a very important desideratum in every case, selected for operation.

The power of distinguishing light from darkness, is even more satisfactory, than motion of the iris. I saw many years ago, in St. Bartholomew's and the York hospitals, several cases of complete gutta serena in both eyes, in which there was the freest contraction and dilatation of the pupils. Had such patients been also afflicted with

cataract (a complication by no means unfrequent) and a surgeon, induced by the moveable state of the iris, had undertaken an operation, it must of course have proved unavailing, since the rays of light could only have been transmitted to an insensible retina. Richter, and Wenzel, make mention of these peculiarities, and the latter refers the phenomenon to the iris deriving its nerves wholly from the lenticular ganglion, while the immediate organ of sight, is constituted entirely by another distinct nerve. Hence, motion of the iris is not an infallible criterion, according to several authors, (*Wathen*) that the retina is endued with sensibility. Relating to this subject, Mr. Lucas has made a curious remark: he attended, in conjunction with Hey and Jones, five children of a clergyman at Leaven, near Beverley, who were all born blind. He writes, "None of them can distinguish light from darkness, and, although the pupil is, in common, neither too much dilated nor contracted, and has motions, yet these do not seem to depend upon the usual causes, but are irregular." (*Med. Obs. and Inq.* Vol. 6.)

The reciprocal sympathy between the two organs of sight, is so active, that no one, solicitous to acquire either physiological or pathological knowledge respecting them ought, for a moment, to forget it. Hence, in the examination of cataracts, it is of the highest importance to keep one eye entirely secluded from the light, while the surgeon is investigating the state of the iris in the other; for, the impression of the rays of light upon one eye, sensible to this stimulus, is known to be often sufficient to produce corresponding motions of the iris in the opposite one, although in the state of perfect amaurosis. In other examples of cataract, the pupil may be quite motionless, and yet sight shall be restored after the performance of an operation. (*Wenzel*.) There are two circumstances, however, which may prevent us from ascertaining, whether the retina is sensible to light or not: the first is, a circular adhesion of the crystalline capsule to the iris. Here Richter thought, that some opinion might be formed of the nature of this case, by observing the distance between the cataract and pupil: inferring, that when the space, between the pupil and opaque lens, was inconsiderable, such an adhesion had happened; and, when the cataract did not seem particularly close to the pupil, and yet the patient could not discern light from darkness, that it was complicated with amaurosis. The second circumstance, sometimes utterly preventing the ingress of any light to the healthy retina, is the round bulky form of the cataract.

But, although the power of distinguishing light from darkness is more satisfactory, than motion of the iris, it is not an unequivocal test of the retina being perfectly free from disease. While the gutta serena is incomplete, the patient can yet distinguish light, and the shadows of objects. Dilatation of the pupil is, also, a deceitful criterion of the

complication of gutta serena with the cataract. When the cataract is large, or adherent to the iris, the pupil is frequently much dilated, however natural and sound the state of the optic nerve may be: the pupil often continues quite undilated in a perfect gutta serena. (*Richter*.)

From all this it must be manifest, 1st, that the irregularity, and inconstancy of the symptoms of gutta serena, together with the possibility of particular states of the cataract rendering the patient utterly unconscious of the stimulus of light, make it necessary for the surgeon to be particularly attentive to the appearance, and to the history of the origin and progress of the disease, in order to understand the real condition of certain cases. 2d, That when the patient can distinguish light from darkness, though the iris may be motionless, there is good ground for trying an operation. Possibly, in this circumstance, an incipient amaurosis may exist, but, the chance of the defect of the iris arising from other causes; the certainty, that the opaque body must be removed from the axis of sight, (even if the disease of the retina be cured,) ere sight can be restored; and the improbability, that an operation to cure the cataract, will render the other complaint at all less remediable; fully justify the attempt. Frequently, the patient has a full formed cataract in one eye, which presents the signs of amaurosis, while an incipient cataract, or one as much advanced, exists in the other, which, at present, is free from these symptoms: in this case (says Mr. Travers,) the cataract of the latter should be removed, without delay. (*Synopsis*, &c. p. 314.)

The concurrent testimony of almost all writers upon the subject tends to prove that the restoration of sight has sometimes been effected in the most hopeless cases, and I am, therefore, of opinion with Mr. Lucas, that in all doubtful cases, an operation should be tried as a remedy, by no means violent or hazardous. (*Med. Obs. and Inquiries*, Vol. 6, p. 257.)

I shall conclude this part of the subject, with annexing the sentiment of Mr. Travers, viz. that it would be incorrect to say, that the operation is unadvisable in all cases of cataract, in which the patient has no sense of light; for, it is possible, that the density of the lens may be such as absolutely to exclude the light, and that the motions of the iris may be therefore suspended; or from some degree of pressure of the lens, or adhesion of the uvea to the capsule, that the pupil may be undilated, and the circumference of the lens permanently covered. But, undoubtedly, says Mr. Travers a case of this description is unpromising. "A strong sense of light, by which at least to know the direction, in which it enters the apartment, to be sensible of its falling on the eye, and of a shade, as the hand for example, intercepting it, with a corresponding freedom of motion of the pupil, is the most favourable state for the operation." (*Synopsis of the Diseases of the Eye*, p. 315.)

As it not unfrequently happens, that cataracts, produced by external violence, spontaneously disappear, (*Pott, Hey, &c.*) the operation should never be too hastily recommended for such instances.

Respecting the question, whether an operation ought to be done, when only one eye is affected with cataract, and the other is sound, I find some difference of opinion prevails.

One reason assigned by the condemners of this practice, viz. that one eye is sufficient for the necessities of life, is but of a frivolous description; and, another, that the patient would never be able to see distinctly after the operation, by reason of the difference of the focus in the eyes, is, (I have grounds for believing) only a gratuitous supposition, inconsiderately transmitted from one writer to another. In support of what I have here advanced, and to prove that success does sometimes, probably in general, (if no other causes of failure exist,) attend the practice of couching, and extraction, when only one eye is affected with a cataract, I shall first adduce a fact from Maitre Jan. (*Traité des Maladies de l'Oeil. Edit. Paris, 1741, 12mo. Obs. sur une Cataracte laiteuse, p. 196.*)

"Le 17 Octobre de l'année 1785. J'allai à Savière pour abaiser une cataracte dans l'oeil gauche d'un jeune garçon appelé Nicolas Very, valet de Sebastien Coutan, laboureur. Cette cataracte me paroissoit d'une bonne couleur, la pupille se dilatoit lentement, et beaucoup, et se resserroit de même, quand je passois la main entre l'oeil et le grand jour, le *sain étant fermé*," &c. After describing the operation, he continues, "Quelques jours après je retournai le voir, et je trouvai que l'aumeur aqueuse étoit fort éclaircie, et qu'il distinguoit toutes sortes d'objets: je le vis encore sept ou huit jours après en passant par son village, et je le rencontrai faisant son ouvrage, et entièrement guéri, sans qu'il parût qu'il eût jamais été incommodé de cataracte."

Baron Wenzel was in the habit of extracting cataracts with the most successful result, when only one eye was affected with the disease, as may be learnt by referring to the cases here specified. (*Cases 6, 13, 16, 19, 22, 25, 29, 30, 31, 34, &c. Treatise on the Cataract.*) It will be necessary to quote here only two cases, related by this eminent oculist. "Madame Harvey, a tobaccoist, at Chalons sur Marne, presented a complicated case similar to the preceding. She had a cataract in the right eye, combined with an opacity in the anterior portion of the capsule, as appeared by the white spots and inequalities of which I have spoken above, in the surface of the crystalline.—*Her left eye was sound.* I operated on the right eye in the year 1782, &c. The patient suffered some pain in consequence of the operation, but was soon removed by bleeding her in the foot; and notwithstanding this obstacle, the sight was soon recovered to as great a degree of perfection as was

possible after such an operation." (*Wenzel on the Cataract, p. 138, Case 16.*)

The following case is as explicit as possible on the point under consideration. "A poor woman, de la Ferté sous Jouarre, who had a cataract in the right eye upwards of ten years, came to consult me in the year 1780. I found all the symptoms of the case favourable to an operation," &c. (after describing the manner of doing it, he continues;) "I immediately bound up, not only the eye that had undergone the operation, but the *sound one* also; a precaution, which it is necessary to use after all operations on the eye, even the most simple; it being almost impossible, that one eye should not follow the motions of the other, &c. In a fortnight she was perfectly cured; and, though the pupil remained larger than it was before the operation, or than that in the left eye, and had much less motion, yet this eye, as well as the other, perceived objects very distinctly." (*Case 22, p. 166.*) In the Medical and Physical Journal for May 1808, I have read an ingenious paper, defending the practice of operating, when only one eye is affected.

I next proceed to notice what Richter has remarked upon this head. He was formerly convinced, that the advice not to operate, when there is a cataract only in one eye, ought, for several reasons, to be disregarded; he reminds us of the wonderful consent between the eyes, so that one is seldom diseased without the other, sooner or later, falling into the same state; and hence he questions whether it may not be possible to prevent the loss of the sound eye by a timely operation? *An non caveri possit jactura integri oculi tempestive extrahendo cataractam prioris?* (*Obs. Chir. Fascic. 1.*) He adverts to the remarkable case related by St. Ives, where a man was wounded in the right eye by a small shot, and, shortly afterwards, had a cataract in it; he then gradually became blind in the left, but soon recovered his sight in it, after the cataract had been extracted from the right one. Here let us notice, that St. Ives (*Maladies des Yeux, Chap. 15, Art. 3.*) makes no mention of any confusion in vision, in consequence of the different refracting powers of the two eyes in question. Another reason, judiciously assigned by Richter, (*Obs. Chirurg. Fascic. 1.*) for disregarding the above precept, is, that in waiting until a cataract forms in the other eye, the existing one, which is at this moment, perhaps, in the most favourable state for the operation, may soon change so much for the worse (for instance it may contract such adhesions to the iris,) as either to destroy all prospect of relief, or, at most, afford but a very precarious and discouraging one. The length of time necessary to wait is also uncertain and tedious. I once saw a man in St. Bartholomew's Hospital, who had had a cataract in one eye fifteen years, during all which time the other continued quite sound; and another case of twenty

years standing has lately been communicated to me. It is right to state, that Richter latterly inculcated a contrary opinion to what he formerly espoused, yet, without specifying the particular facts which induced him to revoke his former sentiments. The principal reason stated by him is, that the patient not only does not see much more acutely with the two eyes after the operation, than with one before it, but, he frequently sees more confusedly, because the eye that has been operated on, cannot see well without the aid of a glass, which, perhaps, the sound one does not require. (*Anfangsgrunde der Wundarzn. Dritter B. p. 199.*)

When I remember that no cases are adduced by this author to contradict the rationality of his former sentiments; when I also reflect upon the facts recorded by Maitre-Jan, St. Ives, and Wenzel; when I contemplate that Callisen mentions, as the feeble ground of his adopting the common opinion, that, in one single instance of this description, he was unsuccessful, without particularizing from what immediate cause the failure arose; there appears to my mind strong cause to believe, that the advice, not to operate, when there is only one cataract, and the other eye is perfect, is at least a subject which merits further investigation. Warner's objection is similar to that specified by Richter: he writes, "the eye, from which the crystalline lens is removed, cannot be restored to a degree of perfection at all equal to that of the sound eye, without the assistance of a convex glass:" (*Description of the Human Eye and its Diseases, p. 85.*) but, is not the power of using both eyes at the same time, even with the inconvenience of being necessitated to employ a glass for the purpose, preferable to being blind of one? The cases quoted, at all events prove, that confusion in vision is not always the result of the practice: whether the fact is concordant with the modern theory of vision, is entirely another consideration; if it should be found incompatible with it, we must infer, that our knowledge of optics still continues imperfect; not that such well-attested axamples as some alluded to, are unworthy of belief.

When there is a full-formed cataract in one eye, and vision is retained in the other, Mr. Travers thinks the postponement of the operation wrong. "I am satisfied," (says he) that the cataractous eye, if it becomes the subject of an accidental inflammation, is strongly disposed to go into amaurosis; and, further, that the retina loses its vigour by the permanent exclusion of light, I speak from repeated observation of the fact. The objection to the operation on the ground of inconvenience, arising from the difference of focus of the two eyes, when one only is the subject of disease, is trivial, and a consideration altogether subordinate: such a defect may always be remedied by glasses properly adjusted. In several cases of amaurosis, ensuing upon cataract, I have been disposed

to regard the change in consistence and volume of the lens, as productive of a destroying inflammation; in others, of a partial absorption of the vitreous humour."—(*Synopsis of Diseases of the Eye, p. 313.*)

For some decided information on the foregoing interesting question, I have referred to Beer; but he seems not to have entered into its consideration at all. The only instance in which he approaches the subject, is, when he notices the custom of covering the eye, which yet possesses more or less vision, when the other alone has a cataract in a fit state for an operation.—(*Lehre von den Augenkr. B. 2, p. 351.*)

The reason which has induced me to allot so much space for the consideration of the question, whether an operation should be undertaken, when only one eye is affected, is a conviction of the importance of the decision made about it. Were I to judge only from what has been said by writers, I should be confident, that a determination in the negative must be erroneous; but, when I know that my experienced and judicious friend Mr. Lawrence joins in the belief, that the practice is not productive of advantage, the only inference which I venture to make, is, that the subject deserves further experiment.

When there are cataracts in both eyes, most authors are of opinion, that there is no reason why one should not be operated upon immediately after the other. As, however, the ophthalmia is likely to be more severe, *ceteris paribus*, when both eyes are operated upon at the same time, Scarpa, who gives the preference to the needle, disapproves of this mode of proceeding, and assures us, that, in patients with cataracts in both eyes, his experience has taught him, that it is by no means advantageous to operate upon one immediately after the other; but that it is better to wait till one eye is well, before any attempt is made upon the other. (*Saggio di Osservazioni, &c. p. 255.*)

On this point, the following is Beer's sentiment:—When cataracts are completely formed in both eyes, the patient willing, and every thing promises a favourable result, both eyes may be operated upon at the same time. On the contrary, when any circumstances are present, which render the event of the operation very doubtful, it is most adviseable to make the attempt only on one eye, even though the patient absolutely wish more to be done, so that if the first operation should fail, but the complication of this cataract afterwards change considerably to the advantage of the patient, one eye would still be left for a second more favourable attempt. (*Lehre von den Augenkr. B. 2, p. 350.*)

Some years ago, it was the common doctrine, that no operation should be undertaken for a cataract, before the patient had attained the age of docility and reason, and, in a point of view abstractedly surgical, there can be no doubt of the rectitude of such advice; but, when it is further considered, how essential sight is to the acquirement of

education; that youth is the condition best adapted for this indispensable pursuit; that when the child's head is steadily fixed, the needle admits of being employed; that, with the aid of an assistant, this object can most effectually be accomplished; that, when the operation is delayed, the cataract may acquire adhesions; that, persons have not only had cataracts successfully depressed or broken, at a very early age, but with the assistance of a *speculum oculi*, have even had them extracted, (See *Ware's Note, p. 90, of Wenzel's Treatise*;) which is universally acknowledged to be a far more difficult process; and that the pupil of the eye in a young subject, is nearly as large as in an adult; (*Warner's Description of the Human Eye and its Diseases, p. 34.*) I cannot help thinking with Mr. Lucas, that after a child is old enough to bear an operation, the attempt to cure a cataract with the needle *may be proper* at any age. Surgeons do not refuse to operate for the hare-lip, as early as two years of age; they do not wait for docility and reason in the patient, to make him manageable, and sensible of the propriety of submitting quietly to the performance of the operation; they render him tractable by force, and thus they wisely succeed in making perhaps, with more certainty, than reliance upon the fortitude of any human being would afford, a very precise incision, such as the nature of the operation demands; and, why should they refuse to attempt the cure of cataracts, in children, when the motives are more urgent, and it is equally in the power of art to substitute means, quite as effectual as docility and reason in surgical patients? What experienced operator would trust to these qualities, when he undertakes any grand operation, even on the most rational and firm adult? (*Critical Reflections on the Cataract, 1805.*)

Of late years, the attention of surgeons has been much drawn to the subject of operating on the cataracts of children, and the propriety of the practice seems to be now firmly fixed on the basis of experience. It is even ascertained, that the needle may be successfully employed on children of the most tender age. The late Mr. Saunders, surgeon to the London Infirmary for curing diseases of the eye, may be said to have had the principal share in promoting the adoption of this important improvement. His practice confirmed, what reason had long ago made probable, and the judgment, tenderness, and skill, with which he operated on the eyes of infants, as well as those of adults, were followed by a degree of success, which had never been previously witnessed, and which infused quite a new spirit into this most interesting branch of surgery. Subjects from eighteen months to four years old, received most benefit from Mr. Saunderson's operations; and, if any intermediate time be selected, Dr. Farre (the editor of this gentleman's publication) is inclined to recommend the age of two years. "The parts have then attained a degree of

resistance, which enables the surgeon to operate with greater precision, than at an earlier period; yet, the capsule has not become so tough and flexible, as it does at a later period, after the lens has been more completely absorbed.

"But, this is not the greatest, although a considerable advantage of an early operation; for, in cases, in which the patient has no perception of external objects, the muscles acquire such an inveterate habit of rolling the eye, that, for a very long time after the pupil has been cleared by an operation, no voluntary effort can control this irregular motion, nor direct the eye to objects with sufficient precision for the purpose of distinct and useful vision. The retina too, by a law, common to all the structures of an animal body, for want of being exercised, fades in power. Its sensibility, in many of the cases, cured at the ages of four years, and under, could not be surpassed in children, who had enjoyed vision from birth; but, at eight years, or even earlier, the sense was evidently less active; at twelve, it was still more dull; and from the age of fifteen and upwards, it was generally very imperfect, and sometimes the mere perception of light remained. But, these observations do not apply to those congenital cataracts, in which only the centre of the lens and capsule is opaque, the circumference being transparent, for, in those, the retina is exercised by a perception, although an imperfect one, of external objects, the motions of the muscles, which direct the globe, are associated, and an absorption of the lens does not take place: therefore, in this variety of the disease, the argument in favour of an early operation, is not so much a medical, as a moral one—it is preferable for the purposes of education and enjoyment." (*Saunders on Diseases of the Eye, p. 153, 155.*)

Besides Mr. Saunders, several other surgeons of the present day have become zealous advocates for operating upon the cataracts of children. Even Mr. Ware, before his death, strongly recommended the use of the needle in the congenital cataract of infants and children. His mode of operating I shall hereafter notice. The late Mr. Gibson, of Manchester, likewise urged the propriety of couching young subjects, and fixed on the age of six months, as preferable to that of two years. "Whatever objections (says he) have been urged against the safe and effectual use of the couching needle in infants, have always appeared to me so slight, and so easily surmountable, that, without inquiring particularly into the real state of the question, I have long concluded, that the same motives, which would induce an operator to couch a cataract at any period of adult life, would equally lead him to perform that operation at any earlier period, when a cataract existed. Acting upon this presumption, I have operated upon children of all ages, for ten years past." (*See Edinb. Med. and Surgical Journal, Vol. 7, p. 394.*)

Mr. Gibson's paper being dated June, 1811, we are of course given to understand, that he pursued this practice from the year 1801, and he asserts, that his experience had embraced a considerable number of cases.

"In performing the operation of couching infants, it has always appeared to me, (says this gentleman) that the advantages to be gained by restoring vision at so early a period, are so important, as to bear down any obstacles which may occasionally be opposed to the safe use of the needle. Even the risk of deranging the figure of the pupil forms no solid objection to its use; and may always be avoided by steadiness and good management. Should even a slight change in its figure be produced, it is seldom in the least detrimental to distinct vision, and can scarcely be considered a blemish in the eye of any one; except, perhaps, in that of a geometrician; who may easily reconcile to himself the presence of an oval opening, where one of a circular form should exist. It may farther be observed, that, if an operator cannot depend upon his management of the eye, so as to render it steady by the introduction of the couching needle, he can avail himself of the assistance of a speculum to restrain its motions.

"The following observations will apply principally to infants under twenty months old. The advantages, which an operator possesses, in operating upon a child of this age, as compared with a child of three years old, or upwards, are important. An infant is not conscious of the operation intended: it is free from the fears created by imagination, and can oppose very feeble resistance to the means employed to secure it with steadiness. At an early age, it has not acquired the power of retracting the eye deep in the socket, so that the operator has always a good prospect of introducing the couching needle with ease, by watching a proper opportunity. The eye has not, at this time, acquired the unsteady rolling motion, which, after a few years, is so common and remarkable in children born blind, or reduced to that state soon after birth. So that this impediment to the easy introduction of the needle does not exist in infants a few months old. The operator also has it in his power, to administer a dose of opium, sufficient to render the steps necessary to expose the eye, almost entirely disregarded by his patient. With respect to the state of the eye itself, but, particularly, that of the cataract, this is more favourable for the operation, than any future period of life. *In infants, the cataract is generally fluid, and merely requires the free rupture of its containing capsule, which is in that case generally opaque. The capsule, however, is tender, and easily removed by the needle, so as to leave an aperture sufficiently large for the admission of light. The milky fluid, which escapes from the capsule, is soon removed by absorption. If, on the other hand, (says Mr. Gibson) the cataract should be soft, it is generally of so palpy a softness,*

that the free laceration of the anterior part of its capsule, and the consequent admission of the aqueous humour, ensure its speedy dissolution, and disappearance, without the necessity of a second operation. Should the cataract happen to be hard, there will be no more difficulty in depressing it, than in an adult. So uniformly favourable is the state of the cataract to the success of the operation, that I may venture to pronounce, that an operator of common experience and expertness, will seldom fail of success, if he can, in an adult, depress a hard cataract, or rupture the containing capsule, and break down the substance of a soft, or fluid cataract when it occurs.

"Such (continues Mr. Gibson) are the advantages, derived from the age of the patient, and state of the eye, which would induce an operator to use the couching needle a few months after birth. If, however, a surgeon had even difficulties to encounter, which do not occur in adults, surely the invaluable benefit, conferred by enabling an infant to become an intelligent being, like other children, instead of remaining in a state approaching to idiotism, would incline him to run some risk of failure, and to make more than common exertions, especially as there is little chance of injuring the eye, when proper cautions are used. Yet so important a consideration appears to have had little influence upon oculists; and hence, many children have been doomed to years of darkness, happy in the estimation of their parents and friends, if they could distinguish black from white; or discern any perceptible difference between the brightness of the sun, and the glimmering of a tallow candle.

"These advantages, which an operator will possess, when he attempts the removal of a cataract in a child of a few months old, are peculiar to that period. In proportion as the age of the patient advances, until he arrives at the age of discretion, and can estimate, in some measure, the value of sight, by feeling its loss, the difficulties, opposed to the use of the couching needle, increase. His fears of the operation, the unsteadiness of the eye, and his power of retracting it within the orbit, present considerable, but not insuperable obstacles; such, however, as every surgeon would willingly dispense with, if he had it in his power.

"Before an operation, at an early age is recommended, the practitioner ought (as at any other age) to ascertain, that the cataract is not complicated with a defective state of the retina, or with a complete amaurosis. Such cases are by no means uncommon. Some years ago, I recollect to have seen five or six children, the families of two sisters, who were all totally blind, and in an idiotic state, with cataracts accompanied by amaurosis." (*Gibson Op. et loco cit.*)

I find also in this gentleman's paper, some arguments, which have been repeated in Mr. Saunderson's work. "Few practitioners, at all conversant with cases with blindness from birth, will deny, that it is highly prob-

able, that the eye may lose a considerable part of its original powers, from the mere circumstance of its having so long remained a passive organ. Hence, probably it happens, that, in some cases of congenital cataract, the only benefit conferred on the patient, by an operation, is that of enabling him to find his way in an awkward manner, and to discriminate the more vivid colours. Such patients have never been able to discern small objects, or to judge in any useful degree, of figure or magnitude; I am well aware, however, says Mr. Gibson, that, in some rare instances, such a defective state of the eye exists from birth.

"Another circumstance, which must have attracted the attention of oculists, is, that in a few years, the eye of a patient born blind, acquires a restless and rolling motion, which is at length so firmly established by habit, that he has little control over it. This motion unfortunately continues, for a considerable time, after sight has been restored to such a person, and is a very material obstacle to the early attainment of a knowledge of the objects of vision. He cannot fix his eye steadily upon one point for a moment, and the inconvenience which arises from this unsteadiness, is, to such a person, occasionally as great a bar to the distinct view of an object, as the unsteady motion of the same object would be to one, whose vision is perfect. This inconvenience any one can appreciate, and, as far as I know, it is completely avoided by restoring sight at an early age.

As a motive for operating on infants, Mr. Gibson also comments on the loss of those years, which ought to be spent in education. (See *Edinb. Med. and Surgical Journal*, Vol. 7, p. 394, 400.)

When once it is decided to operate upon a cataract, the sooner the operation is generally done, the better, because the anxiety of the patient increases, as Beer says, with every day, nay, with every hour. Just before the operation, care must be taken not to let the patient eat a great deal, nor load his stomach with substances difficult of digestion; and, if the stomach and bowels should already be disordered by what they contain, their contents ought to be carefully removed previously to the operation. In the same manner, if the surgeon wish to keep off much inflammation, and the patient should be constipated, this state must be obviated by suitable medicines. And, lastly, when, at the request of the patient himself, the operation is deferred for a few days, the greatest caution must be used not to let him expose himself to any causes, likely to bring on catarrhal or rheumatic complaints. (Beer, *B. 2*, p. 344.) The following advice delivered by Scarpa, with respect to the preparation of patients for operations on the eye with the needle, is valuable: In ordinary cases, there is not the least occasion for any preparatory treatment previous to the operation; all that prudence requires is, that the patient should abstain from animal food, and fermented liquors, for a few days, be-

fore submitting to it, and should take one dose of a gentle purgative. But, this, like every other general observation, is liable to particular exceptions. Hypochondriacal men, hysterical women, and patients subject to affections of the stomach and nervous system, should take, for two or three weeks before the operation, tonic bitter medicines, particularly the infusion of quassia, either with or without a few drops of the æther vitriolicum to each dose; or, in other cases, ʒj of Peruvian bark, with ʒj of valerian, may be administered two or three times a day with particular benefit. It is observed by the most accurate writers upon this subject, that, in such persons, the symptoms consequent to operations upon the eyes, are often much more violent than in common cases; and it therefore seems proper to endeavour, previously, to meliorate their constitutions. When the patient is timid, it is very adviseable to give him, half an hour before the time of operating, about fifteen drops of the tinctura opii, with a little wine.

Some patients, besides being afflicted with cataracts, have the edges of the eyelids swollen and gummy, with relaxation, and chronic redness of the conjunctiva. In this case, before undertaking to couch, it is adviseable to apply a blister to the nape of the neck, and to keep it open for two or three weeks, by means of the savin cerate, and to insinuate every morning and evening, between the palpebræ and globe of the eye, a small quantity of the unguentum hydrarg. nitratis, prepared according to the pharmacopœia of St. Bartholomew's Hospital, increasing its strength gradually. (R. Unguenti hydrargyri nitratis, ʒiv. Adipis Suillæ ʒviij. Olei Olivæ, ʒij.) In obstinate cases, when this ointment does not produce the desired effect, an ointment recommended by Janin, (*Memoires sur l'Oeil*), should be substituted: it consists of ʒss of hog's lard, ʒij of prepared tutty, ʒij of armenian bole, and ʒj of the white calx of quicksilver. At first, care should be taken to use it lowered, with twice or thrice its quantity of lard. In the day time, a collyrium, composed of ʒiv of rosewater, ʒss of the mucilage of quince seeds, and gr. v. of the sulphate of zinc, may also be frequently used with considerable advantage. By such means, the morbid secretion from the Meibomian glands, and membranous lining of the eyelids, will be checked, and the due action of the vessels, and natural flexibility of the eye-lids, will be restored. (*Saggio di Osservazioni, &c. sulle principali malattie degli occhi*, Venez. 1802.)

There are three different operations practised for the cure of cataracts, viz. one termed *coughing*, or *depression*, of which the method, called *reclination*, is a modification, as will be hereafter explained; another, named *extraction*; and a third denominated *keratonyxis*, which consists in puncturing the cornea with a needle, the point of which is to be conveyed through the pupil, so as to reach the cataract which is to be

gently broken into fragments. As Beer observes, each of these modes has, in particular cases, manifest advantages over the other two; but, no single method will ever be exclusively preferred, and invariably followed, by any man of experience and judgment. In every operation for a cataract, the position of the patient, assistants, and surgeon, is of great importance. In order to enable the assistant who stands behind the patient, to be conveniently near the head of the latter, Beer prefers letting the patient sit on a stool, which has no back. However, as I shall presently notice, some eminent surgeons have urged good reasons in favour of employing a chair, which is completely perpendicular. When the left eye is to be operated upon, the same assistant is to apply his right-hand under the patient's chin, and press the head of the latter against his breast, at the same time that he inclines it and himself more or less forward towards the operator, who sits upon rather a high stool, in front of the patient. In this country, a music-stool is commonly preferred, the height of which can be regulated in a moment, by simply turning the seat round to the right, or left, whereby the screw, with which it is connected, is made to rise, or descend, as may be found most desirable. The same assistant then places his left-hand flat upon the left side of the patient's forehead, with the points of the fore and middle fingers, somewhat under the edge of the upper eye-lid; and, with the fore-finger, he is now to raise the edge of this eye-lid, as much as possible, following that finger immediately with the middle one, so as to fix the eye-lid with greater certainty. The ends of these fingers, however, must be so applied, as not to touch the globe of the eye in the slightest manner, much less make any pressure upon it, yet, so that the upper part of the eye-ball and cornea may be gently resisted by them, when the eye rolls upwards away from the instrument about to be introduced, whereby this position, which is extremely convenient to the operator, may be immediately rectified. The patient should also sit obliquely opposite a clear window, so that a sufficient light may fall obliquely upon the eyes, without any rays being reflected to the cornea, and becoming a hinderance to the operator. Nor should light from any other quarter be ever allowed to fall upon the eyes. The surgeon should sit in front of the patient, whose head ought to be directly opposite the operator's breast, whereby the latter will be enabled to see from above, with the greatest correctness, every thing in the eye during the operation, and will not be under the necessity of raising his arms too considerably. Supposing it to be the left eye, which is to be operated upon, he next effectually draws down the lower eye-lid with the left fore-finger, the end of which must be placed over the edge of the eye-lid, towards the globe of the eye, just like those of the assistant, who supports the upper

eye-lid. The middle finger is then to be applied in a similar way over the caruncula lachrymalis. The operator now takes in his right-hand the requisite instrument for the operation, viz. the needle, or knife, which is to be held, like a pen, between the thumb and the fore and middle fingers. By this particular arrangement of the fingers of the assistant and operator, which, indeed, is partly ineffectual where the fissure of the eye-lids is very narrow, and the eye-ball is diminutive and sunk in the orbit, the restless eye of the timid patient is fixed; for a point of the finger is disposed on every side, to which the eye can possibly turn away from the instrument about to be introduced, and when the cornea is gently touched with the extremity of the finger, the wronged position, which the eye is about to take, is immediately prevented. This method of fixing the eye, says Beer, is not merely indispensable for young operators, but is the only perfectly unobjectionable one, which can be employed on this delicate organ, since all mechanical inventions for this purpose, like the speculum oculi, which keeps the eye steady, by considerable pressure, or other contrivances, like Rumpelt's instrument, which does the same thing by means of a short-pointed instrument attached to a kind of thimble, and with which the sclerotica is pierced, and held motionless, are found by experience to be worse than useless. And, as a proof of this fact, Beer adverts to the numerous patients, who come out of the hands of such operators as employ these instruments, with a more or less hurtful loss of the vitreous humour, and other ill consequences: a statement, which nearly agrees with the observations of Wenzel and Ware.

Baron Wenzel considers all instruments, for fixing the eye, quite unnecessary: they render the operation more complicated, more dreadful to the patient, more embarrassing to the operator, and are very liable to irritate and wound the eye. If he could approve of any kind of speculum, he should give the preference to Rumpelt's thimble, at the end of which is a sharp-pointed instrument, like the pique of Parnard. The thimble is placed on the middle finger of the operator, and it has the advantage of not obstructing the use of the fore-finger, but leaves it at liberty to keep down the lower eye-lid.

The pressure, occasioned by all contrivances for fixing the eye, is a serious objection to their employment, as it is apt to cause a sudden protrusion of great part of the vitreous humour. (*Wenzel*.)

The late Mr. Ware coincided with Wenzel, respecting the general objections to specula. At the same time, he remarks, that, in some instances, of children born with cataracts, he had been obliged to fix the eye with a speculum; without the aid of which, he found it totally impracticable to make the incision through the cornea, with any degree of precision, or safety. His speculum is an oval ring, the longest

diameter of which is about twice as long as the diameter of the cornea, and the shortest about half as long again as this tunic. Annexed to the upper rim of the speculum is a rest, or shoulder, to support the upper eye-lid, and by its lower rim, it is fixed to a handle of such a length, and bent in such a way, as may render it convenient to be held. (Ware.)

Nor does Beer entertain a higher opinion of other inventions, made for the purpose of enabling surgeons to operate on both eyes with the right hand; for, says he, the right eye should always be operated upon with the left-hand, and the left with the right, and he who cannot learn to be equally skillful with both his hands, must always remain a bungler. (*Lehre von den Augenkr. B. 2, p. 347—350.*)

Mr. Alexander, whose great skill in operations on the eye is universally acknowledged, employs no assistant for raising the upper eye-lid, or fixing the eye, which objects he accomplishes himself; and, in Germany, this independent mode of proceeding has been particularly commended by Barth. (*Ueber die Ausziehung des grauen Staare, für den geübten Operateur, 8vo. Wien. 1797.*)

The preceding directions, respecting the position of the assistant, the seats for the patient and surgeon, and the mode of fixing the eye, are chiefly those of Professor Beer. Whether these instructions are in every respect better than the following, which combine the sentiments of some other writers of experience, the impartial reader must judge for himself. The patient should be seated rather low, opposite a window where the light is not vivid, and in such a manner, that the rays may fall laterally upon the eye about to be couched. The other eye, whether in a healthy or diseased state, ought always to be closed, and covered with a handkerchief, or any thing convenient for the purpose; for, so strong is the sympathy between the two organs, that the motions of the one constantly produce a disturbance of the other. The surgeon should sit upon a seat, rather higher than that upon which the patient is placed; and, in order to give his hand a greater degree of steadiness in the various manœuvres of the operation, he will find it useful to place his elbow upon his knee, which must be sufficiently raised for this purpose, by a stool placed under the foot. The chair, on which the patient sits, ought to have a high back, against which his head may be so firmly supported, that he cannot draw it backward during the operation. The back of the chair must not slope backward, as that of a common one, but be quite perpendicular, in order that the patient's head may not be too distant from the surgeon's breast. (*Richter's Anfangsgr. der Wundarzn. p. 207, 3 B.*)

The propriety of supporting the patient's head rather upon the back of the chair, on which he sits, than upon an assistant's breast, as Bischoff has observed, is founded

upon a consideration, that the least motion of the assistant, even that necessarily occasioned by respiration, causes, also, a synchronous motion of the part, supported on his breast, which cannot fail to be disadvantageous, both in the operation of extraction, and of couching. Hence, Callisen and Richter, both recommended the method of supporting the patient's head against the perpendicular back of the chair. But, as this is not at present the common practice, possibly the inconvenience of having the back of the chair between the assistant and the patient, may more than counterbalance the circumstance, in which it seems to be advantageous.

In certain cases, where the muscles of the eye and eye-lids, are incessantly affected with spasm; or, where the eye is peculiarly diminutive, and sunk as it were, in the orbit, the elevator for the upper eye-lid, invented by Pellier, and approved by Scarpa, may possibly prove serviceable: in young subjects, I think it might contribute much to facilitate the operation.

The particular sentiments of Wenzel and Ware, concerning the mode of fixing the eye, will be further explained in the description of the extraction of the cataract.

OF COUCHING, OR DEPRESSION OF THE CATARACT, AND RECLINATION.
