A
DICTIONARY
OF
¹²²
Practical Surgery :

COMPREHENDING

ALL THE MOST INTERESTING IMPROVEMENTS, FROM THE EARLIEST
TIMES DOWN TO THE PRESENT PERIOD ;

AN ACCOUNT OF THE INSTRUMENTS, REMEDIES, AND APPLICATIONS
EMPLOYED IN SURGERY ;

THE ETYMOLOGY AND SIGNIFICATION OF THE PRINCIPAL TERMS ;

AND

Numerous References to Ancient and Modern Works, forming together a "Catalogue
Raisonné" of Surgical Literature :

WITH

A VARIETY OF ORIGINAL FACTS AND OBSERVATIONS.

BY SAMUEL COOPER,

FORMERLY SURGEON TO THE FORCES ; MEMBER OF THE ROYAL COLLEGE OF SURGEONS ;
OF THE MEDICAL AND CHIRURGICAL SOCIETY OF LONDON ; AND
OF THE MEDICAL SOCIETY OF MARSEILLES.

WITH

NOTES AND AN APPENDIX,

BY WILLIAM ANDERSON,

OF THE COLLEGE OF SURGEONS OF EDINBURGH ; PROFESSOR OF ANATOMY AND
PHYSIOLOGY TO THE VERMONT ACADEMY OF MEDICINE ; AND
LECTURER ON SURGICAL ANATOMY IN NEW-YORK.

IN TWO VOLUMES.

VOL. II.

FROM THE FOURTH LONDON EDITION.

NEW-YORK :

PUBLISHED BY COLLINS & HANNAY, 230 PEARL-STREET.

1823.

WO
C 787d
v. 2
1823

Southern District of New-York, ss.

BE IT REMEMBERED, That on the second day of December, in the forty-seventh year of the Independence of the United States of America, COLLINS & HANNAY, of the said District, have deposited in this office the title of a book, the right whereof they claim as proprietors, in the words following, to wit :

"A Dictionary of Practical Surgery, comprehending all the most interesting Improvements, from the earliest times down to the present period; an Account of the Instruments, Remedies, and Applications employed in Surgery; the Etymology and Signification of the Principal Terms; and Numerous References to Ancient and Modern Works, forming together a "Catalogue Raisonné" of Surgical Literature; with a Variety of Original Facts and Observations, by Samuel Cooper, formerly Surgeon to the Forces; Member of the Royal College of Surgeons; of the Medical and Chirurgical Society of London; and of the Medical Society of Marseilles. With Notes and an Appendix, by William Anderson, of the College of Surgeons of Edinburgh, Professor of Anatomy and Physiology to the Vermont Academy of Medicine, and Lecturer on Surgical Anatomy in New-York."

In conformity to the Act of the Congress of the United States, entitled "An Act for the encouragement of Learning, by securing the copies of Maps, Charts, and Books, to the authors and proprietors of such copies, during the times therein mentioned." And also to an Act, entitled "An Act supplementary to an Act, entitled An Act for the encouragement of Learning, by securing the copies of Maps, Charts, and Books, to the authors and proprietors of such copies during the times therein mentioned, and extending the benefits thereof to the arts of designing, engraving, and etching historical and other prints."

JAMES DILL,
Clerk of the Southern District of New-York.

DICTIONARY
OF
PRACTICAL SURGERY.

This mark () will signify, that the Word which it precedes is further spoken of in the Appendix.*

HER

HERNIA. (From *ἑρνος*, a branch, from its protruding forward.) Surgeons understand by the term *hernia*, a tumour, formed by the protrusion of some of the viscera of the abdomen, out of that cavity, into a kind of sac, composed of the portion of peritoneum, which is pushed before them. However, there are certainly cases which will not be comprehended in this definition: either because the parts are not protruded at all, or have no hernial sac, as the reader will learn in the course of this article.

"The brilliant progress which surgery has made in modern times (says Scarpa) is, properly speaking, only the result of pathological anatomy, that is to say, of exact comparisons of the natural state of our organs with their different diseases, which may depend upon an alteration of texture, a derangement of functions, a solution of continuity, or a change of situation. It is from morbid anatomy, that the most rational curative methods, with which modern surgery is enriched, are deduced as so many corollaries; methods, to which we are also indebted for the perfection of operations.

"There are indeed a certain number of surgical operations, for the prompt and safe execution of which, mere anatomical knowledge will suffice; but in many others, the surgeon cannot promise himself success, even though he be well acquainted with anatomy, unless he has particularly studied the numerous changes of position, and alterations of texture, of which the parts, upon which he is about to operate, are susceptible. If he has not the requisite information upon all these points, false appearances may deceive his judgment, and make him commit mistakes, sometimes of a very serious and irreparable kind.

"In order to have a convincing proof of this truth, it will be sufficient to take a view of the different species of *herniæ*. and their numerous complications. Assuredly, no anatomist would believe, that the intestine cæcum, naturally fixed in the right ileum, and the urinary bladder, situated at the bottom of the pelvis, could undergo, without being torn, so considerable a displacement as to protrude through the abdominal ring,

HER

and descend even into the scrotum; that the same intestine, the cæcum, could pass from the right iliac region to the umbilicus, protrude at this opening, and form an umbilical *hernia*; that the right colon could have been found protruded from the abdomen at the left abdominal ring, and the left colon through the right one; that the liver, spleen, and ovary could sometimes form the contents of umbilical, inguinal, and femoral *herniæ*; that the cæcum could engage itself within the colon, and even protrude at the anus; that the stomach could be forced through the diaphragm, and form a *hernia* within the chest: that the omentum, or intestine, or both these parts together, could sometimes escape from the belly through the foramen ovale, or sacro-ischiatic notch of the pelvis; that a noose of small intestine, after being engaged in the abdominal ring, or under the femoral arch, could suffer the most violent strangulation, without the course of the intestinal matter being intercepted; lastly, that in certain circumstances, the intestine and omentum could be in immediate contact with the testicle, within the tunica vaginalis, without the least laceration of this latter membrane. These and several other analogous facts, says Scarpa, are so surprising, that they would yet be regarded as incredible, had they not been proved by numerous observations on individuals affected with *hernia*: their possibility (repeats this experienced professor) would not even have been suspected, either by the anatomist or physiologist." (See *Scarpa, Traité des Hernies, Pref.*)

The parts of the body, where *herniæ* most frequently make their appearance, are the groin, the navel, the labia pudendi, and the upper and forepart of the thigh; they do also occur at every point of the anterior part of the abdomen; and there are several less common instances, in which hernial tumours present themselves at the foramen ovale; in the perinæum; in the vagina; at the ischiatic notch, &c.

The parts, which, by being thrust forth from the cavity, in which they ought naturally to remain, mostly produce *herniæ*, are either a portion of the omentum, or a part

of the intestinal canal, or both together. But the stomach, the liver, spleen, uterus, ovaries, bladder, &c. have been known to form the contents of some hernial tumours.

From these two circumstances of situation and contents, are derived all the different appellations, by which herniæ are distinguished. If a portion of intestine alone forms the contents of the tumour, the case is called *enterocele*; if a piece of omentum only, *epiplocele*; and if both intestine and omentum contribute to the formation of the tumour, it is called an *entero-epiplocele*. When the contents of a hernia protrude at the abdominal ring, but only pass as low as the groin, or labium pudendi, the case receives the name of *bubonocèle*, or *inguinal hernia*; but if the parts descend into the scrotum, it is called an *oscheocèle*, or *scrotal hernia*. The *crural*, or *femoral hernia*, is the name given to that which takes place below Poupart's ligament. When the bowels protrude at the navel, the case is named an *exomphalos*, or *umbilical hernia*; and *ventral* is the epithet given to the swelling, when it occurs at any other promiscuous part of the front of the abdomen. The *congenital rupture* is a very particular case, in which the protruded viscera are not covered with a common hernial sac of peritoneum, but are lodged in the cavity of the tunica vaginalis, in contact with the testicle, and, as must be obvious, it is not named like herniæ in general, from its situation, or contents, but from the circumstance of its existing from the time of birth.

When the protruded bowels lie quietly in the sac, and admit of being readily put back into the abdomen, the case is termed a *reducible hernia*; and when they suffer no constriction, yet cannot be put back, owing to adhesions, or their large size in relation to the aperture, through which they have to pass, the hernia is termed *irreducible*. An *incarcerated*, or *strangulated hernia* signifies one, which not only cannot be reduced, but suffers constriction; so that if a piece of intestine be protruded, the pressure to which it is subjected, stops the passage of its contents towards the anus, excites inflammation of the bowel, and brings on a train of alarming, and often fatal consequences.

The causes of herniæ are either *predisposing*, or *exciting*. Among the former, writers mention a preternaturally large size of the openings, at which the bowels are liable to protrude; a weakness and relaxation of the margins of these apertures; a preternatural laxity of the peritoneum; an unusually long mesentery, or omentum, &c. With regard to the abdominal ring, the transverse tendinous fibres, which naturally cross and strengthen its upper and outer part, are much weaker in some subjects than others. No idea seems more prevalent in books, than that taking a good deal of oil with our food, is conducive to the formation of hernial diseases. Some of the alleged predisposing causes, may justly excite scepticism; but several circumstances tend to prove, that a natural deficiency of resistance, in any

part of the parietes of the abdomen, promotes the occurrence of hernia. Hence, persons who have had the peritoneum wounded, are very liable to the present disease; (*Richerand Nosogr. Chir. T. 3, p. 317*; *Schmucker, Vermischte Chir. Schriften, B. 1, p. 197*;) and men are much more liable than women, to inguinal hernia, owing evidently to the larger size of the abdominal ring; while in women, as there is a larger space for the protrusion of the viscera, below Poupart's ligament, they are more exposed than men to femoral herniæ.

With regard to the *exciting* causes, our knowledge is involved in less doubt. The grand cause of this kind, is the powerful action of the abdominal muscles and diaphragm on the viscera. In feats of agility, such as jumping, &c. the pressure which the contents of the abdomen must often encounter, sufficiently accounts for their protruding at any part, where the abdominal parietes do not make adequate resistance. The same consideration explains, why herniæ very often take place in lifting and carrying heavy weights, running, vomiting, straining at stool, parturition, &c. and in people who inhabit mountainous countries.

This diminution of the capacity of the abdomen, by the action of the abdominal muscles and diaphragm, in many occasional exertions, must take place in every body by reason of the common habits and necessities of life. But as only a certain number of persons meet with the disease, it is fair to infer, that either the exciting causes must operate with greater force in them, than in the generality of people, or else that their abdominal parietes have not been capable of the ordinary degree of resistance. Many patients, who meet with herniæ, in making violent efforts and exertions, may be in the former circumstance; while others whose viscera protrude from such trivial things as coughing, sneezing, crying, &c. must be considered, as being under the influence of some predisposing cause. A gentleman, who has gained great honour by a most valuable treatise on hernia, remarks, that "herniæ, which originate in predisposition, generally come on gradually, and almost imperceptibly; while those which are produced by bodily exertions, are formed suddenly, and by the immediate action of the exciting cause. The occurrence of the complaint is often indicated, in the first instance, by a fulness, combined with a sense of weakness, about the abdominal ring. The swelling is increased by any action of the respiratory muscles, and disappears on pressure, and in the recumbent position of the body. It gradually finds its way through the tendon of the external oblique muscle, into the groin, and afterward into the scrotum. When a hernia takes place suddenly, it is generally attended with a sensation of something giving way at the part, and with pain." (*Lawrence on Ruptures, p. 29, Edit. 3.*)

Upon the subject of the immediate cause of herniæ, it is observed by Scarpa, that se-

veral distinguished modern surgeons, as, for instance, Warton, (*Adenograph. cap. 11.*) Benevoli, (*Dissertationi Chirurgiche, 1.*) Rossius, (*Acta Nat. cur. T. 2, Obs. 178.*) Brendel, (*de herniarum natalibus,*) and Morgagni, (*de sed. et caus. morb. epist. 43, art. 13.*) consider a relaxation and elongation of the mesentery as the principal cause of herniæ in general, and of the bubonocèle in particular. Hence, say they, the whole mass of intestines, or only a portion of an intestine, descends against the inner orifice of the inguinal ring, presses against this opening, and gradually makes its way out of the abdomen. In examining this pathological point without prejudice, it is incontestable, says Scarpa, that an intestine cannot be moved beyond its natural limits, unless that part of the mesentery, which retains and fixes the bowel in its proper place, be at the same time elongated. But it does not follow from this, that a relaxation of the mesentery must precede the displacement of the intestine. It appears to Scarpa much more probable, that these two events are simultaneous, and depend upon one and the same cause.

"In the healthy state, the abdomen, considered altogether, is submitted to two opposite forces, which reciprocally balance each other. One is the pressure of the viscera against the abdominal parietes; the other is the reaction of the same parietes upon the viscera which they contain. If these two forces were in perfect equilibrium in all individuals, and under all the circumstances of life, we should not be in the least subject to herniæ. If, when the equilibrium has been broken, every point of the parietes of the belly were to yield equally to the impulse of the viscera, an increase of the volume of the whole abdomen would be the consequence; but a true hernia would never happen. The cavity of the abdomen is always completely full. The containing and contained parts react upon, and reciprocally compress one another. It is by the effect of this moderate, but equal and unremitting pressure, that all the viscera mutually support each other. Without it, the ligaments of the liver, those of the spleen, and the various membranous bands of the intestines in general, would only be feeble means for fixing such parts in their respective situations. But there are certain points of the abdominal parietes which naturally present much less resistance than others, and which react with much less power against the pressure made from within outwards by the abdominal viscera. Such is particularly the part which extends from the pubes to the anterior superior spinous process of the ilium. This relative weakness of some points of the abdominal parietes is very marked in certain individuals, in consequence of a defect of organization. It may also be increased by internal or external causes, which are as various as they are numerous. When in one of these cases the pressure made by the viscera is unusually increased, as happens in a violent effort, a defect in the equi-

librium between the two forces above mentioned is occasioned; that is to say, the reaction of the abdominal parietes is no longer proportioned, at least at certain points, to the force of the impulse of the viscera. The conjoined powers of the abdominal muscles, diaphragm, and levator ani, are then directed and concentrated against the most feeble point of the abdomen, towards which they propel the nearest viscus, or that, which from its moveableness, is the most liable to displacement. If such viscus should happen to be the noose of an intestine, it is evident that the power which tends to make it protrude from the belly, must at the same time act upon the corresponding portion of the mesentery; and the intestine, in passing through the parietes of the abdomen, drags the mesentery after it, and makes this membrane yield and become elongated. When the displaced viscera meet with little resistance on the part of the parietes of the abdomen, the hernia is quickly formed, and the elongation of the mesentery occurs with equal celerity. We have an example of this in the inguinal congenital hernia: in this case the intestine is, in some measure, precipitated into a sac previously prepared for its reception. On the contrary, in the ordinary inguinal hernia, a totally different disposition of the parts renders the progress of the disease much slower. In most instances, the hernia is not formed immediately the equilibrium between the impulse of the viscera and the reaction of the abdominal parietes is broken. But in the groin, a slight elevation is first observed, in the direction from the anterior superior spinous process of the ilium towards the inguinal ring. Some time afterward, when the intestine has made its appearance on the outside of the ring, the enlargement of the hernia, and the elongation of the mesentery, make much more rapid, though always simultaneous progress.

"Numerous practical observations, (says Scarpa) concur in proving, that we must not search for the immediate cause of herniæ in the relaxation of the mesentery, but rather in a want of equilibrium between the pressure of the viscera and the resistance of one or several points of the abdominal parietes. Indeed herniæ are seen occurring from the slightest causes in infants, in whom the neck of the tunica vaginalis is not speedily obliterated, and in individuals, who from being fat, have all on a sudden become extremely thin. Such women as have had children, are more subject to the disease than others. Persons also of both sexes, who carry considerable burdens, or who play upon wind instruments, or who have suffered a forcible contusion of the abdomen, are particularly exposed to the disorder, even though there is not the least reason for suspecting in them a relaxation of the mesentery. Vaginal herniæ, which arise after difficult labours, afford another proof of the same truth: their cause is owing to a laxity and weakness of the parietes of the vagina, which, not being capable of making any further resistance to

the pressure of the viscera, situated in the cavity of the pelvis, at length suffer these parts to protrude.

"With respect to the second proposition, that during the formation of a hernia, the combined force of all the abdominal muscles is, as it were, directed and concentrated against the most feeble point of the parietes, we see a proof of it in a fact that occurs to our observation every day. In order to convince ourselves of this, we need only notice what happens in individuals afflicted with hernia: if they cough, or sneeze, or make the slightest effort, they instantly find the size of the swelling increased, and hasten to support the part with their hand. During the slightest efforts, which render the hernia larger it is also indisputable, that the mesentery is elongated in the same proportion as the intestine protrudes. All the viscera have such a tendency to be displaced and carried towards the weakest point of the parietes of the abdomen, that even those, which are naturally the most distant from it, and are the most firmly fixed by the folds of the mesentery, may in their turn descend into the hernia. Anatomical knowledge alone would never have led us to have a suspicion of the possibility of these occurrences. Sandifort and Palella have found, in an umbilical hernia, the cæcum, with a portion of the ileum and colon. (*Obs. Pathol. cap. 4, & Nova Gubernaculi testis Descriptio*.) Mauchart, Camper, and Bose, have met with the cæcum in an inguinal hernia of the left side. (*De Hern. Incur. in Halleri Disput. Chirurg. Tom 3. Demonstrat. anat. patholog. lib. 2, p. 18, & Animadvert. de hern. inguin. p. 5.*) Lassus has seen the left colon protrude at the right inguinal ring. (*Médecine Opératoire, T. 1, p. 173.*) If it be proved by all these facts, that such viscera, as are the most closely united to the great sac of the peritoneum and neighbouring parts, are nevertheless liable to form hernia; and if such displacements cannot happen without a considerable elongation of the membranous bands fixing these bowels, in their natural situation, how can we refuse to admit, that a noose of intestine, pushed by degrees through the inguinal ring, drags along with it the corresponding portion of the mesentery? In order to explain this event, there is no necessity for supposing a partial relaxation of the mesentery." (*Traité Pratique des Hernies, Par A. Scarpa, trad. de l'Italien, p. 37—43.*)

The general symptoms of a hernia, which is reducible, and free from strangulation, are an indolent tumour in some point of the abdomen, most frequently descending out of the abdominal ring, or from just below Poupart's ligament, or else out of the navel; but occasionally, from various other situations, as will be presently explained. The swelling often originates suddenly, except in the circumstances above related, and it is subject to a change of size, being smaller when the patient lies down on his back, and larger when he stands up, or holds his breath. It frequently diminishes when pressed, and

grows large again when the pressure is removed. Its size and tension often increase after a meal, or when the patient is flatulent. In consequence of the unnatural situation of the bowels, many patients with hernia are occasionally troubled with colic, constipation, and vomiting. Sometimes, however, the functions of the viscera seem to suffer little or no interruption.

If the case be an *enterocæle*, and the portion of intestine be small, the tumour is small in proportion; but, though small, yet, if the gut be distended with wind, inflamed, or have any degree of stricture made on it, it will be tense, resist the impression of the finger, and give pain upon being handled. On the contrary, if there be no stricture, and the intestine suffer no degree of inflammation, let the prolapsed piece be of what length it may, and the tumour of whatever size, yet the tension will be little, and no pain will attend the handling it; upon the patient's coughing, it will feel as if it were blown into; and, in general, it will be found very easily returnable. (*Pott*.) A gurgling noise is often made when the bowel is ascending.

If the hernia be an *epiplocele*, or one of the omental kind, the tumour has a more flabby and a more unequal feel; it is in general perfectly indolent, is more compressible, and (if in the scrotum) is more oblong, and less round, than the swelling occasioned in the same situation by an intestinal hernia; and, if the quantity be large, and the patient adult, it is in some measure distinguishable by its greater weight. (*Pott*.)

If the case be an *entero-epiplocele*, that is, one consisting of both intestine and omentum, the characteristic marks will be less clear, than in either of the simple cases: but the disease may easily be distinguished from every other one, by any body in the habit of making the examination. (*Pott, P. 28.*)

As the smooth slippery surface of the intestine generally makes its reduction easier than that of the omentum, we may infer, with Mr. Lawrence, "that, if a portion of the contents slip up quickly and with noise, leaving behind something which is less easily reduced, the case is probably an *entero-epiplocele*." (*See Treatise on Ruptures, Edit. 3, p. 32.*)

On the subject of prognosis, Mr. Pott remarks, that the age and constitution of the subject, the date of the disease, its being free, or not free from stricture, or inflammation, the symptoms which attend it, and the probability or improbability of its being returnable, necessarily produce much variety.

If the subject be an infant, the case is not often attended with much difficulty or hazard, the reduction being easy as well as the descent; and though from neglect, or inattention, the bowel may fall down again, yet it is as easily replaced, and mischief seldom produced: Mr. Pott says seldom, because he has seen an infant, one year old, die of a strangulated hernia, which had not been down two days, with all the symptoms of mortified intestine. (For other examples of

strangulated hernia in very young infants, refer to *Gooch's Chir. Works*, Vol. 2, p. 33; *Lawrence on Ruptures*, p. 65, Edit. 3; *Edinb. Med. and Surgical Journal*, Vol. 3, p. 470, &c.)

"If the patient be adult, and in the vigour of life, the consequences of neglect, or of maltreatment, are more to be feared than at any other time, for reasons too obvious to need relating. The great and principal mischief to be apprehended, in an intestinal hernia, is an inflammation of the gut, and an obstruction to the passage of the aliment and feces through it; which inflammation and obstruction are generally produced by a stricture made on the intestine. In very old people, the symptoms do not usually make such rapid progress, both on account of the laxity of their frame, and their more languid circulation; and also that their ruptures are most frequently of ancient date, and the passage a good deal dilated; but then, on the other hand, it should also be remembered, that they are by no means exempt from inflammatory symptoms; and that if such should come on, the infirmity of old age is no favourable circumstance in the treatment, which may become necessary. (Pott.)

If the disease be recent, and the patient young, immediate reduction, and constant care to prevent another protrusion, are the only means whereby it is possible to obtain a perfect cure.

"If the disease be of long standing, has been neglected or suffered to be frequently down, and has given little or no trouble, the aperture in the abdominal muscle, and the neck of the hernial sac, may both be presumed to be large; which circumstances in general render immediate reduction less necessary and less difficult, and also frustrate all rational expectation of a perfect cure. On the contrary, if the rupture be recent, or, though old, has generally been kept up, its immediate reduction is more absolutely necessary, as the risk of stricture is greater from the supposed smallness of the aperture, and narrowness of the sac. If the rupture be very large and ancient, the patient far advanced in life, the intestine not bound by any degree of stricture, but does its office in the scrotum regularly, and no other inconvenience be found to attend it, but what proceeds from its weight, it will in general be better not to attempt reduction, as it will, in these circumstances, most probably prove fruitless, and the handling the parts in the attempt, may so bruise and injure them as to do mischief."

With respect to the correctness of the advice here delivered, some doubt may be entertained, because, though it would certainly not be right to protract the attempts at reduction, so as to do mischief, it must be equally wrong to make no trial, whether the hernia is reducible or not; and, if reducible, I should say, that it ought to be reduced without delay, and a truss applied. This opinion, however, seems to agree with the injunctions delivered by Pott in another

place, as will be seen in the next section of this article.

With regard to the contents of a hernia, Mr. Pott observes, that "if it be a portion of omentum only, and has been gradually formed, it seldom occasions any bad symptoms, though its weight will sometimes render it very troublesome. But, if it be produced suddenly by effort or violence, that is, if a considerable piece of the caul by accident slip down at once, it will sometimes prove painful and cause very disagreeable complaints; the connexion between the omentum, stomach, duodenum, &c. being such as to render the sudden descent of a large piece of the first sometimes productive of nausea, vomiting, colic, and all the disagreeable symptoms arising from the derangement of these viscera. When the piece of caul is engaged in such a degree of stricture as to prevent the circulation of blood through it, it will sometimes, by becoming gangrenous, be the occasion of very bad symptoms and even of death, as I have more than once seen: and thus, as a mere omental hernia, it may sometimes be subject to great hazard. But even though it should never be liable to the just-mentioned evil, that is, though the portion of the caul should remain uninjured in the scrotum, yet it renders the patient constantly liable to hazard from another quarter; it makes it every moment possible for a piece of intestine to slip into the same sac, and thereby add to the case all the trouble and all the danger arising from an intestinal rupture. It is by no means an uncommon thing for a piece of gut to be added to a rupture, which had for many years been merely omental, and for that piece to be strangulated, and require immediate help

"An old omental hernia is often rendered not reducible, more by an alteration made in the state of the prolapsed piece of caul, than by its quantity. It is very common for that part of the omentum, which passes through the neck of the sac, to be compressed into a hard, smooth body, and lose all appearance of caul, while what is below in the scrotum is loose and expanded, and enjoys its natural texture; in this case, reduction is often impossible, from the mere figure of the part; and I have so often seen this, both in the living and the dead, that I am satisfied, that for one omental rupture, rendered irreducible by adhesions, many more become so from the cause above-mentioned.

"In the sac of old omental ruptures that have been long down, and only suspended by a bag truss, it is no very uncommon thing to have a pretty considerable quantity of fluid collected: this, in different states and circumstances of the disease, is of different colour and consistence, and seldom so much in quantity as to occasion any particular attention to it; but, on the other hand, it sometimes is so much in quantity as to become an additional disease to the original one. I have more than once been obliged to let it out, in order to remove the incon-

venience arising from its weight, and the distention of the scrotum, which I have also seen become gangrenous by the neglect of this operation.

"If the hernia be of the intestinal kind merely, and the portion of gut be small, the risk is greater, strangulation being more likely to happen in this case, and more productive of mischief, when it has happened: for the smaller the portion of gut is which is engaged, the tighter the tendon binds, and the more hazardous is the consequence. I have seen a fatal gangrene, in a bubonocoele, which had not been formed forty-eight hours, and in which the piece of intestine was little more than half an inch.

Another observation made by Pott is, that "if the hernia be caused by a portion of the intestine ileum only, it is in general more easily reducible, than if a part of the colon has descended with it, which will also require more address and more patience in the attempt. The reduction of a mere intestinal hernia too (*cæteris paribus*) will always remain more practicable, than that of a mere omental one, after it has attained to a certain size and state, as the part contained within the former is liable to less alteration of form than that within the latter; which alteration has already been mentioned as no unfrequent hinderance of the return of an old caul rupture.

"Not that the parts within a mere intestinal hernia are absolutely exempt from such an alteration as may render their return into the belly impracticable, even where there is no stricture; for, says Pott, I have seen that part of the mesentery, which has lain long in the neck of the sac of an old rupture, so considerably hardened and thickened, as to prove an insuperable obstacle to its reduction."

Upon the whole, this author infers, that an intestinal rupture is subject to worse symptoms, and a greater degree of hazard, than an omental one, though the latter is, by no means, so void of either as it was formerly supposed to be; that bad symptoms are more likely to attend a recent rupture, than one of ancient date; that the descent of a very small piece of intestine is more hazardous than that of a larger; and that the hernia, which consists of gut only, is in general attended with worse circumstances, than that which is made up of both gut and caul.

Mr. Hey coincides with Pott, in thinking the prognosis more unfavourable when the tumour is small. I think it is not a bad general rule, that the smaller the hernia, the less hope there is of reducing it by the taxis. Long-continued efforts to reduce a prolapsed intestine, are most likely to succeed in old and large hernias, when no adhesions have taken place." (*Pract. Observ. in Surgery*, p. 208.)

"The opening (says Mr. Lawrence) through which the parts protude, is narrower in some situations than in others; the progress of the case will therefore be more

rapid, and the danger of the patient more urgent. The aperture is generally very small in femoral hernia; this kind of rupture in men, and the bubonocoele in women, have a particularly narrow entrance. - On the same grounds, femoral, inguinal, and umbilical ruptures are more dangerous than the ventral, perineal, or vaginal kinds. (*Treatise on Ruptures*, p. 63, Ed. 3.)

TREATMENT OF A HERNIA CAPABLE OF EASY AND IMMEDIATE REDUCTION, AND NOT ATTENDED WITH ANY TROUBLESOME OR BAD SYMPTOMS.

"This case," says Mr. Pott, "is very frequently met with in infants, and sometimes in adults, and is too often neglected in both. In the former, as the descent seldom happens but when the infant strains to cry, and the gut is either easily put up, or returns *sponte*, as soon as the child becomes quiet, it often is either totally unattended to, or an attempt made to restrain it only by a bandage made of cloth, or dymity, and which being ineffectual for such purpose, lays the foundation for future trouble and mischief.

"This is, in great measure, owing to a common opinion, that a young infant cannot wear a steel truss; a generally prevailing error, and which ought to be corrected. There is no age at which such truss may not be worn, or ought not to be applied; it is, when well made, and properly put on, not only perfectly safe and easy, but the only kind of bandage that can be depended upon; and as a radical cure depends greatly on the thinness of the hernial sac, and its being capable of being so compressed as possibly to unite, and thereby entirely close the passage from the belly, it must therefore appear to every one who will give himself the trouble of thinking on the subject, that the fewer times the parts have made a descent, and the smaller and finer the elongation of the peritoneum is, the greater the probability of such cure must be.

"The same method of acting must, for the same reasons, be good in every age in which a radical cure may reasonably be expected; that is, the prolapsed parts cannot be too soon returned, nor too carefully prevented from falling down again, every new descent rendering a cure both more distant and more uncertain.

"As soon as the parts are returned, the truss should be immediately put on, and worn without remission, care being taken, especially if the patient be an infant, to keep the parts on which it presses constantly washed, to prevent galling.

"It can hardly be necessary to say, that the surgeon should be careful to see that the truss fits, as his success and reputation depend on such care. A truss which does not press enough, is worse than none at all, as it occasions loss of time and deceives the patient, or his friends; and one which presses too much, or on an improper part, gives pain and trouble, by producing an inflam-

mation and swelling of the spermatic chord, and sometimes of the testicle.

"In adults, whose ruptures are of long standing, and accustomed to frequent descent, the hernial sac is generally firm and thick, and the aperture in the tendon of the abdominal muscle large; the freedom and ease with which the parts return into the belly when the patient is in a supine posture, and the little pain which attends a rupture of this kind, often render the persons who labour under it careless: but all such should be informed that they are in constant danger of such alteration in their complaint, as may put them into great hazard, and perhaps destroy them. The passage from the belly being open, the quantity of intestine in the hernial sac is always liable to be increased, and when down, to be bound by a stricture. An inflammation of that portion of the gut which is down, or such obstruction in it as may distend and enlarge it, may at all times produce such complaints as may put the life of the patient into imminent danger; and therefore, notwithstanding this kind of hernia may have been borne for a great length of time, without having proved either troublesome or hazardous, yet as it is always possible to become so, and that very suddenly, it can never be prudent or safe to neglect it.

"Even though the rupture should be of the omental kind, (which considered abstractedly is not subject to that degree or kind of danger to which the intestinal is liable) yet it may be secondarily, or by accident, the cause of all the same mischief; for while it keeps the mouth of the hernial sac open, it renders the descent of a piece of intestine always possible; and consequently always likely to produce the mischief which may proceed from thence.

"They who labour under a hernia thus circumstanced, that is, whose ruptures have been generally down while they have been in an erect posture, and which have either gone up of themselves, or have been easily put up in a supine one, should be particularly careful to have their truss well made, and properly fitted; for the mouth of the sac, and the opening in the tendon being both large and lax, and the parts having been used to descend through them, if the pad of the truss be not placed right, and there be not a due degree of elasticity in the spring, a piece of intestine will, in some posture, slip down behind it; and render the truss productive of that very kind of mischief which it ought to prevent." (See *Truss*.)

Mr. Pott then comments upon the importance of having the parts completely reduced before the truss is applied, and upon the danger that may be incurred by laying such bandage aside after it has been worn some time; since the partial closure of the ring, whereby the descent of the gut is rendered less easy, will also make the reduction more difficult, if a piece should happen to slip down; and hence he insists, that a truss "should be long, and unremittingly worn by all those, whose time of life makes the ex-

pectations of a perfect cure reasonable, many of the ruptures of adults being owing to the negligent manner in which children at school are suffered to wear their trusses."

Besides the danger of strangulation, and the loss of all chances of a radical cure, when a reducible hernia is neglected, and allowed to remain down, there are other motives for keeping up the tumour with a truss, and preventing its increase of size. "The vast size, to which neglected herniæ sometimes increase, not only prohibits all active exertion, but by involving, in the male, the integuments of the penis, incapacitates the subject from the act of copulation, and gives rise to excoriation from the discharge of the urine over the swelling. Probably too, the testis may be affected by the pressure of a very large scrotal hernia. (*Morgagni de Caus. et Sed. Ep. 33. Art. 12; Schmucker Vermischte Chir. Schriften, B. 3, p. 195.*) Disorders of the intestinal functions invariably attend these large ruptures, and increase in frequency and violence in proportion to the size of the swelling, and age of the patient. All the moveable viscera of the abdomen gradually find their way into the hernial sac, if a rupture be entirely neglected. (*Lawrence on Ruptures, p. 67, Edit. 3, 1816.*)

TREATMENT OF IRREDUCIBLE HERNIÆ, FREE FROM INFLAMMATION, AND UNATTENDED WITH TROUBLESOME OR DANGEROUS SYMPTOMS.

Mr. Pott, and all the best writers on ruptures, ascribe the incapacity of reduction, in most cases, either to the largeness of the quantity of the contents, an alteration made in their form and texture, or to adhesions, which they have contracted with each other, or their containing bag.

Mr. Pott was also aware, that ruptures are sometimes rendered difficult to be reduced, by the cœcum being contained in the hernial sac. Of which fact, he was as much convinced as the nature of such kind of things would permit; that is, by observations made both on the living and the dead. This statement, which was made by Mr. Pott very many years back, deserves particular notice, because its truth is confirmed by the modern observations of Scarpa, whose very important explanations of the cause of the difficulty of reduction, may be seen in the second vol. of the *First Lines of Surgery*.

Mr. Pott has adverted to the kind of impediment to reduction, produced by the thickening of the neck of the sac, when the hernia is long neglected, and suffered to remain in the scrotum, without any bandage to support its weight.

The same author reckons an alteration produced by time, and constant, though gentle pressure in the form and consistence, or texture of the omentum, as no infrequent cause, why neglected omental ruptures become irreducible.

When a portion of omentum "has been suffered to remain for a great length of time

in the scrotum, without having ever been returned into the belly, it often happens, that, although that part of it, which is in the lower part of the hernial sac, preserves its natural soft, adipose, expansile state, yet all that part which passes through what is called the neck of the sac, is, by constant pressure, formed into a hard, firm, incompressible, carious kind of body, incapable of being expanded, and taking the form of the passage in which it is confined, exactly filling that passage, and rendering it impossible to push up the loose part which fills the scrotum.

"The same reason for incapacity of reduction is also sometimes met with in ruptures of the intestinal kind, from an alteration produced on that part of the mesentery which has been suffered to lie quiet for a great length of time in the neck of an old hernial sac.

"The other impediment, which I mentioned to the return of old ruptures, is the connexion and adhesion of the parts, either with each other, or with the bag containing them. This is common to both the intestinal and omental hernia, and is produced by slight inflammations of the parts which have been permitted to lie long in contact with each other, or perhaps in many cases from the mere contact only. These adhesions are more or less firm in different cases, but even the slightest will almost always be found an invincible objection to the reduction of the adherent parts, by the hand only.

"Many, or perhaps most of these irreducible ruptures become so by mere time and neglect, and might at first have been returned; but when they are got into this state, they are capable of no relief from surgery, but the application of a suspensory bag, to take off or lessen the inconvenience arising from the weight of the scrotum.

"People in this situation should be particularly careful not to make any attempts beyond their strength, nor aim at feats of agility; they should take care to suspend the loaded scrotum, and to keep it out of the way of all harm from pressure, bruise, &c. When the tumour is very large, a soft quilted bolster should be worn at the bottom of the suspensory, to prevent excoriation, and the scrotum should be frequently washed for the same reason; a loss of skin in this part, and in such circumstances, being sometimes of the utmost importance. They ought also to be particularly attentive to the office of the intestinal canal, to see that they do not by any irregularity of diet disorder it, and keep themselves from being costive." Mr. Pott observes, however, that the quiet, inoffensive state of this kind of hernia is by no means to be depended upon; many things may happen to it, by which it may be so altered, as to become hazardous, and even fatal: an inflammation of that part of the gut which is down, any obstruction to the passage of the aliment or feces through it, a stricture made by the abdominal tendon, either on what has been long down, or on a new portion which may at any time be added to it, are always capa-

ble of so altering the state of the case, as to put the life of the patient into danger.

"Indeed the hazard arising from a stricture made on a piece of intestine contained in the sac of an old irreducible hernia, is in one respect greater than that attending one that has been found at times reducible; since from the nature of the case it will hardly admit of any attempt toward relief, but the operation, which in these circumstances must necessarily be accompanied with additional difficulty.

"Among the ruptures, which have been thought not reducible, and treated as such, there have been some which, upon more judicious and more patient attempts, have been found capable of reduction.

"When this is suspected to be the case, the proper method is by absolute rest, in a supine posture, for a considerable length of time, by great abstinence, and the use of evacuants, so as to lessen the size of the parts in the hernial sac, and render them capable of passing back again into the belly." (*Pott on Ruptures.*)

Fabricius Hildanus gives an account of a man who was radically cured of a rupture, of twenty years date, by six months confinement to bed. (*Cent. 5, Obs. 54.*)

Le Dran and Arnaud relate instances of monstrous bubonocoeles, which disappeared entirely after the patients had been long confined to bed, and rendered much emaciated by tedious illnesses. Some of the moderns have imitated this operation of nature, and by frequent bleedings, and repeated purges, have sometimes so far reduced the size of the hernia, that it has been returned into the abdomen. Mr. Hey has several times succeeded in this way. (*P. 219.*) But the practice cannot prove successful, when the viscera adhere to the sac, or to the peritoneum, just within the abdomen. The greatest objection to this method of cure, is the want of an absolute criterion for distinguishing when the parts do, or do not adhere to the hernial sac, and in advanced years, though one were sure that the viscera were free from the sac, the possibility of hurting the body by the necessary evacuations, is also another objection. (*Sharp's Critical Inquiry, p. 15.*)

Were the plan to be thought worthy of trial, keeping up a constant pressure on the tumour, by means of a suspensory bandage, made to lace in front, would be proper for promoting the absorption of the thickened parts in the hernial sac. Mr. A. Cooper has reduced such herniæ, after applying ice to them, the good effects of which he imputes to its producing a contraction of the scrotum, and thus a strong and permanent compression of the tumour. Mr. Earle lately informed me of a method of keeping up a general pressure on the swelling, by means of a bladder containing quicksilver, the quantity of which can be regulated according to circumstances.

Whenever any attempts of this kind succeed, a truss should be immediately put on, and worn constantly without remission.

However, there are instances on record, where the capacity of the abdomen had become so adapted to the diminished quantity of the viscera, that when the contents of the hernia were reduced, serious complaints arose from their introduction into the belly. Schmucker met with several such cases, in which he was obliged to take off the truss again. Petit has known the reduction of a hernia of this kind prove fatal, the parts not descending again when the truss was removed, the nausea and vomiting continuing, and peritonitis taking place. (*Chirurgische Wahrnehmungen*, Vol. 2, p. 243. *Traité des Maladies Chir.* T. 2, p. 392.)

Mr. Pott remarks, that "an omental rupture, which has been so long in the scrotum as to have become irreducible, is very seldom attended with any bad symptoms; considered abstractedly; but it is constantly capable of being the occasion of an intestinal hernia, and all its consequences; neither is that all, for the omentum, either so altered in form and texture, or so connected as to be incapable of reduction, may by accident inflame, and either become gangrenous, or suppurate, and the occasion of a great deal of trouble." In a few instances, epiploceles produce very bad symptoms indeed, cases of which are to be found in Garengnot, Dionis, &c.

Sometimes, in old cases of entero-epiplocele, the intestine is reducible, but the omentum is not, in which case some writers advise keeping up the piece of bowel with a truss, the pad of which must be so contrived as not to press on the omentum. Mr. Pott, however, considers this method not often practicable, and should such a truss be used, he recommends great caution in its construction and application, lest a small piece of gut slip down, and being pressed on by the truss, produce fatal mischief.

"Irreducible herniæ must of course be exposed to all the consequences of external injury and violence; hence, various cases are recorded, in which the bowels have been burst by blows, falls, &c." (*Lawrence on Ruptures*, p. 110. Edit. 3.)

For examples of such accidents, Mr. Lawrence refers to *A. Cooper on Hernia*, Part 2, Pref. p. 2, and to *Travers's Inquiry into the Process of Nature*, &c. p. 37. A case is also quoted from Scarpa, p. 310, where a violent exertion caused a sudden return of a hernia, which had been long regarded as cured. The viscera lay in the tunica vaginalis, which was burst to the extent of an inch.

SYMPTOMS AND TREATMENT OF A STRANGULATED, OR AN INCARCERATED HERNIA.—MEANS TO BE TRIED, BEFORE AN OPERATION.

"Difficulty of reduction (says Pott) may be owing to several causes. The size of the piece of omentum, or the inflamed state of it; the quantity of intestine and mesentery, an inflammation of the gut, or its distention by feces, or wind; or the smallness of the aperture of the tendon, through which the hernia passes. But to whatever cause it be

owing, if the prolapsed body cannot be immediately replaced, and the patient suffers pain, or is prevented thereby from going to stool, it is called an *incarcerated hernia*, a *strangulated hernia*, or a *hernia with stricture*.

"The symptoms are a swelling in the groin, or scrotum, resisting the impression of the fingers: if the hernia be of the intestinal kind, it is generally painful to the touch, and the pain is increased by coughing, sneezing, or standing upright. These are the very first symptoms, and if they are not relieved, are soon followed by others, viz. a sickness at the stomach, a frequent retching, or inclination to vomit, a stoppage of all discharge per anum, attended with a frequent, hard pulse, and some degree of fever."

A patient, thus circumstanced, is in some danger, and demands immediate assistance. A stricture made on the prolapsed part of the gut, by the aperture through which it passes, is the immediate cause of all the bad symptoms, and of course, the removal of such stricture is the only thing which can bring relief. This object can only be accomplished by returning the bowel back into the abdomen, or dividing the parts which form the stricture. The former plan is always the most desirable, when practicable.

We next proceed to notice the various measures to be adopted for the relief of a strangulated hernia, so as to obtain the best chance of doing away the necessity of an operation. After treating of the merits of each plan, a few remarks will be offered on the order in which the means should be put in practice.

Taxis—This is the term applied to the operation of reducing a hernia with the hand. It is much promoted by the position of the body; which Winslow thought should be placed on an inclined plane, and the thighs bent towards the trunk. Mr. A. Cooper advises the same practice, observing, that this posture, by relaxing the fascia of the thigh, relaxes also the aperture, through which the hernia passes. Every degree of tension, and relaxation of the femoral fascia, must undoubtedly be attended with a corresponding change in the abdominal ring. But flexion of the thigh, besides relaxing this fascia, also relaxes the abdominal, internal iliac, and psoas muscles. In cases of inguinal hernia, the pressure made on the tumour by the hands of the surgeon, should always be directed upwards and outwards, along the course of the spermatic cord, and Mr. A. Cooper advises it to be continued from a quarter to half an hour. (*On Inguinal and Congenital Hernia*.)

As the femoral hernia passes downwards, and then forwards, the pressure must be directed first backwards, and then upwards. No violence should ever be used; for, besides being unavailing, it greatly aggravates the inflamed state of the contents of the hernial sac, and has been known even to burst the intestine. (See *Cooper on Inguinal Hernia*, &c. p. 23.)

Besides bending the thigh, care should also be taken to rotate it inwards, which will

have great effect in relaxing the femoral fascia, and tendon of the external oblique muscle. Suspension of the patient over the shoulders of an assistant has been thought to facilitate reduction: "I have tried it often, (says Mr. Hey;) but have not found it to be of such superior efficacy, as some authors have represented." (P. 144.)

The return of a piece of intestine is generally preceded by a peculiar noise, caused by the passage of air through the stricture. It recedes at first gradually, and then slips up suddenly. The omentum goes up slowly to the very last portion, which must be actually pushed through the opening. If the taxis should not succeed at first, it will often do so after the warm bath, bleeding, or cold applications. Small herniæ, being attended with the closest stricture, are the most difficult to reduce, and for the same reason, crural ruptures do not so often yield to the taxis, as inguinal herniæ in the male subject. The taxis becomes less likely to succeed, the longer the inflamed viscera have been down, because adhesions are liable to form. Mr. Lawrence observes, (p. 63.) "When the rupture becomes painful, we are no longer justified in persevering in attempts at reduction by the hand. A sufficient pressure cannot now be endured; and the force which is employed only tends to increase the inflammation, and accelerate the approach of gangrene. *At this period the operation is required, and should be performed without delay.*" Desault even proscribed the taxis altogether in the inflammatory strangulation, until the previous use of other means had produced a change in the state of the swelling.

That the taxis is frequently abused, and the cause of serious mischief, is a truth which cannot be doubted. "Strangulated herniæ, (says Scarpa) very frequently mortify from the negligence of the patients, and their repugnance to submit to an operation, and perhaps, still more frequently from the effect of the taxis, unskilfully exercised by uninformed surgeons, who are determined, at any price whatsoever, to accomplish the speedy reduction of the viscera. The majority of them make no distinction between the *acute* and the *chronic* strangulation. In both cases, no sooner are the symptoms of strangulation evinced, than they begin to handle the swelling roughly, and to push the viscera with all their force, in order to make them return into the abdomen; whilst, when the strangulation is *acute*, and the patient young and strong, the taxis ought never to be practised, before all the means proper for diminishing the strength, calming spasm, and relaxing the parts which are to be reduced, have been employed for a certain time. These means we know, are bleedings, fomentations, emollient clysters, and especially the warm bath, which, next to bleeding, holds the first rank. At this school of surgery, I have frequently had opportunities of observing the salutary effect of this treatment. My pupils have, more than once, seen herniæ, which had been painfully

handled without any good, reduced, as it were, spontaneously, after a bleeding, or whilst the patient was in the bath. If what I have said upon the subject of the *acute* strangulation, and the treatment that it requires, were generally known by surgeons, I think that operations for strangulated herniæ would be less frequent. Things are different with regard to the *chronic* strangulation of old large herniæ, in feeble, or aged persons: for in these cases, it is of great importance to support the patient's strength. Bleeding, the warm bath, and other weakening means, should also be avoided, which, in producing a general atony, might bring on gangrene of the intestine, either during the strangulation, or after the reduction of the viscera. It is ascertained that these kinds of strangulation are almost always occasioned by an accumulation of fecal matter, or an extraordinary quantity of air in the hernia. Nothing is more efficacious than cold applications, for promoting the action of the bowel on the matter which distends it, or for lessening the volume of the air. They produce a corrugation of all the scrotum, and contractions of the cremaster, which alone sometimes suffice for reducing the viscera, in a much better manner than could be done by the hands of the most experienced surgeon." (Scarpa, *Traité des Hernies*, p. 244—247.)

Bleeding.—The inflammation which attacks the protruded viscera, and spreads thence over the whole abdomen, and the temporary weakness and often fainting, which the sudden loss of blood induces, and which is a peculiarly favourable opportunity for reducing the hernia by the hand, are the reasons in favour of bleeding. Sharp, Pott, B. Bell, Sabatier, Richter, Callisen, and Scarpa, names which can never be surpassed in respectability, are all subscribed in favour of bleeding. Wilmer, Alanson, and A. Cooper, have published against the practice. Mr. Hey has related two cases, which strongly evince the manner in which bleeding facilitates the return of a hernia: the protruded viscera, in one instance, went up spontaneously, on blood being taken away; in the other, the taxis succeeded immediately afterward, though the previous attempt had been made in vain. (P. 125, 126.) Mr. Hey's experience, however, leads him to concur so far with Wilmer and Alanson, as to declare, that bleeding has generally failed to procure a reduction of the strangulated intestine, though he is persuaded, that in many cases it may be used with advantage. But he cannot agree with Wilmer, that it generally renders the subsequent operation more dangerous. (P. 126.) The majority of candid practitioners I believe will allow, that bleeding is always proper when the hernia is small and recent; the abdomen tense and painful; and the patient young, strong, and plethoric.

Purgative Medicines.—My experience, (says Mr. Hey) leads me to condemn almost universally the use of purgatives while an intestine remains firmly strangulated. In the

entero-epiplocele, when the intestine has retired, and the omentum remains strangulated: or in a simple strangulation of the omentum, where the intestine has not been prolapsed, purgatives are of great utility. So likewise in very large and old hernias, where there is reason to doubt, whether the disease is not to be considered as a morbid affection of the intestinal canal, rather than the effect of strangulation, purgatives may be as useful as in the simple ileus without hernia. While the intestine remains firmly strangulated, they usually increase the vomiting, and add to the distress of the patient. If they are to be tried at any time with hope of success, the trial would appear to have the greatest advantage when the vomiting has been removed by means of an opiate; yet I have repeatedly given them in vain during such an interval of relief. (*Practical Observations in Surgery*, p. 128.)

Purgatives are supposed to operate by exciting the peristaltic action of the intestine, and thereby extricating it from the stricture. Besides the above eminent surgeon, Pott and Richter have joined in their general condemnation, and to all appearances, with very great reason. Purgative clysters certainly have not the objection of increasing the irritation; but their efficacy is not deserving of much confidence. Mr. Hey says, that he has never seen one case, in which either purgative, or emollient clysters, produced a return of a strangulated hernia. Such injections will empty the large intestines; but they do no more. It is common also for a natural evacuation to be the immediate consequence of strangulation. (P. 131.)

Warm Bath.—"Many instances (says Hey) are upon record of the good effect of warm bathing in procuring the reduction of a strangulated hernia. I have often seen it useful; but I have also often seen it fail. Whenever it is used in this disease, the patient should be placed, if possible, in a horizontal position. Gentle efforts with the hand to reduce the prolapsed part are perhaps attended with less danger, and with greater prospect of success, while the patient lies in the bath, than in any other position. The free use of opiates coincides with that of warm bathing, and under some circumstances, these means deserve to be tried in conjunction." (P. 132.)

Cold Bath, and Cold Applications.—The cold bath, and dashing of cold water on the patients, are little to be depended upon, though success has sometimes been obtained in this manner. (*Petit, Traité des Chir.* T. 2, p. 325; *Hey*, p. 136.)

Wilmer strongly recommended the application of cold to the tumour itself, and this plan has acquired the approbation of the most celebrated modern surgeons. It is generally tried in conjunction with the effect of tobacco clysters, which will be presently noticed. Cold applications, in the form of ice, were indeed particularly recommended by B. Bell. The best way is to pound the ice, tie it up in a bladder, and place it on

the rupture. When ice cannot be procured, Mr. A. Cooper employs a mixture of equal parts of nitre and muriate of ammonia. To one pint of water, in a bladder, ten ounces of the mixed salts are to be added. "If, after four hours, (says this distinguished surgeon) the symptoms become mitigated, and the tumour lessens, this remedy may be persevered in for some time longer; but, if they continue with unabated violence, and the tumour resist every attempt at reduction, no farther trial should be made of the application." (*On Inguinal and Congenital Hernia*.) When ice is not at hand, aether sometimes proves a good substitute, when allowed to evaporate from the surface of the swelling.

Care must be taken, that the cold be not so applied as to freeze the scrotum, and bring on sloughing. (*A. Cooper*, p. 15.)

Opiates.—Mr. Hey met with several cases in which opiates, given freely, (in athletic persons after bleeding) procured a reduction of strangulated hernia.

He cannot say, however, that this remedy is generally successful; but it has the advantage of removing, for a time, the pain and vomiting usually attendant on strangulation, even though it prove ultimately inefficacious. Opiates should be given in large doses, when it is wished to try their effect in procuring reduction; and whenever the symptoms of strangulation return, after having been removed by opiates, the operation should be performed without delay. (P. 134, 135.)

Tobacco Clysters.—For this purpose, some surgeons prefer a decoction of tobacco, made by infusing, or boiling, one dram of the plant for ten minutes in a pint of water; others employ the smoke, which is prepared and introduced into the rectum by means of an apparatus, sold at almost every surgical instrument maker's. Perhaps both methods are equally efficacious; but, as one requires an apparatus, while the other does not, and is equally proper, the decoction may be entitled to most recommendation. The machine for the smoke is also frequently out of order. Next to the operation, tobacco clysters are the most certain means of bringing about the reduction of the strangulated parts. Besides exciting the action of the intestines, they exert a peculiar depressing influence on the whole system, reducing the pulse, and causing nausea and sickness, cold sweats and fainting, under which circumstances the parts often recede spontaneously, or may be easily reduced. Mr. A. Cooper prudently advises injecting half the above quantity at first; for he has seen two drams, and even one, when used as an infusion, and introduced at once, prove fatal. (P. 24.) The rest should be injected presently, when it appears that the tobacco does not operate with the extraordinary violence with which it does in a few particular constitutions.

A case recently published by Mr. C. Bell looks to me very much like an example of the occasional poisonous effects of the tobacco clyster, though not reported as such

by the author. At least, no particulars of any fatal mischief, either in the tumour or abdomen, are detailed, and it is remarked of the patient: "His strength held up until the tobacco clyster was administered to him, after which he very suddenly fell low, and sunk." (*Surgical Obs. Part 2, p. 189.*) The smoke proved fatal in an instance witnessed by Desault, (*Œuvres de Chir. T. 2, p. 344.*) and an infusion of ℥ij. to ℥viij. of water, seemed to produce sudden mortal effects in another example on record. (*Edinb. Med. and Surgical Journ. Vol. 9, p. 159.*)

Poultices and Fomentations have not the confidence of any experienced or intelligent surgeon. Whoever, in these urgent cases, wastes time in trying the effects of such applications, merits censure for his credulity, ignorance, and unfitness to undertake the treatment of a rapid disease, in which, as Pott remarks, if we do not get forward, we generally go backward; and whatever does no good, if it be at all depended upon, certainly does harm, by occasioning an irretrievable loss of time.

OF THE ORDER IN WHICH THE PRECEDING METHODS AND REMEDIES SHOULD BE TRIED, AND OF THE TIME WHEN THE OPERATION SHOULD NOT BE DELAYED.

In the treatment of a strangulated hernia, a surgeon cannot be too deeply impressed with the danger of spending time in the trial of methods of inferior efficacy, or of such as are evinced to be ineffectual in the cases before them.

The rapidity with which gangrenous mischief sometimes arises, and the patient loses his life, has been proved in a multitude of unfortunate examples, and should operate as a warning to all practitioners against the danger of deferring the operation too long. In the course of my reading, however, I have not met with so remarkable an instance of the sudden mortification, and rapidly fatal termination of a hernia, as the following case recorded by Baron Larrey, in speaking of the fatiguing and forced marches performed by the French soldiers in Egypt. These marches, he says, brought on in one case, a hernia which formed suddenly, and became at the same time strangulated. The man was immediately brought to my ambulance; but a spontaneous gangrene, which had all on a sudden attacked the intestine, and extended to the other abdominal viscera, caused the patient's death in the space of two hours, and made it impossible for me to do the operation for him. This is the second example that I have been acquainted with, in which the effects of the accident were thus rapid." (*Larrey, in Mém. de Chirurgie Militaire, T. 1, p. 196.*)

The taxis is generally among the first things to be tried, and Mr. A. Cooper thinks the attempts should be continued for a quarter or half an hour. When these have been ineffectual, the patient, if the circumstances do not forbid, should be immediately bled, and have a large opening

made in the vein, so that the suddenness of the evacuation may be most likely to bring on fainting. The taxis should then be tried again.

When the strangulation is very acute, and the patient young and strong, perhaps it may be most advisable to follow the advice delivered by Scarpa and Desault, which is to bleed the patient and put him in the warm bath, before the taxis is attempted at all.

If bleeding alone has been practised, and the manual efforts at reduction should not now succeed, the warm bath may be employed, *provided it can be got ready in a very short time*, but none should ever be lost in waiting for it to be prepared. When the bath is used, the taxis may be attempted as the patient lies in the water; a situation in which I have succeeded in reducing several herniæ.

Certainly not more than one hour should ever be allotted for putting in practice the first attempts at reduction, bleeding, and the warm bath.

The plan should be, while the trial of one thing is going on, another should be preparing. So when the preceding measures have been tried in vain, the application of a bladder filled with ice, or the solution of nitre and muriate of ammonia, and the injection of tobacco, in the form of smoke or decoction, should never be delayed for want of due previous preparation of all the requisites. Both these measures should be practised at the same time, immediately after the failure of the taxis, bleeding, and the warm bath. Mr. A. Cooper computes, that four hours are enough for the trial of the tobacco clyster, together with cold applications.

In omental herniæ, the necessity for operating may frequently be obviated by the good effects of bleeding, purgative medicines, and clysters, and leeches applied to the tumour. Mr. Lawrence has justly observed, that "when, as it very frequently happens, the aid of the surgeon is not required until the complaint has lasted for some time, a trial of the tobacco, together with the topical use of cold, should be immediately resorted to, as circumstances will not admit of delay in the previous use of less powerful remedies." (*P. 148, Edit. 3.*)

Every man who has seen much of herniæ will immediately recognize the propriety of the following sentiments of the experienced Mr. Hey:

"I can scarcely press in too strong terms the necessity of an early recourse to the operation, as the most effectual method of preserving life in this dangerous disease. If Mr. Pott's opinion be true, that the operation, when performed in a proper manner, and in due time, does not prove the cause of death oftener than perhaps once in fifty times; it would undoubtedly preserve the lives of many, to perform it almost as soon as the disease commenced, without increasing the danger by spending much time in the

use of means which cannot be depended upon for a cure.

"I have twice seen this disease prove fatal in about twenty-four hours. In such cases, it is evident there is little time for delay. A surgeon who is competent to perform the operation, is not perhaps consulted till the intestine is on the point of being mortified, or is actually in a state of mortification. The dilemma into which he is then cast is painful indeed. But, when the fullest opportunity is afforded him of using the best mode of treatment, I am satisfied that his success will be the greatest when the operation is not long delayed. This, at least, has been my own experience. When I first entered upon the profession of surgery, in the year 1759, the operation for the strangulated hernia had not been performed by any of the surgeons in Leeds. My seniors in the profession were very kind in affording me their assistance, or calling me into consultation when such cases occurred; but we considered the operation as the last resource, and as improper until the danger appeared imminent. By this dilatory mode of practice, I lost three patients in five, upon whom the operation was performed. Having more experience of the urgency of the disease, I made it my custom, when called to a patient who had laboured two or three days under the disease, to wait only about two hours, that I might try the effect of bleeding (if this evacuation was not forbidden by some peculiar circumstances of the case) and the tobacco clyster. In this mode of practice, I lost about two patients in nine, upon whom I operated. This comparison is drawn from cases nearly similar, leaving out of the account those cases in which a gangrene of the intestine had taken place.

"I have now, at the time of writing this, performed the operation thirty-five times; and have often had occasion to lament that I had performed it too late, but never that I had performed it too soon. There are some cases so urgent, that it is not advisable to lose any time in the trial of means to produce a reduction. The delay of a few hours may cut off all hope of success, when a speedy operation might have saved the life of the patient." (P. 141, &c.)

To determine the exact moment, when to give up the trial of the preceding measures, and to have immediate recourse to the operation, is certainly difficult; but no one can doubt, that it is generally better to operate too early than too late.

All directions must be general ones, liable to many exceptions: in rapid cases, little or no time should be allotted to the trial of any plan, and the operation should be done without the least delay. In other instances, we have full time to try the effects of every thing at all likely to succeed. The symptoms, which ought to guide us, in having recourse to the operation, arise from an attack of inflammation in that part of the intestine contained in the hernial sac, and from its spreading into the abdominal cavity. It is in proportion to their violence, that we

ought to urge the performance of the operation. Mr. A. Cooper considers pain on pressing the belly, and tension, as the symptoms which point out its immediate necessity. He adds, "Indeed, there is scarcely any period of the symptoms, which should forbid the operation; for, even if mortification has actually begun, the operation may be the means of saving life, by promoting the ready separation of gangrenous parts." (*On Inguinal and Congenital Hernia*, p. 27.)

Whenever the surgeon has succeeded in reducing the parts, without having recourse to the knife, if the symptoms of pain, inflammation, &c. ran high before such reduction, they will not always cease immediately afterward. As they probably depend on the reduced bowel having been inflamed by the stricture, the body should be kept open, and the diet and regimen should be low and sparing, whilst the least degree of pain and tension remain; in short, till all complaint is absolutely removed from the abdomen, and the intestines do their office freely, and without trouble. (Poll)

PROGRESS OF THE SYMPTOMS OF A STRANGULATED HERNIA.

The earliest symptoms have been already related, viz. "tumour in the groin, or scrotum, attended with pain, not only in the part, but all over the belly, and creating a sickness and inclination to vomit, suppression of stools, and some degree of fever. These are the first symptoms, and, if they are not appeased by the return of the intestine, that is, if the attempts made for this purpose do not succeed; the sickness becomes more troublesome, the vomiting more frequent, the pain more intense, the tension of the belly greater, the fever higher, and a general restlessness comes on, which is very terrible to bear. When this is the state of the patient, no time is to be lost; a very little delay is now of the utmost consequence, and if the one single remedy, which the disease is now capable of, be not administered immediately, it will generally baffle every other attempt. This remedy is the operation whereby the parts engaged in the stricture may be set free. If this be not now performed, the vomiting is soon exchanged for a convulsive hiccup, and a frequent gulping up of bilious matter; the tension of the belly, the restlessness and fever having been considerably increased for a few hours, the patient suddenly becomes perfectly easy, the belly subsides, the pulse, from having been hard, full, and frequent, becomes low, languid, and generally interrupted; and the skin, especially that of the limbs, cold and moist; the eyes have now a languor and a glassiness, a lacklustre not easy to be described; the tumour of the part disappears, and the skin covering it sometimes changes its natural colour for a livid hue; but whether it keeps or loses its colour, it has an emphysematous feel, a crepitus to the touch, which will easily be conceived by all who have attended to it,

but is not so easy to convey an idea of by words: this crepitus is the too sure indicator of gangrenous mischief within. In this state, the gut either goes up spontaneously, or is returned with the smallest degree of pressure; a discharge is made by stool, and the patient is generally much pleased at the ease he finds; but this pleasure is of short duration, for the hiccough and the cold sweats continuing and increasing, with the addition of spasmodic rigours and subultus tendinum, the tragedy soon finishes." (Pott.)

ANATOMY OF INGUINAL HERNIA.

This subject must necessarily precede the account of the operation, which would otherwise be unintelligible. It is chiefly in the anatomical information, relative to herniæ, and in the mode of operating, that modern surgeons have a decided superiority over their predecessors; for before Gimbernat, Camper, Hey, Lawrence, Cooper, Scarpa, and Hesselbach, published their several works on herniæ, the anatomy of the disease was only imperfectly understood.

The tendinous fibres of the aponeurosis of the external oblique muscle, as they run downwards and forwards towards the pubes, separate from each other, so as to leave a triangular opening, called the abdominal ring, which is usually more capacious in the male than the female subject. The upper and inner pillar (as it is termed) of this aperture is inserted into the symphysis of the pubes, and is the weakest of the two; the lower and outer one, which is the strongest, is chiefly a continuation of Poupart's ligament, (*Hesselbach über den Ursprung, &c. der Leisten-und-Schenkelbrüche, p. 4.*) and is fixed into the angle and crista of the same bone. Some tendinous fibres cross the upper and outer angle of the ring, so as to diminish the triangular appearance of the whole aperture: these are said to be very strong in old herniæ. The anterior and thicker layer of the aponeurosis of the internal oblique muscle joins the tendon of the external oblique; the posterior and thinner one joins that of the transversalis; but the lower portion of this tendon, together with the corresponding part of the transversalis, goes wholly in front of the rectus muscle. Thus the inferior border of the obliquus internus and transversalis, which originates from the upper part of Poupart's ligament, lies behind the outer pillar of the abdominal ring. Mr. A. Cooper first noticed, that a thin fascia proceeds from the inner edge of Poupart's ligament, and spreads over the posterior surface of the transversalis. This fascia forms the only partition between the peritoneum and the outer opening of the abdominal ring, and were it not for its existence, inguinal herniæ would probably be much more frequent. The partition in question, however, is said by Scarpa to be formed by the aponeuroses of the internal oblique and transverse muscles, while Hesselbach, who has named the small smooth point, situated directly behind the outer

opening of the abdominal ring, its *crural surface*, distinctly states, that it is formed by delicate fleshy and tendinous fibres of the internal oblique muscle; (*Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche, p. 4.*) and that behind them is the weakest part of what he names the *internal inguinal ligament*, in the rear of which is the peritoneum, with the intervention of a very loose cellular substance. (*Op. cit. p. 26.*) The *internal inguinal ligament* of Hesselbach, is therefore clearly the same thing as the above fascia pointed out by Mr. A. Cooper. This point of the abdomen is one of the three weak places on the inside of the inguinal region, where herniæ are liable to occur; yet, weak as it appears to be, it is not the most common situation of such tumours. A computation has been made, that in an hundred cases of inguinal hernia, not ten occur at the point here specified. (*H. J. Brunninghausen, Unterricht über die Brüche, &c. Würzb. 1811.*)

The spermatic vessels, joined by the vas deferens, run in front of the epigastric artery, very near the place of its origin. They then pass through the above fascia, go under the edge of the internal oblique and transverse muscles, and next obliquely downwards and forwards, between the above fascia, and aponeurosis of the external oblique muscle to the opening of the ring. When arrived on the smooth surface, immediately behind the ring, they describe an obtuse angle, and pass forwards and downwards into the scrotum. (*Hesselbach, op. cit. p. 5.*)

Thus we see, that the spermatic cord, before it actually emerges at what is named the abdominal ring, runs through a kind of canal, to which the epithet *inguinal* is often applied. This oblique passage of the cord through the abdominal parietes, was well known to, and elegantly delineated by Albinus; Gimbernat makes distinct mention of it in his *Account of a new Method of Operating for Femoral Hernia, p. 19, 32*; but Mr. A. Cooper has the merit of having given the earliest correct account of the inguinal canal, in reference to hernia; a subject rendered complete by the more recent elucidations of Hesselbach and Scarpa.

The abdominal ring is then only the outer opening of the canal, or passage, through which the spermatic cord passes before it emerges. The inner one, at which the viscera first protrude in the most common cases of inguinal hernia, is situated about an inch and a half from the abdominal ring, in the direction towards the anterior superior spinous process of the ilium; or, according to Hesselbach, the inguinal canal is almost an inch and a half in length, the average distance of the outer pillar of the abdominal ring, from the inner pillar of what he terms the posterior ring, being about sixteen lines. (*Op. cit. p. 14.*) This inner opening is rather nearer the pubes than the ilium, and its upper border is formed by the lower edge of the internal oblique, and transverse muscles, which can be plainly felt with the finger, in-

roduced upward and outward into the abdominal ring.

"The precise point at which the hernia most commonly begins, (says Scarpa,) is that which corresponds, in the fetus, to the communication of the tunica vaginalis with the peritoneum, and, in the adult, to the passage of the spermatic cord under the transverse muscle. In the sound state, the peritoneum presents at this part a small funnel-like depression, the depth of which increases in proportion as the spermatic cord is pulled from above downwards. It is this small pouch, this sort of digital appendage, whose progressive augmentation constitutes the hernial sac. Resting upon the anterior surface of the spermatic cord, it first makes its appearance under the inferior edge of the transverse muscle; thence it extends itself in the separation of the inferior fleshy fibres of the internal oblique muscle, always following the spermatic cord, in front of which it is situated; and after having in this manner passed through the whole of the canal, which extends from the iliac region to the pubes, it lastly protrudes at its external orifice, which is the inguinal (or abdominal) ring, properly so called. In all this track, the hernial sac, as well as the spermatic cord, is situated above the femoral arch, the direction of which it follows. The canal, which it traverses, is of a conical shape, the apex of which is towards the flank, and the base at the external orifice of the ring." (Scarpa, *Traité des Hernies*, p. 44, 45.)

The epigastric artery runs behind the spermatic cord, along the inner margin of the internal opening of the above canal, then upwards and inwards, so as to pass at the distance of half an inch or an inch from the upper extremity of the outer opening, or abdominal ring.

In common cases of inguinal hernia, the viscera, protruded at the inner opening of the inguinal canal, lie over the spermatic cord, and form a tumour on the outside of the abdominal ring.

When the viscera have entered the above described digital pouch of the peritoneum, but do not protrude through the abdominal ring, the case is sometimes termed an *incomplete inguinal hernia*; and *complete* when they pass out of that opening. The viscera may continue for a long while quite within the inguinal canal, and even become strangulated there: sometimes, also, they are prevented from passing further towards the ring by some kind of impediment; and, in this circumstance, if the hernial sac have any addition made to its contents, it may expand between the external and internal oblique muscles, as Hesselbach had an opportunity of seeing in the body of a female. (*Ueber den Ursprung, &c. der Leisten- und Schenkelbrüche*, p. 28.) The stricture may take place either at the internal or external opening of the inguinal canal. In recent and small hernia, according to Mr. A. Cooper, the strangulation is most frequently situated at the inner opening; in large old ruptures, at the abdominal ring. Even when the parts

are completely protruded out of the latter opening, the strangulation may exist at the inner one; but there may occasionally be two strictures, viz. one at each opening. (See *Lawrence on Ruptures*, p. 183, *Edit. 3.*)

The hernial sac descends through the abdominal ring over the spermatic cord, and is covered by a fascia, sent off from the tendon of the external oblique muscle. Beneath this fascia, the cremaster muscle is also situated over the sac, which, after it has descended a certain way, lies on the tunica vaginalis, as well as the spermatic cord.

As the epigastric artery naturally runs first behind the spermatic cord, and then along the inner margin of the internal opening of the ring, and as the viscera are protruded over the cord, they must be situated on the outer side of the artery, which runs first behind the neck of the sac, and then on its inner side. Hence, the inner margin of the sac, when inspected on the side towards the abdomen, seems to be formed, as it were, by the track of the vessel. (See *Lawrence*, p. 179.) That this is the ordinary situation of the epigastric artery, in relation to the inguinal hernia, is confirmed by the concurrent testimonies of Camper, Chopart, Desault, Sabatier, A. Cooper, Hesselbach, Scarpa, &c. and by preparations to be seen in almost every museum.

In recent inguinal herniæ, the internal and external openings of the ring are at some distance from each other, the first being situated obliquely upwards and outwards in relation to the former; but the pressure of the protruded viscera, gradually forces the internal opening more towards the pubes, and nearer to the abdominal ring, so as to render the posterior side of the neck of the hernial sac, and of the inguinal canal, very short. (Hesselbach, p. 29.) Thus, in large herniæ of long standing, the opening into the abdomen is almost direct, and the epigastric artery becomes situated nearer the pubes, than in the natural state.

Though such is the ordinary direction, in which a bubonocoele protrudes, there are occasional varieties. In one of these, the viscera, instead of descending through the canal of the ring, are at once thrust through the abdominal ring itself, and the opening into the belly is then direct: the hernial sac, instead of passing on the external side of the spermatic vessels, as is usual, now lies on their inner, or pubic side; and the epigastric artery, which is commonly situated behind, now pursues its course, in front of the sac, at its usual distance from the upper and outer angle of the abdominal ring.

The following is Scarpa's description of the displacement of the epigastric artery in the greater number of cases of inguinal hernia. "This artery, which in the natural state, runs about ten lines from the abdominal ring, has its situation and direction so changed, in subjects affected with hernia, that it crosses the posterior part of the neck of the hernial sac, and is pushed from the outer to the inner side of the abdominal ring. In order to comprehend the reason of this

displacement, it is necessary to recollect what I have elsewhere said of the formation of inguinal hernia, and of the manner, in which the spermatic cord crosses the epigastric artery. The hernia begins to form at the very place, where the spermatic cord passes under the inferior margin of the transverse muscle; and this place is rather nearer the flank, than that where the epigastric artery passes towards the rectus muscle. In its progressive extension, the hernial sac constantly follows the same track as the spermatic cord, since it is situated upon its anterior surface. As has been already explained, this cord crosses the epigastric artery; consequently, the hernial sac must necessarily pass with the cord above this artery, before protruding from the canal of the abdominal ring. At the same time, the internal orifice of the hernia becoming larger, and the inguinal canal shortened by the approximation of its two orifices to each other, it follows, that at the period when the hernia begins to make its appearance in the groin, the epigastric artery is unavoidably situated behind the neck of the hernial sac, and is pushed from the outer to the inner side of the ring. Let us suppose a piece of string to be passed from the inside of the abdomen into the scrotum, all through the inguinal canal, and the middle of the hernia; and that this string is pulled so as to bring the internal orifice of the hernia, which is situated beyond the point where the spermatic cord crosses the epigastric artery; this artery will immediately be found to be carried from the outer to the inner side of the neck of the hernial sac. The same thing happens from the effect of the enlargement of the hernia. The removal of the epigastric artery from one side of the ring to the other, (says Scarpa) is a phenomenon, which may be regarded as almost constant in the inguinal hernia. I have examined the bodies of a great number of subjects, affected with this species of hernia; and it has been only in a very few, that I met with the epigastric artery retaining its natural situation on the outer side of the abdominal ring. In investigating the reason of this exception, I have observed, in all the individuals who presented it, a very remarkable weakness and flaccidity of that part of the abdominal parietes, which extends from the flank to the pubes. In all the displaced viscera had passed through the aponeuroses of the transverse and internal oblique muscles, not in the vicinity of the ilium, as is commonly the case, but, at a little distance from the pubes, giving to the upper pillar of the ring a curvature that is extraordinary, and disproportioned to the smallness of the hernia. I observed, also, that the neck of the hernial sac did not pass in an oblique direction, from the flank to the pubes, but, that it protruded from the abdomen almost in a direct line from behind forwards. In short, in these individuals, the small cul-de-sac of the peritoneum, which constitutes the origin of the hernial sac, had not begun to be formed under the edge of the transverse muscle, at the point where the spermatic

cord runs outward; but, it had passed through the aponeuroses of the internal oblique and transverse muscles, at a little distance from the pubes, and within the point at which the spermatic cord crosses the epigastric artery. The small hernial sac, having at this part come into contact with and united to the spermatic cord, protrudes at the external orifice of the inguinal canal, without displacing the epigastric artery from its natural situation.

This species of hernia, properly speaking, is a mixture of the ventral and inguinal. It resembles the former, inasmuch as the hernial sac pierces the aponeuroses of the transverse and internal oblique muscles; the latter, inasmuch as it passes out at the abdominal ring, conjointly with the spermatic cord." (*Scarpa, Traité des Hernies, p. 68, &c.*)

Hesselbach particularly adverts to a triangular space to be seen on the inside of the inguinal region: the upper boundary of it is formed by the outer edge of the rectus muscle; the lower by the horizontal branch of the os pubis; and the external shortest boundary by the crural vein and epigastric artery. Now, says he, when it is considered, that this artery ascends obliquely inwards, between the inner opening of the ring, and the above triangular space, one cannot fail to know on which side of the neck of the sac the artery must lie in the two species of inguinal, as well as the crural, hernia; for, in those herniæ, which originate in the above triangular space, this artery lies at the outer side of the neck of the hernial sac; while, in every hernia that takes place through the inner opening of the inguinal canal, the same vessel is situated at the inner side of the neck of the sac. To one species of bubonocoele, Hesselbach applies the epithet *external*; and to the other, *internal*; according to the situation of the point at which they first protrude. The external inguinal hernia is much more frequent than the internal, and is said to happen oftener on the right, than the left side of the body: a circumstance, coinciding with another observation, viz. that in children, the tunica vaginalis remains longer open on the right than the left side.

The circumstance of there being two forms of inguinal hernia formerly caused considerable perplexity: surgeons knew, that the epigastric artery lay sometimes at the inner, sometimes at the outer side of the neck of the hernial sac, but knew not how to account for this variation. Hence arose the very different opinions about the proper method of dividing the ring when the hernia was strangulated; some authors directing the incision to be made obliquely inwards and upwards; and others, upwards and outwards. But, as a modern writer has judiciously remarked, had they paid greater attention to the direction of the swelling, formed by the neck and body of the hernial sac in the groin, and to the position of the spermatic cord, which is as inconstant as that of the epigastric artery; and had they dissected the parts in the diseased, as well as healthy, state, they could not fail soon to

have suspected, that every inguinal hernia does not originate exactly at one and the same point. For the first establishment of this very important distinction, the world is indebted to Mr. A. Cooper; and the tract, in which Hesselbach pointed out the fact in a very particular manner, I believe, is the next publication in which the subject is explained. (*Anat. Chir. Abhandlung über den Ursprung der Leistenbrüche*, Würzb. 1806; and *Neueste Anat. Pathol. Untersuchungen über den Ursprung, &c. der Leisten- und Schenkelbrüche*, 4to. Würzb. 1814, p. 18, 26, 28, &c.) According to the latter author, since each form of inguinal hernia also presents characteristic appearances externally, the surgeon can have no difficulty in determining the species of hernia; which discrimination must be highly important in the taxis, the application of a truss, and especially the operation. The sac of the external scrotal hernia can only pass down within the expansion of the cremaster as far as this part is separate from the cord and tunica vaginalis. Hence, the testis, covered by its tunica vaginalis, lies under the lowest part of the hernial sac, while the vessels of the spermatic cord, in a more or less separated form, are situated behind the posterior part of the sac; viz. the spermatic veins externally, and the vas deferens internally, and the artery in the middle. Should the hernia descend still further, the testis being included as well as the sac within the tedious expansion of the cremaster, it cannot glide out of the way, but must be pressed still further downwards by the sac, so as to continue invariably under its fundus, but sometimes inclined a little behind it. (*Hesselbach*, p. 34.) And, as the same author justly observes, the position of the spermatic cord and testis, and the oblique direction of the swelling in the external species, are the two strongest characters by which every case of inguinal hernia may be discriminated.

Although the spermatic cord commonly lies behind, or under, the hernial sac, there are cases in which the vas deferens is found on the outer side of it, while the rest of the spermatic cord lies, as it usually does, on the inner side, or rather under it. (*Cooper*.) Le Dran, Schmucker, and Blizard, found the whole cord situated in front of the sac. Sometimes the vas deferens runs on the front and inner part, and the rest of the cord on the back and external part of the swelling. (*Camper, Hey*.) The cord has been known to be before, and the vas deferens behind, the sac. (*Camper, A. Cooper*.)

Upon this part of the subject, the reader may deem the following passage interesting. "While the hernia is of moderate size, (says Scarpa) the surrounding cellular substance is not very greatly compressed, and no change is observed in the situation of the spermatic vessels. The artery and veins of this name always form, with the vas deferens, one single cord, which is intimately adherent to the posterior surface of the hernial sac. But, in proportion as the tumour increases in size, the cellular substance, which

immediately surrounds it, and unites it to the spermatic cord, is more and more distended and compressed. At length, at a certain period, the distention is carried to such a pitch, that the spermatic vessels are separated from one another, and change their position with respect to the hernial sac. This kind of gradual unravelling of the spermatic cord is quite similar to that, which would be produced by pulling the surrounding cellular substance in two opposite directions. Such is the reason, why in scrotal hernia of large size, the spermatic artery, the vas deferens, and the spermatic veins are found separated upon the posterior surface of the sac. All these vessels, instead of being conjoined in one cord, are divided by interspaces, which are sometimes very considerable. Ordinarily, the vas deferens is less separated from the spermatic artery, than from the vein of this name. In some subjects, Camper has seen it situated on one side of the sac, and the artery and veins on the other. (*Icones Herniarum*, Tab. 5, L. O. Tab. 8. 1, 2.) The displacement and splitting of the spermatic cord take place equally in adults and in children affected with large scrotal herniæ. (*Camper, loco cit.*) In general, towards the upper part and neck of the hernia, the vessels are not much separated; but as they proceed downwards, they diverge more and more. Sometimes, when the hernia is very old and bulky, they are no longer found at the posterior part, but rather at the sides, and even on the front surface of the sac; they show themselves through the cremaster muscle, which covers them, and form a sort of vascular train, which arrests the hand of the operator at the moment when he is about to open the hernial sac. Le Dran relates, that in operating upon a large scrotal hernia, he found the spermatic cord on the anterior surface of the hernial sac. (*Operations de Chir.* p. 127.) This fact has been the cause of numerous conjectures, and has appeared altogether inconceivable to such surgeons as have not been acquainted with the changes, to which the spermatic cord is exposed, in cases of large scrotal herniæ. (Lassus could not (*Med. Operat.* T. 1, p. 152,) conceive the possibility of the occurrence.) The observation of Le Dran is not the less true and exact; it exemplifies a very important fact, of which it is easy to give a true explanation when the state of the spermatic cord in ordinary inguinal herniæ, and in those which have obtained a considerable size, has been comparatively examined. In the first, the spermatic cord quite entire is always found situated on the posterior surface of the hernial sac; but, in the second, the spermatic vessels are so separated from one another, that they sometimes extend over the sides and even the forepart of the hernial sac." (*Scarpa, Traité des Hernies*, p. 61, &c.)

The hernial sac is commonly described as an elongation of peritonæum. When more minutely examined, however, it is found, in cases of inguinal hernia, to consist of the portion of peritonæum, pushed out with the

viscera; of a layer of cellular substance on the outside of this, which becomes more or less thickened by the pressure of the rupture in different cases; of a fascia, sent off from the tendon of the external oblique muscle; and of the cremaster muscle, which latter parts form the exterior covering, which consisting of several layers, often leads the operator to fancy that he has opened the cavity of the sac, when, in reality, he has not.

It is observed by Professor Scarpa, that "the cremaster muscle, in cases of old large scrotal herniæ, acquires a thickness, which is really surprising. Its fibres, which are naturally very thin, become from four to six times more considerable. Being spread over the neck and body of the hernial sac, they sometimes present a remarkable consistence, and a yellowish colour. Such alteration, however, does not prevent the muscular texture from being discovered, and Haller was not mistaken about it. (*Opusc. Patholog.* p. 317.) Pathology furnishes us with several examples of similar changes of organization. In certain cases, the muscular coat of the bladder, that of the stomach and intestines, and even the exceedingly delicate fleshy fibres of the ligaments of the colon, are found to have become yellow, and much thickened.

"In old scrotal herniæ (says Scarpa) it is not unusual to find an intimate adhesion of the fibres of the cremaster muscle to the edges of the abdominal ring. This may depend on the pressure, which the contents of the hernia makes on those edges, and perhaps it may also depend on the union of the cremaster muscle with the prolongation of the aponeurosis of the fascia lata, which is continued from the margins of the ring to the groin and scrotum. Howsoever it may be, certain it is, that in old large scrotal herniæ, there is much difficulty in introducing a probe between the fleshy fibres of the cremaster and the margin of the abdominal ring; and that, on the contrary, in recent herniæ, a probe passes as easily between the edges of the ring and the cremaster, as between this muscle and the hernial sac.

"Few authors (according to Scarpa) have spoken of the sheath, formed by the cremaster muscle, in which are enclosed the hernial sac, the spermatic cord, and the tunica vaginalis of the testicle. Sharp (*Critical Inquiry*) and Monro, the father, (*Anat. and Chirurg. Works*, p. 553.) were the first to dwell upon this important pathological point. Monro had seen the cremaster muscle covering the hernial sac; but he did not believe, that the same thing occurred in all individuals affected with inguinal hernia. In this respect he was mistaken; for this disposition of the cremaster muscle is one of the essential characters of the disease. Petit has not omitted to describe the relations which exist between the cremaster and the hernial sac. (*Euvres Posthum.* T. 1, p. 288.) On this subject, he even relates an interesting fact, from which it results, that in certain cases, this muscle may

by its contractions alone cause a reduction of the hernia. Guntz explains, with tolerable perspicuity, how the cremaster and its aponeurosis form one of the coverings of the inguinal and scrotal hernia. (*Libellus de Herniis*, p. 50.) Morgagni once saw its fleshy fibres extended over the hernial sac; (*De sed. et caus. morb. epist.* 34, art. 9; *epist.* 31, art. 15.) and Neubaver positively assures us, that he made the same remark upon the dead body of a man affected with an entero-epiplocele. (*Dissert. de Epiplooschecele*.) After these facts, so positively and accurately observed, I cannot comprehend (says Scarpa) how in our time Pott, Richter, and several other authors, should have passed over in silence, or only mentioned vaguely, this point, so important in the history of the inguinal and scrotal hernia." (*Scarpa, Traité des Hernies*, p. 48, 50.)

When surgeons speak of a hernial sac being usually thicker and stronger, in proportion to the magnitude and duration of the hernia, their language is not at all correct; for in fact, the peritoneal investment of the hernia is seldom, or never, thus altered. I can declare (says Scarpa) after numerous observations, that in the majority of cases, the hernial sac, strictly so called, is not perceptibly thickened, and that in general it does not differ from other parts of the peritonæum, however large and old the scrotal hernia may be. (*Traité des Hernies*, p. 53.)

In a very enormous hernia, the pressure of the contents is so great, that instead of thickening the sac, it renders it thinner, and even makes it ulcerate. The protruded viscera have been met with immediately beneath the integuments, when the sac has been burst by a blow. (*Cooper; J. L. Petit.*)

The outer surface of the peritoneal part of the hernial sac, is always most closely adherent to the other more external covering by means of cellular substance. This connexion is formed so soon, after the first occurrence of a hernia, that any hopes of returning a hernial sac into the abdomen are now generally considered as chimerical. There must, however, be a certain space of time, before adhesions form, though it is, no doubt, exceedingly short.

Upon this point, Scarpa does not adopt the opinion commonly received.

There is no doubt, he observes, that in recent and small inguinal herniæ, the intestine, strangulated by the neck of the hernial sac, has been known, in more instances than one, to have been reduced by the taxis, and carried with it the whole of the sac into the abdomen. Observations, not less authentic, inform us, that after the operation for hernia, when the viscera could not be reduced on account of their adhesions to the sac, they have been seen, notwithstanding such adhesions, to get nearer to the ring daily, and at length, spontaneously to return into the belly together with the hernial sac. Louis, he thinks, was wrong in denying the possibility of these facts. (*Acad. Royale de Chir.* T. 11, p. 486.)

Scarpa argues, that "under certain circumstances, the cellular substance will bear, without laceration, a considerable elongation, and afterward shrink again. Thus we often see a viscus, which has suffered a considerable displacement, return spontaneously into its natural situation. In the inguinal hernia, the spermatic cord is elongated, and descends farther, than in the natural state. No laceration of the cellular substance, however, is then occasioned; for, if the hernia be kept reduced, the spermatic cord becomes shorter, daily retracts, and at last has only the same length, which it had previously to the disease. When a sarcocele becomes large and heavy, the portion of the spermatic cord naturally situated within the belly, is by degrees drawn out into the scrotum; but, after the tumour is extirpated, this portion ascends again, and of itself returns into its original situation.

"The same thing happens after the operation for the strangulated inguinal hernia. All practitioners have noticed, that the hernial sac retracts and reascends progressively towards the ring. This alone would prove, that the cellular substance, which surrounds the spermatic cord, and unites it to the hernial sac, is highly endued with the property of yielding, and afterward returning to its original state. Can the same property be refused to the cellular substance, which unites the sac to the cremaster muscle and other surrounding parts?

"While the inguinal hernia is recent, and not of much size, the cellular substance in question, possesses all its elasticity, and hence, the hernial sac and the spermatic cord, may easily ascend towards the abdominal ring. I have had occasion (says Scarpa) to make this observation upon the dead body of a man, who had an incipient inguinal hernia. The small hernial sac was capable of being pushed back into the ring with the utmost facility; and in carefully examining the parts, both within and without the belly, it appeared to me, that the cellular substance, which united the sac to the spermatic cord and cremaster muscle, was disposed to yield equally from without inwards, and in the direction precisely opposite; that is to say, it made an equal resistance to the protrusion and the reduction of the hernial sac. Monteggia has seen a case exactly similar: although, according to his own expressions, (*Instituz. Chirurg. T. 3, sez. 2, p. 249.*) the hernial sac was not very small, it adhered very loosely to the surrounding parts, and it admitted of being entirely reduced into the abdomen with great facility."

In large old scrotal herniæ, Scarpa allows, that such reduction is quite impracticable: "In these, the cellular substance, which unites the sac to the spermatic cord, and cremaster muscle, has acquired such a density, that it does not oppose less resistance to the further enlargement of the hernia, than to the efforts of the surgeon, who endeavours to effect its reduction." (*Scarpa, Traité des Hernies, p. 57, &c.*) Though

Scarpa thus reasons about the elasticity of the cellular substance, as forming the connexion between the sac and surrounding parts, many surgeons would refer the connexion to the adhesive inflammation, and explain the diminution and shrinking of parts, after the distention and weight are removed, not by the elasticity of the cellular substance in particular, but by the same property inherent generally in the elongated parts, which elasticity, and the action of the absorbents together, produce the alteration in question.

We shall conclude this anatomical account of the inguinal hernia, with the following explanation of the parts as they appear on dissection: "the removal of the integuments exposes the exterior investment of the hernial tumour, continuous with the margins of the ring, and formed of tendinous fibres from the aponeurosis, the cremaster muscle, &c. This is connected by cellular substance with the proper hernial sac, formed of the peritonæum. This production of the peritonæum passes within the ring of the external oblique, and then goes upwards and outwards. Behind and above the ring, the inferior margin of the obliquus internus and transversalis crosses the neck of the sac. When these muscles are reflected towards the linea alba, the fascia, ascending from Poupart's ligament, and forming the upper opening of the ring, is exposed, and the epigastric artery is discovered emerging from the inner side of the neck of the hernial sac, (*Camperi Icones, Tab. X. F. M.*) which, at this precise point, becomes continuous with the peritonæum, lining the abdomen. The removal of the hernial sac will disclose the course of the spermatic cord in its descent towards the testicle; and when this is also elevated, the first part of the course of the epigastric artery, and its origin from the iliac trunk, are exposed." (*Lawrence on Hernia, p. 182, Edit. 3.*)

In females, the round ligament of the uterus bears the same relation to the tumour, as the spermatic cord in males. In the former subjects, bubonocèles are uncommon. Mr. Lawrence had a very rare instance pointed out to him, in which a bubonocèle in a female was situated on the inner side of the epigastric artery. A still rarer case was examined by Hesselbach: it was not only an example of internal bubonocèle in a woman, but of one in which the epigastric artery arose from the obturator artery an inch from the origin of this latter vessel from the inner side of the external iliac: the obturator first passed an inch obliquely downwards and inwards over the crural vein, and immediately afterward, on the horizontal ramus of the pubes, made a sudden turn backward and downward to the obturator foramen; and at this bend arose the epigastric artery, which ran transversely inward along the horizontal ramus of the pubes, behind the neck of the hernial sac, at the inner side of which it ascended to the rectus muscle, accompanied by the liga-

mentous remains of the umbilical arteries, which were close behind it. (*Ueber den Ursprung, &c. der Leisten und Schenkelbrüche*, p. 17.)

MARKS OF DISCRIMINATION BETWEEN OTHER DISEASES AND INGUINAL HERNIE.

The disorders, in which a mistake may possibly be made, are *Cirsocele*, *Bubo*, *Hydrocele*, and *Hernia Humoralis*, or *Inflamed Testicle*.

For an account of the manner of distinguishing the first complaint from a bubonocoele, see *Cirsocele*.

"The circumscribed incompressible hardness, the situation of the tumour, and its being free from all connexion with the spermatic process, will sufficiently point out a bubo, at least while it is in a recent state; and when it is in any degree suppurated, he must have a very small share of the *tactus eruditus*, who cannot feel the difference between matter, and either a piece of intestine, or omentum.

"The perfect equality of the whole tumour, the freedom and smallness of the spermatic process above it, the power of feeling the spermatic vessels and the vas deferens in that process, its being void of pain upon being handled, the fluctuation of the water, the gradual formation of the swelling, its having begun below and proceeded upwards, its not being affected by any posture or action of the patient, nor increased by his coughing or sneezing, together with the absolute impossibility of feeling the testicle at the bottom of the scrotum, will always, to an intelligent person, prove the disease to be a hydrocele." Mr. Pott, however, allows that there are some exceptions, in which the testicle cannot be felt at the bottom of the scrotum in cases of hernia. "In recent bubonocoeles, while the hernial sac is thin, has not been long, or very much distended, and the scrotum still preserves a regularity of figure, the testicle may almost always be easily felt at the inferior and posterior part of the tumour. But in old ruptures, which have been long down, in which the quantity of contents is large, the sac considerably thickened, and the scrotum of an irregular figure, the testicle frequently cannot be felt, neither is it in general easily felt in the *congenital hernia* for obvious reasons." (Pott.)

"In the *hernia humoralis*, the pain in the testicle, its enlargement, the hardened state of the epididymis, and the exemption of the spermatic cord from all unnatural fulness, are such marks as cannot easily be mistaken; not to mention the generally preceding gonorrhœa. But, if any doubt still remains of the true nature of the disease, the progress of it from above downward, its different state and size in different postures, particularly lying and standing, together with its descent and ascent, will, if duly attended to, put it out of all doubt, that the tumour is a *true hernia*." (Pott.)

When an inguinal hernia does not de-

scend through the abdominal ring, but only into the canal for the spermatic cord, it is covered by the aponeurosis of the external oblique muscle, and the swelling is small and undefined.

Now and then, the testicle does not descend into the scrotum till a late period, and its first appearance at the ring, in order to get into its natural situation, may be mistaken for a hernia, unless the surgeon pay attention to the absence of the testicle from the scrotum, and the peculiar sensation occasioned by pressing the swelling.

POINTS OF DIFFERENCE BETWEEN THE EXTERNAL AND INTERNAL INGUINAL HERNIA, &c.

According to Hesselbach, the characteristic marks of the external bubonocoele and scrotal hernia are; 1st. The direction of the tumour in the groin. 2dly. The fleshy fibres of the cremaster. 3dly. The position of the spermatic cord and testis. 4thly. The situation of the epigastric artery. 5thly. The origin of the hernia itself. 6thly. A preternatural shape of the body of the hernial sac.

1. The neck of the hernial sac, distended by the protruded viscera, raises up the front side of the inguinal canal, and superincumbent integuments, into an oblong swelling, which extends obliquely inwards and downwards towards the abdominal ring, and terminates in the tumour, formed by the body of the hernial sac. From its origin it becomes gradually more prominent and broad, and the greater the quantity of viscera protruded, and the larger the body of the sac, the more manifest is this oblique swelling, particularly when the neck of the hernia is of its natural length. In strangulated cases, the direction of the tumour is still more striking, every part of the hernial sac being then considerably distended. When the inguinal canal, and of course the neck of the hernial sac are shortened, the swelling undergoes a proportional diminution in its length; and then its resemblance to the tumour attending an internal inguinal hernia, where the opening through which the parts pass, is long and slanting, is so great, that the cases can only be discriminated by one circumstance, viz. the situation of the spermatic cord, and even this criterion is of course wanting in females. (Hesselbach, p. 57, 58.) Hesselbach clearly explains, that the obliquity of the swelling is seated in the neck of the hernial sac. He observes, that when an internal bubonocoele in a female subject passes into the labium, the descent takes place in a very sloping direction inwards, and therefore, may at first be supposed to be an external case. But, on further examination, the oblique swelling will be found to occupy the body of the hernial sac, and to reach upwards and outwards from the labium to the abdominal ring. Now this hernia cannot be mistaken for an external bubonocoele, the course of which from the ring is obliquely upwards and outwards.

Hesselbach reminds us, that an internal, inguinal, or scrotal hernia may be conjoined with an external incomplete bubonocoele; a kind of case easily made out with a little attention; for the place of division between the two sacs is indicated by a more or less deep groove. The nature of the disease will also be still clearer, if one of the tumours admit of reduction. A specimen of such a double hernia is to be seen in the museum at Wurzburg.

It is further noticed by Hesselbach, that, when the situations of the external and internal herniæ are compared, the first of these swellings will be found to be rather further than the other, from the symphysis of the pubes: a difference ascribed to the effect of the internal oblique muscle, the lower fibres of which, attached to the horizontal ramus of the pubes, run in a curved direction transversely over the anterior and inner part of the neck of the hernial sac, and are applied so closely to it, that it cannot approach quite so much towards the symphysis of the pubes as the neck of the internal bubonocoele does. The muscular fibres in question are situated directly behind the inner pillar of the abdominal ring.

2. Most of the fibres of the cremaster lie on the back of the neck of the sac, but others are also scattered over its external and internal sides. Some fibres may also be perceived on its forepart, which are remarkable, because they run in a transverse curved direction with their convexity downwards, and two fasciculi of which descend below the abdominal ring. These are the fibres of the cremaster, which proceed within the ring transversely upwards over the spermatic cord, and are pushed out of that opening by the hernial sac. These arched fleshy fibres are not always, though generally, perceptible; and, when they are present on the forepart of the hernial sac, Hesselbach accounts them a sure criterion of an external scrotal hernia; but, he has not yet ascertained, whether they are visible, while the rupture is confined to the groin.

3. The situation of the spermatic cord and testis in the external inguinal hernia, and,

4. That of the epigastric artery, and its displacement inwards by the neck of the sac, have been sufficiently explained.

6. With respect to the mode, in which the hernia originates, the disease often takes place suddenly, without any exciting cause being observed, capable of accounting for the effect. Here, says Hesselbach, the predisposing cause must have been great; for instance, the communication between the cavity of the peritonæum and that of the tunica vaginalis has remained a long while unclosed; and, when a hernia of this description is examined, the other marks of an external inguinal hernia are associated with the sudden formation of the disease. In this quick manner, the congenital hernia, which is one of the external cases, frequently arises. The internal inguinal hernia is also observed mostly to take place very sud-

denly, yet only after violent occasional causes.

6. A preternatural form of the body of the hernial sac, Hesselbach remarks, is particularly seated in the sheath of the spermatic cord, and can never happen in the internal scrotal hernia; for, it is only in external cases, that the above sheath is ever converted into the hernial sac. Hesselbach here refers to the partial contraction, often noticed at the lower part of the above sheath in cases of congenital hernia; a circumstance, which is always discovered previously to the business of dividing the ring.

In adults, an external inguinal, or scrotal hernia, on the right side, contains some of the ileum, and, when the swelling is large, it may include the cœcum, and sometimes a piece of omentum. In one child, ten weeks old, and in another still younger, the appendix vermiformis was protruded and connected by a natural band to the posterior side of the peritonæum. When, in these ruptures of the right side, the cœcum, or, in those of the left, the colon are met with closely adherent to the hinder side of the hernial sac, the adhesion is not to be looked upon as the effect of disease, since it is the perfectly natural connexion of those bowels with the peritonæum. On the left side, the parts most commonly protruded are the colon and omentum.

With regard to the *internal inguinal hernia*, the place of its first protrusion has been already described. The protruded peritonæum and viscera, according to Hesselbach's account, *pass from behind straight forwards*, between the fibres of what he names the internal inguinal ligament, and the fleshy fibres of the internal oblique muscle: they then pass, at the inner side of the spermatic cord, out of the abdominal ring, where the hernia presents *a circular globular swelling, suddenly formed in consequence of some violent effort*. The neck of the hernial sac is very short; shorter than it can ever be in an external inguinal hernia, and, when the tumour is of the above shape, the passage through which it passes is annular, narrower in some instances than others, and its margin is tendinous. From the few cases, which Hesselbach has seen of this form of the disease, he is led to conjecture, that the hernial sac is rarely so large as in the external inguinal hernia. (P. 41.) The earlier dissections made by Hesselbach, led him to suppose, that, in the internal inguinal hernia, the opening, through which the protrusion happens, is always annular, and the swelling in front of the ring globular; but subsequent cases, which he has met with, have informed him, that the opening is frequently sloping and longish, in which circumstance, the resemblance of the tumour to that of the external bubonocoele with a shortened neck, is such, that the only mark of distinction between the two cases is the position of the spermatic cord. In females, even this criterion is of course deficient. (Hesselbach, p. 57.) Though individuals of almost every age are subject to internal bubonocœles, they

are much less common than external cases. According to Hesselbach, they may be known by the following characters. 1. The swelling, formed by the body of the hernial sac, immediately in front of the abdominal ring. 2. The situation of the spermatic cord. 3. That of the epigastric artery.

1. The neck of the hernial sac, besides being very short, does not, like that of an external inguinal hernia, take an oblique direction, but advances straight from behind forwards through the abdominal ring, and as the body of the sac lies directly over the neck, none of the swelling, formed by the distention of the latter part, can be felt. Nor does any other tumour, produced by the body of a hernial sac, ever cause a circular spherical swelling directly before the abdominal ring. The situation of the neck of this kind of hernia must already apprise us, that the internal bubonocoele is nearer, than the external, to the symphysis of the pubes. In women, the shape of the tumour is the only character, by which the case can be distinguished. (*Hesselbach, p. 43.*)

2. After what has been already stated, respecting the situation of the spermatic cord in the internal inguinal hernia, I shall merely notice one or two observations of Hesselbach. The cord lies either upon the outer side, or outer half of the forepart of the upper portion of the hernial sac, the blood-vessels forwards, and the vas deferens backwards. When the sac is adherent to the whole length of the cord, the testis is not situated under the fundus of the sac, as in the external scrotal hernia, but either at the forepart or outer side of the body of the sac. The hernial sac, as far as the abdominal ring, is excluded from the common peritoneal covering of the spermatic cord, but at this opening, it descends between the cord and the internal thin part of the sheath of the cremaster, which, however, is somewhat stronger towards the front and outer side of the hernia, over which part alone the fleshy fibres of the cremaster are spread. (*P. 44.*)

3. The epigastric artery always ascends obliquely inwards at the outer side of the neck of the hernial sac. Hesselbach has never seen but one case of internal bubonocoele, in which there was a deviation from this rule. The example has been already mentioned, and was one in the epigastric artery, arose from the obturator about an inch from the origin of this last vessel. The viscera, usually contained in an internal inguinal, or scrotal hernia, on the right side, are the lower part of the small intestines, and sometimes omentum; on the left, a part of the small intestines, frequently omentum, and when the tumour is large, the colon may also protrude. A protrusion of the bladder may accompany the disease, but that organ is of course always excluded from the cavity of the hernial sac. When the remains of the umbilical cord are situated more outward than usual, and lie over the centre of the space, at which the protrusion happens, an internal bubonocoele may be double, the prolapsus happening on each

side of that ligamentous substance, which is itself also pushed outwards. In consequence of the accidental presence of some very strong tendinous fibres at the centre of the fascia, called by Hesselbach the internal inguinal ligament, there may also be two distinct protrusions, with separate hernial sacs. (*P. 46.*)

When the surgeon, by a due consideration of the foregoing circumstances, has formed a judgment respecting the nature of the hernia, he will be better qualified to regulate the treatment of the case. Thus, in the external inguinal hernia, he will know, that the pressure, employed for the reduction of the bowels, should be made in the direction of the neck of the hernial sac, viz. obliquely upwards and outwards, towards the anterior superior spinous process of the ilium; but that, when the neck of the same kind of hernia is very short, and the posterior side of the inguinal canal has been removed, the pressure should be made nearly in a straight line from before backwards. For what Hesselbach terms the long-necked external inguinal hernia, the pad of a truss should be so constructed, as not merely to press upon the abdominal ring, but also upon the neck of the sac and the inner opening of the inguinal canal. But, when the neck of the hernia is very short, the pad should be nearly of the same form, as that required for an internal inguinal hernia. (*Hesselbach, p. 38; and Brunninghausen, Gemeinnütziger Unterricht über die Brüche, &c. Würzb. 1811.*) In attempting the reduction of an internal inguinal hernia, the pressure should be directed nearly straight backwards; and the pad of the truss should only act upon the abdominal ring. (*Hesselbach, p. 46.*)

THE OPERATION FOR STRANGULATED INGUINAL HERNIA, OR BUBONOCOELE

Consists in dividing the integuments; dissecting down to the sac, and opening it; removing the stricture; and replacing the protruded viscera.

The external incision should begin an inch above the external angle of the ring, and extend over the middle of the tumour to its lower part. The advantage of beginning the wound so high, is to obtain convenient room for the incision of the stricture. By this first cut, the external pudic branch of the femoral artery may be divided; it crosses the hernial sac near the abdominal ring, and sometimes bleeds so freely, as to require to be immediately tied. In general, however, a ligature is unnecessary.

When this incision is carried low down, the caution, given by Camper, should always be remembered, viz. that there is a possibility of dividing the spermatic vessels, should they happen to be situated, as they sometimes are, in front of the hernia. And, in order to avoid such an accident, which is particularly apt to occur in cases of internal inguinal, or scrotal hernia, the incision

through the skin should be made obliquely downwards and inwards. (*Hesselbach, p. 46.*) The division of the integuments brings into view the fascia, which is sent off from the tendon of the external oblique muscle, and covers the hernial sac.

The layers of tendinous fibres, cellular substance, &c. intervening between the skin and sac, should be carefully divided, one after another, with the knife and dissecting forceps, the edge of the former instrument being turned horizontally, lest the incisions be carried too deeply at once, and the viscera contained in the sac wounded.

After making a small opening through a part of the fascia covering the sac, some practitioners introduce a director, and divide this fascia upward and downward as far as the tumour extends. The same manner they next pursue with regard to the cremaster muscle. Thus the sac becomes completely exposed. When this method is followed, Mr. A. Cooper advises the incisions not to be carried upward, nearer than one inch, to the abdominal ring, for reasons which will be presently explained.

However, it may be rationally doubted, whether there is any good in these formal and successive divisions of the whole length of the coverings of the sac; and it is certain, that they protract the operation very much; for the manner in which the sac adheres to the outer investment of it, prevents the latter from being raised and cut without trouble and delay. As the grand object, after the skin has been divided, is to make a small opening into the sac, sufficient for the introduction of a director, dissecting down at one particular place answers every purpose, and enables us, in the end, to lay open the whole of the sac and its coverings in the shortest time. Let the operator only take care to raise the successive layers of fibres with the forceps, and divide the apex of each elevated portion with the knife held horizontally. As there is commonly a quantity of fluid in the sac, and it gravitates to the lower part, to which place the intestine seldom quite descends; this is certainly the safest situation for making the first opening into the sac. The operator, however, should not rely upon the presence of such fluid, and cut too boldly; for sometimes it is absent, and the viscera may be in immediate contact with, nay, adherent to, the inner surface of the sac.

The circular arrangement of the vessels of a piece of intestine, and its smooth polished surface, sufficiently distinguish it from the hernial sac, which has a rough cellular surface, and is always connected with the surrounding parts, although these adhesions, in a very recent case, may be but slight. (*Laurence on Ruptures, p. 214, Edit. 3.*)

I have mentioned, that Mr. A. Cooper only advises cutting the fascia, and other coverings of the sac, under the skin, to within an inch of the abdominal ring; and, of course, he also recommends limiting the division of the sac itself to the same extent. His reasons for this practice, are to

avoid making the closure of the wound more difficult, and to lessen the danger of peritonæal inflammation.

Having laid open the hernial sac with a probe-pointed bistoury, guided by a director, or the fore-finger introduced into the opening, made at the lower part of the sac, the next desideratum is to divide the stricture, unless the viscera admit of being easily reduced, without such an incision being made as occasionally happens.

From the anatomical account, which has been given of the bubonocoele, it appears, that the stricture may either be situated at the abdominal ring, and be formed by the margins of this opening, or else at the inner aperture of the canal, about one inch and a half, in a direction upward and outward, from the outer opening in the tendon of the external oblique muscle. This latter strangulation is caused by the semicircular edge of the transversalis muscle and its tendon, which pass over the neck of the hernial sac, and by a fascia, arising from Poupart's ligament, the semicircular border of which passes under this part of the sac.

The common, and probably the best practice is to divide the hernial sac, together with the stricture. When this is situated at the abdominal ring, the surgeon is to introduce the end of a director a little way into the neck of the sac, within the aperture in the tendon, and with a probe-pointed bistoury, guided on the latter instrument, *he is to cut the stricture upward and outward, or else directly upward*; a manner, which Mr. A. Cooper recommends, because it is applicable to all cases, even the less frequent ones, in which the hernia protrudes at the inner side of the epigastric artery; and, in all common instances, we know, that this vessel runs upward round the inner side of the neck of the sac; a course prohibiting the division of the stricture upward and inward.

In the external inguinal hernia, the method of cutting the stricture upward and outward is perfectly safe; but when the case is what Hesselbach calls internal, and the viscera descend on the inner side of the epigastric artery; it is a plan which would endanger the latter vessel, and ought never to be adopted, notwithstanding any statement made in its favour by Rudtorffer. (*Abhandlung über die einfachste und sicherste operations-Methode eingesperrter Leisten- und Schenkelbrüche. Wien. 1808.*) In this work the erroneous plan of cutting the ring inwards is inculcated, both in the external and internal inguinal rupture. The author, however, seems to have performed many operations in this manner, without any accident from hemorrhage; a piece of good fortune, which Professor Langenbeck ascribes to the circumstance of the knife having always been applied, as Rudtorffer directs, to the middle of the inner pillar of the ring, and to the cut having been very limited. Langenbeck is of opinion, that, if the knife had been applied a little lower, and the incision carried to any extent, the epigastric artery, in

ordinary cases, would not have escaped injury. Mr. A. Cooper's rule of always cutting in one direction, viz. upward, which I believe was first advised by Autenrieth, *Dissect. Moment. circa Herniolum. præcipue circa evitandam art. epigastr. læsionem, Tub. 1799*) is perhaps a very good one, because it is at least easy for the memory, and will answer very well even when it is not in the power of the surgeon to pronounce positively whether the case is a short-necked external bubonocoele, or an internal one with an oblong oval fissure, cases having a great external resemblance, especially in women, in whom there is not the spermatic cord as a criterion; for, after all, this part, when present, is the surest guide, and that on which Desault founded his perfectly safe advice, viz. when the cord is at the posterior or inner side of the neck of the hernial sack, to divide the ring upwards and outwards, but inwards and upwards when it lay at the outer or on the forepart of the sac. (*Œuvres Chir. de Bichat, T. 2.*) At least, this advice is subject but to one exception, which is the very rare one of the epigastric running round the inner side of the neck of the sac in an internal bubonocoele; a possibility which has been already explained, and which leads Hesselbach particularly to recommend the division of the ring in every internal inguinal hernia, to be made straight upwards. (*P. 47.*) Indeed, the long-necked external bubonocoele is the only case in which he thinks the latter plan should give way to that of cutting upwards and outwards. The safety and propriety of the method of always cutting upward, are strikingly illustrated by what Scarpa observes: he states, that the right direction of the incision of the ring is directly upwards, parallel to the linea alba. "I have (says he) operated in the way which I recommend upon several dead subjects, who had either external or internal inguinal herniæ, directing my incision in the course of a line drawn from the upper part of the ring parallel to the linea alba; in all, I constantly left the epigastric artery untouched, even when I extended the cut about an inch above the inguinal ring." (*Scarpa, Traité Pratique des Hernies, p. 111.*) Only one objection, as far as I know, has been made to this plan, and it is founded on the alleged impossibility of introducing the knife, so as to cut straight upwards, when the neck of the hernial sac is long, because then the posterior side of the inguinal canal is in the way. (*Hesselbach, p. 40.*) No more of the parts forming the stricture, should be cut than is just sufficient for allowing the protruded viscera to be reduced without bruising or otherwise hurting them; and I consider the middle of the upper margin of the ring the safest place for making the necessary incision.

Mr. A. Cooper, in his valuable work on the Inguinal Hernia, advises a mode of dividing the stricture, considerably different from the usual method. He directs the finger of the operator to be introduced into the sac, (which, in his plan, we know is left un-

divided for the space of one inch below the ring.) When the stricture is felt, a probe-pointed bistoury is to be conveyed over the front of the sac into the ring (between the two parts,) and the latter only is then to be divided, in the direction upward, opposite the middle of the neck of the sack, and to an extent just sufficient to allow the protruded parts to be returned into the abdomen without their being hurt. The two chief advantages which Mr. A. Cooper imputes to this method, are, that the danger of peritoneal inflammation will be less, and that the epigastric artery, if wounded, would not bleed into the abdomen. I am of opinion, that Mr. Lawrence's remarks, concerning this proposal, are judicious: "An accurate comparative trial of both methods would be necessary, in order to determine the weight of the first reason. The second circumstance cannot be a matter of any importance, if we cut in such a direction as to avoid the risk of wounding the artery. Many circumstances present themselves as objections to this proposal. The manœuvre itself, although perhaps easy to the experienced hand of such an able anatomist as Mr. C., would, I am convinced, be found highly difficult, if not impracticable, by the generality of surgeons. This difficulty arises from the firm manner in which the sac and surrounding parts are connected, we might almost say consolidated, together. The experience of Richter (*Traité des Hernies, p. 118*) shows, that this objection is founded in reality. He once tried to divide the ring, without cutting the sac, but he found it impracticable. If the stricture is so tight as to prevent the introduction of the finger, there must be great danger of wounding the protruded parts. The practice would still be not adviseable, even if it could be rendered as easy as the common method of operating. Mr. C. leaves an inch of the sac, below the ring, undivided; thus a bag remains ready to receive any future protrusion, and the chance of a radical cure is diminished. It would be better to follow the advice of Richter, and scarify the neck of the sac, in order to promote an adhesion of its sides. He has found this practice so successful in accomplishing a radical cure, that he advises (*p. 191.*) its employment in every operation for strangulated hernia." (*See Lawrence on Ruptures, p. 321, Edit. 3.*)

If the stricture should be at the inner opening of the canal for the spermatic cord, Mr. A. Cooper advises the operator to introduce his finger into the sac, as far as the stricture, and then to insinuate a probe-pointed bistoury, with the flat part of its blade turned towards the finger, between the front of the sac and the abdominal ring, till it arrives under the stricture, formed by the lower edge of the transversalis and obliquus internus. Then the edge of the instrument is to be turned forward, and the stricture cut in the direction upward. This plan of not cutting the neck of the sac, is liable to all the objections stated by Mr. Lawrence, in regard to the case in which the

strangulation takes place at the abdominal ring. Mr. A. Cooper's bistoury is a very proper one for dividing the stricture, as it only has a cutting edge to a certain distance from the point. Perhaps, on the whole, we may infer, that it is both most easy and advantageous to divide the neck of the sac, together with the stricture, whether this be situated at the ring, or more inward. The method of cutting the stricture from without inwards I consider objectionable, on the ground of the risk of wounding the bowels in this mode, being greater, than that of any accident wounding the epigastric artery, when it arises in an unusual manner, and deviates from its regular course; a reflection, which has made Dr. Hesselbach, junior, an advocate for the practice. (See *Sicherste Art des Bruchschnittes*, 4to. Bamberg. 1819.)

Room being made for the reduction of the protruded parts into the abdomen, by the division of the stricture, they are immediately to be returned, if sound, and free from adhesions. This object is considerably facilitated by bending the thigh. The intestines are to be reduced before the omentum, but when a portion of mesentery is protruded, it is to be returned before either of the preceding parts. The intestine should always be reduced, unless it be found in a state of actual mortification. It often appears so altered in colour, that an uninformed person would deem it improper to return it into the abdomen. However, if such alteration should not amount to a real mortification, experience justifies the reduction of the part. Mr. A. Cooper has judiciously cautioned the operator not to mistake the dark chocolate brown discolorations, for a state of gangrene. With these the protruded part is frequently found affected; and as they generally produce no permanent mischief, they ought to be carefully discriminated from the black-purple, or lead-coloured spots which usually precede mortification. To determine whether a discoloured portion of intestine be positively mortified, some recommend pressing forward the blood contained in the veins, and if they fill again, it is looked upon as a proof that the bowel is still possessed of life.

In returning a piece of intestine into the abdomen, the surgeon should first introduce the part nearest the ring into this aperture, and hold it there until another portion has succeeded it. This method is to be continued till the whole of the protruded bowel is reduced.

Writers on surgery cannot too severely reprobate the employment of any force, or violence, in the endeavours to return the contents of a hernia in the operation: a method the more pernicious, because such parts are more or less in a state of inflammation. It is always better to enlarge the stricture, than pinch and bruise the bowel in trying to get it through an opening, which is too small. Distention of the intestine sometimes prevents the reduction: but when

this is the only impediment, the part may generally be returned, as soon as its contents have been compressed into the intestinal canal within the stricture. It is better, however, to dilate the strangulation a little more, than use any force in trying to get the intestine back into the abdomen in the manner just suggested.

Reduction is sometimes impeded by the protruded parts adhering to each other, or to the hernial sac. The intestines are not often found very firmly adherent together. The omentum and inside of the sac are the parts which are most subject to become intimately connected by adhesions. The fingers will commonly serve for breaking any recent slight adhesions which may have taken place between the intestines and inside of the hernial sac. When those adhesions are firm, and of long standing, they must be cautiously divided with the knife; an object which can be most easily and safely accomplished, in case they are long enough to permit the intestine to be elevated a little way from the surface of the sac.

But, provided their firmness and shortness keep the external coat of the bowel and inner surface of the sac in close contact, the greatest care is requisite in separating the parts with a knife, so as to avoid wounding the intestine. In doing this, the most prudent and safe method is not to cut too near the bowel, but rather to remove the adherent parts of the sac, and return them with the intestine into the abdomen. Every preternatural connexion should always be separated, before the viscera are reduced: Mr. A. Cooper mentions, that a fatal obstruction to the passage of the intestinal matter has arisen from the mere adhesion of the two sides of a fold of intestine together. (P. 31.) When the adhesions, which prevent reduction, are situated about the neck of the sac, and out of the operator's view, it is best to make the wound through the skin and abdominal ring somewhat larger, so as to be able to separate the adhesions with more safety.

Having reduced the parts, the operator should introduce his finger, for the purpose of being sure that they are fairly and freely returned into the abdomen, and no longer suffer constriction, either from the inner opening, from the ring, or the parts just within the cavity of the peritonæum.

TREATMENT OF THE OMENTUM.

In an entero-epiplocele, this part, if healthy and free from gangrene, is to be reduced after the intestine. When, however, it is much diseased, thickened, and indurated, as it frequently is found to be, after remaining any considerable time in a hernial sac, the morbid part should be cut off. Its reduction, in this circumstance, would be highly improper, both because an immoderate enlargement of the wound would be necessary, in order to be able to put the diseased mass back into the abdomen, and be-

cause, when reduced, it would, in all probability, excite inflammation of the surrounding parts, and bring on dangerous symptoms. (See *Hey*, p. 172.)

The diseased omentum should always be cut off with a knife; and if any of its arteries should bleed, they ought to be taken up with a tenaculum, and tied separately with a small ligature. An unreasonable apprehension of hemorrhage from the cut end of the omentum has led many operators to put a ligature all round this part, just above the diseased portion which they were about to remove. This practice cannot be reprobated in terms too severe; for a frequent effect of it is to bring on a fatal inflammation, and even mortification of the omentum, extending within the abdomen, as high as the stomach and transverse arch of the colon. Mr. A. Cooper has remarked with great truth, that it is surprising this custom should ever have prevailed. The very object of the operation is to extricate the omentum from its strangled state, arising from the pressure of the surrounding tendon, and no sooner has this been done, than the surgeon includes it in a ligature, which produces a more perfect constriction, than that which existed before the operation was undertaken.

"When the omentum has suffered strangulation for a few days (says Mr. Lawrence) it often becomes of a dark red, or livid colour; and there is an appearance, on cutting it, as if some blood were extravasated in its substance. This, I believe, is the state which surgeons have generally described under the term of gangrene." (P. 262.)

When cut in this state, it does not bleed. I need hardly observe, that the dead part must be amputated, and never reduced. Some have advised leaving the omentum in the wound, especially in cases of old herniæ, in which it has been a long while protruded. Hey mentions cases, showing that granulations form very well, and that the wound becomes firmly healed, when this plan is followed. (P. 180, &c.) Every one, however, will acknowledge the truth of what Mr. Lawrence says on this subject.

The method "is attended with no particular advantage, but certainly exposes the patient to the possibility of ill consequences. The omentum, left in the wound, must be liable to injury, inflammation, or disease; and hence arises a source of danger to the patient. Unnatural adhesions, formed by this part, have greatly impaired the functions of the stomach. Cases are recorded, where the unfortunate patient has never been able to take more than a certain quantity of food, without bringing on instant vomiting; and even where it has been necessary for all the meals to be taken in the recumbent position, with the trunk curved, and the thighs bent. (Gunz.) To avoid the possibility of such afflicting consequences, we should, after removing any diseased portion, carefully replace the sound part of the omentum in the abdominal cavity." (See *Lawrence on Ruptures*, p. 274, Edit. 3.)

TREATMENT, WHEN THE INTESTINE IN THE SAC IS MORTIFIED.

Sometimes, on opening the hernial sac, the intestine is found to be in a gangrenous state, although the occurrence could not be previously known, owing to the integuments and the hernial sac itself not being affected with the same mischief. In ordinary cases, however, both the skin and sac become gangrenous at the same time with the contents of the hernia. The tumour, which was previously tense and elastic, becomes soft, doughy, emphysematous, and of a purple colour. Sometimes the parts also now spontaneously return; but the patient only survives a few hours.

Mr. A. Cooper has accurately remarked, that in other instances, the skin covering the swelling, sloughs to a considerable extent, the intestine gives way, and as the feces find vent at the wound, the symptoms of strangulation soon subside. When the patient continues to live in these circumstances, the living part of the intestine becomes adherent to the hernial sac, the sloughs separate and come away, and thus an artificial anus is established, through which the feces are sometimes discharged during the remainder of life. (See *Anus, Artificial*.)

Frequently, however, things take a more prosperous course; the feces gradually resume their former route to the rectum, and in proportion as the artificial anus becomes unnecessary, it is shut up. Many instances of this sort have fallen under my own observation in St. Bartholomew's Hospital.

The chance of a favourable event is much greater in some kinds of hernia, than in others. When the strangulation only includes a part of the diameter of the gut, the feces are sometimes only partially discharged through the mortified opening. This quantity lessens as the wound heals, and the patient gets perfectly well. (*Louis, Mem. de l'Acad. de Chir. T. 3. P. S. Palm, De Epiplo-enterocece crurali incarcerata sphacelata, cum deperditione notabili substantiæ intestini, sponte separati, feliciter curata alvo naturali restituta*, 4to. Tub. 1748. Haller, *Disp. Chir.* 3, 2.) A small gangrenous spot, or two, may end in the same manner. Mortification, as well as wounds of the large intestines, is much more frequently followed by a recovery, than the same affection and similar injuries of the small intestines. Mortification of the cæcum and its appendix, in a hernial sac, has happened several times, without materially disturbing the usual course of the feces to the anus, and the patients very soon recovered. (*Med. Obs. and Inq. Vol. 3. p. 162; Hey's Pract. Obs. p. 162, &c.*)

The grand thing, on which the establishment of the continuous state of the intestinal canal depends, in all these cases, is the adhesion which the living portion of the bowel, adjoining the mortified part, contracts with the peritonæum all round. In this manner, the escape of the contents of

the bowels into the cavity of the peritonæum becomes in general completely prevented. The two ends of the sound portion of intestine, after the mortified part has separated, open into a membranous cavity, which previously constituted a portion of the peritonæal sac, and now unites the extremities of the gut. The gradual contraction of the wound closes the membranous cavity externally, and thus the continuity of the canal is restored. The two ends, however, are not joined so as to form a continued cylindrical tube, like that of the natural gut; but they are united at an angle more or less acute, and the matter, which goes from one to the other describes a half circle in a newly formed membranous cavity that completes the canal; a subject which has been more fully explained in another part of this work. (See *Anus, Artificial*.)

It is an observation of Mr. A. Cooper's, that the degree of danger, attending an artificial anus, depends on the vicinity of the sphacelated part of the intestinal canal to the stomach. Thus, if the opening be in the jejunum, there is such a small extent of surface for absorption, between it and the stomach, that the patient dies of inanition.

Let us now suppose, that the mortified state of the intestine has only been discovered, after laying open the hernial sac in the operation. The mischief may only consist of one or more spots; or of the whole diameter of the protruded bowel. In the first case, the proper practice is to divide the stricture, and return the intestine into the abdomen, with the mortified spots towards the wound. Mild purgatives and clysters are then to be exhibited. The most favourable mode, in which a case of this kind ends, is when the intestinal matter gradually resumes its natural course, after being either partly or entirely discharged from the wound. But sometimes the patient sinks under the disease, or an artificial anus continues for life.

The repeated observations of modern surgeons have now decided, that no ligature, passed through the mesentery, to keep the gangrenous part of the bowel near the wound, is at all necessary. The parts, in the neighbourhood of the ring, have all become adherent together, in consequence of inflammation, at the same time that the parts in the hernial sac mortify; and of course, the partially gangrenous bowel, when reduced, is mechanically hindered, by these adhesions, from slipping far from the wound. Desault and De la Faye, both confirm the fact, that the intestine never recedes far from the ring; and even were it to do so, the adhesions, which it soon contracts to the adjacent surfaces, would, as Petit has explained, completely circumscribe any matter which might be effused, and hinder it from being extensively extravasated among the convolutions of the viscera. (*Mem. de l'Acad. de Chir.* T. 1, 2.)

Where the chief part, or the whole of the diameter of the protruded bowel is mortified, the first and most urgent indication is to relieve the bad symptoms arising from the dis-

tention of the intestinal canal above the stricture. "Let a free incision (says Mr. Lawrence) be made through the mortified part of the gut, in order to procure that evacuation of the loaded canal, which nature attempts by the process of gangrene." If the intestine has already given way, a free division of the integuments and sac allows the exit of the accumulated matter; and the opening in the gut may be enlarged, if necessary. (*Lawrence on Ruptures*, p. 283.)

Here the division of the stricture is unnecessary, since all the mischief, which the bowel can receive from it, is done. This subject is well explained by Mr. Travers. (See *Inq. into the Process of Nature in Repairing Injuries of the Intestines*, &c. p. 300, &c.) Mild purgatives and clysters will be proper to unload the bowels, and determine the course of the feces towards the anus. Should, however, the stricture appear after the mortification, to impede the free escape of the intestinal contents, a moderate dilatation of it must undoubtedly be proper.

Mr. Lawrence, in his valuable Treatise on Ruptures, has clearly exposed the impropriety of sewing the ends of the intestinal canal together, introducing one within the other, supported by a cylinder of isinglass, &c. put in their cavity, in those cases, in which the whole circle of the intestine has mortified, and been cut away, as was advised by former writers. By drawing the intestine out of the cavity, in order to remove the dead part, the adhesion behind the ring, on which the prospect of a cure chiefly depends, must be entirely destroyed; and new irritation and inflammation must be unavoidably produced, by handling and sewing an inflamed part. (See *Lawrence on Ruptures*, p. 298, &c.)

Instead of such practice, this gentleman judiciously recommends dilating the stricture, and leaving the subsequent progress of the cure entirely to nature. The sloughs will be cast off, and the ends of the gut are retained by the adhesive process in a state of apposition to each other, the most favourable for their union. Thus, there is a chance of the continuity of the intestinal canal becoming established again.

Whatever experiments it may be allowable to make in wounds with protrusion and division of the bowels, nothing, I think, is now more completely established, than the absurdity and danger of attempting to stitch the bowels in cases of hernia.

OPERATION FOR VERY LARGE INGUINAL HERNIÆ.

When the tumour is of long standing, exceedingly large, perhaps extending half way down to the knees, and its contents have never admitted of being completely reduced, the indication is to divide the stricture, provided a strangulation takes place; but without laying open the hernial sac, or attempting to reduce the parts.

The reasons against the common plan of operating, under such circumstances, are,

the difficulty of separating all the old adhesions; the hazardous inflammation, which would be excited by laying open so vast a tumour, and the probability that parts so long protruded, might even bring on serious complaints, if reduced. J. L. Petit, and afterward Dr. Monro, advised the sac not to be opened. (See *Mal. Chir. T. 2, p. 372. Description of Bursa Mucosa*, 1788.)

OPERATION WHEN THE HERNIA IS SO SMALL THAT IT DOES NOT PROTRUDE EXTERNALLY THROUGH THE RING.

In this kind of case, there is little appearance of external tumour; consequently, the disease is very apt to be overlooked by the patient and surgeon, and some other cause assigned for the series of symptoms. The manner of operating, in this form of the disease, differs from that in the common scrotal hernia; the incision is to be made parallel to the direction of the spermatic cord, and the stricture will be found at the internal ring. (*A. Cooper on Inguinal Hernia*.)

TREATMENT AFTER THE OPERATION.

Evacuations from the bowels should be immediately promoted by means of clysters, oleum ricini, or small doses of any of the common salts, dissolved in peppermint water. For some time, the patient must only be allowed a low diet. When symptoms of inflammation of the bowels and peritonæum threaten the patient, general bleeding, leeches applied to the abdomen, fomentations, the warm bath, blisters, doses of the oleum ricini, and clysters, are the means deserving of most dependence, and should be resorted to without the least delay. When all danger of peritonæal inflammation is past, and the patient is very low and weak, bark, wine, cordials, and a generous diet, must be directed. The effervescing saline draught, with opium, is the best medicine for quieting sickness, after the operation. Opium and cordials are the most eligible for checking diarrhœa. As the operation does not usually prevent the parts from becoming protruded again, a truss must be applied before the patient leaves his bed, and afterward constantly worn.

PROPOSALS FOR THE RADICAL CURE OF THE BUBONOCELE,

Of castrating the patient, applying caustic, or of the operation of the punctum aureum, with this view, I need only say, that they are barbarous, and not at all adapted for the attainment of the desired end. A description of these methods may be found in Paré, Wiseman, &c.

The old operation, termed the *royal stitch*, was one of the most promising plans. It consisted in putting a ligature under the neck of the hernial sac, close to the abdominal ring, and then tying that part of the sac, so as to render it impervious, by the adhesive inflammation thus excited.

The royal stitch, performed in this manner,

has been actually attended with success. (*Heister, Vol. 2.*) The umbilical rupture was cured by Saviard, on similar principles; and Desault radically cured nine cases of the exomphalos in children, by tying the hernial sac.

Schmucker cured two irreducible ruptures, free from strangulation, by cutting away the body of the sac, after tying its neck (*Chir. Wahrnehmungen, B. 2.*) In one case, Mr. A. Cooper found cutting away the sac, alone insufficient.

Dissecting away the whole hernial sac, or even laying it open, must be a formidable operation, compared with merely making a small incision down to the neck of the sac, and applying one ligature. If the hernia were reducible, and the upper part of the sac could be rendered impervious by the ligature, all other more severe plans would be superfluous. However, Petit, Sharp, Acrel, &c. record cases, which tend to prove the danger and inefficacy of the royal stitch; though it is true, that none of these surgeons operated exactly in the simple manner above suggested.

Richter recommends scarifying the neck of the sac, with the view of producing an adhesion of its sides to each other; a plan, which, he says, he found very successful.

From the account, however, which has been given of the anatomy of the bubonocœle, it is obvious, that none of these methods could do more than obliterate the sac as high as the ring, and never that portion of it, which is within the inguinal canal. Hence, the neck of the sac must still remain open for the descent of the viscera. This consideration, and that of the chances of bad and fatal symptoms from any operation undertaken solely for this purpose, and not urgently required for the relief of strangulation, are the grounds on which these experiments are now disapproved.

CRURAL, OR FEMORAL HERNIA.

Verheyen, who wrote in 1710, first demonstrated the distinct formation of crural hernia, which until then had been generally confounded with bubonocœle.

The parts, composing this kind of hernia, always protrude under Poupart's ligament, and the swelling is situated towards the inner part of the bend of the thigh. The rupture descends on the inside of the femoral artery and vein, between these vessels and the os pubis, through the *crural ring*, or canal for the transmission of the same vessels. And, as Hesselbach has remarked, the inner opening of this ring or canal is the predisposing cause of the disease, the peritonæum spread over it, being gradually propelled into it by various occasional causes, so as to complete the tendency to hernia. The actual protrusion of the bowels may be formed either suddenly, or by degrees. As soon as the bowels have once passed the outer aperture, or what Cloquet terms more properly the lower opening of the crural canal, the hernia has more room for extending itself forwards,

and to each side, and the integuments now become elevated into an oval swelling, the long diameter of which is nearly transverse. (Hesselbach, p. 47.) Gimbernat names the passage through which the femoral hernia protrudes from the abdomen, the *crural*; Hey, the *femoral ring*; and Cloquet, the *crural canal*.

Females are particularly subject to this kind of rupture. It has been computed, that nineteen out of twenty married women, afflicted with hernia, have this kind; but, that not one out of an hundred unmarried females, or out of the same number of men, have this form of the disease. (Arnaud.)

"The crural hernia," says Scarpa, is frequently observed in women who have had several children; it very seldom afflicts young girls; and still more rarely men. In the latter, the viscera can more easily escape through the inguinal ring, by following the spermatic cord, than they can descend along the crural vessels, and raise the margin of the aponeurosis of the external oblique muscle, that forms the crural arch. In women, an opposite disposition prevails, in consequence of the smallness of the inguinal ring, which, in them, only gives passage to the round ligament of the uterus, and besides, is situated lower down, and nearer the pubes, than it is in men, whilst on the contrary, the crural arch is more extensive, by reason of the wider form of the pelvis. Morgagni expressly says, that he never met with the crural hernia in the dead body of any male subject. *Mihi, ut verum fatear, nondum nisi in fœminis accidit ut eam viderem.* (De sed. et caus. morb. Epist. 34, 15.) Camper gives us to understand almost the same thing. (Icones Herniarum, in Præfat.) Hævin often operated for this kind of hernia in females, but only once in the male subject. (Pathol. et Therap. p. 406.) Sandifort and Walter have both seen but a single instance of it in the dead body of the male subject. (Obs. Anat. Pathol. cap. 4, p. 72. Sylloge comment. anat. p. 24, obs. 21.) Arnaud himself, to whom modern surgery is highly indebted for many important precepts on the operation for the strangulated crural hernia in both sexes, candidly confesses, that he never had an opportunity of dissecting a hernia of this kind in the male subject." (Scarpa, Traité des Hernies, p. 201.)

Scarpa had at his disposal a male subject, in which there was a crural hernia, and he availed himself of the opportunity of examining the parts with the utmost care. He first injected the blood-vessels; he afterward attentively dissected all the parts concerned in the disease; and he has published an exact description of the particulars, illustrated by an engraving.

According to Hesselbach, the femoral hernia, though not common in men, is more frequent than is generally believed, and often overlooked on account of its being very small. (Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche, p. 47.) Thus, in an example published in a modern work, an inguinal and femoral hernia were met

with together in a gentleman, sixty-three years of age. On examination of the body after death, a small piece of intestine, forming a crural hernia, was found strangulated, and concealed under an inguinal rupture and a mass of fat. (C. Bell's Surgical Obs. Vol. 1, p. 187.)

According to the observations of Scarpa, and all the best modern writers upon surgery, the crural hernia forms, both in the male and female subject, in the cellular substance, which accompanies the crural vessels below Poupart's ligament. The swelling follows the internal side of those vessels, and gradually descends into the fold of the thigh, between the sartorius, gracilis, and pectineus muscles. "Many surgeons believe (says Scarpa,) that the hernial sac, and the intestines, which it contains, are ordinarily situated above the crural vessels and trunk of the vena saphena, and sometimes between these vessels and the anterior superior spine of the ileum. But as far as my knowledge extends, this assertion is not supported by a single accurate description of the crural hernia in the early stage. It is true, that when the tumour has in time acquired a large size, and its fundus is inclined in a parallel manner to the fold of the thigh, it partly or entirely covers the crural vessels, and even the crural nerve, as Walter says he once observed. (Sylloge comment. anat. p. 24.) But it is not thence to be concluded, that the tumour in the beginning descended over the crural vessels, much less betwixt them and the anterior superior spinous process of the ileum. Neither must it be imagined, that the neck of the hernial sac becomes removed from the inner to the outer side of these vessels. If these two cases ever happen, they must be very rare; and the best authors who have treated of crural hernia, concur in stating, that in performing the operation, they have constantly found the viscera situated on the inside of the crural vessels, but never on their outside. Even when the tumour, after acquiring a considerable size, is situated transversely over the crural vessels, the neck of the hernial sac has always been found upon their inner side, that is to say, between them and the pubes. Le Dran, (Observ. de Chir. T. 2, p. 2.) La Faye, (Cours d'Opérations de Dionis, p. 358.) Petit, (Œuvres Posthumes, T. 2, p. 219.) Morgagni, (De Sed. et Caus. Morb. epist. 34, 15.) Arnaud, (Mem. de Chir. Tom. 2, p. 768.) Gunz, (De Herniis libellus, p. 78.) Bertrandi, (Trattato delle Operazioni, T. 1, annot. p. 218.) Pott, (Chirurg. Works, Vol. 2, p. 152.) Desault, (Traité des Mal. Chirurg. p. 191, 195.) B. Bell, (A System of Surgery, Vol. 1, p. 387.) Richter, (Traité des Hernies, chap. 34.) Nessi, (Institut. Chir. T. 2, p. 198.) Lassus, (Méd. Oper. T. 1, p. 198.) and many other writers, all concur upon this point. In support of their opinion, (says Scarpa,) I could cite a great number of cases of my own, which I have collected either in operating on several individuals for crural hernia, or in dissecting

the same kind of hernia in the bodies of many female subjects, and in that of the man, from whom I have taken the 8th plate. Lastly, also, having had an opportunity of dissecting in a female an enormous crural hernia, which descended one-third of the way down the thigh, I observed that the neck of the sac did not encroach at all upon the crural vessels, but lay entirely on their inner side." (*Scarpa, Traité des Hernies*, p. 203, 206.)

The tumour, on account of its situation, is liable to be mistaken for an enlarged inguinal gland; and many fatal events are recorded to have happened from the surgeon's ignorance of the existence of the disease. Mr. Lawrence once saw an hospital surgeon mistake a crural hernia for a glandular tumour, and the patient died, without any attempt being made to afford relief by the operation. (P. 391. See also *Petit, Traité des Mal. Chir. T. 2, p. 293, &c.*) A gland can only become enlarged by the gradual effects of inflammation; the swelling of a crural hernia comes on in a momentary and sudden manner, and when strangulated, occasions the train of symptoms already described in our account of the inguinal hernia, which symptoms an enlarged gland could never occasion. Such circumstances seem to be sufficiently discriminative; though the feel of the two kinds of swelling, is often not of itself enough to make the surgeon decided in his opinion. It is particularly remarked by Hesselbach, that, while a femoral hernia is incomplete, that is to say, within the outer opening of the passage, through which the parts descend, the disease presents itself as a round firm swelling, on the outer side of which the femoral artery can be felt pulsating: this small hernia may be mistaken for an inflamed gland, and the case can only be discriminated by the history of its origin and symptoms. (*Ueber den Ursprung der Leisten-und-Schenkelbrüche*, p. 51.) A femoral hernia may be mistaken for a bubonocoele, when the expanded part of the swelling lies over Poupart's ligament. As the taxis and operation for the first case ought to be done differently from those for the latter, the error may lead to very bad consequences. *The femoral hernia, however, may always be discriminated, by the neck of the tumour having Poupart's ligament above it. In the bubonocoele, the spine of the pubes is behind and below this part of the sac; but in the femoral hernia, it is on the same horizontal level, and a little on the inside of it.* (See Lawrence on *Ruptures*, p. 392, 393, Ed. 3.)

In the male subject, "the crural hernia, in the early stage, (says Scarpa) is situated so deeply in the bend of the thigh, that it is difficult, even in the thinnest persons, to feel its neck, and in examining its circumference with the extremity of the finger, the tendinous margin of the opening, through which the parts are protruded, can only be perceived with considerable difficulty. On the contrary, the inguinal hernia, however small it may be, is always less

deeply situated; it is about half an inch above the bend of the thigh. In carrying the finger round its neck, the tendinous margin of the inguinal ring can be easily felt at its circumference; and at the posterior part of the small tumour, the cord composed of the spermatic vessels is distinguishable. *When the crural hernia has acquired a considerable size, its neck is always deeply situated in the bend of the thigh; but its body and fundus assume an oval form, and their great diameter is situated transversely in the bend of the thigh.* Whatever may be the size of the inguinal hernia, it always presents a tumour of a pyramidal form, the base or fundus of which, far from being directed towards the ileum, follows exactly the direction of the spermatic cord, and descends directly into the scrotum. Besides the symptoms, common to all hernial swellings, the crural hernia, when it has attained a certain size, presents some others which are peculiar to it, such as *a sense of stupor and heaviness in the thigh, and œdema of the leg, and even of the foot, of the same side.*" The reason, why œdema and numbness of the limb, are particularly remarkable in cases of femoral hernia, is justly referred by Hesselbach, to the circumstance of the femoral vessels and nerves, with numerous lymphatics, taking their course through the crural ring, and according to his observations, the numbness and œdema are especially great, when the protrusion is omentum, which makes stronger pressure on the vessels and nerves, than commonly happens in a case of enterocoele. (P. 53.)

"In women, however, as Scarpa observes, it is less easy to distinguish the crural hernia from the inguinal. In fact, the absence of the spermatic cord, and the nearer situation of the ring to the crural arch, may easily occasion a mistake. Sometimes, a woman may even be supposed to have a double crural hernia of the same side, whilst, of these two distinct, though neighbouring herniæ, one may be inguinal, and the other crural. Arnaud (*Mém. de Chir. T. 2. p. 605.*) relates an instance of such a mistake." (*Scarpa, Traité des Hernies*, p. 207, 208.)

This interesting writer takes occasion to observe further, upon this part of the subject, that the portion of the inferior pillar of the abdominal ring, which separates this opening from the internal and inferior angle of the crural arch, is so slender in women, that it is sometimes hard to distinguish the crural from the inguinal hernia, which is not the case in male patients.

Until a few years ago, the stricture, in cases of femoral hernia, was always supposed to be produced by the lower border of the external oblique muscle, or, as it is termed, Poupart's ligament. A total change of opinion on this subject, however, has latterly taken place, in consequence of the observations first made by Gimbernat, in 1768. "In the crural hernia, (says he) the aperture through which the parts issue, is *not* formed by two bands, (as in the inguinal hernia) but it is a foramen almost round, proceeding

from the internal margin of the crural arch (Poupart's ligament,) near its insertion into the branch of the os pubis, between this bone and the iliac vein; so that, in this hernia, the branch of the os pubis is situated more internally than the intestine, and a little behind; the vein, externally, and behind; and the internal border of the arch, before. Now it is this border which always forms the strangulation." (See *A new Method of Operating for the Femoral Hernia*, by Don Antonio de Gimbernat, p. 6, Trans. by Beddoes.)

The utility of knowing, that it is not Poupart's ligament which produces the strangulation, in cases of femoral hernia, is important; for we then know, that cutting the lower and outer border of the external oblique muscle, is quite erroneous. This proceeding is the more to be reprobated, because the lower pillar of the abdominal ring, in both sexes, will be divided by directing the incision upward, or upward and inward; and thus the abdominal and crural rings will be made into one common aperture, large enough to make the future occurrence of hernia very likely to happen. In the male, there is also considerable danger of the spermatic cord being cut. Cutting Poupart's ligament obliquely outwards, is attended with still more danger; for the epigastric artery will infallibly be divided at its origin; and with all these hazards, the incision must be quite useless, unless carried on to the internal edge of the crural arch. (Gimbernat, p. 16.)

The inclination, however, of several modern writers to refer the strangulation entirely to Gimbernat's ligament, is not sanctioned by the most careful observers, like Hesselbach and Langenbeck. (*Neue Bibl. B. 2. p. 132.*) The former justly remarks, that a complete femoral hernia may be strangulated in two places, either at the outer or inner opening of the passage, through which the protrusion happens. Nay, says he, that the strangulation is sometimes caused by the outer opening, was known to former surgeons, for they remarked, that the constriction was removed by dividing the fascia. (*P. 53.*) And, in addition to these two modes of strangulation, is to be enumerated a third, in which the viscera are constricted by protruding through some weaker point, or accidental opening, in the anterior parietes of the crural canal (Hesselbach, p. 48; also Langenbeck, *Op. cit. p. 132.*) or even through an aperture in the inner side of this passage, as we find depicted in the twentieth plate of Langenbeck's treatise, "*De Structurâ Peritonæi.*"

I know of no surgical writer, who has given a clearer account of the anatomy of the femoral hernia, than Langenbeck (*Neue Bibl. B. 2, p. 112, &c.*) He observes, that when the dissection is begun at the inside of the inguinal region, the following circumstances are noticed: after the removal of the peritonæum from the abdominal muscles, and from the psoas, iliacus internus, and the great vessels, the inner surface of the trans-

versalis, and which is always a white glistening aponeurosis. From the place, where the femoral artery lies under Poupart's ligament, to the anterior superior spine of the ilium, the preceding fascia is extended in a strong fibrous form behind the inner surface of Poupart's ligament, and a thin continuation of it is extended over the iliacus internus and psoas muscles, where it is named by Mr. A. Cooper and Cloquet the *fascia iliaca*. The fascia of the transverse muscle closes the belly behind Poupart's ligament, as completely as the peritonæum does, so that between the femoral artery and the anterior superior spine of the ilium none of the bowels can protrude, which occurrence is still further prevented by the fascia lata, which below Poupart's ligament is closely attached to the muscles of the thigh. By the pelvis being thus shut up, the origin of a crural hernia on the outside of the femoral vessels is rendered quite impossible. (Langenbeck, *op. cit.*) This part of the explanation very nearly resembles that delivered by Mr. A. Cooper, except that the latter describes the iliac fascia, and not what Cloquet calls the transverse fascia, as closing the pelvis from the spine of the ilium to the crural vessels. But, this difference is easily accounted for by the circumstance of Mr. A. Cooper extending the name *fascia iliaca* beyond the limits given it by Cloquet and Langenbeck.

Near the anterior superior spinous process of the ilium, Langenbeck remarks that the fascia of the transverse muscle has some strong fibres, which proceed inwards under the internal opening of the inguinal canal, of which they form, as it were, the bottom, and are named by Hesselbach the *internal inguinal ligament*. They go over the femoral artery and vein, are connected above with the fascia of the transverse muscle, and below are continued into the fascia of the psoas and iliac muscles. Where these fibres pass over the femoral vessels, they expand into a firm aponeurosis, which passing downwards, is intimately attached at the inner side of the femoral vein to the horizontal branch of the os pubis, close to the symphysis, and then joins the aponeurosis of the recti muscles. The expanded portion of the foregoing tendinous fibres, thus continued along the crista of the os pubis to the sheath of the rectus, forms the inner surface of Gimbernat's, or the *femoral or crural ligament*. The inner edge of this ligament is falciform, and concave, the concavity being turned towards the femoral vein. Now where the fascia of the transverse muscle extends downwards, on the outer side of the crural artery, to the fascia of the psoas and iliac muscles so as to close the pelvis between that vessel, and the anterior superior spinous process of the ilium, it also forms, like Gimbernat's ligament, a falciform edge, the concavity of which lies close over the external convexity of the crural artery. Thus, partly by the concave edge of Gimbernat's ligament, directed towards the crural vein, and partly by the concave edge of the

extension of the fascia of the transverse muscle to the fascia iliaca, which edge is turned towards the crural artery, an aperture is produced, through which the femoral vessels pass out of the pelvis. This opening is named by Cloquet the *upper opening of the crural canal*, or as many English surgeons would say, of the *crural or femoral ring*. By Hesselbach, it is called the *internal opening for the femoral vessels*. However, as these vessels do not lie loosely and unconnectedly in this aperture, the opening itself is shut up, as it were, and cannot be seen without dissection.

On the above described fasciæ, there is a considerable quantity of cellular substance, which covers the vessels in the pelvis, forms a sort of sheath for the crural artery and vein, and accompanies these vessels through the inner opening of the crural canal, or ring, which is itself accurately shut up by it. When this cellular substance is removed, the white glistening fasciæ are plainly seen passing through the same opening, and coming nearer together in a funnel-like manner. Where the fascia of the transverse muscle forms the outer falciform edge of this aperture, and is passing over the *arteria circumflexa ili* to the *psoas* and *iliac* muscles, it sends off through the opening a process, which becomes connected with the outer side of the crural canal, or ring: while from the internal inguinal ligament, which lies above this opening, and constitutes the upper edge of the inner aperture of the crural canal, a production is sent, which is connected with the anterior side of this canal. As for the posterior and inner sides, they have a connexion with the fasciæ of the *psoas* and *levator ani*.

When the groin is externally dissected, in order to have a view of the crural ring or canal, on the outside of the pelvis, the following appearances present themselves: after the removal of the common integuments, one finds below Poupart's ligament, a quantity of fat, glands, lymphatics, veins, and arteries, which vessels come out through small openings in the fascia lata. As soon as the outer surface of the external oblique muscle is cleared, its aponeurosis is found to become stronger at the anterior superior spinous process of the ilium, and its fibres to collect together, and assume the form of a band, which is Poupart's ligament, called by Hesselbach the *external inguinal ligament*, and by Gimbernat, Cloquet, and others, the *crural arch*. This ligament, as is well known, passes obliquely inwards and downwards towards the *os pubis*, and after forming the external pillar of the abdominal ring, is first closely inserted into the angle or tubercle of the *os pubis*, and then being continued inwards, or backwards, in the form of a firm fascia, is attached to the horizontal ramus of that bone, making the *anterior or outer surface of Gimbernat's, or the femoral Ligament*, which is consequently produced by the junction of Poupart's with Hesselbach's internal inguinal ligament along the spine of the *os pubis*. Thus, just as the in-

ternal inguinal ligament is a strengthened part of the fascia of the transverse muscle, the outer inguinal ligament, (or, as it is here commonly called) Poupart's ligament, is produced by the strengthened fibres of the lower portion of the aponeurosis of the external oblique muscle, the fibres of it making the external pillar of the ring, being continued further towards the symphysis of the pubes, in the form of the outer surface of Gimbernat's ligament. (*Langenbeck, Neue Bibl. B. 2, p. 120, 121.*) English surgeons make the formation of Gimbernat's, or the femoral ligament more simple: thus Mr. Lawrence states, that when Poupart's ligament approaches the pubes, "it becomes suddenly broader; that it is fixed by this broad portion, along the whole length of the angle and crista of the pubes; that it has a rounded and strong anterior edge, a thin and sharp posterior margin; and that the former of these is nearer to the surface, while the latter is comparatively deeply seated. The breadth of this part varies, in different subjects: it is generally from three quarters of an inch to an inch. Sometimes, as Gimbernat has stated, it measures more than an inch. Dr. Monro has observed, that it is broader in the male than in the female subject; and from this structure, he explains in part the more rare occurrence of this rupture in the male." (*P. 368, Ed. 3.*)

The fascia lata, which is spread over the muscles of the thigh, is only a continuation of the aponeurosis of the external oblique muscle, and, as it proceeds downwards from Poupart's ligament, is very closely attached to the muscles of the thigh, all the way from the anterior superior spinous process of the ilium, to the femoral artery, drawing as it were Poupart's ligament downwards and inwards, or backwards, towards the cavity of the pelvis, so as to give to its external edge a convex appearance, and shut up the outside of the pelvis, from the anterior superior spine of the ilium as far as the crural nerve and artery, so firmly, that the formation of a femoral hernia at this part is impossible. And, if small apertures, filled with fat, be discernible in this portion of the fascia lata, still no hernia can here take place, because, as Langenbeck has already explained, here the interior of the pelvis is again shut up by fasciæ already described.

Under the fascia lata are situated the anterior crural nerve, the vein and artery. The *vena saphena magna* lies on the outside of it, and passes through an opening in it into the femoral vein. This aperture in the fascia lata is at the inner side of the groin, opposite the internal opening of the crural ring, or canal. It is named by Hesselbach the *external aperture for the femoral vessels*, and described by him as an oblique fissure about fifteen lines in length. He takes notice of its external semilunar edge, and two horns, which are directed inwards; the parts first particularly described by Mr. A. Burns of Glasgow, under the name of the *semilunar, or falciform process of the fascia lata*.

The lower horn bends rather inwards and upwards, and terminates in the production of the fascia lata spread over the pectinalis muscle. The upper horn, which is less curved, baries itself under the external pillar of the abdominal ring. Over the lower horn of the opening, just now described, the vena saphena magna ascends into the femoral vein. Through the same aperture also pass nearly all the superficial lymphatics of the lower extremity. According to Cloquet, the fascia lata consists of two layers, of which the anterior superficial one is closely attached to the crural arch, extends over the femoral vessels, and forms the anterior side of the crural canal. The other layer, near the pubes, quits the former, and, covering the pectinalis muscle, constitutes the hinder side of that canal. The anterior layer of the fascia then forms an oval aperture, through which the vena saphena passes, and which is considered by Cloquet as the lower opening of the crural canal. This opening, called by Hesselbach the external foramen for the femoral vessels, is well delineated both in his excellent work, and in the twenty-third plate of Langenbeck's book (*De Structura Peritonæi, testiculorum tunicis, &c. Sec. Göt. 1817.*) According to the investigations of the last anatomist, as soon as the integuments are removed, this opening in the fascia lata, with its external semilunar edge, and two horns, are regularly seen. The front side of the crural canal is formed by the fascia lata. Where this fascia proceeds in the form of Hesselbach's upper horn under and behind the external pillar of the abdominal ring, and makes the outer layer of Gimbernat's ligament, it is continued as a thin aponeurosis over the vena saphena, so that it makes not merely the upper horn, but reaches further downwards, and forms the outer side of the crural canal. The outer side then of the crural canal, or ring, according to Langenbeck, extends from the outer semilunar edge of the external opening for the femoral vessels, or, as English surgeons would say, from the edge of the *falciform process of the fascia lata*. The larger the preceding thin continuation of fascia is, the smaller is the external opening for the femoral vessels, the more is the upper horn bent downwards, and the more determinate is the form of the canal. (*Langenbeck, Neue Bibl. B. 2. p. 124, 125.*)

According to Mr. Lawrence, "the fascia lata, or fascia of the thigh, has two distinct insertions at the upper and anterior part of the limb. It is attached to the front edge of the pubes, over the origin of the pectineus, the fibres of which it closely covers, and it is also fixed to the front of the crural arch. The former of these is continuous, behind the femoral vessels, with the iliac fascia: the latter is not inserted along the whole length of the tendon, its attachment ceasing on the inner side of the vessels, which it covers anteriorly. Here, therefore, the femoral artery and vein are interposed between the two divisions." (*On Ruptures, Edit. 3, p. 371.*)

Where the insertion of the fascia lata

into Poupart's ligament ends, it forms what Mr. Burns of Glasgow calls the *falciform process*, the upper part of which is attached to the above ligament, while the lower proceeds further down the thigh. The concavity of the falciform process is directed towards the pubes. This anatomical connexion is one chief cause, why extending the thigh, and rotating it outward, render the crural arch tense.

The hernia, being situated in front of the pectineus, must of course be exterior to the fascia lata. In my opinion, surgeons are very much indebted to Mr. Lawrence for his able explanation of this fact. As for myself, I am candid enough to own that, until I read his clear and concise account of the anatomy of the crural hernia, I could never reap any accurate notions, concerning the relative situations of the hernial sac and fascia of the thigh, from other more prolix works, with the exception of those of Hesselbach and Langenbeck, by whom the anatomy is made perfectly intelligible. Mr. Lawrence reminds us, however, that the particular crural hernia, contained in the sheath of the femoral vessels, lies under the fascia; p. 382, Edit. 3. And he mentions, that "the falciform process of the fascia lata, passes along the upper and outer part of the tumour. The iliac vein is placed on the outer side of the neck of the sac; the pubes is directly behind it; and the upper and inner parts are bounded by the thin posterior edge of Poupart's ligament."

The inner side of the crural ring or canal, as already explained, is connected with the fascia of the transverse muscle. And, according to Langenbeck, below the part of the fascia lata, which forms the external foramen for the femoral vessels, the front side of the crural canal is sometimes formed by a continuation of the fascia of the transverse muscle, as he found was the case in both groins of one female subject. In such a case, there is a good deal of fat between the fascia lata, and the aponeurosis of the transverse muscle, and the two parts are easily separable. Langenbeck admits, however, that the same appearance may arise from a splitting of the layers of the fascia lata. Frequently the front side of crural ring is so short, that the opening cannot rightly be termed a canal, and it is always shorter than the posterior side. When the outer side exits, it is extended across the inner over the space between the two horns, and is then connected with the aponeurosis of the pectinalis derived from the fascia of the psoas and levator ani muscles. In the anterior and inner sides of the crural canal, there are some small openings. Doubtless, this stricture is referred to by Hesselbach, when he says, that, in the male subject the outer opening for the femoral vessels is further closed by a net-like web of tendinous fasciculi. The posterior side of the crural canal, or ring, is entirely formed by the part of the fascia of the psoas, which enters its inner opening, and joins the aponeurosis of the pectinalis mus-

cle. The outer side of the canal lies under the fascia lata, and joins the anterior and posterior sides, where the aponeuroses of the transverse and iliac muscles proceed to the outside of the femoral artery. Langenbeck thinks the opening, by which the vena saphena passes over the lower horn of the falciform process of the fascia lata, might be named the lower aperture of the crural canal. (See Langenbeck's *Neue Bibl. für die Chirurgie*, B. 2, p. 126, 127, 8vo. Hannover, 1819.)

According to Hesselbach, in femoral hernia, the two openings of the passage now termed the crural or femoral ring, are one half larger than natural. The outer portion of the inner of these apertures is propelled more outward, and with it the epigastric artery. The femoral vein no longer lies at the external end of this opening, but rather at the back of the canal or passage. The external semilunar edge (the falciform process) of the outer opening, is carried more outward and upward, and is tightly applied over the distended hernial sac. In this state of the parts, the outer opening forms an oval firm tendinous ring, the direction of which, like that of the inner opening for the passage of the femoral vessels, is transverse. The neck of the hernial sac is that portion of it, which lies within the canal between the two openings. The posterior side of this canal, or passage, now frequently named the crural, or femoral ring, is longer than the anterior. In one large hernia, Hesselbach found it an inch and a half in length, but the anterior side of the passage more than one-third shorter. The greatest diameter of the inner opening was one inch five lines, while that of the outer one was only one inch four lines. Most of the posterior part of the neck of the hernial sac, with the hinder side of the canal, lies upon the pectineus muscle, and towards the outside upon the femoral vein. The neck of the hernial sac adheres more firmly to the anterior, than to the posterior side of the passage. At the outer opening of the passage, the neck terminates at almost a right angle forwards in the body of the sac, the upper portion of which lies upon Poupart's ligament, but the largest part of it is situated on the deep-seated layer of the femoral fascia, by which the outer side of the body of the sac, as high as the neck, is separated from the crural vessels and nerves. In the male subject, when the tendinous fibres, mixed with the cellular substance covering the outer opening of the passage, make great resistance at particular points, the hernial sac of a femoral hernia may be double, or even divided into several pouches, a preparation exhibiting which occurrence is in the anatomical museum at Wurzburg. (Hesselbach, p. 48.) Except in a few cases, in which the origin and course of the epigastric artery are unusual, this vessel runs very close to the external side of the neck of the hernial sac, much nearer than it does in an internal bubonocoele.

The sac of the femoral hernia is exceedingly narrow at its neck; and, where its body begins, it becomes expanded in a globular form; the sac of the bubonocoele is generally of an oblong pyramidal shape. The body of the sac of the femoral hernia, makes a right angle with the neck, by being thrown forward and upward, a circumstance very necessary to be known in trying to reduce the parts by the taxis. Though the tumour, formed by the body of the sac, is oval and nearly transverse, it is found, when attentively examined, to take the direction of the groin, which extends obliquely downwards and inwards, the outer, rather smaller end of the swelling being somewhat higher than the inner. (Hesselbach, p. 50.)

The sac of the femoral hernia is said by Mr. A. Cooper to be immediately covered by a kind of membranous expansion, consisting of condensed cellular substance, and named by him, the *fascia propria*. According to the same gentleman, a weak aponeurosis derived from the superficial fascia of the bend of the thigh, also covers the swelling, and is described as lying immediately beneath the skin and adipose substance. Under this fascia is the condensed cellular substance, or fascia propria, then some adipose substance, and lastly the true peritoneal sac itself. It is of infinite use to remember these circumstances in operating, lest one should think the hernial sac divided when it is not so.

All late writers on hernia, have remarked how very small the aperture is, through which the viscera protrude in the femoral rupture; how much greater the constriction generally is, than in the bubonocoele; consequently, how much more rapid the symptoms are; how much less frequently the taxis succeeds; and how much more dangerous delay proves. (See A. Cooper, Hey, Lawrence, &c.)

Though the crural ring is almost always small, yet in a few instances, in which the tumour is large, and of long standing, it becomes very capacious, just as the opening often becomes, through which the inguinal hernia protrudes. Dr. Thomson, of Edinburgh, Mr. Hey, and Mr. Lawrence, have related examples of this kind.

The remarks already made, concerning the treatment of hernia, before having recourse to the knife, are all applicable to the present case, and need not be repeated. In attempting to reduce the femoral hernia by the taxis, the surgeon should recollect, however, that relaxing Poupart's ligament, and the femoral fascia, is of the highest consequence. Hence, the thigh should be bent, and rolled inwards. The pressure ought also to be first made downwards and backwards, in order to push the swelling off Poupart's ligament; and afterward, the parts should be propelled upwards, so that they may return through the crural ring.

OPERATION FOR THE FEMORAL, OR CRURAL HERNIA.

Mr. A. Cooper says, "the incision of the

integuments is to be begun an inch and a half above the crural arch, in a line with the middle of the tumour, and extended downwards to the centre of the tumour below the arch. A second incision, nearly at right angles with the other, is next made, beginning from the middle of the inner side of the tumour, and extending it across to the outer side, so that the form of this double incision will be that of the letter T reversed.' The angular flaps are, of course, to be next dissected off, and reflected.

The making of two incisions, however, is not deemed necessary by the majority of surgeons; and, in all the numerous operations which I saw performed in St. Bartholomew's Hospital, during a space of nearly fifteen years, a transverse wound was not found necessary. The division of the skin should begin about an inch above the crural ring, and be continued obliquely downwards and outwards. In this manner, we cut exactly over the place, where the incision of the stricture should be made.

"The first incision (says Mr. A. Cooper) exposes the superficial fascia, which is given off by the external oblique muscle, and which covers the anterior part of the hernial sac; but, if the patient is thin, and the hernia has not been long formed, this fascia escapes observation, as it is then slight and delicate, and adheres closely to the inner side of the skin. When this fascia is divided, the tumour is so far exposed, that the circumscribed form of the hernia may be distinctly seen; and a person not well acquainted with the anatomy of the parts, would readily suppose that the sac itself was now laid bare. This, however, is not the case, for it is still enveloped by a membrane, which is the fascia, that the hernial sac pushes before it, as it passes through the inner side of the crural sheath. This membrane, the fascia propria, is to be next divided longitudinally from the neck to the fundus of the sac; and if the subject is fat, an adipose membrane lies between it and the sac, from which it may be distinguished, by seeing the cellular membrane passing from its inner side to the surface of the sac.

"This is, in my opinion, the most difficult part of the operation; for the fascia propria is very liable to be mistaken for the sac itself; so that when it is divided, it is supposed that the sac is exposed, and the intestine is laid bare; following upon this idea, the stricture is divided in the outer part of the sac, and the intestine, still strangulated, is pushed, with the unopened sac, into the cavity of the abdomen.

"The hernial sac being exposed, is to be next opened; and, to divide it with safety, it is best to pinch up a small part of it between the finger and thumb; to move the thumb upon the finger, by which the intestine is distinctly felt, and may be separated from the inner side of the sac; and then to cut into the sac, by placing the blade of the knife horizontally. Into this opening, a director should be passed, and the sac opened

from its fundus to the crural sheath. (*On Crural and Umbilical Hernia.*)

Sometimes the contents of the hernia, thus exposed, admit of being returned, without the further use of the knife. When this object, however, cannot be readily done, the protruded parts should never suffer injury from repeated manual attempts; and it is safest to divide the stricture at once.

The merit of having first proposed the safest plan of cutting Poupart's ligament, even before surgeons were aware of the parts which really form the strangulation, is assigned by Gimbernat to Mr. B. Bell, who introduced his finger below Poupart's ligament, between the ligament and the intestine, (an evident proof, says Gimbernat, that there was no strangulation there;) he then made a very superficial incision from above downwards, into the thickest part of the ligament to its lower edge; and, without cutting quite through it, he continued his incision about an inch. He rested the back of the scalpel upon his finger, which served as a guide to the instrument, and, at the same time, as a defence to the intestine. The incision, however, having been continued for an inch, would, as Gimbernat remarks, inevitably cut the internal edge of the crural arch. Now, cutting this, only for a few lines, gives sufficient room for the easy reduction of the parts, and there is no necessity to touch the ligament, as it never occasions the strangulation.—(*Gimbernat, p. 27.*)

Gimbernat's method of dividing the stricture, in cases of femoral herniæ, is now frequently regarded as the safest and most effectual. "Introduce, along the internal side of the intestine, a cannulated or grooved sound, with a blunt end, and a channel of sufficient depth. This is to be directed obliquely inwards, till it enter the crural ring, which will be known by the increased resistance; as also when its point rests upon the branch of the os pubis. Then suspend the introduction; and keeping the sound (with your left hand, if you are operating on the right side, and v. v.) firmly resting upon the branch of the os pubis, so that its back shall be turned towards the intestine, and its canal to the symphysis pubis, introduce gently with your other hand, into the groove of the sound, a bistoury, with a narrow blade and blunt end, till it enter the ring. Its entry will be known, as before, by a little increase of resistance. Cautiously press the bistoury to the end of the canal; and employing your two hands at once, carry both instruments close along the branch to the body of the pubis, drawing them out at the same time. By this easy operation, you will divide the internal edge of the crural arch at its extremity, and within four or five lines of its duplicature; the remainder continuing firmly attached, by the inferior band, or pillar, of which it is the continuation. This simple incision being thus made, without the smallest danger, the internal border of the arch, which forms the strangulation, will be considerably relaxed, and the parts will be

reduced with the greatest ease." (*Gimbernat*, p. 45, 46.)

Mr. A. Cooper recommends the stricture to be divided "obliquely inwards and upwards, at right angles to the crural arch."

After advising us to open the sac of a femoral hernia, with particular care, on account of its being much thinner than that of a bubonocoele, and (as might be added) on account of its seldom containing any fluid, and often having no omentum in it covering the intestine, Mr. Hey remarks, "The stricture made upon the prolapsed parts is very great, as I have already observed; but if the tip of the finger can be introduced within the femoral ring, to guide the bubonocoele knife, a small incision (for the ring is narrow) will be sufficient to set the parts at liberty. If the tip of the finger cannot be introduced at the proper place, a director with a deep groove must be used instead of the finger; but I prefer the latter. The finger, or director, should not be introduced very near the great vessels; but on that side of the intestine or omentum which is nearest to the symphysis of the ossa pubis. The incision may then be made directly upwards. The surgeon must take especial care to introduce his finger or director within that part where he finds the stricture to be the greatest, which, in this species of hernia, is the most interior part of the wound." (*P.* 155.)

Gimbernat's mode is preferable to Mr. Hey's, because, were the operation done on a male, cutting directly upward would endanger the spermatic cord.

Mr. Lawrence has noticed, that "an incision of the most interior part of the stricture is free from all danger, in the ordinary course of the vessels. But that variety, in which the obturator artery, arising from the epigastric, runs along the inner margin of the sac, seems to preclude us from cutting even in this direction. Hesselbach met with a remarkable instance of such irregularity in the origin and course of the obturator artery in the body of a female, in whom there were two small crural herniae. On the right side, the epigastric and obturator arteries arose, by a common trunk, from the crural artery below Poupart's ligament. They soon separated from one another; the epigastric taking its ordinary course upwards at the outer side of the neck of the hernial sac, while the obturator made a considerable turn, and ran transversely inwards over the strong fibres of the femoral ligament, and encircled the anterior and inner side of the neck of the hernia, whence it afterward proceeded obliquely downwards and outwards, behind the horizontal branch of the os pubis, towards the obturator foramen. (*Hesselbach*, p. 52.) A mode of operating has been lately proposed, (*Edinb. Med. and Surg. Journal*, Vol. 2, 205.) with a view of avoiding this danger. We are directed to make an incision through the aponeurosis of the external oblique muscle, just above the crural arch, and in a direction parallel to that part: to introduce a director under the

stricture from this opening, and to divide the tendon to the requisite extent, by means of a curved knife passed along the groove. (*Treatise on Ruptures*, Edit. 3, p. 407.) For reasons which Mr. Lawrence states, this plan is certainly not altogether eligible, and, upon the whole, Gimbernat's method of cutting the stricture is the safest. Monro computes that the obturator artery may arise from the epigastric, once in twenty-five or thirty subjects. But, allowing that it originates more frequently, it then does not always deviate from its usual course along the outside of the sac. Mr. A. Cooper says: "in all cases, which I have myself dissected, where this variety existed with crural hernia, the obturator has passed into the pelvis, on the outer side of the neck of the sac, entirely out of the reach of any danger of the knife." (*On Crural Hernia*, p. 21.) Mr. Lawrence concludes, that the comparative number of instances, in which it is found on the opposite side, cannot be more than one in twenty, and consequently if we admit, that the obturator artery arises from the epigastric once in five times, it would only be liable to be wounded once in a hundred operations. (*P.* 412, *Edit.* 3.)

When the origin and course of the epigastric artery differ from what is common, this vessel, as Hesselbach remarks, sometimes passes inwards along the horizontal branch of the os pubis, ere it ascends towards the rectus muscle; and when this variation exists in a case of femoral hernia, the artery does not pass over the outer side of the neck of the sac, but first under it, and then round its inner side. Hesselbach has seen only one instance of this irregularity of the epigastric artery in a female, and never in a male subject. (*Ueber den Ursprung, &c. der Leisten- und Schenkelbrüche*, p. 52.)

The industrious Cloquet examined 250 bodies, for the purpose of estimating the average number of cases, in which the origin and course of the obturator artery are different from what is most common. He found, that when this artery and the epigastric arise by one common trunk, they sometimes separate from each other above, and rarely below the upper opening of the crural canal. In the first case, the longer their common trunk is, the closer do they lie to Gimbernat's ligament, and to the inner edge of the upper opening of the above canal. In the second case, the common trunk of these arteries arises within this canal, and the two vessels then return into the abdomen. In 160 bodies, of which 87 were male, and 73 female, the obturator artery arose on both sides from the hypogastric, and only in 56, of which 21 were male, and 35 female, did it originate on both sides from the epigastric. In 28, of which 15 were male, and 13 female, the obturator arose on one side from the hypogastric, and on the other from the epigastric. In 6 bodies, viz. 2 male, and 4 female, it originated from the crural. (*See Recherches Anal. sur les Hernies*, 4to. Paris.)

It is observed by Professor Scarpa, that

"the round ligament of the uterus, in passing through the abdominal muscles, follows precisely the same track as the spermatic cord. It is equally situated behind Poupart's ligament, with the difference, that it does not become so distinct from the internal extremity of this ligament, as the spermatic cord does, because it has not so far to run, in order to get from that ligament to the inguinal ring, the latter opening being situated lower in the female, than the male subject. The round ligament, like the spermatic cord, also crosses the epigastric artery, before reaching the inguinal ring. And as the crural hernia always begins at the internal and inferior angle of the arch of this name, as well in the male as the female, it follows, that, in the two sexes, the epigastric artery remains in its natural situation, and invariably corresponds to the external side of the neck of the crural hernia; whilst the spermatic cord, in men, and the round ligament, in women, pass over the extremity of the front of the neck of the hernial sac. In the operation for the crural hernia, in females, the incision of the neck of the hernial sac, and crural arch, when directed upward towards the linea alba, cannot wound the epigastric artery, which it is of the most consequence to avoid; but it always divides, either totally or partially, the round ligament of the uterus, which cannot lead to any dangerous hemorrhage; for, except in the period of pregnancy, the arteries of the round ligament are very small; they are almost obliterated in women advanced in years; and in general, they are quite capillary in the extremity of the ligament adjoining the ring. Hence, it cannot be surprising, that so many crural herniæ have been successfully operated upon in women, by cutting the hernial sac and crural arch directly upward, while not a single instance can be cited of such an incision being made in man without mischief, although, in both sexes, the epigastric artery may have been avoided in operating by this process." (Scarpa, *Traité des Hernies*, p. 240.)

In operating for the crural hernia in males, Scarpa recommends us to follow a method, which he calls new, but which, in fact, is the same as that advised by Gimbernat. I have found (says Scarpa) that, in man, the neck of the hernial sac may be divided without danger, by giving to the incision a direction exactly contrary to that which is practised in the female subject. After having opened the hernial sac, it is to be drawn outward by one of its sides sufficiently to allow the introduction of a small director between its neck and the strangulated intestine, the groove of the instrument being turned downwards towards the internal and inferior angle of the crural arch. A probe-pointed bistoury, the edge of which is also to be directed downwards towards the point of insertion of Poupart's ligament to the pubes, is to be pushed along the groove. By this means, the neck of the hernial sac will be divided its whole length, at its internal and inferior side, and Poupart's ligament will be cut

close to its attachment to the top of the os pubis. The epigastric artery will certainly be avoided, because it lies upon the opposite side of the hernial sac. As for the spermatic cord, I have demonstrated, that it is situated on the forepart of the neck of the hernial sac; consequently, it cannot be touched by an incision made from above downwards, whilst it is constantly cut in the ordinary method, since the knife is carried from below upwards. In the first case, this part may be the more easily avoided, as it lies at some distance from the internal and inferior angle of the crural arch. In fact, it is at this place that it quits, as we have seen, the edge of Poupart's ligament, in order to ascend towards the inguinal ring. The incision that I propose (says Scarpa) not only has the advantage of slitting open the neck of the hernial sac its whole length, it also divides a part of the insertion of Poupart's ligament into the upper part of the os pubis, a thing that gently contributes to relax the crural arch, and facilitate the reduction of the viscera; of those, at least, which are not adherent to the sac." (Scarpa, *Op. cit.* p. 235.)

Although this accurate anatomist and surgeon appears to be quite unacquainted with many of the late valuable publications on hernia, which have made their appearance in this country, it is curious to find, both in his account of the inguinal and crural hernia, how strongly his doctrines and observations tend to confirm every thing that has recently been insisted upon in modern works, respecting the place where the bubo-nocele first protrudes, its passing through a sort of canal before it comes out of the abdominal ring, the advantage of cutting in the crural hernia the internal and inferior angle of Poupart's ligament, or, in other terms, that part of the ligament which was first particularly pointed out by Gimbernat, as causing the principal part of the strangulation, and about which so much has been said by Mr. A. Cooper, Mr. Hey, &c.

Hesselbach considers an incision through the outer side of the crural ring safer than one through Gimbernat's ligament, and safer in women than men. In women, he recommends the cut to be made through the middle of the forepart of the ring, nearly straight upwards, or a little inclined inwards, in which mode the epigastric artery cannot be hurt, whether it lie at the outer, or inner side of the neck of the sac. In men, this incision, directed obliquely upwards and inwards, he says, cannot be made, on account of the nearness of the spermatic cord: therefore, in the male subject, he advises cutting the inner side of the opening, that is to say, Gimbernat's, or the femoral ligament directly inwards towards the symphysis of the os pubis. (*Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche*, p. 54.) When the epigastric, or obturator, artery deviates from its usual course, and surrounds the inner side of the neck of the hernia (which variety can never be ascertained a

priori,) a wound of the vessel Hesselbach regards as unavoidable.

From the views taken of femoral hernia in this article, I consider the unrestricted direction always to cut Gimbernat's ligament in the operation perfectly erroneous. For, as Langenbeck has stated, the seat of strangulation may either be in the external aperture of the crural canal, or in an opening of the front or inner side of this passage, or in its inner opening, where then Gimbernat's ligament is truly concerned. When the strangulation is of the two first descriptions, only the fascia lata need be cut: but, in the third, most frequent case, the inner semilunar edge of the internal opening of the ring must, of course, be divided. In all cases, says Langenbeck, whether the strangulation be caused by the inner or external opening of the crural canal, or by an aperture in the front parietes of this passage, the stricture must be cut inwards, as directing the cut in the least outwards would injure the epigastric artery. When it is perceived in the operation, that the neck of the hernial sac is strangulated, close below and behind the external pillar of the abdominal ring, then the inner opening of the crural canal must be divided inwards, with the knife directed along the horizontal ramus of the os pubis, under the external pillar of the ring, towards the symphysis of the pubes. If, in such a case, the knife were carried inwards and upwards, that part of Poupart's ligament forming the upper side of the crural canal might be cut, and the spermatic artery injured. (*Neue Bibl.* 2 B. p. 133.)

Dr. Trüstedt has published some remarks in favour of employing dilatation instead of an incision, in the operation for the strangulated crural hernia. He observes, that even when the common trunk of the obturator and epigastric arteries is short, the bowels may protrude under the first of these arteries, which will lie upon the upper and inner side of the hernia. In an operation performed upon a woman, in la Charité, at Berlin, for a strangulated femoral hernia, the crural ligament was divided in Gimbernat's way by an incision exactly parallel to the horizontal ramus of the os pubis, and the obturator artery was wounded. The patient died eight days after the operation, having been previously attacked by trismus and opisthotonos. On dissection, about six ounces of putrid blood were found in the lesser cavity of the pelvis, and the above artery cut. The vessel arose from the epigastric, ran over the upper edge of the inner opening of the crural canal, or ring, and then descended along its inner edge, towards the obturator foramen. This occasional course of the obturator artery leads Dr. Trüstedt to suggest the following rules: if, after the hernial sac is opened, the bowels cannot be returned, the outer opening of the crural canal should be cut directly inwards, in order to produce a considerable relaxation. But, if the reduction should yet be impracticable, (the strangulation being at the inner opening of the canal) then an attempt is to be made to

insinuate the end of the finger through the constriction, a plan said to have answered very often in the practice of Surgeon-General Rust. Should the resistance be too great, however, for this method to succeed, Trüstedt advises the crural ligament to be forcibly drawn inwards and upwards, towards the navel, with Arnaud's tenaculum, assisted by the introduction of the finger, or with two hooks. When this plan fails, he recommends Schreger's practice of dividing the anterior edge of Poupart's ligament with a pair of blunt-pointed scissors, and then the use of Arnaud's tenaculum again. (*See Rust's Magazin für die gesammte Heilkunde*, B. 3, H. 2.) The consideration, however, which will ever prevent the common adoption of Dr. Trüstedt's suggestion, is, that fifty times more lives would be lost by the mischief done to the protruded bowels by the forcible introduction of the fingers and hooks, than by hemorrhage from the obturator, or epigastric artery, when the course of the vessel is irregular.

CONGENITAL HERNIA.

Before the beginning of the sixth month of the foetal state, the testicle is situated near the kidney, where it receives a covering from the peritonæum, just like the other abdominal viscera. Between the beginning of the sixth month and end of the seventh, the testicle has either descended as low as just above the abdominal ring, or else is passing through it, or arrived a little below it. (*Wrisberg. Comm. Reg. Societ. Gotting.* 1785.)

When the testicle passes through the abdominal ring into the scrotum, it is received in a production of the peritonæum, which afterward constitutes the tunica vaginalis; while that peritoneal investment, which was given to the testicle in the loins, is closely adherent to this body, and forms what is named the tunica albuginea.

After the descent of the testicle into the scrotum, the communication between the cavity of the tunica vaginalis and that of the abdomen commonly becomes obliterated, which latter event is usually effected before birth, sometimes not till afterward, and, in a few subjects, even as late as the adult state.

In the congenital hernia, the protruded viscera are situated in the tunica vaginalis, in contact with the testicle: having descended into this position before the closure of the communication with the abdomen. Of course, the tunica vaginalis itself is the hernial sac. The nature of this case was not understood, before it was elucidated by Haller in 1755, and the two Hunters in 1762 and 1764. (*See Hunter's Med. Comment.*; *Haller's Opuscula Patholog. and Opera Minora*, T. 3.) Many particulars, relating to the origin and formation of this hernia, having been described in the 2d vol. of the *First Lines of Surgery*, I shall not here repeat them. Before the periods now named, surgeons imputed the circumstance of the contents of the hernia and testicle being in contact, to the

bowels having made their way, by laceration, through the tunica vaginalis, from the ordinary hernial sac of a bubonocoele. The old surgeons, indeed, frequently cite this instance in proof of their doctrine, that some herniæ were attended with a laceration of the peritonæum. (See *Sharp's Inquiry*.)

From the term *congenital*, we might suppose that this hernia always existed at the time of birth. The protrusion, however, seldom occurs till after this period, on the operation of the usual exciting causes of herniæ in general. It does not commonly happen till some months after birth; and, in certain instances, not till a late period. Mr. Hey relates a case in which a hernia congenita was first formed in a young man, aged sixteen, whose right testis had, a little while before the attack of the disease, descended into the scrotum. In the generality of cases which actually take place when the testicle descends into the scrotum before birth, the event may be referred to the testicle having contracted an adhesion to a piece of intestine, or omentum, in its passage to the ring. In an infant, which died a few hours after birth, Wrisberg found one testicle which had not passed the ring, adhering, by means of a few slender filaments, to the omentum, just above this aperture.

The appearance of a hernia in very early infancy, Mr. Pott observes, will always make it probable that it is of this kind; but he was not correct in asserting, that in an adult, there is no reason for supposing his rupture to be of this sort, but his having been afflicted with it from his infancy; and that there is no external mark, or character, whereby it can be certainly distinguished from one contained in a common hernial sac. This statement is erroneous, inasmuch as the hernia congenita is attended with an impossibility of feeling the testis, which part in the common scrotal hernia is always distinguishable under the fundus of the hernial sac. The hernia congenita, when returnable, "ought, like all other kinds of ruptures, to be reduced, and constantly kept up by a proper bandage; and when attended with symptoms of stricture, it requires the same chirurgical assistance as the common hernia."

Mr. Pott notices, "that in very young children, a piece of intestine, or omentum, may get pretty low down in the sac, while the testicle is still in the groin, or even within the abdomen. In this case, the application of a truss would be highly improper; for, in the latter, it might prevent the descent of the testicle from the belly into the scrotum; in the former, it must necessarily bruise and injure it, give a great deal of unnecessary pain, and can prove of no real use. Such bandage, therefore, ought never to be applied on a rupture in an infant unless the testicle can be fairly felt in the scrotum, after the gut or caul is replaced; and when it can be so felt, a truss can never be put on too soon."

Many additional observations on the foregoing topic are contained in the 2d vol. of
VOL. II.

the First Lines of Surgery, for which reason I do not here expatiate upon it. Mr. Pott explains, that an old rupture, originally congenital, is subject to a stricture made by the sac itself, as well as to that produced by the abdominal ring, or, as might have been added, to that caused by the inner opening of the inguinal canal.

The fact he noticed several times, both in the dead and in the living. "I have seen (says he) such stricture made by the sac of one of these herniæ, as produced all those bad symptoms which render the operation necessary: and I have met with two different strictures, at near an inch distance from each other, in the body of a dead boy, about fourteen, one of which begirt the intestine so tight that I could not disengage it without dividing the sac.

"In this kind of hernia I have also more frequently found connexions and adhesions of the parts to each other than in the common one; but there is one kind of connexion sometimes met with in the congenital hernia which can never be found in that which is a common hernial sac, and which may require all the dexterity of an operator to set free; I mean that of the intestine with the testicle.

"When a common hernial sac has been laid open, and the intestine and omentum have been replaced, there can be nothing left in it which can require particular regard from the surgeon; but by the division of the sac of a congenital hernia, the testicle is laid bare, and after the parts composing the hernia have been reduced, will require great regard and tenderness in all the future dressings, as it is a part very irritable, and very susceptible of pain, inflammation, &c.

"If a large quantity of fluid should be collected in the sac of a congenital hernia, and by adhesions and connexions of the parts within, the entrance into it from the abdomen should be totally closed, (a case which I have twice seen) the tightness of the tumour, the difficulty of distinguishing the testicle, and the fluctuation of the fluid, may occasion it to be mistaken for a common hydrocele; and if, without attending to other circumstances, but trusting merely to the feel and look of the scrotum, a puncture he hastily made, it may create a great deal of trouble, and possibly do fatal mischief.

"By what has fallen within my observation, I am inclined to believe that the sac of a congenital hernia is very seldom, if ever, distended to the degree which a common hernial sac often is: it also, from being less dilated, and rather more confined by the upper part of the spermatic process, generally preserves a pyriform kind of figure, and for the same reason, is also generally thinner, and will therefore require more attention and dexterity in an operator when he is to open it. To which, I believe, I may add, that common ruptures, or those in a common sac, are generally gradually formed, that is, they are first inguinal, and by degrees become scrotal; but the congenital are seldom, if ever, remembered by the patient to have

been in the groin only." (*Pott on Ruptures, Vol. 2.*)

The sac of a congenital hernia, especially when the case is strangulated, is every where equally tense, (*Hesselbach, p. 36*) and below it the testis cannot be felt.

The reader must not conclude, however, from the above account, that every rupture in children is congenital. Mr. Lawrence has related a case of strangulated bubonocoele, which took place in an infant only fourteen months old. (*P. 65, Edit. 3*)

The common inguinal hernia, which first protrudes at the inner opening of the inguinal canal and which has the epigastric artery on the inner side of its neck, has been named by Hesselbach *external*, while the less common instance, in which the viscera burst directly through the aponeuroses of the transverse and internal oblique muscles, and pass directly out of the abdominal ring, leaving the epigastric artery on the outer side of the neck of the sac, is distinguished by the epithet *internal*. (*Anat. Chir. Abhandlung über den Ursprung der Leistenbruch, Würzb. 1806.*) "The inguinal congenital hernia (says Scarpa) cannot be divided into *external* and *internal*: it is evident, that it must always be *external*, since the neck of the tunica vaginalis invariably corresponds to the point, at which the spermatic cord passes under the margin of the transverse muscle. As for other circumstances, the tunica vaginalis lies in its whole course in the same manner as the sac of a common inguinal hernia: like this, it passes completely through the inguinal canal from one end to the other, resting upon the anterior surface of the spermatic cord. Consequently, it passes between the separation of the inferior fibres of the obliquus internus, and the principal origin of the cremaster muscle. (See *Wrisberg. syllog. comment. anat. p. 23.*) After coming out of the ring, as it is always united to the spermatic cord, it is enclosed in the muscular and aponeurotic sheath of the cremaster muscle, which accompanies it to the bottom of the scrotum. Since the tunica vaginalis, including the displaced viscera, enters the inguinal canal on the outside of the point, at which the spermatic cord crosses the epigastric artery, it is manifest, that, as it follows exactly the direction of that, as it must also cross the artery, and remove it from the outer to the inner side of the ring, according to the mechanism already explained in speaking of the common inguinal hernia. Hence, the displacement of the epigastric artery constantly happens in the inguinal congenital, just as it does in the ordinary external inguinal hernia.

"But, if these two species of inguinal herniæ have some analogy to each other, in regard to the parts which constitute them, yet, they present some remarkable differences. 1. The common inguinal hernia, whether internal or external, when it extends into the scrotum, cannot descend beyond the point at which the spermatic vessels enter the testicle. There the cellular substance of the spermatic cord terminates.

There the hernial sac must unavoidably terminate. On the contrary, in the congenital hernia, the viscera may descend lower than the testicle, with which they are in immediate contact; and, at length, they even occupy the situation of this organ, which is then pushed upward and backward. 2. In the case of a congenital hernia, the descent of the viscera from the groin to the scrotum commonly takes place in a very short time, and in some measure precipitately: it is much slower and more gradual in the ordinary inguinal hernia. The reason of this difference is very plain. In the first case, the descent of the testicle, and the formation of the tunica vaginalis, have opened and prepared the way, which the viscera must follow in forming a protrusion; while, in the second, the hernial sac cannot descend into the scrotum, but by gradually elongating the layers of the cellular substance, which joins it to the surrounding parts. This fact is so generally known, that experienced practitioners consider the promptitude, with which the viscera have descended from the groin to the bottom of the scrotum, as a characteristic sign of a scrotal congenital hernia." (*Scarpa. Traité des Hernies, p. 73, &c.; Hesselbach, p. 35; Pott &c.*)

If circumstances will admit of a truss being applied and worn in cases of congenital hernia, in young subjects, there will be a considerable chance of a radical cure being effected, in consequence of the natural propensity of the opening between the abdomen and tunica vaginalis to become closed.

The only material difference in the operation, from that for a bubonocoele, is, that the surgeon has to lay open the tunica vaginalis, instead of a common hernial sac. The stricture is to be divided on the same principle as that of an inguinal hernia, and much in the same manner. As, in a case of congenital hernia, the parts are always protruded on the outside of the epigastric artery, the stricture may be safely divided towards the ilium, as well as directly upwards. (*Lawrence on Ruptures, p. 481 Edit. 3.*) The parts having been reduced, the edges of the wound are to be immediately brought together, and retained so by means of one or two sutures, and sticking plaster, which is much preferable to the plan of applying dressings to the testicle and inside of the tunica vaginalis, so as to heal the part by the granulating process.

A new species of hernia congenita was described by the late Mr. Hey, in which a common peritonæal hernial sac, containing the viscera, is included in the tunica vaginalis. It arises from the parts being protruded after the communication, between the abdomen and tunica vaginalis, is closed, so that the peritonæum is carried down along with the intestine, and forms a hernial sac, within the tunica vaginalis. It is evident also, that such a hernia can only be produced, while the original tunica vaginalis remains, in the form of a bag, as high as the abdominal ring.

Operators should be aware of the possibility of having a sac to divide after laying open the tunica vaginalis. (See the accounts of this hernia in *Hey's Practical Observations*, p. 221, &c. and *A Cooper's Work on Inguinal Hernia*, p. 59.)

UMBILICAL HERNIA, OR EXOMPHALOS.

"The exomphalos, or umbilical rupture, (says Pott) is so called from its situation, and has (like other herniæ) for its general contents, a portion of intestine, or omentum, or both. In old umbilical ruptures, the quantity of omentum is sometimes very great. Mr. Ranby says, that he found two ells and a half of intestine in one of these, with about a third part of the stomach, all adhering together. Mr. Gay and Mr. Nourse found the liver in the sac of an umbilical hernia; and Bohnius says, that he did also. But whatever are the contents, they are originally contained in the sac, formed by the protrusion of the peritonæum. In recent and small ruptures, this sac is very visible; but in old, and large ones, it is broken through at the knot of the navel, by the pressure and weight of the contents, and is not always to be distinguished; which is the reason why it has by some been doubted whether this kind of rupture has a hernial sac or not.

"Infants are very subject to this disease in a small degree, from the separation of the funiculus; but in general they either get rid of it as they gather strength, or are easily cured by wearing a proper bandage. It is of still more consequence to get this disorder cured in females, even than in males, that its return, when they are become adult, and pregnant, may be prevented as much as possible; for at this time, it often happens, from the too great distention of the belly, or from unguarded motion when the parts are upon the stretch. During gestation, it is often very troublesome, but, after delivery, if the contents have contracted no adhesion, they will often return, and may be kept in their place by a proper bandage.

"If such bandage was always put on in time, and worn constantly, the disease might in general be kept within moderate bounds, and some of the very terrible consequences which often attend it might be prevented. The woman who has the smallest degree of it, and who, from her age and situation, has reason to expect children after its appearance, should be particularly careful to keep it restrained.

"In some the entrance of the sac is large, and the parts easily reducible; in others they are difficult, and in some absolutely irreducible. Of the last kind many have been suspended for years in a proper bag, and have given little or no trouble. They who are afflicted with this disorder, who are advanced in life, and in whom it is large, are generally subject to colics, diarrhœas, and, if the intestinal canal be at all obstructed, to very troublesome vomitings. (Hence, patients are often supposed to labour under a

stricture, when they really do not.) It therefore behooves such to take great care to keep that tube as clean and free as possible, and neither to eat nor drink any thing likely to make any disturbance in that part." (*Pott on Ruptures*, Vol. 2.)

Authors, who have published since the time of this celebrated surgeon, have not added much to the stock of information which he has left, relative to the exomphalos. The writings of Mr. A. Cooper, Scarpa, (*Traité des Hernies*, p. 327) and of all the most accurate moderns, confirm the fact described by Pott, that, in the umbilical rupture, there is a hernial sac, just as in other instances of herniæ. Every one, acquainted with anatomy, knows, that behind the opening in the linea alba at the umbilicus, the peritonæum is complete, and consequently must protrude along with the viscera, in cases of exomphalos. In the only two cases which Mr. A. Cooper has seen of a deficiency of the sac, the membrane had been partially absorbed, or lacerated, so as to allow the protrusion of its contents, and threaten, from this cause, a double stricture. Similar appearances, less closely inspected, probably gave rise to the opinion so firmly maintained by Dionis, De la Faye, Garengeot, and J. L. Petit, that, in the umbilical hernia, the peritonæum was always lacerated, and there was no hernial sac. According to Bichat, early infancy is most subject to the umbilical hernia, strictly so called, in which the parts protrude through the navel; while the other periods of life are more liable to false umbilical herniæ, or such as arise in the vicinity of the umbilicus. (*Œuvres Chir. de Desault*, T. 2. p. 315.)

Besides a true hernial sac, the exomphalos is also covered by a more superficial expansion, consisting of condensed cellular substance. In operating, however, a surgeon should always cut with great caution; for, the integuments and hernial sac, in front of the tumour, are inseparably adherent; and sometimes, in large cases, when an absorption of part of the sac has been caused by the pressure of the bowels, they are even found adherent to the integuments.

Pregnant women, and dropsical and corpulent subjects, are peculiarly liable to the exomphalos. In adults, when there is intestine in the sac, there is almost always omentum. The transverse arch of the colon is observed to be particularly often contained in umbilical herniæ, but the small intestines are not unfrequently protruded: and even the cœcum has been found in a rupture at the navel. (See *Lawrence on Ruptures*, p. 427, Edit. 3.)

In the true umbilical hernia, the stricture is made by the tendinous opening in the linea alba. Let us next consider the umbilical hernia in the three particular forms, in which it has been noticed by the latest writers.

CONGENITAL UMBILICAL HERNIA.

Dr. Hamilton has met with about two cases of this kind annually, for the space of

seventeen years; and they strictly deserve the epithet *congenital*, as they appear at birth. The funis ends in a sort of bag, containing some of the viscera, which pass out of the abdomen through an aperture in the situation of the navel. The swelling is not covered with skin, so that the contents of the hernia can be seen through the thin distended covering of the cord. The disease is owing to a preternatural deficiency in the abdominal muscles, and the hope of cure must be regulated by the size of the malformation, and quantity of viscera protruded.

The plans of cure proposed, consist of the employment of a ligature, or of a bandage. The latter seems preferable, and was practised by Mr. Hey, as follows: having reduced the intestine, he desired an assistant to hold the funis compressed sufficiently near the abdomen, to keep the bowel from returning into the hernial sac.

"I procured (says he) some plaster spread upon leather, cut into circular pieces, and laid upon one another in a conical form. This compress I placed upon the navel, after I had brought the skin on each side of the aperture into contact, and had laid one of the lips a little over the other. I then put round the child's abdomen a linen belt; and placed upon the navel, a thick, circular, quilted pad, formed about two inches from one extremity of the belt.

"This bandage kept the intestine securely within the abdomen, and was renewed occasionally. The funis was separated about a week after birth; and at the expiration of a fortnight from that time, the aperture at the navel was so far contracted, that the crying of the child, when the bandage was removed, did not cause the least protrusion. I thought it proper, however, to continue the use of the bandage a little while longer. A small substance, like fungous flesh, projected, after the funis had dropped off, about half an inch from the bottom of that depression which the navel forms. A dossil of lint spread with cerat. e lapide calaminari, and assisted by the pressure of the bandage, brought on a complete cicatrization." (P. 227.)

This gentleman has related another example, in which the intestines were quite uncovered and inflamed, the sac having burst in delivery. The parts were reduced; but the child died. (See also *G. A. Fried de Fatu intestinis plane nudis extra abdomen propendentibus nato. Argent. 1760.*)

UMBILICAL HERNIA IN CHILDREN.

The umbilical hernia, which is sometimes formed in the fœtus, from causes difficult of explanation, takes place, in other instances, at the moment of delivery; and then, as Sabatier remarks, should it be tied by mistake, with the funis, death would be the consequence. Most frequently, however, it is not till the second, third, or fourth month after birth, that the disease occurs; and the numerous cases collected by Desault prove that, of ten infants attacked with this hernia,

nine become afflicted at the periods just mentioned.

The umbilicus, still open, now begins to contract, so as to close the cicatrix, which soon forms an obstacle capable of preventing a protrusion of the viscera. Sometimes, however, the repeated crying of the child propels the viscera through the opening, and thus the closure of the cicatrix of the navel is prevented. By degrees, the umbilical ring becomes more and more dilated, the quantity of protruded bowel increases, and thus a tumour arises, which, from being of trivial size at first, at length attains the size of an egg, or large walnut, and presents itself with all the characteristic marks of a hernia.

The presence of a piece of intestine and omentum in the tumour, keeps the umbilicus open, and opposes the continual tendency which it has to close. Such tendency, however, being sometimes superior to the resistance of the protruded parts, forces them back into the abdomen, obliterates the opening through which they passed, and thus the spontaneous cure of the umbilical hernia in children is accomplished. Two cases illustrative of this fact, are related by Bichat. (*Œuvres Chir. de Desault, T. 2, p. 318*)

Nature, however, does not effect many such cures, and when the case is left to her alone, she not only fails in bringing about a radical cure, but gradually renders it impossible. In short, the propensity of the opening to close diminishes, and is lost, as the subject grows older.

Thus, the umbilical hernia of children seems to be essentially different from that of adults, in the tendency of the aperture to contract. Hence the ease of affecting a radical cure in children, and the almost utter impossibility of doing so in adults. In the former, it is enough to keep the intestines from protruding, and the opening becomes of itself obliterated; in the latter, the opening always remains, whether the bowels continue in it or not. This indisposition of the aperture to contract in the adult, also frequently depends upon the protrusion not being through the umbilical ring itself, but through a fissure in the vicinity of it, not endowed with the same natural tendency to close, which the umbilicus possesses in young subjects. In fact, it would appear from the observations of Scarpa, detailed in the 2d vol. of the *First Lines of Surgery*, that, unless a grown-up person has the protrusion from infancy, it never occurs exactly through the umbilical ring itself.

The means of curing the umbilical hernia of children, are of three kinds; external applications; compression; and the ligature. The first are totally useless; and as they occasion a waste of time, are improper. Compression, and the ligature, are the only rational plans. The former is the most modern; the latter the most ancient treatment, as it is mentioned by Celsus. Desault tells us, that the design both of the ligature and compression is the same, viz. to prevent the lodgment of the protruded viscera in the opening of the umbilicus, and thus faci-

litate the approximation of its sides. To accomplish this end, the ligature retrenches the hernial sac, and skin pushed before it; and, by the union of the cut parts, a cicatrix is produced, which hinders the protrusion of the viscera. At the same time, the sides of the opening, obeying their natural tendency, compression closes the deficiency, or opening, in the parietes of the abdomen, hinders the protrusion of the bowels, and keeps these parts from resisting the contraction of the sac. Desault remarks, that though compression occasions no pain, it is irksome, during the great length of time its employment is necessary. The ligature (he says) produces momentary pain; but it is not at all irksome, and it effects in a few days, what compression, when successful, accomplishes in several months. In one plan, long continual attention is requisite, and if its employment be only for a short time neglected, the previous effect becomes almost destroyed. The other method always accomplishes its object with certainty, independently of the crying of the child, and the care of its attendants. When compression is adopted, it is executed either by means of a flat compress applied to the opening, and which does not enter it, or else by means of some round or oval body, such as a ball of wax, a nutmeg, &c. adapted to the shape of the aperture, and, as Platner and Richter, (in his *Treatise on Hernia*) advise, continually kept within the opening. In the first case, Bichat argues, that if the bandage be exactly applied, the skin and sac will form a fold in the aperture of the navel, hinder its closure, and operate in the same manner, from without, inward, as the protruded intestines did from within outward. In the second case, he observes, the foreign body, being depressed into and maintained in the opening, will occasion, notwithstanding what Richter says, the same inconveniences, and, in a more striking manner, similar consequences. But, on the contrary, when the ligature is employed, the sac and skin of the tumour are removed, while the opening remains free, and nothing prevents its obliteration. In this method, the omentum can never protrude outward; but, in the other, if the compression should ever be inexact, the parts slip out again, above or below, and the disorder prevails on one side of the useless application. The ligature is also commended as producing an adhesion of the sides of the opening, either to each other, or the adjacent parts. This adhesive process arises from the inflammation excited, and occasions a degree of firmness, not producible by any other mode of cure.

With respect to compression, Bichat asserts that children, on whom it is employed, are miserably annoyed with it for years, while the ready success of the treatment with the ligature, is attested by a series of well-authenticated cures, which in Desault's practice, amounted to the number of fifty. In the latter years of his practice, says Bichat, many persons were also seen bringing to his public consultations their children,

which were immediately operated on without any preparation, carried home, and brought the next, and every following day, to be dressed, till the cure was complete.

The children of the poor may be cured in an hospital, with the ligature, in the space of a few days. But, when compression is adopted, the parents are frequently put to repeated expense, as the bandage wears out; and to additional loss from the time consumed in paying the necessary attention.

The ancients had different modes of applying the ligature. One consisted in reducing the parts, and afterward tying the integuments and sac, without opening the latter at all. In the other, an incision was made in the sac, either before or after tying it, for the purpose of being sure, that no piece of intestine was, and could become, strangulated in the ligature. Celsus adopted the first plan; Paulus Aegineta preferred the second; and he was imitated by Avicenna, Albucasis, and Guy de Chauliac.

The first of these methods is less painful, and equally safe; for, we soon become habituated to ascertaining, whether there is still any intestine in the sac, by rubbing the opposite sides of this bag against each other. The other, which is unnecessarily cruel, increases the pain, without making the method at all more successful. Some of the old practitioners simply tied the base of the tumour; others passed through it one, or two needles, armed with ligatures for the purpose of fixing such ligatures in a better manner, and, for this purpose, they even sometimes made a circular incision. Desault's method, which much resembled that of Saviard, was simple, and is described by Bichat as attended with little pain.

The child must be placed on its back, with its thighs a little bent, and its head inclined towards the chest. The surgeon is to reduce the protruded parts, and to hold them so with his finger, at the same time that he raises the hernial sac, and rubs its sides between his fingers, so as to be sure that there is nothing contained in it. Being certain, that the parts which he lifts up, are only the skin and sac, he is to direct an assistant to surround their base several times with a waxed ligature, of middling size, each turn being tied with a double knot in such a manner as only to occasion little pain. The tumour, thus tied, is to be covered with lint, which is to be supported with one or two compresses, and a circular bandage, secured with a scapulary. By the following day a slight swelling has commonly taken place in the constricted parts.

On the second, or third day, the parts shrink, and then the ligature becomes loose, so that a fresh one must now be applied in the same manner as the first, taking care to draw it a little more tightly. The sensibility of the parts, increased by the inflammation, which the constriction of the ligature has already produced, usually renders this second ligature more painful. After the operation, the same dressings, as at first, are to be ap-

plied. The tumour soon becomes discoloured, livid, and smaller. A third ligature, put on in the same way as the preceding ones, entirely obstructs the circulation in it. The part turns black and flaccid, and commonly falls off on the eighth or tenth day. A small ulcer is left, which, being properly dressed, very soon heals, and leaves a cicatrix sufficiently strong to resist the impulse occasioned by coughing, or other efforts of the abdominal muscles. For two or three months, however, after the operation, the child should wear a circular bandage, in order to prevent, with still greater certainty, the viscera from being propelled against the cicatrix, so as to interrupt the process of nature, which is now producing a gradual closure of the umbilical opening. Numerous cases might here be adduced, in confirmation of the above practice; but, several (nine) are already published in the Parisian Chirurgical Journal.

But one may doubt, (says Sabatier) quoting the article in the journal, where Desault treats of the present disease, whether the infants got rid of the hernia, as it might have returned some time afterward. To this observation, Bichat replies, that numerous facts remove the doubt; for, several of the subjects were brought to Desault's public consultation, for other diseases, a long while after they had been operated upon, and the great number of students, who examined them, all acknowledged, that the ring was completely obliterated, and there was no impulse of the viscera in coughing, sneezing, &c. Other children, in the knowledge of the surgeons of the Hôtel-Dieu, remained perfectly cured, and Bichat was acquainted with two young subjects, on whom the operation had been performed four years, and they had had no relapse.

In young infants the operation almost constantly answered; but, in proportion as their age increased, it was found to be less certain. Bichat relates three cases, which tend to prove, that success may be completely obtained at the age of a year and a half; that the cure is difficult, when the child is four years old; and impossible, when it is nine. (See *Œuvres Chir. de Desault, par Bichat*, T. 2, p. 315, &c.)

Mr. Pott notices the plan of curing the exomphalos with the ligature, and expresses himself strongly against the practice in general. To adults the plan is not applicable, particularly when the tumour is large. Mr. Pott was decidedly in favour of compression, and he observes, that, in young subjects, and small herniæ, a bandage, worn a proper time, generally proves a perfect cure. (Vol. 2.)

Anxious that this work should be strictly impartial, I next proceed to relate what has been more recently urged against the employment of the ligature for the cure of the umbilical hernia in children.

The incessant care that a bandage requires, either to keep it clean or make it always keep up the proper degree of pressure, renders its employment difficult in the children of the poorer classes. Scarpa expresses his

opinion, that "this was what induced Desault to revive the operation for the umbilical hernia by the ligature, nearly such as is described by Celsus, an operation (continues Scarpa) which, a long while since, and for good reasons, was altogether abandoned. Celsus has sufficiently described the particulars of it: (*Lib. 7, Cap. 14.*) he states, that the tumour is sometimes to be simply tied, and that, in other instances, its base is to have a needle and double ligature introduced through it, in order that it may be embraced almost in the same way as a staphyloma is tied. But among the causes which contraindicate this operation, he mentions so many circumstances in relation to age, constitution, diseases of the skin, &c. that he seems to consider the cases in which it may be practised with success, as very few. The same reflections were made by several other ancient surgical writers, especially by Fabricius ab Aquapendente. Desault himself has put some restrictions to the employment of the ligature, since he observes, with his usual candour, that this method does not radically cure the umbilical hernia of children, arrived at the age of four years; that it is indispensable, as Celsus inculcates, to employ a needle and double ligature, when the base of the tumour is very large; and lastly, that even in the youngest children, a radical cure cannot be effected by the ligature, unless a methodical compression of the navel, by means of a bandage, be kept up immediately after the operation, and for two or three months. It is perhaps to the omission of this last means, that a relapse is to be ascribed in several of the children operated upon by Desault. "*Desault avoit remis en rigueur la ligature tombée en désuétude. Il s'abusait sur sa valeur; et il n'est pas difficile d'en connoître la cause. Tous les enfans qu'il opéroit à l'Hôtel-Dieu sortoient guéris et n'y revenoient plus: on regardoit alors comme radicale une guérison momentanée.*" (*Richerand, Nosographie Chir.* T. 2, p. 456.) I have carefully watched (says Scarpa) the immediate effects, and the more or less remote consequences of tying the umbilical hernia, either simply or by means of a needle and double ligature; and, after a considerable number of such cases, I believe I can assert, that this operation, however performed, is not always exempt from grave and sometimes dangerous accidents. I can also add, that it never procures a truly radical cure unless the cicatrix, occasioned by it in the umbilical region, be submitted for some months to a methodical and uninterrupted compression. It is not so uncommon, as some surgeons pretend, to see arise after the application of the ligature, a fever attended with symptoms of most violent irritation, and acute sufferings, which cause incessant crying, and sometimes convulsions. The ulcer, which is produced by the detachment of the swelling, is always very large and difficult to heal. Every now and then it becomes painful, and emits fungous granulations, even though dressed with dry applications.

"Latterly, it has been explained by a celebrated surgeon, (*Paletta Memor. del' Insti-*

tute, Tom. 2, Part 1.) that the umbilical vein and the suspensory ligament of the liver, being included in the ligature of the umbilical hernia, the inflammation which originates in these parts may, perhaps, in certain cases, be communicated to the liver, so as to put the child's life in great danger. When, in consequence of the ligature, symptoms of violent irritation come on, they are ordinarily attributed to certain individual circumstances, such as extreme sensibility, or a particular disposition to spasm. Hence, it is believed, that they should be considered as exceptions, which do not exclude the general rule, and prove nothing against the utility of the operation. But how (says Scarpa) can the surgeon ascertain the existence or nonexistence of these individual dispositions in the children upon which he is to operate? Assuredly those subjects, in which I have had occasion to notice the above accidents, enjoyed, before the operation, perfect health in every respect.

"Whatever process be adopted for tying the umbilical hernia, it is evident that the tumour can only be constricted as far as a little way on this side of the aponeurotic ring of the umbilicus, whence it follows that the integuments must always remain prominent and relaxed for a certain extent, at the front and circumference of this opening. Also, after the separation of the strangulated portion, there necessarily remains, under the cicatrix, a portion of the hernial sac, and of the loose integuments which covered it; and as the cicatrix itself never acquires sufficient firmness to resist the impulse of the viscera, which tend to insinuate themselves into the remains of the hernial sac, the hernia sooner or later reappears, and, in a short time, becomes larger than it was before the operation. If the subject is a little girl, it may be apprehended, that the first pregnancy will cause a recurrence of the hernia; for, it is known, that, during gestation, the external cicatrix of the umbilicus is considerably distended; and much disposed to give way."

Pott has seen terrible accidents caused by the rupture of the cicatrix at the navel, during pregnancy. (*Chirurg. Works*, Vol. 2, p. 169.) It is true that, according to this writer, this cicatrix was not the consequence of a hernia, but rather of an abscess in the umbilical region, which abscess had formerly been opened with a bistoury; yet, observes Scarpa, it would not be impossible to raise doubts upon this conjecture. Lastly, after the separation of the tumour, there always remains, between the aponeurotic ring of the navel and the integuments, a small cavity; formed by the neck of the hernial sac; a cavity into which the viscera begin to insinuate themselves after the operation, so as to hinder the complete contraction of the umbilical ring. The demonstration of what I have advanced is, in some measure, to be found in the old method of operating for the inguinal hernia, not in a strangulated state, by the ligature of the hernial sac and spermatic cord. Most of the herniæ, operated upon

by this barbarous process, were subject to relapses, because, in all probability, the cicatrix was not sufficiently firm to resist the impulse of the viscera, which entered the remains of the hernial sac. In the same manner, after the common operation for the strangulated inguinal hernia, although the cicatrix is formed very near the ring, there is no prudent surgeon who does not advise the patient to wear a bandage the rest of his life, observation having proved that the hernia is still liable to recur.

"The experience of several ages leaves no doubt, that compression alone is an extremely efficacious method of radically curing the umbilical hernia of young subjects. It is attended with no risk, and, provided it be executed with the requisite caution, it is hardly ever necessary to continue it longer than two or three months for the purpose of obtaining a complete cure. On the other side, if it be clearly proved, by all that I have been observing, that the ligature never accomplishes a perfect cure without compression, it is manifest, that it cannot be at all advantageous for the children of the poor, since a bandage cannot be dispensed with. It may be said, that in general it does not shorten the treatment; for, in the most successful cases, the ulcer caused by it is not healed in less than a month, and, in order to make the cure certain, an exact compression must afterward be kept up, by means of a bandage, two months longer. It has already been stated, that three months are ordinarily sufficient for obtaining a radical cure by the mere employment of a compressive bandage." (*Scarpa, Traité des Hernies*, p. 344—349.)

In the *Journal Général de Médecine*, T. 41. 1811, M. Girard has published a memoir on the umbilical hernia of children, which was read to the Medical Society of Lyons in May, 1811, and the object of which was to recommend compression as an effectual means of cure. The arguments used were very similar to those adduced by Scarpa. In the course of the discussion, M. Cartier affirmed, that he had seen many children operated upon by Desault, who were not cured of their herniæ.

The subject was afterward taken up by the Medical Society of Paris, and the result of the debate was, that the employment of the ligature ought to be rejected. 1. Because the cure of umbilical hernia is often accomplished by nature alone. 2. Because compression, either alone or aided by tonic remedies, always succeeds. 3. Because the operation of the ligature deserves the triple reproach of being painful, and not free from danger, if unfortunately a piece of intestine should chance to be included in the ligature; of not succeeding in general, except with the assistance of compression; and of being sometimes uselessly practised, as Desault himself gives us instances of. According to M. Cayol, the insufficiency of the ligature was long since acknowledged by Sabatier, Lassus, Richerand, &c.

UMBILICAL HERNIA IN ADULT SUBJECTS.

This case is to be treated on the principles common to all ruptures. When reducible, the parts should be kept up with a bandage or truss; which plan, however, in grown-up persons, affords no hope of a radical cure. Mr. Hey has described some very good trusses for the exomphalos, which are applicable to children, when compression is preferred, as well as to adult subjects. One was invented by the late Mr. Marrison, an ingenious mechanic at Leeds.

"It consists of two pieces of thin elastic steel, which surround the sides of the abdomen, and nearly meet behind. At their anterior extremity they form conjointly an oval ring, to one side of which is fastened a spring of steel of the form represented. At the end of this spring is placed the pad or bolster that presses upon the hernia. By the elasticity of this spring the hernia is repressed in every position of the body, and is thereby retained constantly within the abdomen. A piece of calico or jean is fastened to each side of the oval ring, having a continued loop at its edge, through which a piece of tape is put, that may be tied behind the body. This contrivance helps to preserve the instrument steady in its proper situation. (*Practical Obs. in Surgery*, p. 231.) And, in the second edition of the preceding work, another truss for the exomphalos is described, the invention of Mr. Eagland, of Leeds, but as some account is given of this instrument, with an engraving, in the 2d. vol. of the *First Lines of Surgery*, I shall not here repeat the description.

When the exomphalos is irreducible, and large, the tumour must be supported with bandages.

"It is observed by Scarpa, that the umbilical hernia, and those of the linea alba, are less subject to be strangulated than the inguinal and femoral hernia; but that, when they are unfortunately affected with strangulation, the symptoms are more intense, and gangrene comes on more rapidly, than in every other species of rupture. If the operation be performed, the event is frequently unfavourable, because it is generally done too late. This practical fact is proved by the experience of the most celebrated surgeons of every age. "*Il est certain (says Dionis) que de cette opération il en périt plus qu'il n'en réchappe.*" (*Cours d'Opérations*, p. 98, Ed. 1777, avec les notes de la Faye.) He also adds, that they who have the misfortune to be afflicted with an exomphalos, should rather dispense with their shirt than a bandage. Heister says nearly the same thing. (*Institut. Chirurg. T. 2, Cap. 94.*)

When the omentum alone is strangulated in the exomphalos, or hernia of the linea alba, observation proves, that the symptoms are not less intense, than when the intestine is also incarcerated. There is this difference, however, that when the omentum alone is strangulated, only nausea occurs, and, if vomiting should likewise take place, it is less frequent and violent than when the bowel

itself is strangulated. In the first case, the stools are hardly ever entirely suppressed. The proximity of the stomach is, no doubt, the reason why the strangulation of the omentum, in the umbilical hernia, occasions far more intense symptoms of sympathetic irritation than the strangulation of the same viscus in the inguinal or crural hernia.

Here the operation is not only always necessary, but urgently required. It is not materially different from that which is practised for the strangulated inguinal and crural hernia; but, in general, it demands greater circumspection, on account of the connexion or intimate adhesions, which frequently exist between the integuments and hernial sac, and also the adhesions which often prevail between the latter part and the omentum which it contains. The situation of the intestine, which is frequently covered by and enveloped in the omentum, is another circumstance deserving earnest attention. (*Scarpa, Traité des Hernies*, p. 361, 362.)

Mr. Pott is not such an advocate as Scarpa for the early performance of the operation in cases of exomphalos: "The umbilical, like the inguinal hernia, becomes the subject of chirurgic operation, when the parts are reducible by the hand only, and are so bound as to produce bad symptoms. But though I have in the inguinal and scrotal hernia advised the early use of the knife, I cannot press it so much in this; the success of it is very rare, and I should make it the last remedy. Indeed, I am much inclined to believe, that the bad symptoms which attend these cases are most frequently owing to disorders in the intestinal canal, and not so often to a stricture made on it at the navel, as is supposed. I do not say that the latter does not sometimes happen; it certainly does; but it is often believed to be the case when it is not.

"When the operation becomes necessary, it consists in dividing the skin and hernial sac, in such manner as shall set the intestine free from stricture, and enable the surgeon to return it into the abdomen. (*Pott on Ruptures.*)

The rest of the conduct of the surgeon is to be regulated by the usual principles.

The division of the stricture is properly recommended to be made directly upward, in the course of the linea alba.

In consequence of the great fatality of the usual operation for the exomphalos, I think the plan suggested, and successfully practised by Mr. A. Cooper in two instances, should always be adopted, whenever the tumour is large, and free from gangrene; a plan, that has also received the high sanction of that distinguished anatomist and surgeon, Professor Scarpa. (*Traité des Hernies*, p. 362.) Perhaps I might safely add, that, when the parts admit of being reduced, without laying open the sac, this method should always be preferred. It consists in making an incision just sufficient to divide the stricture, without opening the sac at all, or at all events, no more of it, than is inevitable.

In umbilical herniæ, of not a large size, Mr. C. recommends the following plan of operating: "As the opening into the abdomen is placed towards the upper part of the tumour, I began the incision a little below it, that is, at the middle of the swelling, and extended it to its lowest part. I then made a second incision at the upper part of the first, and at right angles with it, so that the double incision was in the form of the letter T, the top of which crossed the middle of the tumour. The integuments being thus divided, the angles of the incision were turned down, which exposed a considerable portion of the hernial sac. This being then carefully opened, the finger was passed below the intestines to the orifice of the sac at the umbilicus, and the probe-pointed bistoury being introduced upon it, I directed it into the opening at the navel, and divided the linea alba downwards, to the requisite degree, instead of upwards, as in the former operation. When the omentum and intestine are returned, the portion of integument and sac, which is left, falls over the opening at the umbilicus, covers it, and unites to its edge, and thus lessens the risk of the peritoneal inflammation, by more readily closing the wound." (*On Cruel and Umbilical Hernia.*)

LESS FREQUENT KINDS OF HERNIA.

The *ventral hernia*, described by Celsus, is not common; it may appear at almost any point of the anterior part of the belly, but is most frequently found between the recti muscles. The portion of intestine, &c. is always contained in a sac, made by the protrusion of the peritonæum. Mr. A. Cooper imputes the disease to the dilatation of the natural foramina for the transmission of vessels, to congenital deficiencies, lacerations, and wounds of the abdominal muscles, or their tendons. In small ventral herniæ, a second fascia is found beneath the superficial one; but, in large cases, the latter is the only one covering the sac.

Herniæ in the course of the linea alba sometimes occur so near the umbilicus, that they are liable to be mistaken for true umbilical ruptures. They may take place either above, or below the navel. The first case, however, is more frequent than the second, and the following is the reason of this circumstance according to the opinion of Scarpa. "The upper half of the linea alba, that which extends from the ensiform cartilage to the umbilicus, is naturally broader and weaker, than the lower half, the recti muscles coming nearer and nearer together, as they descend from the navel to the pubes. (*Scarpa, Traité des Hernies, p. 333.*)

The hernial sac of ruptures at the upper part of the linea alba may contain a noose of intestine, and a piece of the omentum, though in most cases, a portion of the latter membrane alone forms the contents. In some subjects, the linea alba is so disposed to give way, that several herniæ are obser-

ved to be formed successively in the interspace between the ensiform cartilage and the umbilicus.

"With respect to the small hernia (says Scarpa,) which is considered as formed by the stomach, and concerning which Hoin and Garengeot have written so much (without either of them having related, at least to my knowledge, a single example proved by dissection,) it is at least unproved, that it was exclusively formed by this viscus. I do not see, why the other viscera, particularly the omentum and transverse colon, might not also contribute to it. In my judgment, it only differs from other herniæ of the linea alba, in being situated on the left side of the ensiform cartilage, a situation that must materially influence the symptoms of the case. In fact, whatever may be the viscera, which form it, a sympathetic irritation of the stomach is occasioned, that is much more intense, than that which ordinarily accompanies umbilical herniæ, those of the lower part of the linea alba, or, in short, all other herniæ, which are more remote from the stomach." (*Op. cit. p. 334*)

The following are said to be the circumstances, by which the umbilical hernia, and that which occurs in the linea alba near the navel, may be discriminated.

The first, whether in the infant or the adult, has a roundish neck or pedicle, at the circumference of which the aponeurotic edge of the umbilical ring can be felt. Whatever may be its size, its body always retains nearly a spherical shape. Neither at its apex, or its sides, is any wrinkling of the skin, or any thing like the cicatrix of the navel, distinguishable. In some points of the surface of the tumour, the skin is merely somewhat paler and thinner, than elsewhere.

On the contrary, the hernia of the linea alba has a neck, or pedicle, of an oval form, like the fissure through which it is protruded. The body of the tumour is also constantly oval. If the finger be pressed deeply round its neck, the edges of the opening in the linea alba can be felt; and, if the hernia be situated very near the umbilical ring, the cicatrix of the navel may be observed upon one side of it, which cicatrix retains its rugosity, and all its natural appearance; a certain indication, that the viscera are not protruded through the umbilical ring. (*Scarpa, Traité des Hernies, p. 336.*)

The distinction which Scarpa has established between the umbilical herniæ, properly so called, and those of the linea alba, is not useless in regard to practice. Indeed, when the latter are left to themselves, they make much slower progress, than the former. On account of their smallness, they frequently escape notice, particularly in fat persons, and, when situated at the side of the ensiform cartilage. They occasion, however, complaints of the stomach, habitual colics, especially after meals; and, unfortunately for the patient, he may be tormented a very long time by these indispo-

sitions, before the true cause of them is discovered.

The umbilical hernia may be known, from the earliest period of its formation, by the alteration which it produces in the cicatrix of the navel, and the rapidity of its increase.

In other respects, these two kinds of hernia demand the same means of cure; but those of the linea alba, *cæteris paribus*, are more difficult to cure, than ruptures at the umbilicus. This is probably owing to the natural tendency, which the umbilical ring has to close, when the hernia is kept well reduced, whilst accidental openings in the linea alba have not the same advantage. (*Scarpa*, p. 340.)

When a common ventral hernia is reduced, it should be kept in its place by means of a bandage or truss. When strangulated, it admits, more frequently than most other cases, of being relieved by medical treatment. If attended with stricture, which cannot otherwise be relieved, that stricture must be carefully divided. Mr. A. Cooper recommends the valvular incision, and the dilatation to be made, either upward or downward, according to the relative situation of the tumour and epigastric artery, which crosses the lower part of the linea semilunaris.

Pudendal Hernia.—This is the name assigned by Mr. A. Cooper, to the hernia which descends between the vagina and ramus ischii, and forms an oblong tumour in the labium, traceable within the pelvis, as far as the os uteri. He thinks, that this case has sometimes been mistaken for a hernia of the foramen ovale. When reducible, a common female bandage, or the truss used for a prolapsus ani, should be worn. A pessary, unless very large, could not well keep the parts from descending, as the protrusion happens so far from the vagina. Mr. A. Cooper is of opinion, that, when strangulated, this hernia, in consequence of the yielding nature of the parts, may generally be reduced, by pressing them with gentle and regular force, against the inner side of the branch of the ischium. If not, the warm bath, bleeding, and tobacco clysters are advised. Were an operation indispensable, the incision should be made in the labium, the lower part of the sac carefully opened, and, with a concealed bistoury, directed by the finger, in the vagina, the stricture should be cut directly inward, towards the vagina. The bladder should be emptied, both before the manual attempts at reduction and the operation. (*On Crural Hernia*, &c. p. 64.)

Vaginal Hernia.—A tumour occurs within the os externum. It is elastic, but not painful. When compressed, it readily recedes, but is reproduced by coughing, or even without it when the pressure is removed. The inconveniences produced are an inability to undergo much exercise or exertion; for, every effort of this sort brings on a sense of bearing down. The vaginal hernia protrudes in the space, left between the uterus and rectum. This space is bounded below

by the peritonæum, which membrane is forced downwards towards the perinaum; but, being unable to protrude further in that direction, is pushed towards the back part of the vagina. In one case Mr. A. Cooper advised the use of a pessary, but the plan was neglected. Probably, these cases are always intestinal.

Some hernia protrude at the anterior part of the vagina. (*A. Cooper on Crural Hernia*, &c. p. 65, 66.)

Perineal Hernia.—In men, the parts protrude between the bladder and rectum; in women, between the rectum and vagina. The hernia does not project, so as to form an external tumour, and, in men, its existence can only be distinguished by examining in the rectum. In women, it may be detected both from this part, and the vagina.

In case of strangulation, perhaps, this hernia might be reduced by pressure from within the rectum. An interesting case of perineal hernia, which took place from the peritonæum being wounded with the gorget in lithotomy, is related by Mr. Bromfield; *Chirurgical Obs.* p. 264.

The reducible perineal hernia in women may be kept from descending, by means of a large pessary. Both this kind of rupture and the vaginal may prove very dangerous in cases of pregnancy. (See *Smellie's Midwifery*, Case 5.)

Thyroideal Hernia, or Hernia Foraminis Ovale. In the anterior and upper part of the obturator ligament, there is an opening, through which the obturator artery, vein, and nerve proceed, and through which, occasionally, a piece of omentum, or intestine is protruded, covered with a part of the peritonæum, which constitutes the hernial sac.

In the case which Mr. A. Cooper met with, the hernia descended above the obturators muscles. The os pubis was in front of the neck of the sac; three-fourths of it were surrounded by the obturator ligament; and the fundus of the sac lay beneath the pectineus and adductor brevis muscles. The obturator nerve and artery were situated behind the neck of the sac, a little towards its inner side. This species of hernia can only form an outward tumour, when very large. Garengeot, however, met with an instance, in which there was not only a swelling, but, one attended with symptoms of strangulation: he reduced the hernia, which went up with a gurgling noise; the symptoms were stopped, and stools soon followed.

The hernia of the foramen ovale, when reducible, must be kept up with a suitable truss; and if it were strangulated, and not capable of relief from the usual means, an operation would be requisite, though attended with difficulties. The division of the obturator ligament and mouth of the sac should be made inwards, to avoid the obturator artery. If this vessel, however, were to arise in common with the epigastric artery, it would be exposed to injury by fol-

lowing this plan. (See *Garengot in Mém. de l'Acad. de Chir.* T. 1; *A. Cooper on Cru-ral Hernia, &c.* p. 70; and *First Lines of Surgery*, Vol. 2, p. 80, &c.)

Cystocele.—As Mr. Pott observes, "The urinary bladder is also liable to be thrust forth from its proper situation, either through the opening in the oblique muscle, like the inguinal hernia, or under Poupart's ligament, in the same manner as the femoral.

"This is not a very frequent species of hernia, but does happen, and has as plain and determined a character, as any other.

"It has been mentioned by Bartholin, T. Dom. Sala, Platerus, Boæetus, Ruysch, Petit, Mery, Verdier, &c. In one of the histories given by the latter, the urachus, and imperious umbilical artery on the left side, were drawn through the tendon into the scrotum, with the bladder; in another he found four calculi.

"Ruysch gives an account of one complicated with a mortified bubonocele. Petit says, he felt several calculi in one, which were afterward discharged through the urethra. (See also *J. G. F. Jahn de insolita Calculi Ingentis per Scrotum exclusione*. Wittenberg, 1750.)

"Bartholin speaks of T. Dom. Sala as the first discoverer of the disease, and quotes a case from him, in which the patient had all the symptoms of a stone in his bladder; the stone could never be felt by the sound, but was found in the bladder (which had passed into the groin) after death.

"As the bladder is only covered in part by the peritonæum, and must insinuate itself between that membrane and the oblique muscle, in order to pass the opening in the tendon, it is plain that the hernia cystica can have no sac, and that when complicated with a bubonocele, that portion of the bladder which forms the cystic hernia must lie between the intestinal hernia and the spermatic cord, that is, the intestinal hernia must be anterior to the cystic.

"A cystic hernia may, indeed, be the cause of an intestinal one; for when so much of the bladder has passed the ring, as to drag in the upper and hinder part of it, the peritonæum which covers that part must follow, and by that means a sac be formed for the reception of a portion of gut or caul. Hence the different situation of the two herniæ in the same subject.

"While recent, this kind of hernia is easily reducible, and may, like the others, be kept within by a proper bandage; but when it is of any date, or has arrived to any considerable size, the urine cannot be discharged, without lifting up, and compressing the scrotum; the outer surface of the bladder is now become adherent to the cellular membrane, and the patient must be contented with a suspensory bag.

"In case of complication with a bubonocele, if the operation becomes necessary, great care must be taken not to open the bladder instead of the sac, to which it will always be found to be posterior. And it may also sometimes by the inattentive be

mistaken for a hydrocele, and by being treated as such, may be the occasion of great or even fatal mischief." (Vol. 2.)

The cystocele is always easily distinguishable by the regular diminution of the swelling, whenever the patient makes water.

Verdier and Sharp have accurately described the cystocele. Pott has offered two cases, which fell under his observation; Vol. 3. Pipelet le Jeune mentions a cystic hernia in perinæo, and several cases of its occurrence in the female; *Acad. de Chir.* T. 4. Pott cut into one cystocele, by mistake. Mention is made (*Edinb. Surg. Jour.* Vol. 4, p. 512.) of a cystic hernia, which protruded between the origins of the levator ani, and obturator internus muscles: the tumour made its appearance in the pudendum of an old woman. Much additional information respecting the cystocele, and its various forms, is contained in the second volume of the *First Lines of Surgery*, p. 49, &c., accompanied with references to all the most interesting writers on the subject. An instance of protrusion of the bladder through a wound, caused by a bullock's horn, is recorded by Larrey. (*Mém. de Chir. Mil. T.* 4, p. 289.)

Ischiatic Hernia.—This disease is very rare. A case, however, which was strangulated, and undiscovered till after death, is related in Mr. A. Cooper's second part of his work on hernia. It was communicated by Dr. Jones, so celebrated for his book on hemorrhage. The disease happened in a young man, aged 27. On opening the abdomen, the ileum was found to have descended on the right side of the rectum into the pelvis, and a fold of it was protruded into a small sac, which passed out of the pelvis at the ischiatic notch. The intestine was adherent to the sac at two points: the strangulated part, and about three inches on each side, were very black. The intestines towards the stomach were very much distended with air, and here and there, had a livid spot on them. A dark spot was even found on the stomach itself just above the pylorus. The colon was exceedingly contracted as far as its sigmoid flexure. A small orifice was found in the side of the pelvis, in front of, but a little above the sciatic nerve, and on the forepart of the pyriformis muscle. The sac lay under the glutæus maximus muscle, and its orifice was before the internal iliac artery, below the obturator artery, but above the vein. Mr. A. Cooper remarks, that a reducible case might be kept up with a spring truss, and that if an operation were requisite, the orifice of the sac should be dilated directly forwards. (*On Cru-ral Hernia, &c.* p. 73.) For a further account of the ischiatic hernia, and references to the most interesting works on the subject, see *First Lines of Surgery*, Vol. 2, p. 84, &c.

Phrenic Hernia.—The abdominal viscera are occasionally protruded through the diaphragm, either through some of the natural apertures in this muscle, or deficiencies, or wounds, and lacerations in it. The second kind of case is the most frequent: Morgagni

furnishes an instance of the first. Two cases, related by Dr. Macauley in *Med. Obs. and Inq. Vol. 1*, two more detailed in the *Medical Records and Researches*, and two others published by Mr. A. Cooper, are instances of the second sort: and another case has been lately recorded by the latter gentleman, affording an example of the third kind. A laceration of the diaphragm by fractured ribs, has produced a hernia. A case of this kind was dissected by Mr. Travers, at Guy's Hospital. (*Med. Chir. Trans. Vol. 6, p. 375.*) In this last volume, may also be found the particulars of an interesting example, in which a considerable part of the large curvature of the stomach was protruded through a fissure of the diaphragm. The accident was unattended with any fracture of the ribs, and was caused by the upsetting of a stage coach, on which the patient was an outside passenger. Before death, he vomited up a large quantity of blood, and a small semicircular aperture was discovered on dissection in the lower part of the strangulated portion of the stomach. (*P. 378, 379.*) See also B. Stehelin, *Tentamen Med. quod ventriculorum, qui in thoracem migraverat, &c. describit*, 1721; (*in Hallerii Disp. Anat. 6, 675.*) Hildanus, Paré, Petit, Schenck, &c. also mention cases of phrenic hernia. The disease is quite out of the reach of art.

Mesenteric Hernia.—If one of the layers of the mesentery be torn by a blow, while the other remains in its natural state, the intestines may insinuate themselves into the aperture, and form a kind of hernia. The same consequence may result from a natural deficiency in one of these layers. Mr. A. Cooper records a case, in which all the small intestines, except the duodenum, were thus circumstanced. The symptoms during life were unknown. (*On Crural Hernia, &c. p. 82.*)

Mesocolic Hernia.—So named by Mr. A. Cooper, when the bowels glide between the layers of the mesocolon. A specimen of this disease is preserved at St. Thomas's Hospital.

Every surgeon should be aware, that the intestines may be strangulated within the abdomen from the following causes: 1. Apertures in the omentum, mesentery, or mesocolon, through which the intestine protrudes. 2. Adhesions, leaving an aperture, in which a piece of intestine becomes confined. 3. Membranous bands at the mouths of hernial sacs, which becoming elongated, by the frequent protrusion and return of the viscera, surround the intestine, so as to strangle them within the abdomen, when returned from the sac. (See A. Cooper on *Crural Hernia, &c. p. 85.*)

Pott remarks, that "Ruysch gives an account of an impregnated uterus being found on the outside of the abdominal opening; and so do Hildanus and Sennertus. Ruysch also gives an account of an entire spleen having passed the tendon of the oblique muscle. And I have myself seen the ovaria removed by incision, after they had been some months in the groin." (*Vol. 2.*) More

particulars respecting all the less frequent kinds of hernia are given in the second volume of the *First Lines of Surgery*. Franco, *Traité des Hernies, &c. But, above all, the work, which I feel infinite pleasure in recommending, from a conviction of its superior merit, is a *Treatise on Hernia* by W. Lawrence, 8vo.; the first edition of which was published in 1807, and two more have appeared since that period, under the title of "*A Treatise on Ruptures*."

HERNIA CEREBRI (Fungus Cerebri. Encephalocele.) There are two principal kinds of hernia cerebri: one presents itself in young infants, before the ossification of the skull is completed; the other takes place after the destruction of a part of the skull by the operation of the trephine, accidental violence, or disease.

The congenital hernia cerebri of infants occurs, however, in two very different forms; in one it is covered by the scalp; in the other, the corresponding integuments of the head, and sometimes even the dura mater, are deficient.

The common encephalocele, met with in new-born children, seems to originate from the imperfect ossification of the skull, especially in the situation of the fontanella, and sutures. This case is characterized by a soft swelling, of an equal round shape, which is attended with a pulsation corresponding to that of the pulse; it yields and disappears under pressure, &c. &c. no alteration in the colour of the skin, and is circumscribed by the margin of the defective portion of the skull. (Ferrand, in *Mém. de l'Acad. de Chir.* T. 13, in 12mo. p. 102.) In general, the mental faculties are not affected; and we read of one example, in which a patient had such a hernia cerebri thirty-three years, without his intellects ever having been impaired during the whole of that period. (*Op. cit.* T. 5, in 4to. p. 863.)

It is tolerably well established, that the congenital hernia cerebri, which arises from

the incomplete ossification of the skull, and is covered by the scalp, ought to be treated by the application of constant, yet moderate pressure. M. Salleneuve communicated to the Royal Academy of Surgery in France an example of the good effects of this treatment, which reduces the size of the tumour, and accomplishes a perfect cure as soon as the ossification is completed. M. Salleneuve put a piece of thin sheet lead, properly covered with soft linen, under the child's cap, to which it was sewed in a suitable situation, and the degree of pressure was increased, or lessened, according as circumstances required, by tightening, or loosening the cap. (*Op. cit.* p. 103, T. 13, Edit. 12mo.)

The experience of Callisen also confirms, that hernia cerebri, when of moderate size, may be cured by the foregoing method, the aperture becoming gradually closed. But he adds, that large tumours of this description, especially when situated about the occiput, scarcely admit of any means of relief, except the employment of some contrivance to protect them from external injury. (*Callisen, System. Chir. Hodiernæ, Vol. 2, p. 513, 514 Ed. 1800*)

When the ossification of the sutures in children is late, the cerebellum, as well as the cerebrum, is liable to protrusion. In 1813, two such cases occurred at Paris. In one, Professor Lallement mistook the disease for a common tumour, and commenced an operation for its removal, when, after making some of the necessary incisions, his proceedings were stopped by his seeing the white silvery colour of the dura mater, and that the swelling came out of an aperture in the occipital bone. The day after the operation the child was seized with violent pain in the head, had a hard pulse, prostration of strength, vomiting, &c. and died in the course of a week. On dissection, a part of the tentorium, and an elongation of the two lobes of the cerebellum, about as large as a nut, were found in the protruded sac of the dura mater. Several abscesses were also discovered in the substance of the cerebellum. The other example fell under the observation of M. Balfos, principal surgeon to the Hôpital des Enfants. Upon the death of the child, the dissection evinced similar appearances. (*Richerand, Nosographie Chir. T. 2, p. 319, Ed. 4.*)

Such facts should teach the surgeon to be particularly cautious in ascertaining the nature of tumours about the back part of the head, before he ventures to attempt their removal.

The second kind of congenital encephalocele is that, in which not only large portions of the cranium, but also more or less of the integuments of the head, are deficient. It is rather to be regarded as a malformation than a disease, and, indeed, in most instances, the infants are still-born. The case sometimes consists of the protrusion of most of the brain through the inferior and posterior fontanella, so that the child is born with a largish bag, on the back of its head, hanging down over the posterior part of the

neck. Several specimens of these malformations, taken from infants born in the Hôpital de la Maternité, are preserved in the Museum of the Faculté de Médecine at Paris. (*Richerand, Nosogr. Chir. T. 2, p. 316, Ed. 4.*) In the year 1810, a remarkable case of this last description of congenital hernia cerebri was published by Dr. Barrows. "The whole of the forehead, summit, and a great part of the occiput, were deficient, and in lieu of them, a substance projected of a light mulberry colour, and of the mushroom form, except that it was proportionably broader. From the deficiency of bone, the eyes appeared to project much more than usual.—The child lived six days without either taking sustenance, or having any evacuation." On dissection, the scalp, the os frontis, the parietal, and a great part of the occipital bones, were wanting. Through the parts, at which these bones were deficient, the cerebrum projected, exhibiting its usual convolutions. It was covered with the pia mater; was of a mulberry colour; appeared to be more vascular than the pia mater usually is; and the edge of the scalp adhered to the neck of the tumour. The cerebellum was not more than one-fourth of its usual size; for, the posterior part of the os occipitis was much nearer to the sella turcica than natural. The child was destitute of the power of voluntary motion, and all the secretions appeared to be stopped. (*See Med. Chir. Trans. Vol. 2, p. 52.*)

The most interesting species of hernia cerebri to the practitioner, is that which sometimes arises after the removal of a portion of the skull by the trephine, or the destruction of part of it by disease. Various examples of this disease are recorded in the Memoirs of the French Academy of Surgery, and I have myself seen many instances of it. Although the case has attracted considerable notice, modern surgeons are far from entertaining settled opinions concerning the exact nature of the tumour.

In one example, recorded by Mr. Abernethy, the hernia cerebri arose on the tenth day after trephining, and was as large as a pigeon's egg. The pia mater, covering it, was inflamed; and a turbid serum was discharged at the sides of the swelling, from beneath the dura mater. On the eleventh day, the tumour was as large as a hen's egg, smooth and ready to burst. The man died the next day. On examination, the swelling was found still larger, and of a dark colour, with an irregular granulated surface. This appearance was owing to coagulated blood, which adhered to its surface, as the part bled so much, that the patient's cap was rendered quite stiff with blood. The pia mater was in general much inflamed, and, as well as the dura mater, was deficient at the place of the tumour. The deeper part of the swelling seemed to consist of fibrous coagulated blood, and it was found to originate about an inch below the surface of the brain.

Mr. Abernethy explains the formation of

the disease, as follows: "In consequence of the brain being injured to some depth beneath the surface, disease of the vessels, and consequent effusion of the blood, had ensued; the effusion was for a time restrained by the superincumbent brain and its membranes; but, these gradually yielding to the expansive force exerted from within, and at last giving way altogether, the fluid blood oozed out and congealed upon the surface of the tumour." An organized fungus can hardly be produced so rapidly as these tumours are formed. (*On Injuries of the Head, in Surgical Works, Vol. 2 p. 53.*)

On the contrary, Mr. C. Bell declares, that the swelling is vascular and organized. (*Operative Surgery, Vol. 1.*)

Dr. John Thomson also entertains a different opinion from that of Mr. Abernethy, respecting the mode in which these herniæ cerebri are formed; but I question whether he may not have confounded with the disease now under consideration, fungous tumours of the dura mater. At least, some of the cases to which he alludes, as a reason for his sentiment concerning their mode of formation, must have been the disease so well described by M. Louis. (See *Dura Mater.*) The reader, however, must judge for himself from the following passage: "In a considerable number of those who had the cranium severely contused, or fractured by musket-balls, (says Dr. Thomson) fungous growths took place through the openings, which had been made at first by the ball or afterward by the trepan. These growths, I am inclined to believe, are the consequence of a confusion of the substance of the brain and of the membranes that cover it, which gives rise to the formation of a new organized substance, different in its texture from brain, and are not, as some late writers would endeavour to persuade us, simply protrusions of the brain, resulting from the removal of the natural resistance, which is made to them by the dura mater and cranium. I have known instances of substances, similar to these growths, forming on the surface of the brain, immediately under the place, where the cranium had received a contusion, in cases in which the trepan had not been applied, or any portion of the cranium removed.

"Fungus of the brain, in the greater number of instances, in which we had an opportunity of observing it, was accompanied either with stupor or paralysis, and other symptoms of compressed brain. In a fracture of the vertex of the cranium, produced by a musket-ball, and followed by a fungus of the brain, the paralysis took place in the lower extremities. In a case of wound, made by a musket-ball on the right side of the forehead, and in which spiculæ of bone had been driven in upon the brain, a large fungus protruded. The formation of this fungus was followed by slow pulse, stupor, dilated pupils; slight strabismus, and distortion of the mouth. In the progress of this case, escharotics were applied to the fungus, portions of it were torn off by the patient, and all of it that was exterior to the cranium,

was twice pared off by the knife, with an apparent alleviation, rather than aggravation, of the symptoms. On the death of this patient, nearly the whole of the right hemisphere of the brain was found converted into a soft pulpy mass. The left hemisphere was not changed in structure, though much vascular turgescence appeared on its surface." (See *Dr. J. Thomson's Report of Observations made in the Military Hospitals in Belgium, p. 57, 58.*)

From the investigations of Mr. Stanley, the fact is placed beyond all doubt, that a part of the brain occasionally constitutes the substance of herniæ cerebri; and he thus confirms the opinion formerly entertained upon this point by Quesnay and Louis. Thus, in the first case which Mr. Stanley has recorded, "the whole tumour was sliced off with a scalpel. During the operation, the boy gave no manifestation of positive pain, although not unconscious of what we were doing. Considerable hemorrhage took place from the surface of the brain, exposed by the removal of the tumour, the blood being thrown with great force, and to a considerable distance from numerous vessels, which were attempted to be secured, but ineffectually, by ligatures. After a short time, however, the bleeding ceased. On examination of the part, which had been cut off, its exterior was found to consist merely of a layer of the coagulated blood; the rest of the mass was brain, possessing a natural appearance, the distinction between the cortical and medullary matter being readily seen, with the convolutions and pia mater dipping down between them." In the dissection, after death, "all that part of the dura mater, adjacent to the ulcerated aperture, through which the brain had protruded, was black, sloughy, and much thickened. The exposed surface of the brain, from which the portion had been cut off, exhibited a softened and broken down texture, a state of disorganization, which extended deep into its substance. About an ounce of fetid and dark-coloured fluid was found between the dura mater and arachnoid membrane. Several small effusions of blood were met with, both between the membranes and in the substance of the brain. The arachnoid membrane was thickened and opaque over each hemisphere. The vessels on the surface, and in the substance of the brain, were remarkably free from blood. The lateral ventricles were large, and filled with transparent fluid, and there was some found between the membranes at the basis, so that, altogether the quantity from these two sources was very considerable." (See *Med. Chir. Trans. Vol. 8, p. 15—17.*) In another dissection, a considerable quantity of pus was found on the arachnoid membrane, on each side of the falx. (P. 27.) In most of the cases of hernia cerebri, which I have seen, the patient was at first more or less sensible, but labouring under considerable nervous agitation. The stupor, paralysis, and other symptoms of compressed brain, noticed by Dr. J. Thomson, did not take place, till the latter stage

of the disease, and then convulsive twitches of the muscles and strabismus occasionally came on. (See *Med. Chir. Trans.* p. 26.) The disease is usually attended with great frequency of the pulse.

With regard to the cause of the protrusion, it is a subject very difficult of explanation, because, if the origin of the tumour depended simply on the removal of a portion of the skull, or on any changes of the dimensions of the brain in expiration, the effect would always follow such causes, and prevail in all patients. From the particulars of the dissections, performed by Mr. Abernethy and Mr. Stanley, and those referred to by Dr. Thomson, it is clear, that the hernia cerebri is a disease connected with deep-seated changes throughout a great part of the brain. (See also *Larrey, Mem. de Chir. Mal. T. 4, p. 206.*) The substance of this organ is found more or less pulpy and disorganized; and, after death, large effusions of serum, and even sometimes of blood, and purulent matter, are observed. These appearances leave no doubt of the disease being associated with inflammatory action within the head. It is highly probable, therefore, that a hernia cerebri is only produced when these deep-seated changes are conjoined with the removal of bone. The changes alluded to, may be supposed to cause an increase in the general contents of the skull, and thus a disposition to protusion, as rapid as the serum and other fluids are effused. This statement, however, can only be received as an hypothesis, because we find, that in one of the dissections, described by Mr. Stanley, "there existed a considerable space between the upper surface of the right hemisphere, all around the situation of the protrusion and the internal surface of the dura mater, while in every other part, the brain and dura mater were in close contact." (See *Med. Chir. Trans.* Vol. 8, p. 27.) Now, the idea of an empty space within the cranium is rather inconsistent with the supposition, that the brain is thrust out, in consequence of changes, which augment the quantity of the general contents of the skull, unless such space were filled with air, that had no external communication.

When the bad symptoms disappear, on the tumour being no longer confined by the dura mater, some practitioners deem it best to interfere as little as possible, and let the tumour drop off in pieces. (See *Edinb. Med. Comment.* Vol. 1, p. 98. *Med. Museum*, Vol. 4, p. 463.) The mildest dressings are to be employed; but whether the protrusion should be resisted by pressure, or not, seems unsettled.

When the tumour acquires a very great size it may be pared off with a knife, as was done by Mr. Hill, in several instances with success. (*Cases in Surgery*, 8vo. *Edinb.* 1772.)

In one of the cases, published by Mr. Stanley, the patient, a boy about eleven years of age, recovered after the upper part of the tumour had been pared off, and some of the removed substance found to consist decidedly both of cortical and medullary substance. In this instance, the reproduction

of the tumour was checked by firm pressure with graduated compresses, and a bandage. The protruded brain gradually lost its natural colour; it acquired a light yellow appearance, was split into several portions, and a very fetid odour exhaled from it. Its substance daily became softer, ultimately acquiring almost a semi-fluid state, and in this condition the whole mass gradually wasted away. *Fresh granulations arose to fill up the vacancy, and they were manifestly produced from the exposed substance of the brain.* Compression being continued, the part now quickly healed up. (See *Med. Chir. Trans.* p. 20, 21.) In a third case, the part of the tumour cut off, consisted entirely of cortical and medullary substance, quite healthy in its appearance (p. 24;) and subsequently granulations were formed from the exposed surface of the brain. The case, however, had a fatal termination. By the removal of the swelling, and the use of compression, one cure was effected by Mr. Fring. (See *Edinb. Med. and Surgical Journ.* Vol. 9.)

Richerand affirms, indeed, generally, that when the brain is exposed, in consequence of an injury of the head, the encephalocele should be cut down with a knife, and repressed by gentle compression. (See *Nosogr. Chir. T. 2, p. 318, Ed. 4.*)

The cases published by Mr. Stanley are rather favourable to the employment of pressure, inasmuch as it appeared evidently to check the protrusion, and was mostly borne without inconvenience.

The idea, however, that when the brain protrudes through the dura mater, pressure can effect its return, is, as Mr. Stanley judiciously observes, quite untenable. (*Med. Chir. Trans.* Vol. 8, p. 36.)

Quesnay mentions an instance, in which a patient tore off the protruded mass himself, and the cavity healed up. (*Mém. de l'Acad. de Chir. T. 1.*) Van Swieten relates a case, in which the swelling was repeatedly removed with a ligature, and a cure ensued. (*Comment. T. 1, p. 440.*) The danger of applying styptics, and irritating applications, is shown by Hildanus, *Obs.* 14, and Mr. Hill, p. 198.

Baron Larrey considers the treatment by excision, pressure, and spirituous applications, hurtful and dangerous: his advice is merely to apply to the swelling a pledget of slightly camphorated oil of camomile; to have recourse to cooling aperient beverages; to remove all kinds of irritation; to exclude the air; and apply the dressings with great gentleness. By these means, the only case which Larrey ever saw recover, was saved, and in it the tumour was small. (*Mém. de Chir. Mil. T. 4, p. 206.*)

One would suppose, that cases of this kind must generally require the employment of every thing at all likely to keep off, and diminish inflammation of the brain. *Quesnay, sur la Multiplicité des Trépan, in Mém. de l'Acad. Royale de Chirurgie, T. 2, p. 25, 56, Ed. in 12mo. M. Corvin's Dissert. in Haller's Disputat. Chir. Vol. 2. Mémoire sur l'Encephalocele par M. Ferrand, in Mém. de l'Acad. de Chir. HERNIA HUMORALIS. (*Swelled or inflamed Testicle.*) A very common symptom, attending a gonorrhœa, is a swelling of the testicle, which is only sympathetic, and not venereal, because the same symptoms follow every kind of irritation of the urethra, whether produced by strictures, injections, or bougies. Such symptoms are not similar to the actions arising from the application of venereal matter; for suppuration seldom occurs, and when it does, the matter is venereal. The swelling and inflammation appear suddenly, and as suddenly disappear, or go from one testicle to the other. The epididymis remains swelled, however, even for a considerable time afterward.

The first appearance of swelling is generally a soft pulpy fulness of the body of the testicle, which is tender to the touch; this increases to a hard swelling, accompanied with considerable pain. The epididymis, towards the lower end of the testicle, is generally the hardest part. The hardness and swelling, however, often pervade the whole of the epididymis. The spermatic cord, and especially the vas deferens, are often thickened and sore to the touch. The spermatic veins sometimes become varicose. A pain in the loins, and sense of weakness there, and in the pelvis, are other casual symptoms. Colicky pains; uneasiness in the stomach and bowels; flatulence; sickness; and even vomiting; are not unfrequent. The whole testicle is swelled, and not merely the epididymis, as has been asserted.

The inflammation of the part most probably arises from its sympathizing with the urethra. The swelling of the testicle coming on, either removes the pain in making water, and suspends the discharge, which do not return, till such swelling begins to subside; or else the irritation in the urethra, first ceasing, produces a swelling of the testicle, which continues till the pain and discharge return; thus rendering it doubtful, which is the cause, and which the effect. Occasionally, however, the discharge has become more violent, though the testicle has swelled; and such swelling has even been known to

occur after the discharge has ceased; yet, the latter has returned with violence, and remained as long as the hernia humoralis. (*J. Hunter.*)

Irritation at the mouth of the vasa deferentia, has been mentioned as a cause; but were this true, both testicles would usually be affected at the same time, and the complaint would occur more frequently, when the irritation of the urethra extends far towards the bladder, than when it only reaches about an inch and a half, or two inches from the orifice of the passage.

Hernia humoralis, with stoppage of the discharge, is apt to be attended with stranguary. It is singular, that the inflammation should more frequently come on when the irritation in the urethra is going off, than when it is at its height.

The enlargements of the testicle, from cancer and scrofula, are generally slow in their progress; that of a hernia humoralis very quick. (*J. Hunter.*)

Rest is the best remedy, and the horizontal position of the body is easiest. At all events, the testicle must be well suspended; to which expedient the patient will readily have recourse as soon as he knows the ease which it affords. The case is treated as inflammation in general, by bleeding and purging, and applying fomentations and poultices. In the hernia humoralis from gonorrhœa, however, cold applications are sometimes preferred. (*James on Inflammation*, p. 164.) Leeches have often proved serviceable. The swelling not being venereal, mercury is only useful in removing the induration, after the inflammation has subsided. Vomits have been recommended, and found beneficial. They have even been known to cure the complaint in a surprisingly sudden manner. Opiates are useful. When suppuration occurs, no mercury is requisite, only common treatment.

As the hernia humoralis often appears to depend on the cessation of the discharge, some (*Bromfield*) have advised irritating the urethra with bougies to bring on the gonorrhœa again; but the practice is not followed by the expected good. The introduction of venereal matter into the urethra has also been most absurdly suggested.

A hernia humoralis is at first very quick in subsiding; but some of the swelling remains a long while, and the hardness of the epididymis may even continue for years, nay, for life. However, no inconvenience attends the mere induration. In such instances, the vas deferens may occasionally be rendered impervious, though the occurrence must be by no means frequent.

Frictions with camphorated mercurial ointment; fumigations with aromatic herbs; and electricity; are the best means for dispersing the induration in question. (*J. Hunter.*)

The signs distinguishing a hernia humoralis from a scrotal rupture, are explained in the article *Hernia*.

I once had under my care a patient with hernia humoralis, whose symptoms were se-

were in an extraordinary degree, and strongly resembled those of a strangulated hernia, being attended with much sickness, and obstinate constipation. A swelling of the testis, accompanied with all the symptoms of strangulated hernia, is recorded by Guin-court. (See *Journ. de Méd. par Corvisart*, T. 16.)

Although I had never seen hernia humoralis attended with symptoms so much resembling those of strangulated rupture, as in the case which fell under my own notice, and the patient would not own that he had had any gonorrhœa, yet I remarked some circumstances, which made me avoid an erroneous judgment. In the first place, I could discover no protrusion from the abdominal ring. Secondly; I observed that there was no tension, nor swelling of the belly, as in common cases of strangulated ruptures. Thirdly, I remarked, that the inflammation of the scrotum did not increase as the symptoms advanced, as it usually does in the latter disease. Fourthly; I took notice that the pain in the belly was most severe under the false ribs on the right side, though at periods it was certainly very diffused; but it was never augmented by pressure, as always happens in strangulated hernia, peritonitis, enteritis, &c. from all which disorders too, the absence of tension seemed to distinguish it. Sometimes likewise, the pain was entirely in the tumour; sometimes altogether in the abdomen.

HERPES. (from *ἡρπαιω*, to creep.)

Nothing could be more confused, and undefined, than the idea conveyed by the term *herpes*, as generally employed by medical men before the last few years. In fact, numerous cutaneous diseases, of the most opposite kinds, but which had a tendency to creep, or spread slowly, were designated, as specimens of herpes. Thus, when I first entered the profession, it was common for some of the most eminent surgeons in London frequently to call *noli me tangere*, or *lupus*, herpes of the nose; and to apply the same term to *tinea capitis*, or the *porrigo favosa*.

Happily, this vague mode of regarding diseases of the skin is beginning to give way to the judicious distinctions proposed by the late Dr. Willan, and so ably perfected by Dr. Bateman. The appellation, *herpes*, is limited by these physicians "to a vesicular disease, which, in most of its forms, passes through a regular course of increase, maturation, and decline, and terminates in about ten, twelve, or fourteen days. The vesicles arise in distinct, but irregular clusters, which commonly appear in quick succession, and they are set near together, upon an inflamed base, which extends a little way beyond the margin of each cluster. The eruption is preceded, when it is extensive, by considerable constitutional disorder, and is accompanied with a sensation of heat and tingling, sometimes with severe deep-seated pain in the parts affected. The lymph of the vesicles, which is at first clear and colourless, becomes gradually milky and opaque, and ultimately concretes into

scabs: but in some cases, a copious discharge of it takes place, and tedious ulcerations ensue. The disorder is not contagious in any of its forms." (See *Bateman's Practical Synopsis of Cutaneous Diseases*, p. 221, 222, Edit. 3.) This author notices six species of the complaint: viz. herpes phlyctænodes; herpes zoster; herpes circinatus; herpes labialis; herpes præputialis; and herpes iris.

As most of these cases more properly belong to the physician, than surgeon, I shall briefly describe three of them.

According to Dr. Bateman, the *Herpes Zoster*, or *shingles*, is mostly preceded for two or three days, by languor, and loss of appetite, rigours, headach, sickness, and a frequent pulse, together with a scalding heat, and tingling in the skin, and shooting pains through the chest and epigastrium. Sometimes, however, the precursory febrile symptoms are very slight. Upon some part of the trunk, several red patches occur, of an irregular form, at a little distance from each other, upon each of which, numerous small elevations appear clustered together. These, if examined minutely, are found to be distinctly vesicular, and in the course of twenty-four hours, they enlarge to the size of small pearls, and are perfectly transparent, being filled with a limpid fluid. For three or four days, fresh clusters continue to arise, always extending themselves nearly in a line with the first, towards the spine at one end, and towards the linea alba at the other. While the new clusters are appearing, the vesicles of the first lose their transparency, and, on the fourth day, acquire a milky, or yellowish hue, which is soon followed by a bluish, or livid colour, of the bases of the vesicles, and of the contained fluid. They now become somewhat confluent, and flatten, or subside. About this time, they frequently break, and discharge for three or four days, a serous fluid, which, at length, concretes into thin dark scabs. These fall off about the twelfth or fourteenth day, leaving the surface of the subjacent skin in a red and tender state; and when the ulceration and discharge have been considerable, numerous cicatrices, or pits, are left. All the clusters go through a similar series of changes.

Young persons, from the age of twelve to twenty-five, are most frequently affected; although aged persons are not altogether exempt from the complaint, and suffer severely from the pain of it. Summer and autumn are the seasons, in which it is most common. Sometimes it supervenes to bowel complaints, and the chronic pains remaining after acute pulmonary diseases. In the treatment, Dr. Bateman thinks gentle laxatives, and diaphoretics, with occasional anodynes, when the severe deep-seated pains occur, all that is necessary. No external application is requisite, unless the vesicles be abraded by the friction of the clothes, which are then liable to adhere to the parts: in this case, a little simple ointment may be interposed. For a fuller account, see *Bateman's Pract. Synopsis*, p. 226, &c.

Herpes circinatus, or ringworm, makes its appearance in small circular patches, in which the vesicles arise only round the circumference: these are small, with moderately red bases, and contain a transparent fluid, which is discharged in three or four days, when little prominent dark scabs form over them. The central area, in each vesicular ring, is at first free from any eruption; but the surface becomes somewhat rough, and of a dull red colour, and throws off an exfoliation, as the vesicular eruption declines, which terminates in about a week, with a falling off of the scabs. A succession of these vesicular circles usually arise on the face and neck, or arms and shoulders, thus protracting the case for two or three weeks.

The itching and tingling, which are the only inconveniences of the affection, may be relieved by the application of the popular remedy ink, solutions of the salts of iron, copper, zinc, borax, alum, &c. Some additional interesting observations on other forms of the herpes circinatus, may be found in Dr. Bateman's Synopsis, from which I have extracted the few preceding particulars.

Herpes Præputialis. This local variety of herpes was not noticed by Dr. Willan, and we are indebted to Dr. Bateman for a description of it. The complaint begins with extreme itching, and with some sense of heat in the prepuce, on which one or two red patches occur, about the size of a silver penny. Upon these are clustered five or six minute transparent vesicles. In twenty-four or thirty hours, the vesicles enlarge, become of a milky hue, and lose their transparency; and on the third day, they are coherent, and have almost a pustular appearance. If the eruption is seated on that surface of the prepuce, which is next the glans, so that the vesicles are kept moist, they commonly break about the fourth or fifth day, and form a small ulceration upon each patch. This discharges a little turbid serum, and has a white base, with a slight elevation at the edges; and by an inaccurate, or inexperienced observer, it may be readily mistaken for chancre, more especially, if any escharotic has been applied, which produces irritation, and a deep-seated hardness, like that of a true chancre. If not irritated, the slight ulceration begins to heal about the ninth or tenth day. When the patches occur on the outside of the prepuce, the duration of the eruption is shorter, and ulceration does not actually take place.

In the treatment, Dr. Bateman recommends the avoidance of all stimulating, and moist, or unctuous applications; and if the complaint be within the prepuce, he advises the interposition of a little bit of dry lint between the sore and the glans.

As this gentleman has truly remarked, this case is particularly deserving of notice, because it has often been considered and treated as a chancre.

For a great deal more valuable information respecting Herpes, I beg leave to refer the reader to the publications of Drs. Willan and Bateman, and also to the article *Herpes*,

written by this last able physician for Dr. Rees's Cyclopædia.

HORDEOLUM. (dim of *hordeum*, barley.) A little tumour on the eyelid, resembling a barley corn. *A Stye.* As Scarpa remarks, the stye is strictly only a little boil which projects from the edge of the eyelids, particularly often near the great angle of the eye. This little tumour, like the furunculus, is of a dark-red colour, much inflamed, and a great deal more painful than might be expected, considering its small size. The latter circumstance is partly owing to the vehemence of the inflammation producing the stye, and partly to the exquisite sensibility and tension of the skin which covers the edge of the eyelids. On this account, the hordeolum very often excites fever and restlessness in delicate, irritable constitutions; it suppurates slowly and imperfectly; and, when suppurated, has no tendency to burst.

The stye, like other furunculous inflammations, forms an exception to the general rule, that the best mode, in which inflammatory swellings can end, is resolution. For, whenever a furunculous inflammation extends so deeply as to destroy any of the cellular substance, the little tumour can never be resolved, or only imperfectly so. This event, indeed, would rather be hurtful, since there would still remain behind a greater or smaller portion of dead cellular membrane; which, sooner or later, might bring on a renewal of the stye in the same place as before, or else become converted into a hard indolent body, deforming the edge of the eyelid.

The resolution of the incipient hordeolum may be effected in that stage of it, in which the inflammation only interests the skin, and not the cellular substance underneath, as is the case on the first appearance of the disease. Now repellent, cold applications are useful, particularly ice. But when the hordeolum has affected and destroyed any of the cellular membrane underneath, every topical repellent application is absolutely useless, and even hurtful; and the patient should have recourse to emollient anodyne remedies. The hordeolum and eyelids should be covered with a warm soft bread and milk poultice, which ought to be renewed very often. When a white point makes its appearance on the apex of the little tumour, Scarpa says, the surgeon should not be in a hurry to let out the small quantity of serous matter which exists between the skin and dead portion of cellular membrane. It is better that he should wait till the skin within this white point has become still somewhat thinner, so as to burst of itself, and give a ready vent, not merely to the little serous matter, but to all the dead cellular membrane which constitutes the chief part of the disease. When the contents of the little tumour are slow in making their way outward, through the opening, the surgeon, gently compressing the base of the stye, ought to force them out. After this, all the symptoms of the disease will disappear, and the cavity, left by the dead cellular membrane, in the centre of the little tumour, will

be found quite filled up and healed in the course of twenty-four hours.

Sometimes, though seldom, this process of nature, destined to detach the dead from the living cellular membrane, only takes place incompletely, and a small fragment of yellow dead cellular substance still continues fixed in the cavity, and hinders the cure. In this circumstance, the further employment of emollient poultices is of little or no service. The surgeon should dip the point of a camel-hair pencil in sulphuric acid, and touch the inside of the sty with it, one or more times, until the sloughy cellular membrane comes away. After this, the small cavity remaining will soon close. Should the eyelid continue afterward a little swollen and œdematous, this affection may be removed by applying the *lotio plumbi. acet.*, containing a little spirit of wine. Some persons are very often annoyed with this disease. Scarpa imputes this most frequently to a disordered state of the *primæ viæ*, often met with in persons who live on acrid irritating food, and drink too much spirits.* (*Scarpa, sulle Malattie degli Occhi, cap. 2.*)

HOSPITAL GANGRENE. (*Phagedæna Gangrænosa; Putrid, or Malignant Ulcer; Hospital Sore; Gangræna Contagiosa.*) A severe and peculiar species of humid gangrene, or rather a combination of this affection, with phagedenic ulceration. It is particularly characterized by its contagious or infectious nature; its disposition to attack wounds or ulcers, in crowded hospitals, or other situations, where many of these cases are brought together; and its tendency to convert the soft parts affected into a putrid glutinous, or pulpy substance, in which no trace of their original texture is discernible. (*Delpech, Précis Elém. des Mal. Chir. T. 1, p. 123.*) It is generally believed to be communicated from one sore or wound to another, by its contagious nature; but whether the infection can be transferred only by actual contact, or both in this way and through the medium of the atmosphere, is a question on which the best authors differ. The first origin of the disease, however, is a mysterious subject, which cannot invariably be explained on any certain principles, as will be hereafter noticed.

From the researches of Mr. Blackadder, it appears probable, that several of the ancient writers, in their descriptions of foul, gangrenous bleeding ulcers, must have alluded to the same kind of disease, which is now usually denominated hospital gangrene. Besides the use of the actual cautery, which, according to the modern French writers, is the surest means of arresting this distemper, several of the ancients appear also to have em-

ployed for the cure arsenical applications; as, for instance, *Ætius, Paulus, Rolandus, Avicenna, Guido, &c.* The only doubt whether these authors actually referred to hospital gangrene, depends upon their not having generally described its contagious nature. But, on this point, I would particularly wish the reader to consult Mr. Blackadder's valuable treatise. (*P. 76, &c.*)

Although La Motte made cursory mention of hospital gangrene in 1722, under the name of *pourriture*, and stated, that it had occurred in the Hôtel-Dieu at Paris, yet the first distinct modern account of this disease is contained in the 3d vol. of the posthumous works of Pouteau, published in 1783. In the year 1788, Dusassoy, who succeeded Pouteau as chief surgeon of the Hôtel-Dieu at Lyons, also published a short treatise on the disorder. The first very accurate description of hospital gangrene, in the English language, appeared in the 6th vol. of the London Medical Journal, printed in 1785. The account is entitled "Observations on the Putrid Ulcer, by Mr. Gillespie, surgeon of the Royal Navy." In the edition of Dr. Rollo's work on Diabetes, published 1797, there is a section on this subject, entitled, "A short account of a morbid poison, acting on sores, and of the method of destroying it." In 1799, Sir Gilbert Blane, in the 3d edit. of his book on the diseases of Seamen, gave an account of hospital gangrene, under the name of malignant ulcer; and Dr. Trotter, in the 2d vol. of his *Medicina Nautica*, published in the same year, described that affection by the same appellation. In the 3d vol. of the same work, Dr. Trotter has added to his first account several valuable communications, relating to this disease, received from surgeons of the Royal Navy. Mr. John Bell has also made hospital gangrene the subject of particular remark, in the 1st vol. of his *Principles of Surgery*, published in 1801. According to Dr. Thomson, two excellent theses have likewise been published on the subject in the University of Edinburgh; the first entitled "*De Gangrænâ Contagiosâ*," by Dr. Leslie in 1804; the second by Dr. Charles Johnson, in 1805, under the title of "*De Gangrænâ Contagiosâ Nosocomiale*." (*See Lectures on Inflammation, p. 456—458.*)

Professor Thomson's account of the subject, published in 1813, contained the fullest history of the disease at that time collected. Boyer afterward gave a very fair account of the distemper. (*See Traité des Mal. Chir. T. 1, p. 320, 8vo. Paris, 1814.*)

These descriptions were followed by the valuable essay of Delpech, entitled "*Mémoire sur la Complication des Plaies et des Ulcères connue sous le nom de Pourriture d'Hôpital*;" 1815; some interesting observations by Dr. Hennen, in the London Medical Repository for March, 1815; a paper by Professor Brugman, of Leyden, "in the *Annales de Littérature Méd.*" vol. 19, 1815; and lastly, the treatise of Mr. Blackadder, which contains some of the best remarks ever made concerning this affection, and is

* I have very often found an *alum card*, applied over night in the form of poultice, of great benefit in this disease. When made use of just after suppuration has commenced, the tumour discharges in a few hours, and the patient is freed from a very troublesome and painful companion. It is prepared by putting a piece of alum, about the size of a pea, into a table spoonful of new milk. This, by the flame of a candle, is soon conglutinated, and rendered of a consistence fit to be made use of as a cataplasm.—[*Am. Ed.*]

entitled "Observations on Phagedæna Gangrænosa, 8vo. Edinb. 1818."

According to Mr. Blackadder, who is a believer in the doctrine of the complaint being only communicable by the direct application of the infectious matter, when the morbid matter, which produces the disease, has been applied to some part of the surface of the body, from which the cuticle has been removed, as by a blister, one or more small vesicles first appear, which are filled with a watery fluid, or bloody serum of a livid or reddish brown colour. The situation of the vesicle is generally at the edge of the sore. Its size is not unfrequently that of a split garden pea, and is easily ruptured, the pellicle which covers it being very thin. When the vesicle is filled with a watery fluid, and has not been ruptured, it assumes the appearance of a grayish-white or ash-coloured slough; but, when it contains a dark-coloured fluid, or has been ruptured, it puts on the appearance of a thin coagulum of blood, of a dirty, brownish, black colour. During the formation of the vesicle, there is generally a change in the sensation of the sore, accompanied with a painful feel, like that of the sting of a gnat.

After a slough is formed, it spreads with more or less rapidity, until it occupies the whole surface of the original sore; and, when left to itself, (which seldom happens) there is little or no discharge, but the slough acquires daily greater thickness.

"When the formation of the slough has been interrupted, the stinging sensation becomes more frequent and acute; phagedænic ulceration quickly commences; and such is frequently the rapidity of its progress, that even in the course of a few hours, a very considerable excavation will be formed, while the parts in the vicinity retain their usual healthy appearance." The cavity, the edges of which are well defined, is filled with a thick glutinous matter, which adheres strongly to the subjacent parts. When this matter is removed, the surface underneath presents itself of a fine granular texture, which, in almost all instances, is possessed of extreme sensibility, and is very apt to bleed when the operation of cleaning is not performed with great delicacy. At each dressing, the circumference of the cavity is found enlarged, and if there are more than one, they generally run into each other. The progress of the disease is much quicker in some individuals than others, but it never ceases, until the whole surface of the original sore is occupied. The stinging pain gradually becomes of a darting or lancinating kind; and either about the fourth or sixth day from the time when the morbid matter had access to the sore, or afterward, at the period of what may be termed secondary inflammation, the lymphatic vessels and glands are apt to become affected. The discharge becomes more copious, its colour varying from a dirty yellowish white to a mixture of yellow, black, and brown, depending upon the quantity of blood mixed with it.

"The soft parts, in the immediate vicinity

of the sore, daily become more painful, tumefied, and indurated; and, in a great number of cases, particularly in those of plethoric and irritable habits, an attack of acute inflammation speedily supervenes, and is accompanied by a great increase of pain, the sensation being described to be such as if the sore were burning. The period at which this inflammation begins to subside, is by no means regular. Sometimes it subsides in the course of two days, and sometimes it continues upwards of five; depending very much on the constitution and previous habits of the patient, as well as the treatment that has been adopted. During its progress, the thick, putrid looking, and frequently spongy slough which is formed on the sore, becomes more and more moist, and of a pulpy consistence. (Hence this form of disease is actually named by Gerson *pulpy gangrene*.) In the course of a few days, a very offensive matter begins to be discharged at its edges. The slough then begins to separate; by and by it is thrown off, but only to prepare the way for an extension of the disease by a continued process of ulceration, and by a recurrence of the last-mentioned symptoms. (*Blackadder, on Phagedæna Gangrænosa, p. 28—30.*)

The first symptoms, which indicate hospital gangrene in a wound, or ulcer, are, a more or less acute pain, and a viscid whitish exudation on the surface of the granulations, which lose their vermilion colour, and present at several points spots of a grayish or dirty-white hue, resembling venereal ulcers, or aphthæ. These ulcerated points, thus engrafted (as it were) upon the original ulcer, soon spread, and join together, so as to give to the whole surface of the solution of continuity a gray ash-colour. The surface also becomes more or less indurated, and sometimes bleeds. A red, purplish œdematous circle, of a greater, or lesser extent, is next formed in the surrounding skin. Sometimes, when the patient is of a good habit, the causes of infection less active, and the constitution sufficiently strong, the disorder now stops. According to Boyer, it may not even extend to the whole surface of the ulcer. But, most frequently, its progress is extremely rapid, and occasionally quite terrifying. The edges of the wound, or ulcer, become hardened and everted, the granulations are large and tumid, being swelled up, as Boyer asserts, with a considerable quantity of gas. They are afterward detached in the form of soft reddish sloughs, which very much resemble the substance of the foetal brain, in a putrid state. From day to day, until either nature alone, or aided by art, puts limits to the disorder, it invades new parts both in breadth and depth, so that its ravages extend to aponeuroses, muscles, blood-vessels, nerves, tendons, the periosteum, and even the bones themselves.

Among a number of severe cases, which fell under the notice of Mr. Blackadder, there was one, in which the half of the cranium was denuded, the bones having become black as charcoal, and the integuments

detached posteriorly to the second cervical vertebra, and anteriorly to the middle of the zygomatic process of the temporal bone; and this was originally a superficial wound of the scalp. In another case, the muscles, large arteries, and nerves of both thighs were exposed and dissected, the integuments and cellular substance being entirely removed, with the exception of only a narrow strip of the former, which remained on the outer side of the thighs. This was also originally a simple flesh wound. In other instances, the cavities of the knee, ankle, elbow, and wrist, joints, were laid extensively open, and, in one unfortunate case, the integuments and cellular substance, on the anterior parts of the neck, were destroyed, exhibiting a horrid spectacle, the trachea being also wounded." (*On Phagedæna Gangrænosa*, p. 3.)

According to the last experienced author, when the disease attacks an old sore, where a considerable depth of new flesh has been formed, the first thing generally observed is a small dark-coloured spot, usually situated at the edge of the sore. But, he states, that in several cases of ulcers, the disease, when carefully watched, was found to begin in the form of a vesicle, filled with a livid, or brownish-black fluid, which afterward burst and assumed the appearance of the dark-coloured spot, which is commonly first noticed. Mr. Blackadder always found, that, when there had been a considerable bed of new flesh formed, the phagedenic ulceration made comparatively a very slow progress, and put on rather the appearance of mercurial phagedæna, until the morbid matter had found access to the natural texture of the part, when the progress of the disease became suddenly accelerated; acute inflammation supervened; and a large slough was formed. (*Op. cit.* p. 31.) He notices, that when the morbid matter is inserted in a puncture, or scratch, the first progress of the disease bears a resemblance to that of a part inoculated with vaccine matter. The primary inflammation in gangrenous phagedæna commences at the end of the second, or early on the third day; the inflammation is at its height about the sixth; when the scab begins to form in one disease, phagedenic ulceration begins in the other, and when allowed to proceed, soon affords sufficient proof of the non-identity of the two diseases. (*P.* 33.)

According to Mr. Blackadder, when the disease attacks a recent gun-shot wound, the discharge, two or three days after infection, is found to be lessened, and to have become more of a sanious, than purulent nature. The sore has a certain dry and rigid appearance; its edges are more defined, somewhat elevated, and sharpened; the patient is sensible of a change in the usual sensation in the sore, and complains of the occasional stinging sensation, resembling that produced by the sting of a gnat. At this period, but sometimes a day or two later, the integuments at the edge of the sore become inflamed, and the surface of the sore itself as-

sumes a livid or purple colour, and appears as if covered with a fine pellicle, such as is formed on a coagulum of blood." (*On Phagedæna Gangrænosa*, p. 33.)

At Bilboa, the disease in cases of wound, is said generally to have commenced with a sudden attack of severe pain in the head and eyes, tightness about the forehead, want of sleep, loss of appetite, a quick pulse, and other febrile symptoms; while the wound, which had been healthy and granulating, at once became tumid, dry, and painful, losing its florid colour, and assuming a dry and glossy coat. (*Hennen on Military Surgery*, p. 214, Ed. 2.) When left to itself, the above-described pellicle gradually increases in thickness, forming what has been termed a slough. But, Mr. Blackadder observes, that at this period, the progress of the disease is hardly in any two instances precisely alike. Generally, in the course of from five to ten, or fifteen days, a thick spongy, and putrid-looking slough is formed over the whole surface of the sore, and which is more or less of an ash, or blackish-brown colour. When the pellicle is destroyed, as frequently happens in the process of cleaning, it is not in every case reproduced; but, an offensive matter begins to be discharged, which becomes daily more copious, is of a dirty yellow colour, and ropy consistence, and is very adherent to the sore. The substance, which formed the apparent bottom of the wound, is raised up, and pushing the edges, makes the sore appear considerably enlarged. The edges, which are usually jagged, or pectinated, become extremely irritable, of a deep red colour, and dotted on their inner surface, with numerous small elevated, and angry-looking points, which may be considered as one of the characteristics marks of the disease. The surrounding integuments become indurated and inflamed, assuming, not unfrequently, an anasarine appearance; and the patient complains of a constant burning, lancinating pain. In the vicinity of the sore, the integuments become more and more of a dark red colour, in consequence of the violence of the inflammation, which is of an erysipelatous nature, and apt to terminate in sloughing, and carry off the patient. However, the inflammatory symptoms are sometimes mild, and in other cases, exceedingly violent; a fact accounted for by differences of constitution. (*Blackadder*, p. 34.)

In the hospitals at Bilboa, if the incipient stage was overlooked, the febrile symptoms very soon became aggravated; the skin around the sore assumed a highly florid colour, which shortly became darker, then bluish, and at last black, with a disposition to vesicate; while the rest of the limb betrayed a tendency to œdema. All these threatening appearances occurred within twenty-four hours, and at this period also, the wound, whatever might have been its original shape, soon assumed the circular form. The sore now acquired hard, prominent, ragged edges, giving it a cup-like appearance, with particular points of the lip of a

dirty yellow hue, while the bottom of the cavity was lined with a flabby blackish slough. The gangrene still advancing, fresh sloughs were rapidly formed; the increasing cup-like cavity was filled up and over-topped by them, and the erysipelatous livor and vesication of the surrounding skin gained ground, while chains of inflamed lymphatics could be traced from the sores to the adjoining glands, these exciting inflammation and supuration, which often furnished a new nidus for gangrene. The face of the sufferer assumed a ghastly anxious appearance; his eyes became haggard, and deeply tinged with bile; his tongue covered with a brownish, or blackish fur; his appetite entirely failed; and his pulse was feeble and accelerated. In this stage, the weakness and irritability of the patient was such, that the slightest change of posture put him to torture, increased by his inability to steady the limb, which, if lifted from the bed, was seized with tremors and spasmodic twitches. (*Hennen's Military Surgery*, p. 215, 216, Ed. 2.) Authors vary considerably in their descriptions of the state of the tongue. Dr. Hennen found it brownish, or blackish; Delpech whitish, or yellowish, (*Précis. Elem. T. 1. p. 125.*) and Mr. Blackadder, covered with a white mucus. (*P. 39.*)

It is explained by Mr. Blackadder, that when the disease attacks a large recent wound, the whole surface of the injury is sometimes affected from the first; while, in other instances, the disorder commences on, or near the lips of the sore. When the patient is of an inflammatory diathesis, the sore is generally attacked with acute inflammation between the seventh and fourteenth days; the slough becomes softer, and of a pulpy consistence; matter, of a strong, and peculiar odour, and of a dirty brownish gray colour, begins to ooze out at its edges, and becomes daily more copious. The inflammation gradually subsides; the slough becomes loosened, and finally detached, leaving the subjacent muscles, bones, fasciæ, or ligaments, completely exposed. When the constitution is not prone to acute inflammation, the slough remains long adherent; the discharge is very copious, and burrows under the skin, which then mortifies. Sometimes, after the detachment of a slough, florid granulations spring up, and, notwithstanding a slight recurrence of the phagedenic ulceration, the parts heal up by the almost unassisted operations of nature. However, most commonly after the muscles are exposed, they continue to be gradually dissected; their connecting cellular membrane is completely destroyed, and they are left covered with an offensive, greasy-looking matter.

According to Mr. Blackadder, when a muscle has been wounded, it swells sometimes to a great size, and quickly assumes the appearance of a large coagulum, being altogether deprived of irritability. When it has not been wounded, but has become inflamed, it generally assumes a pale colour, with an appearance as if distended with a fluid, and, occasionally, before losing its

vitality, acquires a very surprising bulk; but when no inflammation has supervened, the muscles become of a pale brick colour, waste away daily, and the patient loses all power in them. As the disease advances, the integuments are undermined and slough; and hemorrhage from small vessels is a common occurrence; but, in a more advanced stage, some of the large vessels are apt to give way, and the bleeding from them frequently destroys the patient.

"When a stump is the site of the disease, and the patient is of a plethoric habit, or accustomed to live freely, the symptoms soon begin to indicate the existence of an intense inflammatory action through its whole substance, the tumefaction, pain, and heat increase rapidly, so that, in a few days, the stump shall have acquired more than twice its former size, being at the same time much indurated, and causing the most excruciating pain. In this state, the patient has, in some instances, become delirious, and has been cut off by an effusion taking place into some of the larger cavities. It more commonly happens, however, that gangrene seizes upon the integuments, and cellular substance: large sloughs are thrown off; and some of the large blood-vessels giving way, the patient sinks under the effects of repeated hemorrhage. For it is commonly found, that the usual modes of stopping hemorrhage from a stump are, in such cases, either inadmissible, or totally inefficacious.

"Sometimes, the progress of the disease in a stump is more gradual, but in the end nearly as fatal; the inflammation is much less acute; there is comparatively but little tumefaction, and the pain is much less severe; but, the discharge is much more copious, and the cellular substance, connecting the integuments and muscles, is rapidly destroyed. Hemorrhage generally comes on later than in the preceding instance, but it is the most common cause of death," (*Blackadder on Phagedæna Gangrænosa*, p. 33—39.)

It is observed by another writer, that artery seems to be the texture, which resists most powerfully the destructive action of hospital gangrene; (*Thomson's Lectures*, p. 460) a remark quite at variance with the statement of Delpech; (*Précis. Elem. T. 1, 129*) but intended to refer, as I conceive, to cases in which the femoral, brachial, or other large artery is seen for several days completely denuded, in the midst of the ravages of the distemper, yet not giving way. I have seen the same thing frequently exemplified in mercurial phagedæna, as well in the groin, as in the arm. As for the smaller arteries, they are quickly destroyed, together with other parts.

"In some rare cases (says Dr. Hennen) I have seen the femoral and axillary artery pulsating awfully, and apparently unaffected with disease; while all the surrounding parts were completely destroyed; but in a vast majority of cases, the blood-vessels partook of the general disease, in which they were imbedded. They were not only completely

separated from their natural connexions, but their coats sloughed away at the immediate point of disease, while the disposition extended far beyond the apparently affected spot. Hence, our ligatures but too often failed on the main branches, and any attempt on the smaller was invariably injurious. We were here naturally induced to tie the artery considerably above the seat of the disease; and this was done once on the femoral, and twice on the axillary artery below the clavicle; the former burst on the third, each of the latter, on the second day afterward." Dr. Hennen further remarks, that, in general, the great vessels sloughed long after the acute symptoms of the disease had abated, and that, in severe cases, the eleventh day of the disease was always dreaded. (*On Military Surgery*, p. 221, Ed. 2.) The indisposition of the large vessels to close, when taken up in the common way, appears referable to three causes, viz. the tendency to rapid ulceration in the arteries in the situation of the ligatures; the formation of no effectual coagulum in the extremity of the vessel, like what happens in other cases of mortification; and the general incapacity of nature in examples of hospital gangrene to establish any process, which can be accompanied with healthy adhesive inflammation.

In the last stage of the disease, as it occurred in the military hospitals at Bilboa, the surface of the sore was constantly covered with a bloody oozing, and, on lifting up the edge of the flabby slough, the probe was tinged with dark-coloured grumous blood, with which also its track became immediately filled. Repeated and copious venous bleedings now came on, which rapidly sunk the patient; the sloughs, whether they fell off spontaneously, or were detached by art, were quickly succeeded by others, and brought into view thickly studded specks of arterial blood. At length, an artery gave way, which was generally torn through in the attempt to secure it with a ligature; the tourniquet, or other pressure was now applied, but in vain; for, while it checked the bleeding, it accelerated the death of the limb, which became frightfully swelled and horribly fetid. Incessant retchings came on, and with coma, involuntary stools, and hiccough, closed the scene. Often, however, the patient survived this acute state of the disease, and sunk under severe irritation, absorption of putrid matter, and extensive loss of substance, with common hectic symptoms. (See *Hennen's Mil. Surgery*, p. 217, Ed. 2.) In the disease at Bilboa, the skin and cellular substance seemed to be the parts originally and principally affected. This, says Dr. Hennen, was obvious, even in the living body; but, on dissection, the disease of these parts was frequently observed to spread much further, than external appearances indicated, as a diseased track was often found running up into the groin, or axilla, and completely dissecting the muscles and great vessels. (*On Military Surgery*, p. 219, Ed. 2.) When the disease

had occupied the outside of the chest, the same gentleman found the lungs in two cases, and the pericardium in a third, covered with gangrenous spots; and, when the parietes of the abdomen had been attacked, he often observed the same appearances on the liver. (P. 220.)

Hospital gangrene must be regarded, as one of the most serious and dangerous complications, to which wounds and ulcers are liable. When the solution of continuity is large, or of long standing, the disorder commits great ravages, renews its attacks repeatedly, and the relapses prove exceedingly obstinate. The same thing is said to happen, when it affects persons labouring under scorbutic or venereal complaints. Hospital gangrene proves particularly dangerous, and mostly fatal, when it complicates large contused wounds, attended with badly fractured bones. All the soft parts of the injured limb are then frequently observed to be progressively destroyed, and the unfortunate patient falls a victim, either to typhoid symptoms, frequent hemorrhages, or hectic complaints. From what has been stated, however, the disease varies considerably in its severity in different cases, being sometimes of small extent, and even capable almost of a spontaneous cure. Patients have been known to continue afflicted more than a month, and when the duration of the disease was thus lengthened, the cases almost always had a fatal termination. In a few cases, the wound puts on a favourable appearance again between the sixth and ninth days; and, in slight examples, the amendment is manifested between the third and fifth. Whatever may be the period of the complaint, its wished-for termination is always announced by a diminution of pain; the pus acquiring a white colour, and more consistence, and losing its fetid nauseous smell. The edges of the ulcer subside, while its surface becomes less irregular, and puts on more of the vermilion colour. The red, purplish, cedematous circle, which surrounds the disease, assumes a true inflammatory nature, and the solution of continuity, restored to a simple state, heals up with tolerable quickness, even when the destruction of soft parts is somewhat considerable, unless any fresh untoward circumstances occur to interrupt cicatrization. But, sometimes, when the patient is on the point of being completely well again, his condition is suddenly altered for the worse; ulcerated spots make their appearance on the cicatrix, and these spreading in different directions occasion a relapse, which may happen several times.

From numerous cases of this disease, seen by Mr. Blackadder at Passage in Spain, this gentleman made the following conclusions:

1. That the morbid action could almost always be detected in the wound, or sore, previous to the occurrence of any constitutional affection.

2. That in several instances, the constitution did not become affected, until some

considerable time after the disease had manifested itself in the sore.

3. That when the disease was situated on the inferior extremities, the lymphatic vessels, and glands in the groin, were observed to be in a state of irritation, giving pain on pressure, and were sometimes enlarged, before the constitution showed evident marks of derangement.

4. That the constitutional affection, though sometimes irregular, was in many cases contemporary with the second, or inflammatory stage.

5. That all parts of the body were equally liable to become affected with this disease.

6. That, when a patient had more than one wound, or sore, it frequently happened, that the disease was confined to one of the sores, while the other remained perfectly healthy, and that even when they were at no great distance from each other. (*On Phagedæna Gangrænosa*, p. 19.)

Thus Mr. Blackadder espouses the opinion, that hospital gangrene is at first a *local*, and not a *constitutional disease*, that is to say, not necessarily preceded, or originally accompanied by any diseased action in the system. It is highly important to weigh this distinction well, not only because it is yet the chief point of difference among the best writers on the subject, but because it involves very directly every theory respecting the causes of the disease, and the great question, whether its ravages are to be resisted principally by local or constitutional means, or by remedies of both descriptions together.

In the hospital gangrene, observed by Dr. Rollo in the artillery hospital at Woolwich, "The action of the poison seemed to be limited and confined to specific effects. *The first were local, producing only a general affection, by a more extensive operation on the sore.* Five or six days from the appearance of the small ulcer or ulceration, when it had extended over one-third of the former sore, with pain and redness in the course of the lymphatics, and the glands, through which they led, with enlargement of them, general indisposition of the body became evident." Delpech, in his interesting memoir, particularly notices, that the constitutional symptoms *always occurred the last in order of succession.*

Mr. Blackadder distinctly declares, that, in no instance, which he had an opportunity of observing, did the constitutional symptoms of gangrenous phagedæna precede the local, unless the case be held an exception, in which a stump became affected, after amputation had been performed, on account of the previous effects of the disease. The period at which the constitution begins to exhibit symptoms of irritation (he says) is extremely irregular,—sometimes as early as the third, or fourth day, and sometimes even as late as the twentieth. The countenance assumes an anxious, or feverish aspect; the appetite is impaired; the desire for liquids increases; and the tongue is covered with a white mucus. The bowels are generally rather constipated; and the pulse, what

may be termed, rather irritated, than accelerated. But, the general symptoms may assume an inflammatory, or typhoid character, according as the causes of one of these modifications may predominate. According to Mr. Blackadder, when an inflammatory diathesis prevails, the system becomes gradually more irritated, until an attack of acute inflammation seizes upon the sore, and which frequently happens about the end of the second week. At this period, the pulse is frequent and sharp, and it is not uncommon for the patient to be seized with one, or more shivering fits, succeeded by a great increase of heat, but seldom, or never terminating in a profuse perspiration. The cold fit is sometimes followed by a bilious discharge from the intestines, and mitigation of the febrile disorder. If the local mischief be not arrested, the strength becomes daily more and more exhausted; the fever loses its inflammatory character; and, unless the patient be cut off by hemorrhage, he falls a victim to extreme debility. When the disease has a typhoid character, the pulse is small and frequent; the appetite and strength gradually fail; and the patient at last sinks, retaining his mental faculties to the last. Not unfrequently diarrhœa hastens the event. (*Blackadder on Phagedæna Gangrænosa*, p. 39, 40.)

On the other hand, the generality of writers, nay, even some of those who represent the disease as always proceeding from a species of infection applied to the wound, take into the account the operation of constitutional causes, as predisposing to, and of course preceding the local symptoms. Dr. J. Thomson believes, that the constitutional symptoms mostly precede the local. (*On Inflammation*, p. 459.) The same sentiment is professed throughout Dr. Hennen's remarks, who placed reliance chiefly upon internal remedies, and regarded external applications, as merely a secondary object. (*On Military Surgery*, p. 222, Ed. 2.) To this part of the subject, I shall return, after adverting to the causes of hospital gangrene.

The hospital gangrene, which occurred in the Artillery Hospital at Woolwich, and was described by Dr. Rollo, did not attack specific sores: venereal, scrofulous, and various ulcers were not attacked, although the patients lay in the wards, where the disease prevailed.

Professor Thomson admits, that specific sores are less liable to attacks of hospital gangrene, than common wounds and ulcers; but, he declares, that he has frequently seen it attack cancerous and venereal ulcers. (*On Inflammation*, p. 460.)

Dr. Hennen mentions a remarkable instance, which also proves the possibility of a specific sore becoming affected, and fatal from this cause in forty-eight hours after the patient had first been exposed to the infection. Dr. Hennen relates the fact to prove, that the contagion may be received, without a long residence in a tainted air. The patient, "who had just landed from England, and was under the influence of mercur-

ry, employed for a venereal complaint, died within forty-eight hours after his admission, the gangrene having seized on an open bubo in his groin, eroding the great vessels in the neighbourhood, and absolutely destroying the abdominal parietes to a large extent." (*Principles of Military Surgery*, p. 218, Ed 2.)

The effects of hospital gangrene should be carefully discriminated from those of the scurvy. Ulcers, attacked with hospital gangrene, are not affected in any degree, like scorbutic ulcers, by the use of vegetable diet and lemon-juice, and they occur among men, who are fed upon fresh meat and vegetables, as readily as they do among those who have been fed altogether upon salt provisions. (*Thomson's Lectures on Inflammation*, p. 482.) Hospital gangrene is almost always accompanied with severe febrile symptoms; but, "as to fevers, (says Dr. Lind,) it may indeed be doubted whether there be any such as are purely and truly scorbutic. The disease is altogether of a chronic nature; and fevers may be justly reckoned among its adventitious symptoms." (*Treatise on the Scurvy*, p. 106.) In cases of hospital gangrene, the general symptoms of scurvy are also absent, such as soreness and bleeding of the gums, livid blotches and wheals on the fleshy part of the legs, œdematous ankles, &c.

Hospital gangrene (says Boyer) is a species of humid gangrene, which attacks in some degree epidemically the wounds and ulcers of patients, who happen to be crowded together in an unhealthy place.

Its occasional causes are; the situation of an hospital upon a low marshy ground; the vicinity of some source of infection; the uncleanness of the individuals, or of the articles for their use; the crowded state of the wards, especially when they are small and badly ventilated; lastly, every thing that tends to corrupt the air which the patients breathe. An infected atmosphere may produce in the most simple wounds unfavourable changes, partly, as Boyer conceives, by its immediate action on the surface of the wound, but no doubt principally by its hurtful influence upon the whole animal economy. The foregoing causes have also sometimes produced alarming and obstinate gangrenes of an epidemic kind, or at least, a state of the constitution, under the influence of which all wounds and ulcers constantly took on a bad aspect, and were often complicated with the most gangrenous mischief. Vigaroux saw such an epidemic disease prevail for twenty months in the two hospitals of Montpellier, and he states, that the most powerful antiseptics were of little avail against the disorder, which often invaded the slightest scratches.

In general, this epidemic species of gangrene is not observed in new-built hospitals, nor in those which are erected out of the central parts of cities, upon high ground.

Hospital gangrene may occur in any season; but, it is most common after the sultry heat of summer.

A bilious constitution, mental trouble, un-

wholesome or insufficient food, a scorbutic diathesis, great debility, and fevers of a dangerous type, are also reckoned by the French surgeons as so many predisposing causes of hospital gangrene.

The observations of Pouteau, and those of some other practitioners, convincingly prove, that hospital gangrene may be communicated to the most simple wound, or ulcer, in a subject of the best constitution, and breathing the purest air, by merely putting into contact with such wound or ulcer, sponges, lint, or charpie, impregnated with the infection of this peculiar disorder. But, this inoculation is conceived to be the more alarming, and to take effect the more quickly, in proportion as patients have been more exposed to the influence of such causes as are themselves capable of producing the disease, and also in proportion as the kind of constitution predisposes to it.

Although the contagious nature of hospital gangrene has been generally admitted by all the best informed writers on the subject, the doctrine was not considered by Dr. Trotter as having a good foundation. Modern authors, however, have not joined this latter gentleman, and Dr. J. Thomson, Dr. Hennen, and Mr. Blackadder, all believe, that the disorder is infectious. "The contagious nature of hospital gangrene (says Professor Thomson) appears to me to be sufficiently proved, 1st, By the fact, that it may be communicated by sponges, charpie, bandages, and clothing, to persons at a distance from those infected with it. 2dly, By its having been observed to attack the slight wounds of surgeons, or their mates, who were employed in dressing infected persons; and that, even in circumstances, where the medical men so employed, did not live in the same apartment with the infected. 3dly, By our being able often to trace its progress distinctly from a single individual through a succession of patients. 4thly, By its attacking recent wounds, as well as old sores, and that in a short time after they are brought near to a patient affected with the disease. 5thly, By our being able to prevent the progress of the disease in particular situations, by removing the infected person, before the contagion, which his sores emit, has had time to operate. 6thly, By its continuing long in one particular ward of an hospital, or in one particular ship, without appearing in other wards, or ships, if pains be taken to prevent intercourse between the infected and uninfected." (*Lectures on Inflammation*, p. 484.) But, although there can be no doubt of the disease spreading partly by its contagious nature, it appears to me equally certain, that the number of cases is also often increased by the continued operation of the same causes, which produced the earliest instance of the disorder in any particular hospital.

It is alleged, that when once a patient has taken the infection, he cannot avoid the consequences, whatever precautions he may adopt. Thus, Boyer informs us, that

he has seen hospital gangrene take place in wounded patients, who, in the hope of escaping this epidemic affection, had quitted the infected hospital, and retired to elevated situations, where they breathed the most salubrious air. (See *Traité de Mal. Chir.* T. 1, p. 322.)

The bad state of the air of a crowded hospital, as Mr. Blackadder observes, is a ready means of accounting for the origin of phagedæna gangrenosa; but, there are various reasons for considering such explanation not altogether satisfactory; and he mentions a case, in which the wound of a soldier was found affected with the disease on his first arrival at an hospital, after having been accidentally detained, with two other wounded comrades, for five or six days, partly in an open building, and partly in a boat, quite exposed to stormy weather. (P. 45.) Dr. Hennen likewise gives an account of about thirty fresh wounded men, in whom hospital gangrene first appeared in their journey from Vittoria to the hospital near Bilboa. (*Principles of Military Surgery*, p. 214, Ed. 2.) Dr. Rollo also remarked, that some men in quarters were affected with this disease. And, according to Mr. J. Bell, "there is no hospital, however small, airy, or well regulated, where this epidemic ulcer is not to be found at times." (*Principles of Surgery*, Vol. 1, p. 112.) For a refutation of the opinion, that the disease ever strictly merits the epithets *endemic*, and *epidemic*, I must refer the reader to the observations of Mr. Blackadder. (P. 143, 53.) Delpech remarks, that the causes of the disease do not appear to have depended upon the state of the atmosphere, (P. 25;) and in almost every instance, he traced the propagation of the disorder to the direct application of the morbid matter to the sores. However, he joins Pouteau in the belief, that it may be communicated through the medium of the atmosphere; an occurrence, which Mr. Blackadder doubts, or, rather considers as very rare, and only possible where the effluvia are allowed to accumulate in a most negligent manner, so as to resemble a vapour bath, which mode he would also regard as equivalent to inoculation. (*On Phagedæna Gangrenosa*, p. 156.) On the whole, I am disposed to think the views, which Mr. Blackadder has taken of the manner in which the disease is communicated, the most correct, hitherto published, and that, while particular states of the air and constitution certainly modify the disorder, they cannot generally have any share in giving origin to the disease; I say generally, because as various facts oblige us to admit, that hospital gangrene sometimes arises, without having been communicated from any patient previously affected, it is impossible to assert, that the earliest example of it, under such circumstances, may not arise from the operation of some unknown and inexplicable circumstances on the constitution, or in other words, from the state of the system itself. Nor can a doubt be entertained, that, at all events, the disorder is

most apt to break out in crowded, badly-ventilated hospitals, and in them appear more extensively and malignantly, than in others, which are well-regulated, properly ventilated, and healthily situated. But, the idea, entertained by Delpech, that hospital gangrene may originate from the same contagion as typhus, or other diseases, is a mere unsupported, irrational conjecture, quite as destitute of the truth, as the suppositions about the endemic and epidemic character of the complaint, independent of its infectious nature. The question, how the first example of the disorder originates, is at present a perfect mystery; but, as it cannot be referred to contagion, or inoculation, we should recollect, that whatever produces it in one individual, may produce it in another, similarly circumstanced, and, on this principle, the disorder may sometimes be formed independently, and at the same time, in a greater or lesser number of patients in the same hospital, as well as spread from these to others by infection.

With the view of preventing the disorder, the wards, in which the wounded are placed, should not be crowded; they ought to be freely ventilated, and, if possible, not communicate. The utmost attention to cleanliness should be paid; and all filth and stagnant water removed. It has been asserted, but with what accuracy I cannot determine, that the predisposition of the wounded to this species of gangrene may be lessened by a well-chosen diet, by drinks acidulated with vegetable acids, or with the sulphuric acid, and by the moderate use of wine. The state of the stomach and bowels should be particularly attended to, and, if out of order, emetics and purgatives ought to be immediately employed, and repeated according to circumstances. The dressings should be applied with extreme attention to cleanliness, and too much care cannot be taken to prevent the infectious matter of one wound from coming into contact with another through the medium of sponges, instruments, &c. "Whatever may be the source of this disease (says a late writer) it is at least sufficiently ascertained, that, when it occurs, its propagation is only to be prevented by the most rigid attention to cleanliness, and by insulating the person, or persons affected, so as to prevent all direct intercourse between them and the other patients; for, so far as I have had an opportunity of observing, ninety-nine cases in the hundred were evidently produced by a direct application of the morbid matter to the wounds, dressings, &c.; while others, who were, in every other respect, equally exposed to its operation, never caught the disease. In attempting to prove this by experiment, I have placed three patients with clean wounds alternately between three other patients, severely affected with the disease. They lay in a part of a ward, which was appropriated for patients, who were labouring under the disease, and of whom there were at the time a considerable number. Their beds were on the floor,

and not more than two feet distant from each other; but, all direct intercourse was forbidden, and they were made fully aware of the consequences that would follow from inattention to their instructions. The result of this trial was, that not one of the clean wounds assumed the morbid action peculiar to the disease, nor was the curative process in any degree impeded." (*Blackadder on Phagedæna Gangrænosa*, p. 46.)

As many experienced writers assert, that the disease may also be communicated from one person to another through the medium of effluvia in the air, I am firmly persuaded that, in the present state of our knowledge of the subject, the cautions, respecting ventilation, cleanliness, (the chief practical deduction from the latter doctrine) are highly necessary and important. This sentiment may be adopted, without implicit faith being placed in the opinion, that the disorder can actually be transmitted from one person to another through contagion in the air, because whether the last idea be true, or not, attention to cleanliness and ventilation must be beneficial to the health, in this, as in every other species of gangrene; and, on this principle, they must be serviceable in diminishing the severity, if not the frequency and extent, of the disease, as I am myself disposed to believe from the consideration of all the evidence adduced. Where circumstances will permit, an entire removal of the patients from the place, in which the disease has either had its first formation, or spread to any extent, appears likewise to be a most beneficial measure. But, when this change of the wards, or hospital, is impracticable, the air which the patients breathe, should be purified, by renewing it as much as possible, fixing ventilators, and especially by using the oxygenated muriatic acid fumigations, as recommended by Guyton-Morveau, or else those of the nitric acid.

The nitric acid fumigations are made by putting into a glass vessel, on the ground, half an ounce of concentrated sulphuric acid, to which an equal quantity of nitre is to be added *gradatim*. The mixture is to be stirred with a glass tube, when an abundance of white vapour will be produced.

The oxygenated muriatic acid fumigations are made, by mixing three ounces two drams of common salt with five drams of the black oxide of manganese in powder. These two ingredients are to be triturated together; they are then to be put into a glass vessel; one ounce two drams of water are to be added, and then if the ward, or chamber be uninhabited, one ounce seven drams of sulphuric acid are to be poured upon the mixture all at once; or gradually, if the patients are there. This quantity will be sufficient for a very large ward.

When one or more of the patients, afflicted with the disorder, before it has become general, are lying in a badly ventilated part of the ward, the surgeon can partly counterbalance the disadvantage of not having a fresh ward, by causing the patients to be put

into a more airy part of the ward, and as far as possible from the quarter, in which they contracted the disease.

With regard to internal medicines, while irritation and febrile heat accompany hospital gangrene, diluent acid drinks are proper, such as nitrated whey sweetened with syrup of violets, lemonade, &c. Blood-letting is admissible in but few instances, not merely because the orifice, made by the lancet, is apt to become gangrenous, but because the fever, which accompanies hospital gangrene, is usually of the typhoid, or asthenic character. (*Thomson*, p. 493.)

Mr. Blackadder, like Dr. Thomson, does not entertain a favourable opinion of venesection, as a general practice, though he would not object to the abstraction of a small quantity of blood, when, owing to the plethoric habit of the patient, *previous treatment*, and other causes, an inflammatory action in the system is present. But he conceives, that all danger of the disease attacking the wound, made with the lancet, may be obviated, if care be taken that the arm of the patient, the hands of the surgeon, his lancet, and the subsequent dressings, be perfectly free from contamination, and that the patient be prevented from undoing the bandage, or touching the incision made with the lancet, before it is cicatrized. (P. 135.) Mr. Blackadder thinks, however, that blood-letting should be avoided, as much as possible, particularly when the previous injury has been extensive. "A general debility of the system, is one of the symptoms which are most to be dreaded; for, when once it takes place, there is no other disease in which it is removed with greater difficulty." (P. 137.) How different these sentiments are from those of Dr. Hennen, who, in speaking of the effects of venesection, when the disorder was accompanied with an inflammatory diathesis, employs the following expressions: "The very patients themselves implored the use of the lancet." For several months we used no other remedy, either as a cure, or preventive."—"We never observed any of the lancet wounds assume a gangrenous appearance, although previously, in almost every other instance, the slightest puncture festered." (*On Military Surgery*, p. 224, Ed. 2.)

In the beginning of the constitutional attack, Pouteau and Dassasoy particularly recommended emetics, and Mr. Briggs, Dr. J. Thomson, and Dr. Hennen, are all advocates for this practice, though the latter gentleman makes his evidence rather ambiguous, by a subjoined note, in which he mentions that want of success, &c. led to the trial of venesection. (*Op. cit.* 222.) As for Mr. Blackadder, he deems the employment of emetics at the commencement of hospital gangrene useful only when the stomach is foul. (*On Phagedæna Gangrænosa*, p. 134.) In the early stage of the case, writers seem all to agree about the utility of purgative and laxative medicines. When there is debility, good generous wine should be allowed, either by itself, or mixed with lemonade according

to circumstances. Bark, whose antiseptic qualities have been so highly praised, is in general more hurtful, than useful; and Dr. Hennen assures us, that he has seen great harm done by large and injudicious doses of this drug, before full evacuations had taken place, and the sloughs begun to separate. Boyer allows, however, that it may be beneficially given, when the feverish heat has abated, and the debility is very great.

In all stages of this disease, unattended with diarrhoea, acids are proper. The sulphuric acid is that which is given with most success: but the acidulous tartrate of potassa is also an excellent medicine. From two drams to half an ounce may be given every day, and the best plan is to make an acid drink with it, which should be sweetened and strained.

In severe cases, attended with a quick and feeble pulse, depression, restlessness, and anxiety, an opiate becomes necessary. "So long as we wish to excite a degree of moisture on the skin, (says Professor Thomson) Dover's powder, or laudanum with antimonial wine, form in general the best opiates." This gentleman, however, is not an advocate for the employment of opium, in the early stage of hospital gangrene, while the heat and other febrile symptoms are at their height (See *Lectures on Inflammation*, p. 494, 495.) For these cases, camphor, in large and frequent doses, was highly praised by Pouteau.

From what has been said concerning internal remedies, it is evident, that none of them can be regarded as means, which can be at all depended upon for arresting the ravages of hospital gangrene, however advantageous they may prove in palliating general symptoms, removing particular complications, enabling the system to support the effects of the local disorder for a greater length of time, or, in a few cases, even placing nature in a condition to throw off the diseased parts herself, and communicate to the subjacent living flesh a healthy action.

If credit can be given to several of the authors, who have had the most extensive opportunities of attending to the nature of hospital gangrene, the local treatment is far more effectual than internal medicines.

"I was told by several of the French surgeons (says a late visiter to Paris,) that they did not rely at all on internal means for stopping the progress of hospital gangrene, and that their experience had proved them to be insufficient, if not wholly inefficacious. Dupuytren, in reply to the account I gave him of the practice and opinions of English surgeons on this subject, assured me, that he had no confidence but in local applications, and that internal remedies alone, as far as he had found, did almost nothing. The same remark has been made in a very recent publication on hospital gangrene, (*Delpech, Mém. sur la Complication des Plaies, &c.* 1815.) although it seems to be rather at variance with its being a constitutional and contagious disease, which the author has admit-

ted." (See *Sketches of the Medical Schools of Paris*, by J. Cross, p. 83.)

Perhaps, there is not a single antiseptic application, which has not been tried as a dressing for wounds, or ulcers, affected with hospital gangrene. All watery applications, and common poultices, and fomentations, are generally condemned as inefficacious, and even hurtful.

Dussasoy was convinced by the observation of numerous cases, that the best application is powder of bark. He recommends the wound to be covered with several layers of this powder, which are then to be moistened with turpentine. When this composition dries, he asserts, that it forms a fragile sort of coat, at the sides of which, and through which, the discharge escapes. After twenty-four hours, the first coat is to be removed, and a fresh one applied. In general, according to this writer, four or five such dressings are sufficient in simple cases, where the disorder is confined to the skin and cellular substance. Healthy inflammation then occurs, the sloughs come away, and the wound puts on a healing appearance. In bad cases, Dussasoy sometimes added one-fifth of powdered muriate of ammonia to the bark. When this treatment failed, the actual cautery was used.

On the subject of bark, as a local application to hospital gangrene, I need only remark, that it is now entirely relinquished, either as possessing no efficacy, (*Delpech*) or even aggravating the symptoms. (*Blackadder*.)

The milder forms of the disease appear sometimes to have yielded to the application of the vegetable and diluted mineral acids; lime juice; lemon juice; vinegar; and the diluted nitric, and muriatic acids. And the same observation may be made, with respect to solutions of the nitrates of silver and mercury. The two latter substances, and the oxygenated muriatic acid, and gas, were found by Dr. Rollo to be capable of effecting a cure. *Delpech*, in particular, speaks of the benefit derived from the application of strong vinegar, after all the pulpy viscid matter has been carefully wiped away from the surface of the living flesh. The vinegar is then poured on the ulcer, which is to be covered with charpie wet with the same liquid. When the case is too far advanced for this treatment to answer, *Delpech* tries caustics, especially the nitrate of silver; and if these fail, he has recourse to the actual cautery, and, when the sloughs are very thick, so as to hinder the cautery from acting to a sufficient depth, he prefers thrusting into the sloughs down to the living flesh angular pieces of caustic potash at small distances from each other! (*Précis. Elem. des Mal. Chir. T. 1, p. 151.*) Surely, this must be far more torturing, and less certain of success, than removing the sloughs, and applying the cautery.

Though the actual cautery is generally admitted to be one of the most powerful means of stopping the progress of hospital gangrene, the surgeons of this country entertain a

strong aversion to the practice; and I confess, that my own dislike to it is such as would always lead me to prefer any other treatment, from which equal efficacy would result. At the same time, it must be granted, that if the actual cautery will more certainly arrest some forms of hospital gangrene, than any other known applications, the surgeon's duty is to put out of the question his own prejudices against it, and consider only his patient's welfare. I am far from thinking, however, that, while there are such powerful caustics as the undiluted mineral acids, and a dressing so effectual as a solution of arsenic, it can often be absolutely necessary to employ red-hot irons.

The merit of having pointed out in modern times the great efficacy of Fowler's solution of arsenic, or the liquor arsenicalis of the London Pharmacopœia, as an application to phagedæna gangrænosa, belongs to Mr. Blackadder. In answer to the objection, that the external use of arsenic is not unattended with danger, he assures us, that he has heard but of one instance of hospital gangrene, in which any deleterious effects were supposed to arise from the absorption of the arsenic, and the patient in question was very soon cured of his uneasy, and possibly merely nervous symptoms." (P. 50.)

"The first thing to be attended to in every case of disease (says Mr. Blackadder) is cleanliness, which, if always of great importance, is, in this instance, indispensable. The surface of the body ought to be made, and kept perfectly clean, by means of the tepid bath, or otherwise by a plentiful use of soap; and the linen, and bed-clothes, should be frequently changed, particularly when soiled with matter from the sore." In order to make the sore perfectly clean, and free it from the viscous discharge, without producing considerable bleeding, and pain, Mr. Blackadder recommends two large tin hospital teapots to be filled with a weak solution of the subcarbonate of potass. One of these solutions is to be cold; the other tepid; because sometimes one, and sometimes the other, is found most agreeable to the patient's feelings, though the warm is the most effectual in cleansing the sore. The liquid is to be poured over the sore, and received into a basin, which ought to be immediately emptied into another vessel placed at a distance from the patient. During this ablution, the glutinous matter, which adheres to the sore, may be gently detached, by means of small dossils of fine tow, or lint, but these (says Mr. Blackadder) should never be used for two different patients, rigid economy, on occasions such as this, being a very mistaken principle. In these cases, the use of sponges, (he justly observes) ought to be entirely laid aside, as they can seldom be used more than once with safety. When the sore has been thus cleaned, a fine piece of dry lint is to be spread over its surface, and gently pressed into all its depressions with the points of the fingers. When the lint is removed, a quantity of the discharge will be found adhering to it: and this operation must be re-

peated with fresh pieces of lint, until the surface of the sore is made perfectly clean and dry.

According to Mr. Blackadder, the solution of arsenic will generally be found strong enough, when diluted with an equal part of water; but, in slight cases, it answered, when weakened with twice its quantity of water; and, in a few examples, it was employed without being at all diluted. Several pieces of lint of the same shape as the sore, but a little larger, are to be prepared: one of these, soaked in the solution, is now to be applied to the cleaned surface of the sore, and renewed every fifteen or thirty minutes, according to the time in which it becomes dry. When the heat and inflammation are considerable, great relief will be derived from the frequent application of linen cloths moistened with cold water, which must be kept from weakening the arsenical solution by means of a small piece of oilskin laid over the pieces of lint. When the disease extends into the track of a gunshot wound, Mr. Blackadder uses a syringe for cleaning the sore, and introducing the solution. "A slip of fine lint, well soaked in the solution, may also be inserted by means of a probe, into the bottom of the wound; and when the openings are at no great distance from each other, and not in the immediate vicinity of the large nerves and blood-vessels, the lint may be drawn through the wound in the form of a seton. (P. 53.) When the pain, caused by the application, is very severe, and the constitution is irritable, and debilitated, Mr. Blackadder prescribes an opiate, though he remarks, that this practice will seldom be absolutely necessary. The morbid action in the sore is destroyed by the arsenical solution sooner, or later, in different cases: *the best plan is to continue the application, until an insensible, dark-coloured, dry slough occupies the whole surface of the sore; and until the patient is completely relieved from the burning and lancinating pain.*

After the slough is formed, Mr. Blackadder employs an ointment, composed of equal parts of the oil of turpentine, and the yellow resinous ointment, or of two parts of Venice turpentine to one of the resinous ointment. "These being melted and mixed together, are to be poured over the sore, as hot as the patient can possibly bear." A pledget of dry lint, or tow, and a bandage, are then applied; and this dressing may be renewed two or three times a day, the sore being each time carefully washed with the solution of potass. As soon as any part of the slough is loosened, Mr. Blackadder removes it with a pair of curved scissors. With the view of expediting the separation of the slough, he sometimes employs a linseed-meal poultice, which had the desired effect, but was found to be too relaxing. When it is used, therefore, Mr. Blackadder found it expedient, at each dressing, to touch the new granulations with the nitrate of silver.

After the detachment of the slough, Mr. Blackadder dresses the sore with the above-

mentioned ointment cold, or with the addition of a small proportion of the subacetate of copper. The pledget of this ointment is covered with a piece of oilskin, lightly rubbed over with soap; and a firm bandage is applied to the whole limb. (See *Obs. on Phagedæna Gangrænosa*, p. 49, &c. 8vo. Edinb. 1818.) The author declares, that, after the introduction of the above treatment, (with the exception of stumps attacked with hospital gangrene) he never saw an instance in which the remedy failed, when applied in time and in a proper manner; that is, before the disease had made such progress as to preclude all rational hope of success from that or any other mode of treatment. (P. 23.)

In Dr. Rollo's treatise on Diabetes, published in 1797, the opinion is plainly stated, that the progress of hospital gangrene might be stopped by very active topical applications, and, in the same work, Mr. Cruickshank says, that "if an actual caustic were to be employed, we should have recourse to the strong nitrous acid." According to Mr. Blackadder, the oxygenated muriate of mercury and the nitrous acid were much recommended, and employed by surgeons in the 16th and 17th centuries, as escharotics, in cases of gangrene and foul ulcers. (P. 113.) Several army surgeons have informed me, that the undiluted nitrous acid was successfully used as an application to hospital gangrene in the military hospitals at Antwerp in the year 1815; but that other strong acids had an equally good effect. Dr. J. Thomson also notices, that "the application of caustic substances, such as the strong mineral acids, the solutions of potass, corrosive sublimate, and arsenic, seemed at Antwerp to arrest the progress of this sore, without exciting inflammation." (*Report of Observations made in the Military Hospitals in Belgium*.)

Delpech was informed by some British surgeons, belonging to the Anglo-Portuguese army in the Peninsula, that the muriatic acid was in common use in the hospitals of that army as a local application for checking the ravages of hospital gangrene, being employed in a diluted state for slight cases, and in a concentrated caustic form for others.

In St. Bartholomew's hospital, the undiluted nitric acid has been used with great success as a local application to phagedenic gangrenous ulcers, as may be seen by an interesting paper recently published by Mr. Welbank. (*Med. Chir. Trans. Vol. 10.*)

Pouteau, Dussasoy, Boyer, and Delpech, all bear testimony to the efficacy of the actual cautery, and they repeat the application of it, until the whole surface of the ulcer is converted into a firm hard eschar. Even the edges of the solution of continuity should not be spared—"ils doivent être torréfiés et rôtis pour ainsi dire." (*Boyer, Traité des Maladies Chir. T. 1, p. 332.*) The latter surgeon then covers the eschar with a thick stratum of bark moistened with turpentine. This application is to be removed in twenty-four,

thirty-six, or forty-eight hours, and the surgeon is then to judge from the appearance of the flesh, and the quality of the discharge, whether a further repetition of the cautery will be necessary.

Home Blackadder, *Observations on Phagedæna Gangrænosa*, 8vo. Edinb. 1818, which is unquestionably the best treatise on the subject, whether his sentiment about the disease being always, or nearly always, communicated by the direct application of the infectious matter to the parts, and not through the contagion in the air, be correct or not; or whether his opinion about the local nature of the disease in the beginning, and its invariable commencement with the local mischief, and not with constitutional symptoms, be liable to exceptions or not. The rest of the subject of Gangrene is treated of in the article *Mortification*.

HYDRARGYRIA. A peculiar eruption occasioned by the use of mercury, and named in Dr. Bateman's synopsis *eczema rubrum*. (See *Mercury*.)

HYDROCELE. (from *ὕδωρ*, water, and *κελε*, a tumour.) The term *hydrocele*, if used in a literal sense, means any tumour containing water; but surgeons have always confined it either to a collection of fluid in the cellular membrane of the scrotum; in a cyst, or the common cellular texture, of the spermatic cord; or in the tunica vaginalis of the testicle.

The celebrated Dr. Alexander Monro of Edinburgh, and Mr. S. Sharp, were almost the only writers, before Mr. Pott, who sensibly and rationally explained the true nature of these diseases.

ANASARCOUS TUMOUR OF THE SCROTUM:

The *hydrocele by infiltration* of French writers; *hydrocele œdematodes*; is most frequently only a symptom of a dropsical habit, and very often accompanies both anasarca and the particular collection within the abdomen, called ascites. Mr. Pott describes it as "an equal, soft tumour, possessing every part of the cellular membrane, in which both the testicles are enveloped, and consequently it is generally as large on one side as on the other; it leaves the skin of its natural colour; or, to speak more properly, it does not redden or inflame it; if the quantity of water be not large, nor the distention great, the skin preserves some degree of rugosity; the tumour has a doughy kind of feel; easily receives, and for a while retains, the impression of the fingers; the raphe, or seam, of the scrotum divides the swelling nearly equally; the spermatic process is perfectly free, and of its natural size; and the testicles seem to be in the middle of the loaded membrane. This is the appearance when the disease is in a moderate degree. But if the quantity of extravasated serum be large, or the disease farther advanced, the skin, instead of being wrinkled, is smooth, tense, and plainly shows the limpid state of the fluid underneath: it is cold to the touch, does not so long retain the impression of the finger, and is always accompanied with a similar distention of the skin of the penis; the preputium of which is sometimes so enlarged, and so twisted and distorted, as to make a very disagreeable appearance. These are the local symptoms: to which it may be added, that a yellow countenance, a loss of appetite, a deficiency of urinary secretion, swelled legs, a hard belly, and mucous stools, are its very frequent companions."

As the cellular membrane on one side of the scrotum is a continuation of that which is situated on the other, and both freely communicate; the accounts delivered by certain authors of the possibility of this species of hydrocele being confined to one side of the scrotum is not credited by some modern surgeons. (See *Dict. des Sciences Med.* T. 22, p. 193.) At all events, such a case is extremely rare, and, when it happens, is probably induced by the irritation of the urine in infants, or of the friction of the clothes in old persons, only acting upon a part of the scrotum; for occasionally, though not often, the disease is acknowledged to proceed from these local causes. (*Vol. et loco cit.*)

The cure of the original disease, when it arises from constitutional causes, comes within the province of the physician, and requires a course of internal medicine: but sometimes the loaded scrotum and penis are so troublesome to the patient, and in such danger of mortification, that a reduction of their size becomes absolutely necessary: and at other times, a discharge of the redundant extravasated serum is ordered as an assistant to the internal regimen. As Mr. Pott observes, the means of making this discharge are two, viz. puncture and incision: the former is made

with the point of a lancet; the latter with the same instrument, or with a knife. According to the same author, and indeed every man of experience, wounds in anasarcoous, or dropsical habits, are apt to inflame, very difficultly brought to suppuration, and "often prove gangrenous, in spite of all endeavours to the contrary. But the larger and deeper the wounds are, the more probable are these bad consequences. Simple punctures with the point of a lancet, are much less liable to be attended by them than any other kind of wound; they generally leave the skin easy, soft, cool, and uninfamed, and in a state to admit a repetition of the same operation if necessary. Incisions create a painful, crude, hazardous sore, requiring constant care. Punctures seldom produce any uneasiness at all; and stand in need of only a superficial pledget for dressing.

It is further explained by the same author, that as the cavities of the cellular membrane of the scrotum all communicate together, a small puncture serves, as well as a large incision, for the discharge of the fluid contained in them, and consequently upon this ground no reason exists for making any extensive, painful, and hazardous wound.

With respect to the practice of making punctures, in cases of anasarcoous hydrocele, I think that it should always be avoided as much as possible, because it sometimes happens, that the slightest pricks of the lancet occasion sloughing. The method should only be adopted, when the distention of the skin of the scrotum is such, as absolutely to require the fluid to be discharged. Care should also be taken not to multiply the punctures unnecessarily, nor to let them be made too near together. (See *Dict. des Sciences Med.* T. 23, p. 195.)

When the œdematous state of the scrotum is not the effect of a general constitutional disease, but proceeds entirely from a local cause, such as friction, or the irritation of the urine, the mode of treatment consists in the removal of the cause, the use of astringent lotions, and the exhibition of a dose of salts. In elderly subjects, the wearing of a bag-truss is recommended for the prevention of the complaint.

HYDROCELE OF THE SPERMATIC CORD

Is of two kinds; the first is described as an œdematous affection, extending to more or less of the cellular substance around the spermatic vessels, and sometimes named the *encysted hydrocele of the cord*; the second form of the disease is that in which the fluid is collected in a particular cavity, or cyst, which has no communication with the cavities of the common cellular substance of the cord. This case is denominated accordingly, the *encysted hydrocele of the cord*. That the cellular membrane of the cord is often distended with an aqueous fluid, when the scrotum is anasarcoous and the habit dropsical, cannot admit of doubt, and hence it is a frequent attendant on the case, which has been described as the hydrocele œdematodes.

But as I have never seen an instance, in which such disease was restricted to the cellular texture of the cord, I am led to suppose that it is a very uncommon case. The following is said by Mr. Pott to be the state of the disease, while of moderate size. The scrotal bag is free from all appearance of disease; except that when the skin is not corrugated, it seems rather fuller, and hangs rather lower on that side than on the other, and if suspended lightly on the palm of the hand, feels heavier: the testicle, with its epididymus, is to be felt perfectly distinct below this fulness, neither enlarged, nor in any manner altered from its natural state: the spermatic process is considerably larger than it ought to be, and feels like a varix, or like an omental hernia, according to the different size of the tumour: it has a kind of pyramidal form, broader at the bottom than at the top: by gentle and continued pressure it seems gradually to recede or go up, but drops down again immediately upon removing the pressure; and that as freely in a supine, as in an erect, posture: it is attended with a very small degree of pain or uneasiness; which uneasiness is not felt in the scrotum, where the tumefaction is, but in the loins.

"If the extravasation be confined to what is called the spermatic process, the opening in the tendon of the abdominal muscle is not at all dilated, and the process passing through it may be very distinctly felt; but if the cellular membrane, which invests the spermatic vessels within the abdomen, be affected, the tendinous aperture is enlarged; and the increased size of the distended membrane passing through it, produces to the touch a sensation not very unlike that of an omental rupture."

While it is small, it is hardly an object of surgery, and may be kept from being troublesome by means of a suspensory; but when it is large, it is very inconvenient both from size and weight, and according to Pott, the only method of cure which it admits, is far from being void of hazard. The plan is to make a free incision into the swelling. It must be confessed, with a modern writer, that these observations on the diffused hydrocele of the cord by Mr. Pott, are far from being satisfactory, and the symptoms, by which he made up his mind to lay open the disease, were but of an equivocal description, and might have arisen from cases of another nature. (See *Dict. des Sciences Med. T. 22, p. 215.*)

THE ENCYSTED HYDROCELE OF THE SPERMATIC CORD

Is a complaint by no means infrequent, especially in children. It was very well known to many of the ancients, and has been accurately described by Albucasis, Celsus, Paulus Aegineta, &c. When Mr. Pott says, that the disease is not infrequent, it ought to be understood, that its frequency, though much greater, than that of the diffused hydrocele of the cord, considered as

a distinct disease independent of general anasarca, is not at all equal to that of the hydrocele of the tunica vaginalis. Riche-rand has calculated, that the average proportion of encysted hydroceles of the cord to those of the latter description, is not more than as 1 to 200. (*Nosogr. Chir. T. 4, p. 262, Ed. 4.*) According to Mr. Pott, the swelling is mostly situated at the middle part of the cord, between the testicle and groin, and is generally of an oblong figure; whence it has by some people been compared to an egg, by others to a fish's bladder. Whether it be large or small, it is generally pretty tense, and consequently the fluctuation of the water within it, not always immediately or easily perceptible. It gives no pain, nor (unless it be very large indeed) does it hinder any necessary action. It is perfectly circumscribed; and has no communication, either with the cavity of the belly above, or that of the vaginal coat of the testicle below it. The testis and its epididymis, are perfectly and distinctly to be felt below the tumour, and are absolutely independent of it. The upper part of the spermatic process in the groin is most frequently very distinguishable. The swelling does not retain the impression of the fingers; and when lightly struck upon, sounds as if it contained wind only. It undergoes no alteration from change of the patient's posture; it is not affected by his coughing, sneezing, &c. and it has no effect on the discharge per anum.

The two diseases with which this kind of hydrocele is most likely to be combined, are, an hydrocele of the tunica vaginalis testis, and a true hernia.

"One mark, or characteristic of an hydrocele of the tunica vaginalis testis is, that it possesses and distends the inferior part of the scrotum; and that the testicle being nearly (though not absolutely) surrounded by the water, it very seldom happens that the former can be clearly and plainly distinguished by the fingers of an examiner; whereas, in the encysted collection, in the membranes of the cord, the tumour is always above the testicle, which is obvious and plain to be felt below it.

"Another circumstance worth attending to is, that although the fluid in a hydrocele of the vaginal coat does so nearly surround the testis as to render it often not very easy to be distinguished, yet the different parts of the tumour have always a very different feel: for instance, in all those points where the vaginal tunic is loose, and unconnected with the tunica albuginea, the tumour is soft and compressible, and gives a clear idea of the contained fluid; but where these two coats are continuous, or make one and the same membrane, and have no cavity between them (which is the case on the middle and posterior part) there will always be found a hardness and firmness very unlike to what is to be found in all those places where the distance between the two tunics leaves room for the collection of a fluid; now the hydrocele of the cord being formed in the mere cellular membrane of it, is the same to the

touch in all the parts of the tumour, and feels like a distended bladder through every point of it.

"The free state of the upper part of the spermatic process, while the tumour is forming below; the gradual accumulation of the fluid, and consequently the gradual growth of the swelling; the indolent and unaltering state of it; its being incapable of reduction, or return into the belly from the first; its being always unaffected by the patient's coughing or sneezing; and the uninterrupted freedom of the fecal discharge per anum, will always distinguish it from an intestinal hernia; and he who mistakes it for an omental one, must be very ignorant, or very heedless."

Mr. Pott met with an encysted hydrocele situated so high toward the groin, as to render the perception of the spermatic vessels very obscure, or even impracticable; but then, the state and appearance of the testicle, and the absence of every symptom proceeding from confinement of the intestinal canal, were sufficient marks of the true nature of the complaint. Several writers describe this kind of hydrocele, as in fact a common encysted tumour, formed in the cellular substance, between the vas deferens and spermatic vessels. (*Delpech, Précis Elem. des Mal. Chir. T. 3, p. 464.*) Yet, since ordinary encysted swellings are very difficult to disperse, there is probably some difference between the two affections, at least, if the observation of Mr. Pott be correct, that in young children, the encysted hydrocele of the cord frequently dissipates in a short time, especially if assisted by warm fomentation, and an open belly.

If it be not absorbed, "the point of a lancet will give discharge to the water; and in young children, will most frequently produce a cure: but in adults, the cyst, formed by the pressure of the fluid, does sometimes become so thick, as to require division through its whole length; which operation may in general be performed with great ease, and perfect safety." Mr. Pott says, in general, because it is most frequently so: though he has even seen this, slight as it may seem, prove troublesome, hazardous, and fatal. (*See Pott on Hydrocele.*)

The late Sir J. Earle proposed treating this case in the same way, as the hydrocele of the tunica vaginalis, viz. by an injection of red wine and water; which method is often successful. (*On Hydrocele, p. 154, edit. 2.*) However, the cure of an encysted hydrocele of the spermatic cord, by means of an injection, is generally regarded by modern surgeons, as less certain and advantageous, than the excision of a part of the cyst. The operation which is described by Bertrandi, Mr. Hey, Richerand, &c. consists in cutting down to the cyst, and removing the forepart of it, while the portion, closely attached to the cord, is to be allowed to remain. For additional observations on this species of hydrocele. (*See the First Lines of the Practice of Surgery, Vol. 2, p. 121.*)

HYDROCELE OF THE TUNICA VAGINALIS.

If the quantity of limpid fluid, which naturally moistens the surface of the tunica vaginalis and the inside of the tunica vaginalis, be secreted in an undue quantity, or if regular absorption of it be by any means prevented, it will gradually accumulate, and distend the cavity of the latter membrane, so as to form the present species of hydrocele. The case in which the fluid is supposed to descend, either partly or entirely from the cavity of the abdomen, in consequence of the communication not being shut up in the usual time, between the cavity of the peritoneum and that of the tunica vaginalis, is well known to surgeons under the appellation of a congenital hydrocele; a disease, of which particular notice has been taken in the 2d Vol. of the last edition of the *First Lines of Surgery, Sec. Lond. 1820*, and to which I shall therefore very briefly advert in this article. Hydrocele of the vaginal coat is a disease from which no time of life is exempt; not only adults are subject to it, but young children are frequently afflicted with it: and infants sometimes born with it. (*Pott.*) And it is remarked to be common in old men, and persons who ride a good deal on horseback. (*Delpech, Précis Elem. des Mal. Chir. T. 3, p. 177.*)

The causes of hydrocele of the tunica vaginalis can scarcely be said to be at all understood; and when Mr. Pott observes, that whatever tends to increase the secretion of fluid into the cavity of that membrane, beyond the due and necessary quantity, or to prevent its being taken up, and carried off by the absorbent vessels, must contribute to the production of the disease, nearly as much is stated, as can be advanced with safety in the present state of our knowledge. Ruysch had a suspicion, that this hydrocele might arise from a varicose state of the spermatic veins; but though Mr. Pott acknowledges that these vessels are very frequently found varicose in patients afflicted with this disorder, he was unable to pronounce what real foundation might exist for the foregoing conjecture, or whether the varicose state of the spermatic veins were a cause, or an effect of the hydrocele. In most instances, the accumulation of fluid takes place without any evident cause; though, in a few cases, it has appeared to be the effect of a contusion, or of rough long-continued friction of the scrotum. The disease is observed to affect persons of the best health, and most robust constitutions, as well as others, and its existence seems quite unconnected with dropsy, or debility. In short, it may be regarded as a disease entirely of a local nature. As Mr. Pott observes, its production is so slow and gradual, and at the same time so void of pain, that the patient seldom attends to it, until it has arrived to some size. Not but that it sometimes is produced very suddenly; and in a very short space of time attains considerable magnitude.

In general, at its first beginning, the tumour is rather round; but as it increases, it frequently assumes a pyriform kind of figure, with its larger extremity downward; sometimes it is hard, and almost incompressible; so much so, that, in some few instances, it has been mistaken for an induration of the testicle: at other times, it is so soft and lax, that both the testicle, and the fluid surrounding it, are easily discoverable. It is perfectly indolent in itself; though its weight sometimes produces some small degree of uneasiness in the back. According to Mr. Pott, the transparency of the tumour is the most fallible and uncertain sign belonging to it: it is a circumstance, says he, which does not depend upon the quantity, colour, or consistence of the fluid constituting the disease, so much as on the uncertain thickness, or thinness of the containing bag, and of the common membranes of the scrotum.

If they are thin, the fluid limpid, and the accumulation made so quick as not to give the tunica vaginalis time to thicken much, the rays of light may sometimes be seen to pass through the tumour: but this is accidental, and by no means to be depended upon. The fluid is most frequently of a pale yellow, or straw-colour; sometimes it is inclined to a greenish cast; sometimes it is dark, turbid, and bloody; and sometimes it is perfectly thin and limpid.

With respect to Mr. Pott's remarks on the transparency of the swelling, as a symptom of hydrocele, they are correct, inasmuch as the absence of this sign is no proof, that the disease is not of this nature; since thickness of the tunica vaginalis, and, as ought also to have been admitted, the opaque quality of the fluid, sometimes prevent the rays of a candle from passing through the swelling. But, on the other hand, it should have been explained by Mr. Pott, that *when the transparency is present, it is one of the surest marks of this species of hydrocele.*

It is next noticed by Mr. Pott, that in the beginning of the disease, if the water has accumulated slowly, and the tunica vaginalis is thin and lax, the testicle may easily be perceived; but if the said tunic be firm, or the water accumulated in any considerable quantity, the testis cannot be felt at all. In most cases, the spermatic vessels may be distinctly felt at their exit from the abdominal muscle, or in the groin; which will always distinguish this complaint from an intestinal hernia. But, in a few examples, the vaginal coat is distended so high, and is so full that it is extremely difficult, nay, almost impossible, to feel the spermatic cord: and the same kind of obscurity is sometimes occasioned by the addition of an encysted hydrocele of the cord; or by the case being combined with a true enterocoele.

In a hydrocele of the tunica vaginalis, the swelling is first noticed at the lower part of the scrotum, whence it ascends in front of the testicle and spermatic cord. The progress of the disease is generally so slow, that six or even eighteen months elapse, be-

fore the tumour approaches the abdominal ring. And, among other characters of the case, are to be noticed the disappearance of the corrugations of the scrotum by the effect of the distention; inclination of the raphe to the opposite side; and the possibility of feeling a fluctuation, when the fingers of one hand are applied to one side of the tumour, and the surgeon slightly taps with the fingers of his other hand upon an opposite point of the swelling.

In the hydroceles of children, the testis occupies a lower situation, than the same organ in the hydroceles of adult persons, and the swelling passes further up towards the abdominal ring.

It is well explained by Mr. Pott, that the tunica vaginalis and tunica albuginea, are so inseparably united at the posterior and superior, or rather the posterior and middle part of the tumour, that no fluid can collect between them; and therefore, the fingers of an intelligent examiner must immediately discover here the firmness and hardness arising from the union of these parts; while in all others, the two membranes being unconnected, and affording a void space for the collection of water, the fluctuation of it will always be distinguishable.

"This (says Pott) must for ever discriminate the simple hydrocele of the tunica vaginalis from the anasarcaous swelling of the scrotum; from the encysted hydrocele of the cord; and from the intestinal hernia. The first is every where equal, tumid, and soft; and every where equally receives and retains the impression of the fingers; the second, though circumscribed, not very compressible, and affording the sensation of fluctuation, yet does not pit, and is alike to the touch in all parts of it; and in the third, if the testicle be distinguishable at all, it is found at the inferior part of the whole tumour."

A collection of fluid in the tunica vaginalis, complicated with a scirrhus or chronic induration and enlargement of the testicle, is well known under the name of *hydro-carcocoele*; a case, which should be carefully discriminated from a simple hydrocele, "one of the marks of the latter being the natural, soft, healthy state of the testicle: and the characteristic of the former being its diseased and indurated enlargement."

Mr. Pott does not mean that, in a true simple hydrocele, the testicle is never altered from its natural state. He admits the contrary, and that it is often enlarged in size, and relaxed in structure, and that the spermatic vessels are frequently varicose. But, the testicle is never indurated. These two diseases are extremely unlike each other, and require very different treatment. That which would cure a simple hydrocele, would dangerously aggravate the hydro-sarcocoele.

Mr. Pott observes, that "it may, and does sometimes become necessary to let out the water from the vaginal coat of a testicle, in some degree diseased; but this should always be done with caution, and under a guarded prognostic; lest the patient be not only disappointed, by not having that per-

manent relief, which, for want of better information, he may be induced to expect; but he also (possibly) subjected to other unexpected inconveniences from the attempt.

"When the disease is a perfect, true, simple hydrocele, the testicle, though frequently somewhat enlarged, and perhaps loosened in its vascular texture, is nevertheless sound, healthy, and capable of executing its proper office; neither is the spermatic cord any way altered from a natural state, except that its vessels are generally somewhat dilated; neither of which circumstances are objections either to the palliative or radical cure of the disease. But in those disorders, which in some degree resemble this, the case is different; either the testicle, or spermatic cord, or both, bearing evident marks of a diseased state."

According to Richerand, a hydrocele may be known from a sarcocele by the following circumstances: in a sarcocele, the tumour mostly retains the shape of the testicle, being oval and a little flattened at the sides, and its size becomes considerable in a short time, without ascending so near the abdominal ring, as a hydrocele does, when of the same magnitude. A large hydrocele leaves no interspace between that opening and the tumour, so that it is difficult to take hold of, and lift up the spermatic cord; but, in a sarcocele, there is always a space between the tumour and the ring, where the cord can be distinctly felt. Lastly, in a sarcocele, the tumour is always opaque, and its weight, in reference to its size, much more considerable, than that of a hydrocele. (*Nosogr. Chir. T. 4, p. 267, Ed. 4.*) The hardness is not a symptom which can be trusted alone, as a criterion of a diseased testicle; for, when a hydrocele is extremely distended, it often feels so indurated as to deceive practitioners of great experience, and a thickened, hardened state of the tunica vaginalis may facilitate the mistake. In some instances of *hydro-sarcocele*, the nature of the disease sometimes remains questionable, until the evacuation of the fluid gives the surgeon a fair opportunity of ascertaining the diseased state of the testicle.

The complication of an hydrocele of the tunica vaginalis with an encysted one of the spermatic cord, may generally be known by the swellings having begun at two different points, and by a kind of constriction between them. The latter symptom, however, is not infallible, because the tunica vaginalis of a common hydrocele is sometimes more or less contracted at the middle of the tumour, which is thus made to appear as if there were two distinct pouches.

The size of a hydrocele, and the thickness of the tunica vaginalis, are generally in a ratio to the time, which the disease has continued. Sometimes the latter membrane acquires nearly a cartilaginous hardness; and portions of it have been found in an ossified state; the only circumstance, in which any free excision of it is now accounted necessary. A hydrocele has been known

to contain four pints of fluid. (*Voigtel, Handbuch der Pract. Anat. B. 3, p. 388.*)

METHODS OF CURING THE HYDROCELE OF THE VAGINAL COAT.

A hydrocele is by no means a dangerous complaint, though its weight and size are a disagreeable incumbrance, and the patient is always obliged to wear a bag truss, in order to prevent a painful extension of the spermatic cord. Troublesome excoriations are also frequently caused by the friction of the tumour against the inside of the thigh; and when the swelling is very large, it draws over itself the integuments of the penis, which appears buried, as it were, in the tumour, and its functions are seriously interrupted. Hence, the greater number of patients are very anxious for relief.

"The methods of cure (says Pott) though various, are reducible to two, (viz.) the palliative, or that which pretends only to relieve the disease in present, by discharging the fluid; and the radical, or that which aims at a perfect cure, without leaving a possibility of relapse. The end of the former is accomplished by merely opening the containing bag in such manner as to let out the water: *that of the latter cannot be obtained, unless the cavity of that bag be abolished, and no receptacle for a future accumulation left*; (a proposition, on which the observations of Mr. Ramsden and Mr. Wadd, published since Mr. Pott's time, have thrown a degree of doubt.) One may be practised at all times of the patient's life, and in almost any state of health and habit: the other lies under some restraints and prohibitions; arising from the circumstances of age, constitution, state of the parts, &c.

"The operation, by which the fluid is let out, is a very simple one. The only circumstances requiring our attention in it, are, the instrument wherewith we would perform it; and the place or part of the tumour, into which such instrument should be passed.

"The two instruments in use, are the common bleeding-lancet, and the trocar.

"The former having the finer point, may possibly pass in rather the easier, (though the difference is hardly perceptible) but is liable to inconveniences, to which the latter is not. The trocar, by means of its cannula, secures the exit of the whole fluid without a possibility of prevention; the lancet cannot. And therefore it frequently happens when this instrument is used, either that some of the water is left behind, or that some degree of handling and squeezing is required for its expulsion; or, that the introduction of a probe, or a director, or some such instrument, becomes necessary for the same purpose. The former of these may in some habits be productive of inflammation: the latter prolongs what would otherwise be a short operation, and multiplies the necessary instruments; which, in every operation in surgery, is wrong. To which it may be added, that if any of the fluid be left in the vaginal coat, or insinuates itself

into the cells of the scrotum, the patient will have reason to think the operation imperfect, and to fear, that he shall not reap even the temporary advantage which he expected. The place where this puncture ought to be made, is a circumstance of much more real consequence; the success of the attempt, the ease, and even sometimes the safety of the patient, depending upon it.

"All the anterior and lateral parts of the vaginal coat are loose and detached from the albuginea; in its posterior and superior part, these two tunics make one; consequently the testicle is, as it were, affixed to the posterior and superior part of the cavity of the sac of an hydrocele; and consequently, the water or fluid can never get quite round it. This being the state of the case, the operation ought always to be performed on that part of the tumour, where the two coats are at the greatest distance from each other, and where the fluid must therefore be accumulated in the largest quantity; and never on that part of it where the fluid cannot possibly be. The consequence of acting otherwise, must not only produce a disappointment, by not reaching the said fluid; but may prove, and has proved, highly and even fatally mischievous to the patient.

"After performing this operation, present practitioners content themselves with a bit of lint and a plaster; and if the scrotum has been considerably distended, they suspend it in a bag truss; and give the patient no farther trouble.

"In most people (continues Pott) the orifice thus made heals in a few hours, (like that made for blood-letting;) but in some habits and circumstances, it inflames and festers; this festering is generally superficial only, and is soon quieted by any simple dressing; but it sometimes is so considerable, and extends so deep, as to affect the vaginal coat, and by accident produce a radical cure. Mr. Pott has also seen it prove still more troublesome, and even fatal; but then the circumstances both of the patient, and of the case, have been particular.

"Wiseman and others have advised deferring the puncture, till a pint of fluid has collected. When there is a sufficient quantity, however, to keep the testicle from the instrument, there can be no reason for deferring the discharge; and the single point on which this argument ought to rest, is this: Whether the absorbent vessels, by which the extravasation should be prevented, are more likely to reassume their office, while the vaginal coat is thin, and has suffered but little violence from distention; or after it has been stretched and distended to ten or perhaps twenty times its natural capacity; and by such distention is (like all other membranes) become thick, hard, and tough? Mr. Pott thinks the probability so much more on the side of the former, that he should never hesitate a moment about letting out the water, as soon as he found

that the puncture could be made securely. And from what has happened within the small circle of his own experience, he is inclined to believe, that if it was performed more early than it generally is, it might sometimes prevent the return of the disease."

The foregoing passage deserves to be particularly recollected, because it evidently implies a belief by Mr. Pott himself, that, under certain circumstances, a radical cure may be effected, though the cavity of the tunica vaginalis be not obliterated; an opinion since promulgated, as I have already said, by Mr. Ramsden, Mr. Wadd, and Mr. Kinder Wood. Indeed, it appears probable, that generally when a hydrocele is permanently cured, by means of such external applications, as do not excite inflammation, but operate by quickening the action of the absorbent vessels, the cavity of the tunica vaginalis is not destroyed; and there can be but little doubt of the same thing, whenever what is termed a spontaneous cure happens, as it sometimes does in young subjects. But, unless the fact were demonstrated by dissection, I should not believe that the cavity is not annihilated, after the completion of a radical cure by any of the methods, calculated to excite inflammation of the tunica vaginalis and tunica albuginea.

The palliative cure should in general be performed at least once on those, who determine to undergo a radical one, as it gives an opportunity of examining the state of the testis, and also of permitting the cavity to be filled again only to such a size, as may be thought to be best calculated to ensure success in any future operation. (*Sir J. Earle on Hydrocele, p. 13, ed. 2.*)

Upon the subject of performing the operation of tapping hydroceles, Professor Scarpa gives us some useful cautions. The analogy, which exists between large scrotal herniæ and hydroceles of considerable size, led this writer to suspect, that, in the latter disease, the displacement and separation of the vessels of the spermatic cord from each other might also happen. Careful investigations, made upon the dead subject, fully justified the conjecture. In all considerable hydroceles, he found the spermatic vessels so displaced and separated, that the artery and vas deferens were ordinarily situated on one side of the tumour, and the veins on the other. Sometimes these vessels all extended over the lateral parts of the tumour, as far as its anterior surface, principally towards the bottom.

It is well known, that in many instances, the operation of puncturing a hydrocele has been followed by a large extravasation of blood within the tunica vaginalis; but Scarpa informs us, that until lately, he was unacquainted with any case of this kind, which was well detailed and authentic enough, to be cited as an example of injury of the spermatic artery in the puncture of a hydrocele. This learned Professor, however, has had such a fact recently communicated to him by Gasparoli, a distinguished surgeon of Pallanza, who, in introducing

the trocar into the lower part of the swelling, had the misfortune to injure the spermatic artery, and the patient was afterward castrated. The wound of this vessel was most clearly proved by the particulars of the case, as detailed in Scarpa's work, to which I must refer the reader.

From the accurate knowledge, (says Scarpa) which we now have upon this pathological point, such an accident may be avoided, by observing the rules, which are elsewhere given for opening the sac of a very large scrotal hernia. In this last operation, as well as that of puncturing an old and voluminous hydrocele, care must be taken to introduce the instrument at a considerable distance from the bottom of the tumour, that is to say, a little below its middle part, and on a line, which would divide the swelling longitudinally into two perfectly equal parts. Experience proves, that for the purpose of completely emptying an hydrocele, it is unnecessary to make the puncture very near the bottom of the tumour. The corrugation of the scrotum, and a slight pressure, made by the surgeon's hand, will suffice for discharging all the fluid contained in the tunica vaginalis, even when the puncture is made at the middle part of the swelling. (*Scarpa, Traité des Hernies, p. 64—68.*) On account of the lower situation of the testicle in the hydrocele of a child, than in that of a grown-up person, these directions of Scarpa will also be of value.

RADICAL CURE OF THIS HYDROCELE.

Besides the employment of external applications, wherewith a permanent cure has occasionally been accomplished, as related in my other work, six different operations have been practised for the same purpose; viz. incision; excision; the application of caustic; the introduction of a tent; the employment of a seton, and injecting some stimulating fluid into the cavity of the tunica vaginalis.

The principle, on which the success of every plan of this kind is commonly believed to depend, is the excitement of such a degree of inflammation in the tunica vaginalis, and tunica albuginea, forming the cavity which contains the water, as shall end in a mutual and general concretion of those membranes with each other, by which it is evident, the receptacle for a future accumulation of fluid is completely obliterated.

All the above plans are not equally eligible. Some of them, indeed, are now quite exploded; and some, which are still practised by a few, are not more successful, though certainly more severe, than one, which will be presently recommended; while others are very uncertain in their effect, as well as painful.

Incision.

Making an incision so as to lay open the cavity containing the fluid, is the most ancient method, being described by Celsus. Paulus Ægineta says, the incision is to com-

mence at the middle of the tumour, and be carried to the upper part of it, in a line parallel to the raphe. This incision is only to go through the integuments; the bag, which contains the water, is then to be opened, and part of the sides of the sac taken away. A director is next to be introduced, and a division of the tunica vaginalis made to the bottom of the swelling. The cavity is afterward to be dressed with lint, and healed by granulations. Hildanus, Dodonæus, Wiseman, Cheselden, Heister, and Sharp, all coincide in stating the dangerous and even fatal consequences sometimes following this mode. Mr. B. Bell, who preferred this operation to every other one, acknowledges, that he has seen it produce great pain and tension of the abdomen, inflammation, and fever. Pott observes, that it can never be said to be totally void of danger, and that it bears the appearance of an operation of some severity. This eminent surgeon abandoned the method, during the last twenty-six years of his life. Severe as it is, it has also been known to fail, as Sabatier and Earle have confirmed.

Excision.

Albucasis gave the first clear account of this operation, though Celsus has certainly mentioned removing some of the sac. White and Douglas used to adopt this method. The latter advises making two incisions, so as to form an oval from the upper to the lower part of the tumour; dissecting off the oval piece of the scrotum, and then making an opening into the sac, and enlarging it with scissors. The tunica vaginalis was next to be entirely cut away, close to where it was connected with the spermatic vessels. The cavity was afterward filled with lint. Sir James Earle justly notices, that this plan must have been tedious, exquisitely painful in the performance, and, as subsequently treated, attended with violent and dangerous symptoms. In modern days, excision is only sanctioned, when the tunica vaginalis is more or less in an ossified state, for a mere thickening of it does not prevent the success of milder plans of treatment. With respect to a mode of excision, recently proposed by Mr. Kinder Wood, it differs entirely from the ancient method, inasmuch as it is perhaps the mildest of every plan yet suggested for the radical cure, since it simply consists in puncturing the hydrocele with an abscess lancet, drawing out a little bit of the sac with a tenaculum, and cutting it off. (*See Med. Chir. Trans. Vol. 9, p. 33.*) But, further experience is requisite to determine, whether this very easy plan is as certain as that with an injection. Whether the cavity is obliterated or not, as Mr. Kinder Wood himself believes, appears also still questionable.

Caustic.

Paulus Ægineta advises destroying the skin with a cautery of a particular form, dissecting off the eschar, and then cauterizing the exposed membrane. Guido di Cauliaco

is, perhaps, the first who described the application of caustic for the cure of hydrocele. Wiseman practised this method. Dionis advises it; but De la Faye and Garengot make objections to it. Mr. Else has left the best account of the manner of using caustic. He recommends laying "a small caustic upon the anterior and inferior part of the scrotum, which it is intended to affect, and, if possible, penetrate through the tunica vaginalis."

The objections to the employment of caustic are, its causing an unnecessary destruction of parts, and producing a tedious painful sore. The action of caustic can never be so regulated as to make an opening with certainty through the tunica vaginalis, so that either its application must sometimes be repeated, or else a lancet, or trocar, used after all. Its success is also less sure, than that of an injection; but, it is preferable to all the other methods, except this latter, the modification of excision proposed by Mr. K. Wood, and, perhaps, the seton.

Tent.

This is first mentioned by Franco. The operation consists in making an opening into the tunica vaginalis, and keeping the wound open with a tent of lint, linen, or sponge, so as to make the cavity suppurate, in which the water was contained. Paré, Guilleman, Covillard, Ruysch, Heister, and Marini, have all described the plan with some variations, one of which consisted in smearing the tents with irritating substances. Dr. A. Monro senior devised the plan of keeping a cannula in the tunica vaginalis; so as to bring on a cohesion of the parts without suppuration. Fabricius ab Aquapendente, however, has made allusion to some surgeons before his time, who used to keep the wound open a few days with a cannula. Mr. Pott tried the cannula, but found it very inconvenient, as its inflexibility hurt the testis whenever the patient moved with inattention, and consequently, he preferred a tent, or bougie, though he speaks of the plan as a very uncertain one.

Of late, Baron Larrey, in consequence of having seen several instances, in which the symptoms, following the use of an injection, were violent, and one case, in which a fatal peritonitis was produced, has recommended exciting the necessary degree of inflammation by keeping a short piece of an elastic gum catheter in the puncture, which instrument also serves afterward to let any fluid escape from the tunica vaginalis. (*Mém. de Chir. Militaire*, T. 3, p. 409, &c.) This author, of course, speaks of the plan as having fully answered his expectations; but, I much doubt whether it has any particular superiority over several of the former methods of employing the tent; methods, which the wisdom, arising from experience, has long since rejected.

Seton

Was first mentioned by Guido di Cauliaco, in 1498, as a means of curing the hydrocele.

In modern times, Pott preferred it to every other method, if we except injection, of which, according to Sir J. Earle, he expressed his approbation before his decease. Mr. Pott found, that the best mode of making the seton was as follows. He employed three instruments: the first was a trocar, the cannula of which was about one-fourth of an inch broad. The second was what he called the seton-cannula, which was made of silver, was just small enough to pass with ease through the cannula of the trocar, and five inches long. The third instrument was a probe six inches and a half long, having at one end a fine steel trocarpoint, and, at the other, an eye, which carried the seton. The seton consisted of so much white sewing silk, as would just pass easily through the cannula, and yet fill it. The thickness of the seton, however, was not so great in the latter part of his practice. Having pierced the inferior and anterior part of the tumour with the trocar, withdrawn the perforator, and discharged the water, Mr. Pott used to pass the seton-cannula through that of the trocar, to the upper part of the tunica vaginalis, so as to be felt there. The probe, armed with the seton, was next conveyed through the latter cannula, and its point pushed through the upper part of the tunica vaginalis, and scrotum. The silk was then drawn through the cannula, until a sufficient quantity was brought out of the upper orifice. The two cannula being withdrawn, the operation was finished.

Injection.

Dr. Monro attributes the first use of injections for the radical cure of hydroceles to an army-surgeon of his own name, who employed spirits of wine. This produced a cure, but the inflammation was so violent, that he afterward tried a milder injection, which consisted of wine. However, Lambert, in his *Œuvres Chir.* published at Marseilles early in the seventeenth century, advised injecting a solution of sublimate in lime water, and he has related cases of success. Mr. S. Sharp also made trial of spirit of wine, which cured the hydrocele, but not without causing dangerous symptoms, and two subsequent abscesses in the scrotum. (*Operations of Surgery*.) Douglas, Le Dran, and Pott, all disapprove of injections in their works; though Sir James Earle informs us, that the latter lived to alter his opinion on the subject.

The violence of the inflammatory symptoms, consequent to the first employment of injections for the radical cure of hydroceles, arose from the fluids used being too irritating. Sir James Earle, at last, preferred wine for several reasons. He found, that it had been used with success in France; its strength is never so great as to render it unsafe; and it may be readily weakened. This injection, in short, produces less pain than any other mode of cure, does nothing more than is intended, and is as certain as any plan.

I have commonly used (says Sir James

Earle) about two-thirds of wine to one-third of water; if the parts appeared insensible, and no pain at all was produced by the first quantity thrown in, I have with drawn the syringe, and added to the proportion of wine; on the contrary, if the complaint was recent, and the parts irritable, I have increased the proportion of water, so that I have hitherto been principally guided by the degree of sensation, which the patient has expressed. I have lately used pure water mixed with wine, and found it answer as well as when astringents were added." (P. 103, *Treatise on the Hydrocele*, Ed. 2.) In the preface, the author says, that he has long disused the pipe with a stop-cock, which he once employed, on account of not being well able to spare a hand, during the operation, to turn it, and its consequently being found awkward. A pipe, one end of which is made to fit into the cannula of a trocar, the other adapted to receive the neck of an elastic bottle, with a valve, or ball, in the centre of the pipe to permit the entrance, and prevent the exit, of the injection, will be found infinitely more convenient and useful. (Earle.) When the hydrocele is very large, Sir James recommends simply letting out the fluid, and waiting till the tumour acquires a more moderate size before attempting the radical cure by injection.

It appears from Sir James Earle's interesting cases, that a cure may be accomplished in this manner, even when the tunica vaginalis is considerably thickened. The following is the common mode of operating; the hydrocele is to be tapped with a trocar at its anterior and inferior part, and, when the whole of the fluid is evacuated, the cavity of the tunica vaginalis is to be distended to its former dimensions with the above injection. This is to be allowed to remain in the part about five minutes, upon the average, after which it is to be discharged through the cannula. The patient usually feels some pain in the groin, and about the kidneys, on the injection being introduced: which symptoms are rather desirable, as they evince that the stimulus of the fluid is likely to have the wished-for effect of exciting the necessary degree of inflammation. This plan, which was brought to a high pitch of perfection by the late Sir James Earle, may be deemed almost an infallible means of obtaining a permanent cure; and being, at the same time, mild, is mostly preferred in England, France, and Germany.

The treatment after the operation is exactly like that of the common swelled testicle, (see *Hernia Humoralis*;) consisting of the use of fomentations, poultices, leeches, saline purges, and, above all, of a bag truss for keeping up the scrotum.

There is a particular case, that has been called the *congenital hydrocele*, by which is implied a collection of water in the tunica vaginalis, with a communication between the cavity of this membrane and that of the peritonæum. Desault used to cure this disease, by a red wine injection. After the protruded viscera had been returned into the belly, and

while the opening between that and the inside of the tunica vaginalis was carefully compressed and closed by a trusty assistant, Desault, after letting out the water in the common way, used to throw in the injection. The method, it is said, succeeded without causing the perilous consequence, one might *a priori* expect, viz. inflammation of the peritonæum.

This kind of hydrocele has not been described by many writers. The case is easily distinguished by the fluid being capable of being pushed into the belly. According to Desault, this disease admits of a cure by injections, care being first taken to press the upper part of the cord, so as to keep the injection from coming into contact with the peritonæum. A successful instance of this practice is related, by which a boy was cured both of a congenital hydrocele and hernia. The patient was nine years old, and had in his scrotum, ever since he was born, a fluctuating semi-transparent tumour, which was free from pain, of the size of a large egg, and disappeared when compressed, and in a horizontal posture. (See *Œuvres Chir. de Desault*, T. 2, p. 442.)

This subject of congenital hydrocele has been more particularly considered in my other work.

One caution it is necessary to offer, before taking our leave of this subject; it has sometimes happened, during the operation, that the cannula has slipped out of the tunica vaginalis, and its inner mouth become situated in the substance of the scrotum, in which event the operator, if he persists in propelling in the injection, will fill the cellular texture of the part with a stimulating fluid, which may cause sloughing, and other unpleasant symptoms, without entering the cavity of the tunica vaginalis, or producing a radical cure of the hydrocele, which, however, I have known happen from this cause, as I have elsewhere related. (See *First Lines of Surgery*, Vol. 2.) When such an accident happens, it is better to defer the operation, till a sufficient quantity of fluid has collected again. Hydroceles have been cured by applying to the scrotum a solution of muriate of ammonia in vinegar and water. (Keale.) But, the application frequently creates a good deal of pain and irritation, and does not often succeed, to say the best of it. (Earle.)

Distending the tunica vaginalis with air, cold water, or even the fluid discharged, has sometimes effected a radical cure. (See *Supplement to Ploucquet*, Tub. 1814, p. 103.)

For many other important remarks, concerning hydroceles, I am obliged to refer to the 2d vol. of the last edition of the *First Lines of the Practice of Surgery*, 1820. *Monro on the Tumours of the Scrotum in the Edinb. Med. Essays*, Vol. 5. John Douglas, *A Treatise on Hydrocele*, 8vo. Lond. 1755; and *Answer to Remarks on that Work*, 8vo. Lond. 1758. Pott on the Hydrocele; Else on the Hydrocele, 8vo. Lond. 1818.

*HYDROPHOBIA. (from *ὕδωρ*, water, and *φοβος*, fear. *A dread of water*.) This being, for the most part, a striking symptom of the fatal indisposition which results from the bite of a mad dog, and some other animals affected in the same way, the disease itself has been named *Hydrophobia*. Some have used the more general term, *hydrophobia*, from *ὕδωρ*, liquid. But strong objection has been made to both these terms, because derived from a symptom, which does not exclusively belong to the disease, nor constantly exist in it.

The old writers, as we learn from Cælius Aurelianus, used the terms *aerophobia*, or *a dread of air*, and *panophobia*, or *a fear of all things*. Since the impression of cold air sometimes excites terror, and the disorder is marked by a singular degree of general timidity and distrust. Others called it *phobodipsos* (*δίψα*, signifying thirst,) because the patient is *thirsty*, yet *fears to drink*. Several modern authors, however, objecting to any appellation expressive only of one symptom, denominate the disease *rabies*, and *rabies canina*, or canine madness. The French call it *la rage*.

With respect to hydrophobia, or the dreadful indisposition produced by the bite of a dog, or other animal, affected with rabies, or by the application of some of the secretions of such animal to a part of the body, the first allusion to it to be found in authors, is that made by Aristotle, (*Hist. Animal. lib. 7, cap. 22*;) but he could have had but very erroneous notions upon the subject, since he sets down man as incapable of receiving the distemper from the bite of a rabid dog.

With respect to a name for the disorder, as the patient does not commonly betray any tendency to fury, while the dread of water is really a customary attendant on the complaint, the terms *rabies* and *la rage* seem strictly even more exceptionable than the word *hydrophobia*. At the same time, in order not to imbibe confused notions, whatever name be thought fittest for the illness

arising in the human subject from the bite of a mad dog, and some other animals similarly affected, it is necessary to understand well, that hydrophobia, in the sense of a horror of water, or other liquids, is an occasional symptom of many diseases, and neither exclusively confined to the indisposition caused by the bite of a rabid dog, or certain other animals, nor even constantly attendant upon it. And, with the same view of avoiding perplexity, all hydrophobic complaints may be arranged in two general divisions:

1. The first, comprising all cases not ascribable to the bite of a rabid animal, or the application of some of its secretions to a part of the body.

2. The second, comprehending the examples preceded by one of those occurrences.

The cases included in the first of these divisions are subdivided into the *symptomatic* and *idiopathic*, or *spontaneous*. By *symptomatic hydrophobia* is understood an aversion or dread of liquids, presenting itself as an occasional symptom of various diseases, as of certain inflammatory, febrile, and nervous disorders, hysteria, epilepsy, injuries of the brain, (Trecourt, in *Recueil Périodique, &c.* T. 6; *Acta Naturæ Curios.* Vol. 2, Obs. 205,) the operation of particular poisons; (Villermay, *Traité des Mal. Nerveuses*, T. 1, p. 90; *Harles über die Hundswuth*, Frankf. 1809; Schmiedel, *Diss. de Hydrophobia ex usu fructuum fagi*, Erlang. 1762, &c.) gastritis, pneumonia, hepatitis, angina, &c. &c. In many of the instances of symptomatic hydrophobia, the aversion, or dread of fluids, occurs on the same day as the cause upon which it depends, or a few days afterward; and, for the most part, may be cured with the disease which has given rise to it, or even independently of it. On the contrary, the hydrophobia from the bite, or infection of a rabid animal, does not come on till a long time after the occurrence of the cause, and, when once formed, has hitherto proved incurable, or very nearly so. Whatever analogy, therefore, may be imagined to exist between symptomatic hydrophobia and rabies, they differ essentially in their causes, progress, degree of curability, and also in the treatment required. (See *Dict. des Sciences Med.* T. 4, p. 38.)

Spontaneous, or *idiopathic hydrophobia*, denotes the questionable form of the complaint, sometimes supposed to be induced by violent mental commotion, anger, fright, &c. unpreceded by any other primary disease, to which it can be referred as a symptom.

Numerous facts upon record leave no doubt concerning the reality of symptomatic hydrophobia; but, perhaps, none of the cases adduced by Raymond (*Mém. de la Soc. Royale de Méd.* T. 2, p. 457,) Roupe (*Nova Acta Physico-Méd.* T. 4,) or Pouteau (*Essai sur la Rage*, Lyons, 1763,) in proof of the possibility of a spontaneous idiopathic form of the disease in the human subject, are sufficiently unequivocal to remove all suspi-

cion, that the complaint either had been preceded by another primary disease (*Dict. des Sciences Méd. T. 22, p. 333.*) or had been the result of an unobserved, or forgotten occasion, on which the infection was received from handling a dog, or cat, never suspected at the time to be affected with rabies. Here a wrong conclusion is the more apt to be drawn, in consequence of the disease being communicable without any bite to fix the patient's attention, and not commencing sometimes for months after the unnoticed receipt of the infection. Thus, Francis Stannier died, in Nov 1787, with symptoms of hydrophobia, though it was not known that he had ever been bitten by a mad dog, (*Lond. Med. Journ. Vol. 9, p. 256.*) yet, what safe inference can be drawn from this case, when the above-mentioned circumstances are recollected, and it is known that the man was often drunk, and in the streets at night? These and other considerations even throw a doubt upon a part of the cases, recorded as instances of symptomatic tetanus, and they lead the generality of the modern writers to incline to the sentiment of Dr. J. Hunter, that a disease, similar in its nature to what is produced by the bite of a mad dog, never arises spontaneously in the human subject. (See *Trans. of a Soc. for the improvement of Med. and Chir. Knowledge, Vol. 1, p. 299—303.*) Many of the symptomatic cases, however, or those in which more or less aversion, or dread of liquids, is evinced as an effect of another disease, are too well authenticated to admit of doubt. In the *Dict. des Sciences Méd. T. 22, art. Hydrophobie*, may be found a great deal of information likely to interest such readers as wish to follow up the subject of the symptomatic forms of the disease. However, in looking over some of the cases there detailed, a suspicion will sometimes arise in an intelligent mind, that the disorder was mistaken; for it will be noticed, that sometimes pain shooting up the limbs preceded the general indisposition, while the rapidity of the disease, and the appearances found on dissection, corresponded precisely to what is usually remarked in hydrophobia. In particular, one patient is described as a man habituated to drinking, and, as a sportsman, to dogs also; he died on the third day, and, on dissection, the stomach and intestines were found inflamed, and even gangrenous in several places, the œsophagus and lungs also participating in the inflammation. (*Commerc. Litter. Noremb. 1743, Hebd. 5.*)

Animals of the dog kind, including the wolf and the fox, are most frequently the subject of rabies; and certain writers have maintained, that, although it may be received and propagated by other animals, yet it always originates in some of the canine race. (*Hillary on Diseases of Barbadoes, p. 246.*) However, it is asserted, that the disease sometimes originates spontaneously in cats, that is to say, without their having been previously bitten by another rabid animal; but the moderns do not incline to the belief,

that it ever has been known to commence in this manner in other animals, though such an assertion is made by Cœlius Aurelianus, Porphyrius, Avicenna, Valeriola, Stalpart-vander Wiel, &c. not only with respect to man, but horses, asses, camels, hogs, bullocks, bears, monkeys, and even poultry. (See *Dict. des Sciences Méd. T. 47, p. 45.*)

It is interesting to inquire, what animals are capable of communicating rabies, and what animals of receiving it? As far as our knowledge yet extends, it appears that animals of the canine species, with perhaps those of the feline race, are the only ones in which this disorder ever arises spontaneously, and they may transmit it to animals of their own kind, to other quadrupeds, and to man. The experiments made by Dr. Zincke, tend to prove also that birds, at least the common fowl, may have the disease communicated to them. (*Neue Ansichten der Hundswuth, &c. Svo, Jena, 1804.*)

But, though it be well known, that animals of the dog and cat kinds can propagate the disorder, it is not settled whether it can be communicated by other animals. In a memoir read to the French Institute, M. Huzard explained that herbivorous quadrupeds, affected with rabies, are incapable of transmitting the disease; a position subsequently confirmed by additional experiments and observations made in the veterinary school at Alfort. Professor Dupuy could never communicate the distemper to cows and sheep, by rubbing their wounds with a sponge, which animals of the same class, already labouring under the disease, had had in their mouths; though the same experiment, made with a sponge, which had been bitten by a rabid dog, propagated rabies by a kind of inoculation. Dupuy has likewise seen, among several flocks, sheep affected with rabies, yet the distemper was never communicated by them to other sheep, notwithstanding the latter were bit in parts stripped of wool. Dr. Gillman inoculated two rabbits with the saliva of a rabid pig; but the disease was not communicated to them. (*On the Bite of a Rabid Animal, p. 38.*) On the other hand, Mr. King, of Clifton, is stated to have communicated rabies to a fowl, by inoculating it with the saliva of an ox, which had just fallen a victim to the disease. (*J. Ashburner, Diss. de Hydrophobia, p. 29.*) The author of the article *Rage* (*Dict. des Sciences Méd.*) observes, respecting this singular case, that, as it is accompanied with no details, doubts must remain, whether the fowl actually died of rabies.

As for some extraordinary cases, in which the disease is alleged to have been communicated to the human subject by the bites of birds, or injuries done with the claws of animals, they are generally dismissed by modern writers, with the inference, that the complaint thus transmitted was not true hydrophobia or rabies. This conclusion is made, with respect to the cases of this kind, reported by Cœlius Aurelianus and Bader, and the notorious example mentioned by A. Baccius of a gardener, who died of the bite

of a cock, which, according to some, was rabid, according to others, merely enraged. Hildanus also details an instance, in which a young man was scratched on the great toe by a cat: and, some months afterward, was attacked with hydrophobia (*Obs. Chir. Cent. 1, Obs. 16*;) but, as a modern writer observes, if the patient were really affected with rabies, it is conceivable that the cat's claw, with which the scratch was made, might have been wet with the animal's saliva. (*Dict. des Sciences Méd. T. 47, p. 47.*)

Another question of considerable importance is, whether hydrophobia, that is to say rabies, can be communicated from one human being to another?—or whether, in man, the disease is infectious or contagious? Many attempts have been made, in vain, to communicate the distemper to several kinds of animals, by inoculating them with the saliva of patients who had perished of the disease. These experiments were made in this country by Gauthier, Vaughan, Babington, &c.; but no infection was the consequence. In France, Giraud inoculated several dogs with the saliva of a man in the convulsed stage of hydrophobia, but none of them afterward took the distemper. (*Bosquillon, Mém. sur les Causes de l'Hydrophobie, in Mém. de la Soc. d'Emulation, 5me année.*) M. Girard, of Lyons, collected some of the frothy saliva the instant it was discharged from a patient's mouth, and he inserted some of it into eight punctures, made on the inside of a dog's four legs; yet, six months after this inoculation, the animal had not suffered the slightest inconvenience. (*Essai sur le Tetanos Rabiens, p. 29.*) A similar experiment was made on three dogs by M. Paroisse, who kept the animals between three and four months afterward, during all which time they continued quite unaffected. (*Bibl. Méd. T. 43.*)

Dr. Bezar published the following experiments:—Pieces of the flesh of a person who had died of hydrophobia, were smeared with his saliva, and given to a dog; another dog was suffered to eat the salivary glands; and a third, the sides of a wound. In three other dogs, incisions were made, the cut parts were then inoculated, and sewed up. Not one of these six animals became affected with rabies. (*See Mém. et Obs. lus à la Soc. Méd. Philanthropique, première année, 1807, p. 17.*)

The preceding experiments only furnish negative results; but one, to which we shall now advert, tends to establish a contrary opinion. On the 19th June, 1813, in the Hotel-Dieu, at Paris, Magendie and Breschet took some of the saliva of a man, who died a few minutes afterward of hydrophobia, and, by means of a bit of rag, they conveyed this saliva to the short distance of twenty paces from the patient's bed, and inoculated with it two healthy dogs. One of the dogs became rabid on the 27th of July, and bit two others, one of which was attacked with complete rabies on the 26th of August. (*C. Busnout; see Collect. des Thèses, in 4to. de la Faculté de Paris, 1814.*) It is

remarked, in the work, from which I have collected these particulars, that the foregoing is one of the best authenticated experiments on the subject; for, in addition to the consideration of the talents and characters of the experimenters themselves, the facts were witnessed by numerous medical students. And, notwithstanding the objections which have been urged against the account, (*see Journ. Gen. de Méd. T. 52, p. 13*) the main points are declared to be entitled to credit. (*See Dict. des Sciences Méd. T. 47, p. 48.*)

With these relations, it is proper to notice certain cases, too credulously promulgated as proofs of the possibility of the disease being communicated from one human being to another. Neither the instance of the maid-servant, who died merely from seeing her mistress vomit, while labouring under hydrophobia (*Mich. Ettmuller, Op. Med. T. 2*;) the case of the peasant's children, which all died on the seventh day, as is alleged from embracing their dying father; the example of a woman contracting hydrophobia from her husband, as detailed by Mangor (*Acta Soc. Reg. Hafniens. V. 2, Obs. 32, p. 408*;) nor other cases of a similar tenor; are now regarded as proving any thing more than that the patients, supposed to have caught the disease by contagion, fell victims either to violent affections of the mind and nervous system, or illnesses accidentally taking place soon after the death of a near relation or mistress. It is clear enough also, that some of the cases were, at most, only instances of symptomatic hydrophobia.

With regard to another opinion, that the bite of a man, or other animal, when merely enraged, may bring on hydrophobia, it is now entirely discarded as erroneous. The cases in support of it, recorded by Cl. Pouteau, Mangetus, Malpighi, Zuinger, Le Cat, &c. when critically examined, only prove that the patients were affected with tetanus, or symptomatic hydrophobia, not arising from any infection; for neither the mode of attack, nor the progress of the symptoms, in any of the examples which are related with sufficient minuteness, lead to the inference, that the patients actually died of rabies. (*See Dict. des Sciences, Méd. T. 47, p. 49.*)

Wrong notions of a very dangerous tendency, have been generally entertained, in regard to the disease, as it appears in the canine race. The writer of the article *Dog*, in Dr. Rees's Cyclopædia, appears to have had extensive opportunities of observing the disorder in dogs, having paid attention to more than two hundred cases. From his remarks, I have collected the following information.

The peculiar symptom which characterizes the complaint in the human subject, has been applied to the disease in the dog, and has occasioned it to be called by the same name, hydrophobia. This is a palpable misnomer; for, in no instance, does there ever exist any dread of water; on the contrary, dogs are in general very greedy after it.

Such unfounded supposition has often conducted to a very fatal error: for, it being the received opinion, that no dog is mad who can lap water, many persons have been lulled into a dangerous security. Another equally false and fatal idea has prevailed, that every mad dog must be wild and furious; but this is so far from being true, that, in the greater number of instances, there is very little of that wild savage fury that is expected by the generality of persons. "Hence," says this author, "as it is evident that the term hydrophobia, characterizing the affection in the dog, is a misnomer, so it is evident that the term madness is equally so. In no instance have I ever observed a total alienation of the mind; in very few have the mental faculties been disturbed. The disposition to do mischief is rather an increased irritability than absence of sense; for, in most instances, even those that are furious, they acknowledge the master's voice, and are obedient." The symptom, which is most frequently first observable in a rabid dog, is a certain peculiarity in his manner; some strange departure from his usual habits. In a very great number of instances, the peculiarity consists in a disposition to pick up straws, bits of paper, rags, threads, or the smallest objects, which may happen to be on the floor. This is said to be particularly common in small dogs. "Others again show an early peculiarity by licking the parts of another dog. In one instance, the approach of the disease was foretold by our observing a very uncommon attachment in a pug-puppy towards a kitten, which he was constantly licking; and likewise the cold nose of a healthy pug that was with him. An attachment to the sensation of cold appears in many cases, it being very common to observe them (the dogs) licking the cold iron, cold stones, &c. Some dogs, early in the disease, will eat their own excrement, and lap their own urine. An early antipathy to strange dogs and cats is very commonly observed, but particularly to cats. As the disease advances, the affected dogs bite those with which they are domesticated, and, lastly, the persons around; but, except in a moment of irritability, they seldom attack the human subject. The irritability that induces them to bite is very strong, but is devoid of wildness. It is more like peevishness than fury. A stick held up at them always excites their anger in a violent degree, and throughout the disease there is generally a wonderful impatience of control, and the animals are with great difficulty frightened. (See *art. Dog*, in *Rés's Cyclopædia*.)

To this passage the following remarks may be added:—Dr. John Hunter calculated, that out of every dozen of rabid dogs, about one evinces no particular tendency to bite. That these animals, and wolves also, have no particular dread of fluid, is proved by facts. Thus, a rabid wolf, at Frejus, swam across several rivers. (*Darluc, Recueil Périod. d'Obs. Vol. 4*.) Duboueix has seen mad dogs drink without difficulty, and plen-

tifully. (*Hist. de la Soc. de Méd. an. 1783*.) Rabid animals will sometimes eat as well as drink. Thus the wolf which bit so many persons at Meyne, in 1718, was found in the morning devouring a shepherd's dog. And Dr. Gilman speaks of a dog, which was not deemed rabid, because it eat and drank well; but, as it seemed indisposed, it was killed, though not before it had bit a man, who fell a victim to hydrophobia. (*On the Bite of a Rabid Animal*, p. 15.)

When a dog bites a person, it should not be immediately killed, but merely chained up, because, by destroying it at once, the possibility of ascertaining whether it was rabid is prevented, and great alarm is thus kept up in the mind of the wounded person and his friends. If the animal be affected with rabies, it will perish in a few days. At the veterinary school at Alfort, when a dog has been bit, it is usual to chain the animal up, for at least fifty days, before it is restored to its master, about six weeks being considered the period when a dog generally becomes rabid after being bitten.

For additional details, relating to the disease as it appears in the dog, I must refer to the above-mentioned paper. Enough, I hope, has been said to make the reader aware, that mad dogs are not particularly characterized by an inability to lap water, or any degree of fury. These animals, when actually affected with rabies, from their quiet manner, have even not been suspected of having the disorder, and have been allowed to run about, been fondled, and even slept with. (See *Mem. of Swedish Acad. 1777*.)

The causes of this peculiar distemper in dogs are at present unknown, and little more than conjecture prevails upon the subject. It is not positively known whether rabies sometimes originate spontaneously in these animals, though I believe this opinion is at present gaining ground; or whether, like small-pox in the human species, it is propagated only by contagion. That the disease is frequently imparted in consequence of one dog biting another, every body well knows. Yet there are many instances in which this mode of propagation cannot be suspected. Several facts render it probable, that, among dogs, the disease is often communicated by contagion. It is observed, that, in insular situations, dogs are seldom affected, and this circumstance is ascribed to such animals being in a kind of quarantine. The celebrated sportsman, Mr. Meynell, secured his dogs from the malady by making every new hound perform a quarantine before he was suffered to join the pack. (See *Trans. for the Improvement of Med. and Chir. Knowledge, Vol. 1, art. 17*.) Great heat was very commonly supposed to be an exciting cause of the disease in dogs; but without much foundation. "A very hot climate, or one exposed to the extremes of heat and cold; a very hot and dry season; feeding upon putrid, stinking, and maggoty flesh; want of water; worms in the kidneys, intestines, brain, or cavities of the

nose," are set down by Boerhaave as causes of the disease. (*Aphorism*, 1134.) We learn from Dr. J. Hunter, that, in the hot island of Jamaica, where dogs are exceedingly numerous, not one was known to go mad during forty years. (*Trans. for the Improvement of Med. Knowledge*, loc. cit.) Cold weather has also been set down as conducive to rabies among the canine race, as is suggested, because the ponds being frozen, these animals cannot quench their thirst. (*Le Roux*.) That neither of these sentiments about heat and cold being the cause of the origin of the disease in dogs is correct, will be manifest enough to any body who has patience to look over the volume of the *Mém. de la Soc. Royale de Méd.* devoted entirely to the consideration of rabies; and, from the investigations of M. Andry, (*Recherches sur la Rage*, 8vo. Paris, 1780,) it appears that January, the coldest month in the year, and August, the hottest, are those which furnish the fewest instances of hydrophobia. On the contrary, the greatest number of rabid wolves is in March and April; and that of dogs, affected with spontaneous rabies, in May and September.

According to Savary, dogs never go mad in the Island of Cyprus, nor in that part of Syria which is near the sea; and Volney assures us that these animals enjoy the same fortunate exemption both in the latter country and in Egypt. (*Voyage in Syrie*, T. 1.) The traveller Brown also declares, that, in Egypt, they are never, or very rarely, attacked with rabies.

"Although (says Baron Larrey) hydrophobia is more frequent in warm than temperate climates, it is not observed in Egypt, and the natives assured us, that they knew of no instance in which this disease had manifested itself, either in man or animals. No doubt this is owing to the species and character of the dogs of this country, and their manner of living.

"It is remarked, that the Egyptian dogs are almost continually in a state of inaction; during the day, they lie down in the shade, near vessels full of fresh water prepared by the natives. They only run about in the night time; they evince the signs and effects of their love but once a year, and only for a few instants. They are seldom seen coupled. On our arrival, there was a vast number of these animals in Egypt, because they were held like many others, in great veneration, and were never put to death. They do not go into the houses; in the day time they remain at the sides of the streets, and they only wander into the country at night, in order to find any dead animals which happen to be unburied. Their disposition is meek and peaceable, and they rarely fight with each other. Possibly all these causes may exempt them from rabies." (*Larrey in Mém. de Chir. Militaire*, T. 2, p. 226.)

This observation, about the exemption of the Egyptian dogs from rabies, is a very ancient one, having been made by Prosper Alpinus, (*Res. Egyptiarum*, lib. 4, cap. 8.) According to Barrow, the dogs in the vic-

nity of the Cape of Good Hope, and in Caffraria, very rarely go mad. (*Travels into the Interior of Africa*.) Several authors assert, that rabies never occurs in South America. (*Bibl. Raisonnée*, 1750. *Van Swieten Comment. in Aphor.* 1129, *Portal &c.*) L. Valentin declares, that it is exceedingly rare in the warm regions of America, but common in the northern part of that continent. (*Journ. Gén. de Méd.* T. 20.) Dr. Thomas, who resided a good while in the West Indies, never saw nor heard of a case of rabies there, (*Practice of Physic*;) and Dr. B. Moseley states that the disorder was not known in those islands, down to 1783. On the other hand, the disease sometimes happens in the East Indies, though not with such frequency as at all to justify the doctrine about heat being the cause of its production. The silence of Hippocrates proves, that in his days hydrophobia must have been very rare in Greece; and, as the disorder is not mentioned in the Scriptures, an inference may be made, that it could not be so common in the hot tracts of the globe, inhabited by the Hebrews, as in the temperate climates of Europe and America.

Neither can the sentiment be received as correct, that rabies is more frequent in the north than in the temperate parts of Europe; for De la Fontaine particularly notices how extremely rare it is in Poland. (*Chir. Med. Abhandl. Breslau*, 1792.) The disease is reported to be very common in Prussian Lithuania; but mad dogs are seldom or never heard of at Archangel, Tobolsk, or in the country north of St. Petersburg.

In Mr. Meynell's account, which was communicated to him by a physician, it is asserted, that the complaint never arises from hot weather, nor putrid provisions, nor from any cause except the bite; for, however dogs have been confined, however fed, or whatever may have been the heat of the season, the disorder never commenced, without a possibility of tracing it to the preceding cause, nor was it ever introduced into the kennel, except by the bite of a mad dog. (See art. *Dog*, in *Rees's Cyclopædia*.)

Dr. Gillman endeavours to prove, that the disease in dogs is probably excited independently of particular climates, of putrid aliment, of deficiency of water, of want of perspiration, or, of the worm under the tongue, to which causes it has been at different times ascribed, and he expresses his belief, that it originates somewhat like typhus in the human subject, and is not always produced by inoculation, or by means of a bite. He thinks that it may be occasionally brought on by the confinement of dogs, without exercise, in close and filthy kennels; and that the success of Mr. Trevalyan, as related by Dr. Bardsley, in clearing his kennel of the disease, by changing even the pavement, after other means of purification had failed, affords presumptive evidence in favour of the opinion; and, consequently, this author thinks, that the method of quarantine, adopted by Mr. Meynell, and recommended by Dr. Bardsley, on the supposition,

that the disease originates exclusively from contagion, will not be a sufficient preventive alone; and he infers, from some facts, reported by Mr. Daniel, that the poison sometimes lies dormant in dogs four, five, and six months; and, consequently, that the period of two months is not a sufficient quarantine. (See *Gillman's Diss. on the Bite of a Rabid Animal*.)

In opposition, however, to some of the sentiments contained in the foregoing passage, it should be known, that Dupuytren, Magendie, and Breschet, have purposely kept many dogs for a long time in the most disgusting state of uncleanness, let them even die in this condition for want of food and water, or even devour each other, yet without exciting rabies. (*Dict. des Sciences Méd. T. 47, p. 53*.) Yet Professor Rossi, of Turin, is said to have produced this, or some similar disease in cats, by keeping them shut up in a room. (*Mém. de l'Acad. Imp. de Turin, 1805, & 1808, p. 93, de la Notice des Travaux*.) On the whole, I consider it well proved, that neither long thirst, hunger, eating putrid flesh, nor filth, will occasion the disease in the canine race. At Aleppo, where these animals perish in great numbers from want of food and water, and the heat of the climate, the distemper is said to be unknown. Nor is rabies found to attack dogs and cats, with particular frequency during the copulating season, and therefore, the *œstrus veneris* cannot be admitted to have any share in its production, as some writers have been disposed to believe. (See *Dict. des Sciences Méd. T. 47, p. 55*.)

Although most writers believe in the reality of a poison, or specific infectious principle, in cases of rabies, the fact has been questioned, or absolutely rejected by others. Bosquillon considered the disease always as the effect of fear, or an impression upon the imagination. This view of the matter is far from being new, and has been ably refuted by many authors, and especially by M. De sault, of Bordeaux, who remarks, that horses, asses, and mules, *quibus non est intellectus*, had died rabid the very year in which he wrote; and, it is observed by Dr. J. Vaughan, that an infant in the cradle is sometimes attacked, while many timorous children escape.

Another notion has partially prevailed, that rabies does not depend upon any virus, but upon the continuance of an irritation in the bitten parts, affecting the whole nervous system. (*Percival; J. Mease; Girard; &c.*) But, this doctrine confounds rabies and tetanus together, and can only apply to the symptomatic non-infectious hydrophobia from an ordinary wound, or laceration.

The facts, in proof of the reality of a peculiar infectious principle in cases of rabies, are too numerous to leave any doubt upon the subject. Twenty-three individuals were bit one morning by a female wolf, of whom thirteen died in the course of a few months, besides several cows, which had been inju-

red by the same animal. How could all these unfortunate persons have had similar symptoms, and especially a horror of fluids, had they not been all under the influence of some cause, besides the bites? The patients who died, were bit on the naked skin; while in the others, who escaped infection, the bites happened through their clothes, which no doubt intercepted the saliva, the vehicle of the virus. In the Essay by Le Roux, mention is made of three persons, bit by a rabid wolf near Autun, in July, 1781, and, notwithstanding mercurial frictions, they all died of hydrophobia. Of ten other individuals bit by a wolf, nine died rabid. (*Rey, Mém. de la Soc. Royale de Méd. p. 147*.) Twenty-four persons were injured in the same manner near Rochelle, and eighteen of them perished. (*Andry, Recherches sur la Rage, Ed. 3, p. 196*.) On the 27th January, 1780, fifteen individuals were bit by a mad dog, and attended at Senlis by the commissioners of the French Royal Society of Physic; ten had received the bites on the naked flesh, and five through their clothes. Of the first ten, only five lost their lives, three of them dying of decided rabies between the 27th of February, and the 3d of April; and the other two between the 29th of February, and the 18th of March. Unless the opinion be adopted, that the disease is caused by an infectious principle, a sort of inoculation, it would be impossible rationally to explain the cause of so many deaths from the bites of rabid animals. If the idea, that rabies originates from fear or nervous irritation were true, how could we account for there being such a difference between the usual consequences of the bite of a healthy dog, and those of the bite of one affected with rabies? Healthy dogs are incessantly quarrelling, and biting each other in the streets, yet their wounds are not followed by rabies; and as a modern author remarks, if hydrophobia were referrible to nervous irritation derived from the wounded part, how does it happen, that among the thousands of wounded after a great battle, hydrophobia is not seen instead of tetanus. (*Dict. des Sciences Méd. T. 47, p. 61*.) But, if it were yet possible to entertain a doubt of an infectious principle in hydrophobia, this possibility would be removed by the reflection, that the disease may be communicated to healthy animals by inoculating them with the saliva of certain other rabid animals. In fact, as I have stated, the bites of such animals are in every point of view only an inoculation; and the same remark may be extended to the numerous instances on record, in which the disease arose in the human subject, as a consequence of a rabid dog, or cat, (not suspected to be in this state at the time) having been played with, fondled, or suffered to lick the naked skin, in which there was at the moment some slight scratch, entirely overlooked.

Many of the ancient writers not only believed in the hydrophobic virus, or infectious principle, but even in its diffusion

through the blood, flesh, and secretions in general; and this hypothesis was professed by Boerhaave, Van Swieten, Sauvages, F. Hoffman, &c. but, in proportion as the humoral pathology lost ground, the foregoing idea was abandoned, and the opinion adopted, that the infection is confined to the saliva, and wounded part, in which it has been inserted.

The tales of some old authors would lead one to think, that hydrophobia may be communicated by eating the flesh of a rabid animal. (*Fernelius, De Obs. Rer. Caus. et Morb. Epidem. lib. 2, cap. 14; Schenckius; Mangetus, &c.*) But, respecting these accounts, it is remarked, that they are not entitled to much confidence; for, it is certain, that rabies never begins as is stated, with regard to some of the cases in question, a few hours after the application of its cause, and its early stage is never characterized by any fury, or disposition to bite. And, besides, how can such relations be reconciled with the practice of the ancients, who, according to Pliny, employed the liver of the mad dog or wolf, as a remedy? Palmarius also fed his patients for three days with the dried blood of the rabid animal. (*Mém. de la Soc. de Méd. p. 136, et le No. 178.*) The flesh of a bullock, which had been bit by a mad dog, and afterward died rabid, was sold to the inhabitants of Medola near Mantua, yet none of them were attacked with hydrophobia. (*Andry, Recherches sur la Rage, &c. p. 30.*) Dr. Le Camus informed Lorry, that he had eaten the flesh of animals which died rabid, but he suffered no inconvenience from the experiment. And, it is stated in the letter of Dr. L. Valentin, that the negroes in the United States of America had no illness from eating the flesh of pigs, which had died of rabies. (*Journ. Gén. de Méd. T. 3, p. 417.*) As for the question, whether the blood is infected? It is generally considered to be settled in the negative, notwithstanding the account given by Lémery of a dog, which was attacked with rabies, as is said, from lapping the blood of a hydrophobic patient, who had been bled. (*Hist. de l'Acad. Royale des Sciences, 1707, p. 25.*) Dupuytren, Breschet, and Magendie, were never able to communicate rabies by rubbing wounds with blood taken from mad dogs; and they even several times injected such blood into the veins of other healthy dogs, yet none of these latter animals were attacked with rabies, though they were kept for a sufficient length of time to leave no doubt upon the subject. (*See Dict. des Sciences Méd. T. 47, p. 63.*)

A point of greater practical interest than the former, is, whether the drinking of the milk of an animal, labouring under rabies, is attended with any risk of communicating the disease? It is asserted by Timæus, that a peasant, his wife, children, and several other persons, were seized with hydrophobia, in consequence of drinking the milk of a rabid cow; and that the husband and eldest child were saved by medical treatment; but, that the wife and four of the

children died. It is further stated, that three or four months afterward, the maid and a neighbour, who had partaken of the milk of the same cow, also died of hydrophobia. (*Cons. 7, Obs. 33.*) In opposition to this account, however, several facts, reported by other writers of greater credit, tend to prove, that hydrophobia cannot be communicated by the milk of a rabid animal. (*Nova Acta Nat. Cur. Vol. 1, Obs. 55; Baudot, in Mém. de la Soc. Royale de Méd. an 1782 et 83, T. 2, p. 91.*)

The cases reported by F. Hoffman and Chabert, with the view of proving the possibility of infection, through the medium of the semen, are of no weight, because, on a critical examination of them, it will be found, that the infection of the women is stated to have taken place very soon after their husbands had been bit, which is quite at variance with the established character of the disease, as it never commences, and of course cannot be propagated in any manner, soon after the receipt of the bite. Besides, these histories are refuted by others of greater accuracy. (*See Baudot in Mém. de la Soc. Royale de Méd. an 1782, &c., p. 92; Rivallier, Vol. cit. p. 136; p. 211; Bouteille, p. 237; Boissière, in Journ. Gén. de Méd. T. 17, p. 296.*)

Neither can hydrophobia be imparted by the breath, notwithstanding the statements of Cælius, Aurelianus, and some other old writers. A nurse, mentioned by Dr. J. Vaughan, repeatedly kissed a hydrophobic infant, which she had suckled, and exposed herself incessantly to its breath, but without the least ill effects. The fear which has also been entertained of the disorder being receivable from the application of the patient's perspiration to the skin, is not founded upon any authentic facts.

Does the infectious principle of rabies reside in the salivary secretion, or in the mucus of the trachea and bronchiæ? The common belief is, that in hydrophobia, the salivary glands are considerably affected. But, it has been remarked by a modern writer, that if these glands exhibit no morbid alteration during the whole course of the disorder; if they are found healthy after death; if the air-passages are the seat of inflammation; if the saliva does not constitute the frothy slaver about the lips; and if such slaver, wherewith the disease may be communicated by inoculation, is derived from the inflamed windpipe and bronchiæ, and consists of mucus converted into a kind of foam by the convulsive manner in which the patient breathes, there is some reason for questioning, whether the saliva, strictly so called, undergoes the alteration generally supposed? (*See Dict. des Sciences Méd. T. 47, p. 66.*) However, this writer is not exactly correct, when he describes the frothy secretion about the mouth, as being altogether composed of mucus from the trachea, since a great part of it is unquestionably true saliva and mucus secreted in the fauces and mouth. In the stomachs of dogs, which died rabid, Dr. Gillman con-

stantly observed traces of inflammation, and he once tried to communicate the disease to two rabbits, by inoculating them with matter taken from pustules, found in the stomach of a rabid dog; but no infection took place. (*On the Bite of a Rabid Animal*, p. 32.)

According to Professor Rossi, of Turin, the nerves, "before they grew cold, participated with the saliva in the property of communicating rabies." He asserts, that he once imparted the disease by inserting in a wound a bit of the sciatic nerve, immediately after it had been taken from a living rabid cat. (*See Mém. de l'Acad. Imp. de Turin, Sciences, Phys. et Mathém. de 1805 à 1808, part. 93. de la Notice des Travaux.*)

After all which has been stated, concerning the hypothesis of the infectious principle of hydrophobia being more or less diffused through the solids and fluids of a rabid animal, and not being restricted to the saliva, perhaps, the safest conclusion to be made is, not to reject the opinion altogether, but to consider it as at present requiring further proof. And from observations of what happens in the human subject, the same inferences should not always be drawn, as from experiments on animals, which are liable to be attacked with spontaneous rabies of a decidedly infectious character. (*See Dict. des Sciences Méd. T. 47, p. 67.*)

Although many cases are to be met with in the records of medicine and surgery, tending to convey an idea, that the mere application of the saliva of a rabid animal to the sound entire skin of the human subject, may give rise to hydrophobia, the assertion is contrary to general experience, and liable to a reflection which must overturn the hypothesis; viz. the slightest prick, scratch, abrasion, or broken pimple on the surface of the body, such as would not be likely in many instances to excite notice, may render the application of the saliva to the part a positive inoculation.

Instances are also reported, the tenor of which is to prove, that the hydrophobic virus may take effect through a sound mucous membrane. (*Palmarius, de Morbis Contag.; Portal, Obs. sur la Rage, p. 131; Matthieu in Mém. de la Soc. Royale de Méd. p. 310, &c.*) But that this does not happen in the human subject is tolerably well proved by the consideration, that formerly a class of men made it their business to suck the wounds, caused by the bites of rabid animals; yet none of them contracted hydrophobia from this bold employment. (*Bosquillon, Mém. de la Soc. d'Emulation, T. 5, p. 1.*) The example of the nurse, who repeatedly kissed a child without the least ill effect, while it was dying of rabies, as recorded by Dr. J. Vaughan, has been already noticed. However, if hydrophobia were apparently to arise in any rare instance from the application of the saliva of a rabid animal to the inside of the lips, no positive inference could be drawn from the fact, unless the means were also possessed of ascertaining, that there were no slight abrasion about the gums, or within the mouth, previously to such application.

For the hydrophobic virus to take effect, therefore, it is generally, if not always necessary, that the infectious saliva be either applied to an abraded, wounded, or ulcerated surface. In the case of a bite, the teeth are the envenomed weapons, which at once cause the solution of continuity, and deposit the infection in the part. But the mere abrasion of the cuticle, and the application of the infectious saliva to the denuded cutis, will often suffice for the future production of the disease. As the mode of communication, therefore, is a true inoculation, it follows, that the danger must depend very much upon the quantity of infectious matter conveyed into, or applied to the part, the effectual manner, in which the saliva is lodged in the flesh, the extent and number of the wounds, and particularly the circumstance of the teeth of the rabid animal having passed through no clothes, by which the saliva might possibly be effectually prevented from entering the wound at all. Hence, bites on the hands and face are well known to be of the most dangerous description, especially those on the face, the hands being sometimes protected with gloves.

From what has been observed, however, it is not to be concluded, that the disease always follows, even when the animal, which inflicts the bite, is decidedly rabid, and some of its saliva is actually applied to the wounded or abraded parts. On the contrary, experience fully proves, that out of the great number of individuals often bit by the same mad dog, and to whom no effectual prophylactic measure is extended, only a greater or lesser number are afterward attacked with hydrophobia. When this difference in the fate of the individuals cannot be explained by the intervention of their clothes, the thickness of the cuticle at the injured part, the small size and superficial nature of the bite, the ablation of the part, or some other mode in which any actual inoculation may have been rendered ineffectual, it can only be referred to some unknown peculiarities, or differences in the constitutions of the several individuals. The latter conjecture seems more probable, when the fact is recollected, that some animals are more susceptible of rabies than others, and some appear to resist the infection altogether.

Dogs are more susceptible of the infection than the human species. Four men and twelve dogs were bit by the same mad dog, and every one of the dogs died of the disease, while all the four men escaped, though they used no other means of prevention but such as we see every day fail. There is also an instance of twenty persons being bit by the same mad dog, of whom only one had the disease.

Dr. Heysham has defined hydrophobia to be an aversion and horror at liquids, exciting a painful convulsion of the pharynx, and occurring at an indeterminate period after the canine virus has been received into the system. Dr. Cullen places it in the class *neuroses*, and order *spasmi*, and defines it a loathing and great dread of drinking any liquids.

from their creating a painful convulsion of the pharynx, occasioned most commonly by the bite of a mad animal. Others have suggested the following definition, as more complete: melancholy, dread of cold air, of any thing shining, and particularly of water; often arising from the bite of a mad animal. (*Parr's Med. Dict.*) However, the latter definition is, perhaps, equally objectionable, because there is not invariably a dread of shining bodies. (See *Dr. Powell's Case*, p. 8.) While some authors represent it as a nervous disorder, others, among whom is Boerhaave, consider it as one of an inflammatory nature. In many systems of surgery, hydrophobia is treated of with poisoned wounds, of one species of which it is strictly the effect.

With regard to the symptoms of hydrophobia, they are generally tardy in making their appearance, a considerable, but a very variable space of time usually elapsing between their commencement and the receipt of the bite. Out of a table of 131 cases, none of the patients became ill before the eleventh day after the bite, and only three before the eighteenth. It is pretended by Pouteau, that one patient was bit by a dog in the morning, and was attacked with hydrophobia at three o'clock in the afternoon. But as this account was communicated to the author a long time after the occurrence, and not by a medical man, it deserves little confidence. Another case, adverted to by Mead, is deprived of all its importance by the same consideration. These examples, as well as another reported by Astruc, in which the patient is said to have had hydrophobia in less than three days after being wounded on the temples, can at most be regarded only as specimens of symptomatic hydrophobia. (*Dict. des Sciences Méd. T. 47, p. 74.*) There appears to be no determinate period, at which the disorder makes its attack after the bite; but it is calculated, that the symptoms most frequently commence between the 30th and 40th day, and that after this time the chances of escape increase. Of 15 patients, whose cases Trollet was acquainted with, seven were attacked between the 14th and 30th days; five between the 30th and 40th; two a little beyond the latter period; and one after 14 weeks. In May, 1784, 17 persons were bit by a rabid wolf, near Brive, of whom 10 were afterward attacked with hydrophobia; viz. one on the 15th day after the bite; one on the 18th; one on the 19th; one on the 28th; one on the 30th; one on the 33d; one on the 35th; one on the 44th; one on the 52d; and the last on the 68th day. (*Hist. de la Soc. Royale de Méd. p. 209.*) Fothergill and Mosely mention cases, in which the disease began four months after the bite; and M. Matthey, of Geneva, details an instance, in which the interval was 117 days. (*Journ. Gén. T. 54, p. 275.*) Haguénor knew of a case, in which the interval between the bite and the commencement of the illness was five months. (*Portul. p. 183.*) Dr. J. Vaughan mentions an interval of nine months; Mead, of 11; Galen, Bauhin, and Boissière,

of a year; Nourse, of 19 months; and R. Lentilius, of three years.

Dr. Bardsley, of Manchester, has recorded a case, in which the most careful inquiries tended to prove, that the patient had never suffered the least injury from any animal, except the bite, inflicted twelve years previously to the commencement of hydrophobia, by a dog apparently mad. (*Mem. of Liter. and Phil. Society of Manchester, Vol. 4, Part. 2, p. 431.*)

A merchant of Montpellier is also stated to have been attacked with hydrophobia ten years after the bite of a rabid dog, which also bit the patient's brother, who died hydrophobic on the 40th day after the accident. (*See Dict. des Sciences Méd. T. 47, p. 75.*) Here may also be found references to cases, in which the interval is alleged to have been 18, 20, and even 30 years. It is certainly difficult to attach any credit to these very late periods of attack. Dr. J. Hunter considers 17 months, and Dr. Hamilton 19, the longest interval deserving belief. (*On Hydrophobia, Vol. 1, p. 113.*) Exposure to the heat of the sun, violent emotions of the mind, and fear, are believed to have considerable influence in accelerating the commencement of the symptoms. That mental alarm is also of itself sometimes capable of bringing on a simple hydrophobia, totally unconnected with infection, is incontestable a case, which has not always been duly discriminated. A most convincing proof of this fact is recorded by Barbantini, in the Italian Journ. of Physic, Chymistry, &c. for January and February, 1817. A young man was bit by a dog, which he fancied was mad, and on the 5th day he evinced symptoms of hydrophobia, of which he was nearly dying, when the dog which had bit him, was shown to him perfectly well, and the intelligence tranquillized him so effectually, that he was quite well four days afterward. Mr. John Hunter is said to have mentioned in his Lectures a very similar case, in which he believed the patient would certainly have died, if the dog which inflicted the bite had not been found, and shown to the patient perfectly well. (*See Journ. Gen. de Med. T. 41, p. 215.*) It is to the effects of terror, that several modern writers are disposed to refer the instances of very late attacks of hydrophobic symptoms after the period when the patients were bitten; though, unless the intellects be changed in the mean time by other causes, it is difficult to conceive, why the alarm should not have the greatest effect earlier, while the impression of the danger is undiminished by time. The idea, that the symptoms begin sooner after the bite of a wolf, than that of a dog, is not adopted by a writer who has taken great pains to collect information on the present interesting disorder. (*See Dict. des Sciences Méd. T. 47, p. 77.*)

Cullen has divided the disease into two stages, the hydrophobia *simplex* and *rabiosa*; or the *melancholy* and *raving* stages of some other writers. But as the early stage is frequently unattended with any thing like me-

lancholy, it is best merely to adopt the distinction of the *first* and *second* stages; one comprehending the effects of the disorder previously to the occurrence of a dread, or decided aversion of liquids; the other, the subsequent changes. The wound, if treated by common methods, usually heals up at first in a favourable manner. At some indefinite period, and occasionally, long after the bitten part seems quite well, a slight pain begins to be felt in it, or the neighbouring parts, now and then attended with itching, but generally resembling a rheumatic pain. If the bite took place on the finger, the pain successively extends from the hand to the fore arm, arm, and shoulder, without any redness or swelling in these parts, or any increase of suffering from pressure or motion of the limb. In a great number of instances the trapezius muscle, and the neck, on the same side as the bite, are the points to which the pain principally shoots. The cicatrix, in the mean while, begins to swell, inflames, and often festers and discharges an ichorous matter. These uneasy painful sensations recur from time to time, and usually precede any dread of water several days; and they are a just reason for apprehension. Sometimes pains of a more flying, convulsive kind, are felt in various parts of the body. As the disease advances, the patient complains of the pain shooting, from the situation of the bite, towards the region of the heart. Sometimes instead of pain, there is rather a feeling of heat, a kind of tingling, or even a sensation of cold, extending up to the chest and throat. Occasionally no local symptoms take place: thus Sabatier, in giving account of several cases, remarks it as worthy of notice, that the bitten parts did not become painful previously to the accession of the fatal symptoms; nor did any swelling, or festering occur. (See *Mém. de l'Institut. National*, T. 2, p. 249. &c.)

Dr. Marcet particularly observed, that the pain follows the course of the nerves, rather than that of the absorbents. In the case which he has related, as well as in one of the cases detailed by Dr. Babington, there was pain in the arm and shoulder, but without any affection of the axillary glands; and in another case, (See *Medical Communications*, Vol. 2,) the pain, occasioned by a bite in the leg, was referred to the hip and loins, without any affection of the inguinal absorbents. (*Medico-Chir. Trans.* Vol. 1, p. 156.) Of the accuracy of the foregoing statement, by Dr. Marcet, there is no doubt: the observation, however, in regard to the irritation not affecting the absorbents, was long ago anticipated by several authors, who urged the freedom of the lymphatic glands from disease, as an argument that the disorder did not depend upon the absorption of any virus. It is also noticed by others, who inclined to the belief, in the absorption of the infectious principle. "Resorptionem virus ope systematis lymphatici fieri verisimillimum videtur; neque tamen nec vasa lymphatica, nec glandulae vicina stimulo morbo, vel tumore adfici videntur; quod in aliis resorptionibus virulen-

tis fieri solet." (*Callisen Syst. Chirurgie Hodiernæ*, Vol. 1, p. 595, *Hafniae*, 1798.)

Pain and heaviness are felt in the head. Sometimes, the headach is at first very severe: sometimes but slight; but, in the latter case, it often becomes intense, general, and accompanied with a sense of pressure upon the temples. In certain instances, the patient's sleep lasts a good while, though disturbed by dreams; while, in other more frequent examples, he is continually restless. The intellectual functions generally seem increased; the memory stronger; the conception more ready; the imagination more fertile; and the conversation more animated. However, some patients are silent and dejected, and, when questions are put to them, the answers are short and peevish. But the greater number are active, lively, and talkative. At the same time, the organs of sense betray signs of increased sensibility; and the eyes, which are very open and bright, avoid a strong light. Sometimes, the pupil is found to be considerably dilated. Extraordinary pains are felt about the neck, trunk, and limbs. It is not uncommon also for the patient to evince great anxiety, or to fall into a state of dull despair and melancholy. These last symptoms, of which great notice is taken by writers, are particularly ascribable to the effect of fear. The disorder of the organs of digestion is sometimes manifested in various ways, though it is far from being so frequent and striking, as the affections of the head, which precede it. The disorder referred to, consists at first in loss of appetite; nausea; vomiting; and afterward constipation, and sometimes colic. In the first stage of the disease, the pulse is generally somewhat more frequent and strong than in health, and the countenance appears more animated.

The above symptoms precede the second stage, or that of decided rabies, only by a few days, usually four or six, though sometimes but two or three. (*Dict. des Sciences Méd.* T. 47, p. 78.)

The second stage of hydrophobia commences with the first manifestation of the dread, or aversion of liquids. The ungovernable agitation and distressing sense of suffocation excited by the sight of liquids, the attempt to drink, or even the mere idea of drinking, is unquestionably the most remarkable symptom of the disorder. The patient is also frequently attacked with the same kind of commotion and suffering, from other causes, such as the least agitation of the air, or exposure to a strong light. Indeed, some patients are so much affected by a blast of wind, that they have been known to endeavour to elude it by walking with their backs towards it; (*Hist. de la Soc. Roy. de Méd.* p. 157,) while others scream out whenever the window or door of their room is opened. (*Morgagni De Sed. et Caus. Morb. Epist.* 8, No. 28.)

Dr. Marcet, in relating the case of the patient affected with hydrophobia, observes, that "on our proposing to him to drink, he started up, and recovered his breath by a deep convulsive inspiration; yet, he express-

ed much regret, that he could not drink, as he conceived it would give him great relief, his mouth being extremely parched and clammy. On being urged to try, however, he took up a cup of water in one hand, and a tea-spoon in the other. The thought of drinking out of the cup appeared to him intolerable; but, he seemed determined to drink with the spoon. With an expression of terror, yet with great resolution, he filled the spoon, and proceeded to carry it to his lips; but before it reached his mouth, his courage forsook him, and he was forced to desist. He repeatedly renewed the attempt; but, with no more success. His arm became rigid and immoveable, whenever he tried to raise it towards his mouth, and he struggled in vain against this spasmodic resistance. At last, shutting his eyes, and, with a kind of convulsive effort, he suddenly threw into his mouth a few drops of the fluid, which he actually swallowed. But, at the same instant, he jumped up from his chair, and flew to the end of the room panting for breath, and in a state of indescribable terror." (See *Med. Chir. Trans.* Vol. 1, p. 158.) Even the splashing or running of any liquid causes a great deal of inconvenience. As the system becomes more and more affected, the patient loses his sleep entirely, and has frequent and violent fits of anxiety and loud screaming from slight causes. The woman, whom Dr. Powell attended, was often attacked in this way, in consequence of so trivial a circumstance as a fly settling on her face. The noise of tea-cups, or the mention of any sort of drink, greatly disturbed her, though she was not at all agitated by the sound of her urine. The currents of air entering her room, whenever the door opened, became very distressing to her, and this more and more so. The pain in her neck became so great, that she could scarcely bear it to be touched; but she made use of a looking-glass without the inconvenience, which hydrophobic patients usually suffer from the sight of shining bodies. Dr. Powell states, that the paroxysms, which this poor woman suffered, resembled those of hysteria, and increased in duration as the disorder lasted. "She described their commencement to be in the stomach, with a working and fullness there, and that a prickling substance passed up into her throat and choked her; she screamed suddenly, and grasped firmly hold of her attendants, as if voluntarily; and muscular convulsions came on, which were sometimes more, sometimes less general and violent. The causes from which these paroxysms arose were extremely slight; the passage of a fly near her face, the attempt to swallow a pill, a stream of air, the sight of oil or wine, or any other liquids, even the sound of water, and other such circumstances, were sufficient; she now also complained of inconvenience from light, which was accordingly moderated. The effect of sounds was peculiar; for though in the subsequent stages their influence became more general, at this period the effect was rather proportionate to the ideas they excited in her mind, than to their vio-

lence. Bells, and other strong noises, did not agitate her, but the clatter of earthenware, the noise of a distant pump, or any thing connected with liquids, produced the paroxysms in all their violence." She could swallow fresh currants with less resistance than any thing else, taking care that they were perfectly dry. Her mind had, till now, been quite calm and composed, and her conversation and behaviour proper, during the intervals of the convulsive attacks. But Dr. Powell was obliged to discontinue the pills of *argentum nitratum*, in consequence of the sufferings which the attempt to swallow them regularly brought on. Fifteen grains of this substance had been given without any sensible effect. The fits, and the irritability to external objects, increased. The pain shot from the back of the neck, round the angles of the jaws, the chin, and throat. At length the paroxysms became more frequent, and, indeed, might be said to come on spontaneously: seven occurred in one hour. She looked pale and exhausted, and a tremor and blueness of her lips and fingers were observable; her pulse became weaker and more rapid, and her scalp so tender, that touching it brought on convulsions. She had, latterly, eructations of wind, and spit up some thick viscid saliva. Her urine now came away involuntarily, and she was more and more irritable and uncontrollable. Indeed, she passed two hours in almost constant convulsions; became extremely irritable and impatient of every thing about her, complained of failure of her sight; wished to be bled to death; her words were fewer and interrupted; she struck, and threatened to bite, her attendants; had copious eructations of air; discharged an increased quantity of viscid saliva with much convulsive effort; said the affection of her throat and stomach had quite left her; and continued in a general perspiration, with a weak pulse from 140 to 150. She afterward bit some of the attendants, and was therefore confined with a waistcoat. From this period, she had lost all control over her mind, and continued for almost four hours in a paroxysm of furious insanity. She now swallowed, with an effort, near half a pint of water: but this was, in a few seconds, vomited up with some mucus, and a greenish fluid. In this violent raving state, she continued till within two hours of her death, which took place forty-seven hours after the first marked occurrence of hydrophobia. In the course of the case she swallowed, once or twice, a little porter; and also some cinnamon-water, with tinct. opii; but they were always vomited up. (*Dr. Powell's Case of Hydrophobia.*)

It is by no means uncommon for a period to occur, when the horror of liquids undergoes a considerable diminution, or even entirely ceases; the patient quenching his thirst, and this sometimes as well as if he were in perfect health, and so as to raise doubts of the existence of rabies. But after a few hours, the dread of fluids comes on again, and with it the convulsive paroxysms, which now become general, violent, and incessant. Dr. Cayol attended a girl, labouring under rabies, who

was never affected with any very great dread of liquids, nor an absolute inability to swallow them, though she certainly disliked them, and swallowed them with difficulty. (*Journ. de Méd. Chir. &c. Avril, 1811, p. 241.*) Nay, patients are sometimes seen, who can manage to swallow red wine and broth, though their aversion to water is already beyond all control; and other patients can sometimes look at a liquid in a black pot without inconvenience; though any fluid offered to them in a glass will bring on a violent paroxysm of spasm and sense of suffocation. The sight of tears has even been enough to bring on the attack. (See *Dict. des Sciences Méd. T. 47, p. 79.*)

The question has sometimes been entertained, whether rabies can ever exist quite unattended throughout its course with a dread of liquids? The possibility of such a case was believed by Mead and others, and an instance is recorded by Mignot, in which the patient died, without having manifested any sign of hydrophobia. (See *Hist. de la Soc. Roy. de Méd. an 1783, 2me Part. p. 48.*) However, it is asserted, that a careful perusal of this case must produce a conviction, that the disorder was not rabies; and it is added, that when the histories of this disease on record are critically investigated, none will be found complete, which do not make mention of a more or less decided aversion to fluids. It also appears from the facts referred to, that the dread of liquids does not depend upon the pain, which the patient has already suffered from his attempts to drink, as it sometimes occurs before any such attempt has been actually made. (*Vol. cit. p. 80.*)

An inclination to bite has been noticed, as happening in the patient, whose case is recorded by Dr. Powell. Yet, this disposition is far from being usual; and it never presented itself in any of the cases which fell under the observation of the author of the article *rage* in the foregoing publication, or P. Desault, Duchoisel, Dr. J. Vaughan, Sabatier, Dupuytren, &c. And even when the patient's imagination is so disordered, that he cannot help biting, he commonly warns the bystanders to avoid the danger. The frothy slobber, which is voided with considerable and repeated efforts, is a symptom, which is said not to commence before the respiration begins to be convulsive. As the disease advances, there is no remission of the sputum, necessary to clear the throat of this viscous secretion; and at the approach of death, when it cannot be expelled, it collects in the mouth, and covers the patient's lips.

The symptoms of what is termed cerebral excitement become stronger and more marked in the second stage of the disease. The eyes, the brightness of which is still further increased, appear, as it were, inflamed; the patient never shuts them again; and as the daylight and brilliant colours are offensive, he prefers darkness. The hearing becomes very acute, and as well as the sight, is troubled with hallucinations. The touch is extremely fine; the speech abrupt and rapid; and the conversation energetic,

and often expressive of the most touching sentiments. (*Dict. des Sciences Méd. T. 47, p. 12.*)

Dr. Marshall made a very just distinction between the real convulsions which came on towards the termination of the case in death, and the strong sudden action of the muscles, excited in the course of the disorder by the light, the sight of liquids, and the feel of the air. (*The Morbid Anatomy of the Brain, &c. p. 88.*) Convulsions and hic-cough, in fact, are the symptoms of dissolution.

Delirium is far from being a constant symptom, and only happens the last day of the disorder. Neither is it always without remissions; for the patients affected with it sometimes give rational replies. Every case upon record, where delirium is described as being one of the first symptoms, or as coming on with the dread of liquids, is set down on good authority, not as true rabies, but a symptomatic hydrophobia, attended with mania.

The dread of swallowing liquids, though the most singular symptom of the disease, constitutes but a small part of it. It is true, that none, or very few recover, who have this symptom, yet they certainly do not die in consequence of the difficulty of swallowing liquids; for the human body could easily exist double the time, at the end of which the disease usually proves fatal, without food or drink. Besides, the sick can often swallow substances that are nourishing, in a pulpy state, without, however, having their life thereby at all prolonged. It is not, therefore, the difficulty, or impossibility of swallowing liquids; but the effects of the poison upon the constitution at large, which occasion death. (*Dr. J. Hunter in Trans. for the Improvement of Med. Knowledge, Vol. 1, p. 305.*)

The extreme sensibility of the sick to all impressions, appears in the displeasure which they express at even the air blowing upon them; in their dislike to a strong light; in their aversion to new faces, or even the sight of their friends and relations; and in the terror they express at being touched, which almost threatens to throw them into convulsions. As the disease advances, the mind is more and more filled with dreadful fears and apprehensions. (*Op. cit. p. 307.*)

In the second stage, the epigastrium, as well as the chest, is the seat of considerable pain; the patient is constipated, but the urine is plentiful and high coloured. Before a certain period, the pulse is generally strong, regular, and a little accelerated; but towards the end of the case, it becomes small, irregular, feeble, and rapid. (See *Dict. des Sciences Méd. T. 47, p. 83.*)

The duration of life, from the appearance of hydrophobia till death, varies from thirty-six hours to four or five days: the most common period is from two to three days. (*Dr. J. Hunter, Op. cit. p. 308.*) The event is said to be directly caused by asphyxia, or the cessation of respiration. Of ten persons, who were bitten by the same animal, nine

lied on the second and third day, from the commencement of the horror of fluids, and only one on the fifth day. There is an account of a child at Senlis, who lived nine days, but the description of the case, and the circumstance of fourteen worms being found in the intestines, may raise doubts about the nature of the disease. (See *Hist. de la Soc. Roy. de Med.* p. 209, 155.)

Whatever may be the resemblance found between rabies and hydrophobia, with regard to the rapidity of their course, their causes, and some of their symptoms, the following considerations as a modern writer observes, will always serve for the discrimination of one disorder from the other: tetanus attacks the muscles of the jaw, which remains motionless, while in rabies, the jaw is not only moveable, but incessantly moving, in consequence of the efforts unremittingly made by the patient to free his mouth from the thick saliva with which it is obstructed. In this last disorder, the muscles are alternately contracted and relaxed; but in tetanus, they always continue rigid. Tetanus is rarely attended with any aversion to liquids, and the patient may be kept for a long time in a bath without inconvenience; and the paroxysms are neither excited, nor increased by a vivid light, a noise, the patient's being touched, or the sight of water, or shining surfaces. In addition to these differences, it is to be remembered, that tetanus is most frequent in warm climates, and that it mostly comes on a few days after the receipt of a local injury, and may occur as a complication of any kind of wound, even that which is made in a surgical operation. (See *Dict. des Sciences Med.* T. 47, p. 86.)

On the subject of prognosis, with respect to the bite inflicted by a rabid animal, and its effects, as evinced in the decided form of rabies, there are several things worthy of attention. According to some writers, small wounds are not less dangerous than others, and an attempt is made to account for the fact, by the more copious hemorrhage from larger wounds, and the frequent neglect of lesser injuries. Perhaps another reason is, that the virus is more likely to be confined in a wound with a small orifice, than in one which is ample, and admits of being more effectually washed. The more numerous the wounds are, the greater is the risk. If it be inquired, what is the average number of persons attacked with rabies out of a given number who have received bites? The question can only be answered by referring to the extremes. Thus, Dr. J. Vaughan speaks of between twenty and thirty individuals, bit by a mad dog, of whom only one was afterward attacked with rabies; and Dr. J. Hunter tells us of an instance, in which out of twenty-one persons bit, only one became affected. (See also *Fothergill in Med. Obs. and Inq.* Vol. 5, p. 195.) On the other hand, out of fifteen persons bit by a mad dog, and taken care of at Senlis, three at least were seized with the disorder, (*Hist. de la Soc. Roy. de Med.* p. 130;) of seventeen

others bit by a wolf, ten were attacked; (*ib.* p. 130;) and of twenty-three, bit by a she-wolf, thirteen died of rabies. (*L. F. Trollet, Nouveau Traité de la Rage, &c. Obs. Chirurgique, &c.* No. 25.)

Two important facts should always be recollected; viz. the disease may often be prevented; it can hardly ever be cured. Experience has fully proved that when hydrophobia once begins, it generally pursues its dreadful course to a fatal termination, the records of medicine furnishing very few unequivocal and well-authenticated cases to the contrary. Hence, the imperious necessity of using every possible means for the prevention of the disorder.

Probably, however, many things which possess the character of being preventive of hydrophobia, have no real claim to such reputation. I would extend this observation to all internal medicines, mercurial frictions, and plunging the patient for a considerable time under water.

The instances, in which a prevention is inferred to have taken place by different writers, in consequence of such means, may all be very rationally ascribed to other circumstances. Facts already cited sufficiently prove, that out of the great number of persons frequently bitten by the same dog, only a limited proportion is commonly affected. The hydrophobic poison is known to reside in the saliva of the animal; consequently the chance of being affected must greatly depend upon the quantity of this fluid which is insinuated into the wound; and if the teeth of the animal should have previously pierced a thick boot, or other clothing, before entering the skin, the danger must be obviously much diminished. Many patients wash and suck the wound, immediately after its occurrence, and thus, no doubt, very often get rid of the poison. Even when it is lodged in the wound, it may not be directly absorbed, but be thrown off with the discharge. All prudent patients submit to excision of the bitten part. Now under each of the above circumstances, escapes have frequently occurred, while internal medicines, if drowning or salivating the patients, had so not been neglected, so that all the efficacy of preventives has too often been most unjustly ascribed to means, which probably never yet had, and never will have, any beneficial effect whatever. What confirms the truth of the preceding statement is these facts: that persons bitten by the same animal have sometimes been treated exactly on the same plan; some of them escaped the disease; others had it, and of course perished on other occasions, some of the patients, bitten by the same animal, have been treated in a particular way, and have escaped hydrophobia; while others bitten at the same time by the animal, also never had any constitutional effects, although they took no medicines, nor followed any other particular plan.

If to these reflections be added the consideration, that it is frequently doubtful, whether the bite has actually been inflicted

by a truly rabid animal, and that the mental alarm will sometimes bring on a symptomatic hydrophobia, it is easily conceivable, how mistaken a person may be, who believes that he has prevented the disorder, and how unmerited is the reputation of the means, which he has employed for the purpose.

The bite of a naturally ferocious beast has often been thought to be attended with more risk than that of an animal naturally tame; and hence the bite of a wolf is said to be more frequently followed by rabies, than that of a dog. This proposition is admitted to be true; but the explanation is erroneous. The true reason of the difference is, that a wolf usually seizes the face, and inflicts a deeper bite; while a dog only snaps as he runs along, and mostly bites through the clothes. (See *Dict. des Sciences, Med. T. 47, p. 88.*) The bite of a rabid animal may be rendered much more dangerous by being situated near a part, or an organ, which increases the difficulty, or risk, of adopting an effectual mode of removing the whole of the flesh, in which the virus may be lodged. Thus, bites near the large arteries, the eyes, the joints, &c. are of a more serious description than others. Dr.

Hunter rated the hazard in some degree by the vascularity of the bitten parts. The prognosis will always be more unfavourable, when no proper measures have been applied to the bite soon after its infliction, and perhaps the risk may be increased by certain causes not having been duly avoided, which, as already stated, are thought to have a tendency to accelerate the attack of rabies. The exact time after a bite, when the prevention of rabies is no longer practicable, is quite an undetermined point; but every fact known upon the subject, evinces in an urgent manner the necessity of adopting preservative measures without the least delay.

In almost all the dissections of patients, who have died of rabies, certain indications of inflammation have been perceptible; more frequently, in some part of the space between the pharynx and the cardiac orifice of the stomach, in the stomach itself, in the lungs, the choroid plexus, and membranes of the brain. (See *Med. Repository. Vol. 3. p. 51.*) M. Trollet opened with the greatest care six bodies of persons destroyed by this disease. The mouth and fauces in each subject were first examined, and found of a pale grayish colour scarcely lubricated with mucus, and quite free from all frothy matter. All the salivary glands seemed perfectly healthy. When the larynx, trachea, and bronchiae were opened, they appeared to have been the seat of inflammation, the traces of which were the most marked low down, where the mucous membrane was of the colour of wine-lees. In four of the bodies, frothy mucus was perceived in the bronchiae, larynx, and trachea. Trollet infers from these appearances, that the frothy matter seen about the outs and lips of patients affected with rabies, is secreted by the inflamed mucous membrane of the bronchiae, and that it is

this secretion, and not the real saliva, which contains the hydrophobic poison. (*Nouveau Traité de la Rage, &c.*) In giving an account of a dissection, Faure also long ago remarked, that the frothy matter was only remarked, that the frothy matter was only remarked, that the air-passages, that the salivary organs were unaffected, and that the saliva itself did not contribute to the formation of the thick slaver, which appeared to have issued from the chest. (*Hist. de la Soc. Roy. de Méd. ann. 1783, p. 39.*) From the preceding observations, and those of Mignot de Genety (*Vol. cit. p. 54.*) Morgagni (*De Sedib. et Caus. Morb. Epist. 8, art. 20, 25, 30.*) Darlue (*Journ. de Méd. de V. monde T. 4 p. 270.*) B. Rush; and Duprey (*Obs. Inédites, No. 138*) it would appear:

1. That the mouth, strictly so called, and the salivary glands, are without any alteration.

2. The mucous membrane of the air-passages is affected with inflammation, which in its highest degree extends from the division of the bronchiæ to the pharynx. When the inflammation is of less extent, the pharynx appears sound; and when yet more limited, it is usually not to be traced in the larynx. The point where it seems to commence and is most strongly marked, is at the lower part of the trachea, or in the bronchiae. Lastly, when none of these parts are found inflamed, the lungs themselves present vestiges of inflammation.

With respect to the theory of Trollet, wherein the hydrophobic poison is said to be contained in the mucous secretion voided from the lungs, and to be the product of inflammation of the membrane of the bronchiæ, and not derived from the salivary glands; the question requires the confirmation of experiment; for, though the salivary glands are not the seat of pain, swelling, &c. it by no means follows, that their secreting process may not have been subject to some peculiar modification, on which the production of the hydrophobic virus depended. Thus, severe and obstinate ptyalism often occurs, and yet there is no manifest change in the state of the salivary glands. According to Van Swieten and Mead, there are also sometimes no morbid appearances either in the head, fauces, chest, or stomach. (*Comment. in Boerh. T. 3, p. 562.*)

In three cases, out of six, the lungs were found emphysematous, that is to say, their interlobular substance was distended with air, and the pleura pulmonalis raised into a great number of transparent vesicles on the surface of the lungs. In a fourth instance, the emphysema was not observed in the lungs themselves, but in the cellular substance between the two layers of the mediastinum; and under the muscles of the neck. Morgagni also noticed vesicles of air on the surface of the lungs of a person, that died of hydrophobia. (*De Sed. et Caus. Morb. Epist. 8, art. 30.*) M. Trollet presumes, that this emphysema is occasioned by the rupture of one of the air-cells, in the convulsive efforts of respiration, as sometimes happens when

a foreign body is lodged in the larynx. (See *Cases by Louis and Lescure in Mém. de l'Acad. de Chir.* T. 4, p. 538; T. 5, p. 527.)

The lungs were of a deep-red colour in all the six subjects dissected by Trollet, and they were observed to be gorged with blood in cases reported by numerous writers: as Bonet (See *Van Swieten*, T. 3, § 1140;) Boerhaave (*Op. Omn.* p. 215;) Morgagni (*De Sedibus et Caus. Morb. Ep.* 8, art. 23, &c.; Mead. Darlue (*Recueil Period.* &c. T. 3. and 4;) Faure (*Hist. de la Soc. Roy. de Med.* p. 39;) De la Caze (*ib.* p. 69;) Portal, Oldknow, Ballingall (*Edinb. Med. and Surg. Journ.*;) Marshall (*Morbid Anatomy of the Brain*, &c. p. 69;) Gorey (*Journ. de Med. Chir.* T. 13, p. 83;) Ferriar (*Med. Hist. and Reflections*, &c.) "Pulmones in quingue nigri ex toto, aut magna parte (says Morgagni,) in quatuor magna item ex parte sanguine pleni." With respect to the state of the organs of the circulation, in three of the cases dissected by Trollet, a good deal of air escaped from the heart and aorta. Morgagni is supposed to be the only other writer, who has noticed a similar occurrence (*Epist.* 8, No. 30,) and who also in another case saw air escape from beneath the dura mater. (*ib.* No. 23.) In two of Trollet's cases, some gelatinous clots were found in the heart and large vessels; but the great mass of blood was black, and very fluid in the heart, arteries, and veins, as in subjects, who have died of asphyxia. In all the six cases, traces of inflammation were noticed in the brain, or its membranes. The sinuses were filled with a dark-coloured fluid blood; and the pia mater was much injected, and of a brownish hue. The same appearances were found above the cerebellum, and the vessels on the investment of the medulla spinalis were considerably enlarged. The surface of the cerebrum was also studded with scarlet spots, which appeared to arise from blood effused from the small vessels of the pia mater into its cellular substance. In two subjects, blood was extravasated towards the base of the brain in larger quantity. The plexus choroides was gorged with blood, and of a brown colour. Besides those and other changes, Trollet remarked, in two of the cases, a thickening of the pia mater. The substance of the brain was generally softer than usual; but the fluid in the lateral ventricles was not in large quantity, though, in two cases, it had a bloody tinge. The late Dr. Marshall believed that in rabies, the brain was the part principally affected. (*Op. cit.* p. 145.)

Hufeland conjectured, that, in hydrophobia, the medulla spinalis is the part originally affected, whence the effects of the disease are propagated to the nerves of the trunk.

(*Bibl. Méd.* T. 55, p. 395, &c.) Dr. R. Reid believed, that an alteration of the spinal marrow was essentially concerned in the disease. (*On the Nature, &c. of Tetanus of Hydrophobia*, 8vo. Dublin, 1817.) A case was also published by M. Matthey, of Geneva, in which a quantity of serum was found within the spinal canal. (*Journ. Gen. de Méd.* T. 54, p. 279.) See on this subject

some observations by Dr. Abercrombie. (*Edinb. Med. and Surg. Journ.* Vol. 14. p. 66.)

According to Trollet, the traces of inflammation in the digestive organs are not so constant as in the lungs and brain. In none of the six cases dissected by him, was there any appearance of inflammation in the pharynx, though some parts of the alimentary canal were affected in this manner. The cases recorded, however, in which the digestive organs presented considerable morbid appearances, are very numerous. Thus Joseph de Aromatarius Darlue (*Recueil Périod.* T. 3. p. 189, et T. 4, p. 270.) Sauvages (p. 107,) Professor Rossi, M. Gorci (*Journ. de Med. Chir. &c.* T. 13.) and Dr. Powell (*Case of Hydrophobia*), found inflammation either in the pharynx, or œsophagus, or both these tubes. Dr. Powell's words are, "the œsophagus was rather redder than natural, and covered with a thin layer of coagulable lymph." A similar coat of lymph was also found by Oldknow (*Edinb. Med. and Surg. Journ.* Vol. 5, p. 280,) Ballingall (*Op. cit.* Vol. 11, p. 76,) Dr. Ferriar (*Med. Hist. &c.* Vol. 3, p. 27.) In dogs, Dr. Gillman found the pharynx and œsophagus in a state of inflammation. (*On the Bite of a Rabid Animal*, p. 13, 23, 26, 44.) It is conjectured, that in many of these instances, the inflammation extended to the œsophagus from the trachea and bronchiæ. (*Dict. des Sciences Méd.* T. 47, p. 98.) Inflammation of the mucous membrane of the stomach and small intestines, has likewise been very generally noticed, as may be seen by referring to the accounts published by Morgagni, Powell, Oldknow, Ferriar, Ballingall, Marshall, &c. In dogs, the same fact was remarked by Dr. Gillman (P. 13, 31, 44;) sometimes, however, according to this last author, no vestiges of inflammation, nor any other morbid appearances, are discoverable in the examination of animals that have died of rabies. (P. 83.) Dupuytren is stated to have found the mucous membrane of the stomach and bowels inflamed in several places, and even almost gangrenous. (*Dict. des Sciences Méd.* T. 47, p. 98.)

From recent investigations, made at the veterinary school at Alfort, by Professor Dupuy, the following are the usual morbid appearances, noticed in the dissection of dogs, horses, cows, and sheep, destroyed by rabies. 1. The lungs and brain universally gorged with blood. 2. Greater or lesser remarks of inflammation in the mucous membrane of the bronchiæ, trachea, larynx, throat, œsophagus, stomach, and frequently even in that of the bowels, vagina, uterus, and bladder. 3. The air-passages filled with frothy mucus. 4. A collection of serum in the ventricles of the brain, and sometimes even between the membranes, covering the spinal marrow. 5. An unusual redness of the investment of the pneumogastric and trisplanchnic nerves. (See *Dict. des Sciences Méd.* T. 47, p. 99.)

Happily, surgery possesses one tolerably

certain means of preventing hydrophobia, when it is practised in time, and in a complete manner. Every reader will know, that the excision of the bitten parts is the operation to which I allude. Indeed, as hydrophobia is often several months before it begins, the wounded parts should, perhaps, always be cut out, even though they are healed, and some weeks have elapsed since the accident, provided no symptoms of the hydrophobia have actually commenced. The operation should be done completely; for a timorous surgeon, afraid of cutting deeply enough, or of removing a sufficient quantity of the surrounding flesh, would be a most dangerous one for the patient. All hopes of life depend on the prevention of the disorder; for in the present state of medical knowledge, none can rest upon the efficacy of any plan, except the extirpation of the part. For this purpose, caustics have sometimes been employed. However, as their action can never be regulated with the same precision as that of the knife, and consequently, they may not destroy the flesh to a sufficient depth, excision should always be preferred. The latter method is also the safest for another important reason, viz. the part, and poison lodged in it, are removed from the body at once; but when the cautery or caustic is used, the slough must remain a certain time undetached. Some surgeons are not content with cutting out the part: but after the operation, fill the wound with the liquor ammoniæ, or cauterize its surface, for the sake of greater security. How late excision may be done with any prospect of utility I am not prepared to say; but, there are practitioners, who deem excision right, even when heat, irritation, or inflammation is observed in the bitten part. (See *Med. Repository*, Vol. 3, p. 54.)

Cases present themselves, in which it is even preferable to amputate the limb, than attempt to extirpate either with the knife, or cautery the whole of the bitten parts; an endeavour, which could not be accomplished with any degree of certainty. Thus, as Delpech observes, when the hand or foot has been deeply bitten in several places, it is obvious, that it would be impossible to make caustic, (or the cautery) certainly reach every part, which the saliva of the rabid animal may have touched. Besides, the mischief resulting both from the injury, and the other proceedings together, might be such as to afford no prospect of saving the limb, or at least, of preserving it in an useful state. (See *Precis Elem. des Mal. Chir.* T. 2, p. 133.) I have known of one or two cases, in which the patients lost their lives, in consequence of the excision, or destruction of the bitten parts not having been attempted, on account of the surgeon's reluctance to cut tendons, or wound a large artery, as one of those at the wrist. In such cases, however, the fear of rendering a muscle useless, or of wounding an artery, is no justification of leaving the patient exposed to a danger, so surely fatal, as that of

the hydrophobic virus, if it once affect the constitution. The artery should be exposed for a sufficient length, and secured with two ligatures, when the requisite extirpation of the parts between them may be safely performed.

When once the hydrophobic symptoms have commenced, there is little or no hope of saving the patient, the disease having almost invariably baffled every plan of treatment, which the united talents of numerous medical generations have suggested. All the most powerful medicines of every class have been tried again and again; mercury; opium; musk; camphor; arsenic; the nitrate of silver; cantharides; belladonna; ammonia; plunging the patient in the sea; bleeding; &c. &c.

The inefficacy of opium is now generally acknowledged: in the space of fourteen hours, Dr. J. Vaughan gave one patient fifty-seven grains of opium, and also half an ounce of laudanum in a clyster, but the fatal termination of the disease was not prevented. Dr. Babington even prescribed the enormous quantity of 180 grains in eleven hours, without the least amendment, or even any narcotic effect. (*Med. Records and Researches*, p. 121.) On the very first day, that rabies decidedly showed itself in a man, who had been bit by a mad dog, Dupuytren injected into the vena saphena, by means of Anel's syringe, two grains of the extract of opium dissolved in distilled water, and as a degree of calm appeared to be the result, four grains more were thrown into the cephalic vein. The patient remained perfectly tranquil three hours longer; but the symptoms afterward recurred with increased violence. The next morning, about six or eight grains more were dissolved, and thrown into the circulation; but, all was in vain, as the patient died in three quarters of an hour after the last injection. (See *Dict. des Sciences Med.* T. 47, p. 181.)

As for belladonna, its employment for the prevention and cure of hydrophobia is very ancient, its external use for this purpose having been mentioned by Pliny, and its internal exhibition, with the same view, by Theod. Turquetus in a posthumous work published in 1696. (See *Præcos Medicæ Syntagma*, &c.) In 1763, belladonna was recommended by Schmid as a remedy for hydrophobia, and in 1779 by J. H. Munch. (See *Richter's Chir. Bibl.*) At present, this medicine, has entirely lost its character of possessing any power against hydrophobia.

Of late years, the public hope has been raised by the accounts given of the virtue of hydro-chlorine, or oxymuriatic acid. Wendelstadt even published the story of an Englishman, who allowed himself to be bit several times by a mad dog, and then saved himself by washing the bites with this acid. And, still more recently Professor Brugnatelli, in the Italian Journ. of Physic, Chymistry, &c. (T. 9, p. 324,) has published some observations, tending to prove the efficacy of the external and internal employment of the medicine for the prevention of rabies.

The bites are washed with it, and then covered with charpie wet with it. And, when the symptoms commence, if it could not be swallowed in a fluid form, Brugnatelli gives bread pills imbued with it. For a child eight years old, the dose is \mathfrak{D} ij four or five times a day, but gradually increased. According to Orfila, hydro-chlorine was long since recommended by Cluzel, as an internal remedy for hydrophobia. (*Séours à donner aux personnes empoisonnées, &c.* 8vo. Paris, 1818, p. 153.) With regard to Brugnatelli's cases, they are said to be so destitute of precision and certainty, that no inference can be drawn from them. (*Dict. des Sciences Méd. T. 47, p. 119.*) In order to give hydro-chlorine a fair trial, it was used internally and externally on seven patients in the Hôtel-Dieu at Lyons in 1817. The bites were washed and bathed with it, and some of them also cauterized; and each patient took daily a dram of the acid, made into an agreeable sweetened drink. All these unfortunate individuals afterward died of rabies, though the treatment was begun the day after the receipt of the wounds. (*L. F. Trollet, Nouveau Traité de la Rage, &c.*) The excision of the bites 70 hours after their infliction, and washing the wound with oxymuriatic acid, did not in Dr. Johnson's case prevent the disease. (*See Edinb. Med. and Surg. Journ. Vol. 15, p. 212.*) In America, the plant *scutellaria lateriflora* has been lately extolled, as a certain specific for hydrophobia. (*See A History of the Introduction and Use of Scutellaria Lateriflora, as a remedy for preventing and curing Hydrophobia, by Lyman Spalding, M. D. New-York, 1819.*) The prussic, or hydrocyanic acid has likewise been proposed, on account of its reputed antispasmodic properties; but, some experiments, made with it on dogs by Dupuytren, Magendie, and Breschet, furnish no results in favour of its being likely to prove useful in the present disorder. (*See Dict. des Sciences Méd. T. 47, p. 132.*) By Dr. Rossi, of Turin, the trial of galvanism was suggested. (*Alibert, Nouveaux Elémens de Thérapeutique, T. 2, p. 436, Ed. 4;*) yet, the only fact brought forward, as an encouragement to persevere with the last means, appears to a modern author, from its symptoms and progress, not to have been a case of rabies. (*Dict. cit. T. 47, p. 126.*) The rapid and powerful effects of the bite of a viper on the whole system, and perhaps the idea, that the operation of this animal's venom might counteract that of the hydrophobic virus, led some experimenters to try what would be the result of subjecting patients, affected with rabies, to the bite of that kind of snake. The project, however, was attended with no success. Three cases of this description were communicated to the Royal Society of Medicine, (*Hist. p. 201;*) two additional ones were recorded by Dr. Gilibert, physician to the Hôtel-Dieu at Lyons, (*Advers. Méd. Pract. p. 257;*) and Viricel, surgeon of the same hospital, repeated the experiment on a child, which yet fell a victim to hydrophobia. Other trials are also said to have been made in France and Ger-

many with no better success. Dr. de Mathiis, in the year 1783, let a viper bite a rabid dog on the throat. The dog's head was attacked with considerable swelling, the hydrophobia ceased, and, according to some accounts, the animal perfectly recovered; but, according to other statements, though it drank freely as soon as its head had swelled, it only survived the experiment a few hours. (*See Dict. des Sciences Méd. T. 47, p. 126.*)

Some facts which occurred a few years ago in the East Indies, tended for a time to raise an expectation, that a copious abstraction of blood might be the means of preserving patients actually attacked with this fatal disorder. Mr. Tymon, assistant surgeon of the 22d Light Dragoons, tried successfully the method of taking away at once an immense quantity of blood from the patient, "I began by bleeding him (says Mr. Tymon) until scarcely a pulsation could be felt in either arm." Opium was afterward given, and the patient salivated with mercury. (*See Madras Gazette of Nov. 23, 1811.*)

Although in the observations, annexed to this case by Dr. Berry, there are some circumstances, which render it probable, that the case was really hydrophobia; yet, as the successful termination of it is an event so extraordinary, I much regret, that some desirable information is omitted. For instance, we have no account of any pain, or changes, in the bitten part, or limb, at the first coming on of the indisposition. The early constitutional symptoms are not described, and the violent spasms, screaming, &c. are the first things mentioned. Some particulars of the dog would also have been interesting.

Such information, indeed, becomes still more essential, when we find it stated, that another man, Serjeant Jackson, was also bitten by the same dog, and had hydrophobia in a mild form, from which he recovered under the use of mercury, blisters to the head, and cathartic injections, without any recourse to bleeding at all. This last case is even more contrary than the former, to what general experience teaches; because mercury, blisters, and injections, have been tried a thousand times unavailingly; while, perhaps, blood-letting, in the manner practised by Mr. Tymon, is a new treatment. Dr. Schoolbred, of Calcutta, published a second case of hydrophobia cured by bleeding ad deliquium animi, and afterward exhibiting calomel and opium. The patient, being threatened with a relapse, was largely bled again. The whole of the success is imputed by Dr. Schoolbred to the venesection. But this gentleman is not so sanguine as to believe, that bleeding will cure every case of hydrophobia. It is probable, that there is a period, beyond which its curative effect cannot extend, and, therefore, it is upon the first appearance of unequivocal symptoms of the disease, that he thinks copious bleeding affords a prospect of success, while the delay of only a few hours may prove fatal. He observes, that the medical profession, taught by numerous disappointments, admit

very cautiously the claims of any new practice to general adoption. If several patients in hydrophobia, therefore, should happen to be bled in an advanced stage of the disease, and die, (as they inevitably would do, whether they had been bled or not,) such cases would be quoted against the new practice, as failures. But Dr. Schoolbred rightly contends, that numerous failures in an advanced stage of the disease can form no just ground for the rejection of a remedy, which has uncontestedly effected a cure in an earlier stage of the disorder. He insists upon the necessity of making a large orifice in the vein, so as to evacuate the blood quickly, which must be allowed to flow, without regard to quantity, *ad deliquium animi*.

Dr. Schoolbred was well aware, that bleeding in cases of hydrophobia had often been tried. But, says he, owing probably to the evacuation not having been pushed far enough, when used in the early stage of the disease; or to the period for its beneficial employment having elapsed; the cases, in which it was tried, afforded little or no encouragement to the continuance of the practice.

Since the preceding cases, the effect of bleeding has had the fairest trials made of it, and some of the reports are in favour of its occasional utility. (See *Particulars of the successful Treatment of a case of Hydrophobia*, by R. Wynne, 8vo. Shrewsbury, 1813; Also Edmonstone in *Land. Med. Repository*, Vol. 3, p. 93.) In almost every instance, however, it fails in hindering the usual melancholy event. (See *Kirriison's Case and Obs. in Med. Repository*, Vol. 2, p. 197.) This unpleasant truth, I think, receives confirmation from the fact, that the practice is far from being new.

Dr. Mead, who was very confident that he had found an infallible preventive of the disease in a little liverwort and black pepper, aided by bleeding and cold bathing before the commencement of the course of medicine, says, "as to all other ways of curing the hydrophobia, I own I have not been so happy as to find any success from the many I have tried. Bathing at this time is ineffectual. I have taken many large quantities of blood; have given opiates, volatile salts, &c. All has been in vain, because too late." Notwithstanding his disappointment, he concludes, "if any relief could be expected in this desperate state, I think it would be from bleeding, even *ad animi deliquium*," &c.

The doctrines of Boerhaave also led him and his pupils to recommend and practise bleeding in hydrophobia. "The distemper (says he) is to be treated as one highly inflammatory, upon the first appearance of the signs which denote its invasion, by blood-letting from a large orifice, continued till the patient faints away; and soon after by enemata of warm water and vinegar, &c. and he adds, "that this practice is supported by some small number of trials." But the particulars of this successful practice, are not given.

Dr. Schoolbred finds, that a trial of it was

made at Edinburgh, more than sixty years ago, by Dr. Rutherford who took away gradually sixty ounces of blood from a patient, who had already been bled the same morning. As the patient lived forty-eight hours after the large bleeding, the method was probably tried somewhat early in the disease; and the case may therefore be set down as a fair instance of a failure of the practice. The trials, which have been made in this country of the practice of bleeding, in cases of hydrophobia, since the receipt of the above reports from India, I am sorry to say, have not confirmed its efficacy, as a means which can be much depended upon for saving the patients.

Bleeding was also recommended in cases of hydrophobia, by Poupard. (See *Hist. de l'Acad. Royale des Sciences, pour l'année 1699*, p. 48.) The practice is likewise mentioned in the *Medical Essays of Edinburgh*, Vol. 5, part 2, § 5; and in the writings of Dr. Rush. See also Dr. Burton's Case, *Phil. Mag. August*, 1805.

After all that has been said, and the little confidence assigned to any practice but that of the early excision, or amputation of the bitten parts, it is necessary, that something should be done after the actual commencement of rabies, and that every practitioner should be prepared for the adoption of some mode of treatment, or another. As however, my own mind is not made up upon the subject, I prefer offering a conclusion or two, made by a modern critical writer: "That experience authorizes the placing confidence in bleeding *ad deliquium*; on vomiting; and perhaps on use of atropa belladonna; and, on tobacco exhibited as a glyster. That it is probable, advantage would result from the combined employment of bleeding, vomiting (see Dr. Satterly's *Obs. in Medical Trans.* Vol. 4,) and purging in the early stage of the disease. That analogy recommends the trial of spirit of turpentine in the convulsive stage of the disease." (*Med. Repository*, Vol. 3, p. 54.) *Jos. de Aromatarius, De Rabie Contagiosa*, 4to. HYDROPHthalmia. (from *ὕδωρ*, water, and *ὀφθαλμός*, the eye.) *Dropsy of the Eye*.

Hydrophthalmus; *Hydrophthalmos*. Also *Bupthalmos*, or *Ox-eye*. As in other organs, dropsy of the eye arises from a disproportion taking place between the action of the secreting arteries, by which the fluid is deposited in the part, and the action of the absorbent vessels, by which it is taken up and returned to the circulation; and, according to this principle, the disease may be supposed to depend, either upon secretion being made too rapidly, or absorption being slower than is proportionate to the natural activity of the vessels by which the secretion of the humours of the eye is effected.

According to Beer, dropsy of the eye is seldom entirely a local disease, but at least is generally combined with an unhealthy constitution, or is a mere symptomatic effect of some other dropsical affection, anasarca, hydrocephalus, &c. Sometimes it appears as a symptom of chlorosis. Beer adds, that the disease may originate either from a preternatural accumulation of the aqueous humour; from that of the vitreous humour; or from an immoderate accumulation of both these humours together. (*Lehre von den Augenkr.* B. 2. p. 616, Wien. 1817.) When the vitreous humour collects in this manner, it usually loses its natural consistence, and becomes thinner and more watery. (*Richter Anfangsgr.* B. 3, p. 392.)

Professor Beer states, that in the case proceeding from a morbid quantity of the aqueous humour, the first indication of the disease is an increase in the dimensions of the cornea, attended with a manifest enlargement of the anterior chamber. The cornea may become in this manner two, three, or even four times wider than natural, without bursting or losing its transparency; for, though a turbid appearance is discernible, this depends rather upon the state of the aqueous humour itself. The iris, which, in the very commencement of the disease, begins to lose its mobility, soon becomes completely motionless, and acquires a duller colour; the pupil always remaining in the mid-state between contraction and dilatation. In the eyeball, an annoying sense of pressure, tension, and heaviness is felt, rather than actual pain. In the beginning of the disease, there is a considerable degree of farsightedness, or *præsyopia*, which

soon changes into a true amaurotic weakness of sight; but never terminates in perfect amaurosis. The free motions of the eyeball are more and more interrupted, in proportion as the organ grows larger, and it has invariably a hard feel, while the sclerotica, to the distance of two lines from the margin of the cornea, is as bluish as it is in the newborn infant.

Respecting the precise cause of the accumulation of the aqueous humour, Beer offers no observation worthy of repetition, excepting perhaps that in which he reminds us, that a similar collection happens apparently as an effect of the conical staphyloma of the whole cornea. (See also *Wardrop's Essays on the Morbid Anatomy of the Eye*, Vol. 2, p. 19.) Indeed, as far as our knowledge yet extends, it is impossible to say whether the changes of the cornea are, in the present disease, to be regarded as the cause or the effect of the increased quantity of the aqueous humour, or whether, as seems to me most probable, both phenomena are only effects of one and the same cause. The examples, somewhat repugnant to this idea, are those referred to by Beer, as symptomatic of other dropsical affections. On the other hand, Mr. Wardrop has never seen a preternatural collection of the aqueous humour, without its being accompanied with disease of the coats of the eye. (Vol. cit. p. 20.)

In hydrophthalmia, the prognosis is generally unfavourable, and, when the sight is nearly or quite lost, scarcely any hope can be entertained, either of restoring vision or preserving the shape of the eye. Yet, according to Beer, things are not always quite so unpromising in the preceding form of the disease, especially when the surgeon is consulted in time, and the patient's constitution is not exceedingly impaired. The same experienced author has never seen any instance in which the eye spontaneously burst; on the contrary, when the habit was decidedly bad, and the treatment ineffectual, the disease became gradually conjoined with the second species of dropsy of the eye, and terminated in a frightful disfigurement of the whole organ, and death. On dissection, the innermost textures of the part were found spoiled and disorganized, and sometimes even the orbit itself carious. (Vol. cit. p. 619.) With respect to the treatment, Beer thinks, that this must depend very much upon the nature of the primary disease, to which the dropsical affection is ascribable as an effect. He has known great benefit sometimes produced by the submuriate of mercury, combined with digitalis, and a drink containing supertartrate of potassa, and borax. When the disease has been preceded by the sudden cure of any cutaneous disease, he has faith in the method of attempting to restore the affection of the skin by inoculation, or, if that be impracticable, by stimulating its surface with antimonial ointment, or making an issue. This plan is to be aided with internal alterative medicines, such as camphor, the sul-

phur auratum antimonii, and flowers of sulphur. The local applications, which he prefers in the early stage, are warm dry bags filled with aromatic herbs, and rubbing the parts about the eyebrow, sometimes with mercurial ointment, sometimes with a mixture of æther and liquor ammoniæ. But, when the disease has made considerable progress, and vision is either weak or nearly lost, while the sclerotica, near the cornea is not much discoloured, and there are no appearances of a varicose affection of the blood-vessels of the organ, Beer recommends making a puncture with a small lancet in the lowest part of the cornea, half a line from the sclerotica, so as to discharge the aqueous humour. The anterior chamber is then to be kept empty for several days or weeks, if possible, by reopening the small wound every day with the point of the lancet. (See also *Richter's Anfangsgr. B. 3, p. 403.*) After the operation, the eye is to be dressed in the same way as after the extraction of a cataract. (See *Cataract*.) Previously to the paracentesis, Beer has often seen every general and local means perfectly useless, but highly beneficial, as soon as that operation had been practised. Even when the paracentesis fails in bringing about a permanent cure, it may still be resorted to as a palliative with great advantage, and be often beneficially repeated, if care be taken not to make the puncture too large. However, when the blood-vessels are generally varicose, and the constitution very bad, such operation is apt to excite violent inflammation, suppuration, and even sloughing of the organ, attended with imminent danger to the patient's life. (Beer, vol. cit. p. 620, 622.)

With regard to the second species of hydrophthalmia, or that depending upon a preternatural accumulation of the vitreous humour, Beer states, that, in this case, it is chiefly the posterior part of the eyeball which is enlarged, so that the whole organ acquires a conical shape, in which the cornea very much participates. The latter membrane remains unaltered in regard to its diameter; but it is more convex than natural, and its transparency is perfect. It is observed by Mr. Wardrop, (*on Morbid Anatomy of the Eye*, Vol. 2, p. 126,) that an increase in the quantity of the vitreous humour happens not unfrequently in staphyloma, in which disease, he says, the enlargement of the eyeball will generally be found to arise more from an increase in the quantity of the vitreous than of the aqueous humour, and he then expresses his belief, that the case, adduced by Scarpa to illustrate the pathology of hydrophthalmia, and cited in the ensuing part of this article, was an example of staphyloma. Be this as it may, one character constant in staphyloma, is often absent in hydrophthalmia; I mean opacity of the cornea. In the case, which consists in an immoderate collection of the aqueous humour, the anterior chamber is always enlarged: on the contrary, in the present form of the disease, that cavity is

manifestly lessened, for the motionless iris is gradually forced so much towards the cornea, that at length the chamber in question almost completely disappears. However, the colour of the iris undergoes no change, and the pupil is always rather diminutive. Around the cornea, the sclerotica is rendered bluish by distention, with a somewhat smutty tinge. In the early stage, the patient is affected with shortsightedness, *myopia*; but his power of vision is always seriously diminished, and, at last, is so totally destroyed, that not a ray of light can be perceived. The motions of the globe of the eye and eyelids are lessened or impeded at a still earlier period than in the first species of hydrophthalamia, and to the touch the organ seems like an egg-shaped stone. The very commencement of the disease is attended with pain, which daily becomes more and more severe, and, at length, is not confined to the eye and its vicinity, but affects all the side of the head, the teeth, and neck, being sometimes so violent as almost to bereave the patient of his senses, who urgently begs the surgeon to puncture the eye, or even is driven by desperation to do it himself, as Beer once knew happen. Even while the pain is less afflicting, the patient is deprived of his sleep and appetite. (Beer, *vol. cit.* p. 623.) Though an increase in the quantity of the vitreous or aqueous humour has generally been treated of as a distinct disease, and denominated hydrophthalamia, Mr. Wardrop has never seen a dropsy of the eye without an accompanying disease of the sclerotic coat, or cornea. (*On the Morbid Anatomy of the Eye, Vol. 2, p. 126.*) Beer offers no valuable remark on the causes of the preceding form of hydrophthalamia, his account of the connexion with scrofula and syphilis being mere conjecture, though delivered as a positive matter of fact. However, another position offered in the paragraph, concerning the prognosis, seems more correct: viz. that as the disease is almost always conjoined with an unhealthy constitution, there can be scarcely any hope of a radical cure. Beer's opinion also is, that, when the disease has made such progress that not a ray can be discerned, and the pain in the eye and head is so violent, by day and night, that the sleep, appetite, and even the senses are lost; it is fortunate if only the most perilous symptoms can be obviated by palliative treatment; for the preservation of a good-shaped eye is then quite out of the question. And even in the most favourable cases, the utmost which can be expected, is to stop the further advance of the disease, a perfect cure being extremely rare.

According to Beer, the first indication is to improve the state of the health by medicines and regimen; for, unless this object be effected, no expectation of curing the dropsical affection of the eye can be entertained. For this purpose a long time will be requisite, and as for local treatment in this case, little or nothing can be accomplished by it. Hence, the disease often con-

tinues to grow worse and worse, and, when the pain becomes violent, the best thing which the surgeon can do, both with the view to the functions of the organ and its form, is to let out the aqueous humour. But Beer reprobates, in the strongest terms, the plan sometimes recommended, of plunging a trocar through the sclerotica into the vitreous humour, and keeping the tube introduced until a certain quantity of that humour is discharged. According to Beer's experience, the usual result of such practice is a carcinomatous disease of the eye, terminating in death, which the removal of the part will not prevent. The method preferred by Beer is that which is mentioned by Richter, (*Anfangsgr. B. 3, p. 400.*) and consists in opening the cornea and capsule of the lens, as in the extraction of the cataract, discharging the lens and vitreous humour, and letting the coats of the eye collapse; but, in order to prevent any reaccumulation of fluid, he afterward cuts away a little bit of the flap of the cornea. The eye is then to be dressed in the same manner, as after the extraction of the cataract. (See *Cataract.*) The third species of hydrophthalamia, or that produced by an accumulation both of the aqueous and vitreous humours together, is excellently described by Scarpa. He observes, that in every case on which he has performed the operation, and in other examinations of the different stages of the disease, made on the dead subject, he has constantly found the vitreous humour more or less altered in its organization, liquefied, and converted into water, according as the disease was ancient or recent. In some instances he could not distinguish whether the increased quantity of the vitreous, or aqueous humour, had most share in the formation of the disease.

Scarpa also dissected a dropsical eye, taken from the body of a child three years and a half old, who died of marasmus. The vitreous humour was not only wanting in this eye, and the cavity destined for its reception filled with water, but the vitreous tunic was converted into a substance, partly of a spongy, partly of a fatty nature. This dropsical eye was one-third larger than natural. The sclerotica was not thinner than that of the other eye; but, in consequence of being yielding, flaccid, and separated from the choroides, it had lost its plumpness, and globular shape. The cornea formed a disk, one-third larger than that of this membrane in a sound state; it did not retain its natural pulpy structure, and was obviously thinner than the cornea of the healthy eye. There was a considerable quantity of an aqueous, reddish fluid, between the cornea and iris. The crystalline lens, with its opaque capsule, had been pushed forward a little way into the anterior chamber, but could not advance further on account of a firm adhesion which the capsule had contracted with the iris, around the edge of the pupil. As soon as the capsule was opened, the lens issued from it half dissolved, the rest exceedingly soft. It was impossible to

detach the whole of the posterior layer of the capsule from a hard substance, which seemed to be the altered membrane of the vitreous humour. Scarpa, therefore, slit open the choroides, from the ciliary ligament to the bottom of the eye, when a considerable quantity of a reddish aqueous fluid gushed out, without, however, one particle of the vitreous humour. In lieu of the latter body, there was found a small cylinder of a substance, partly of a fungous, partly of a fatty nature, surrounded with a good deal of water, which was effused in the longitudinal axis of the eye, from the entrance of the optic nerve, as far as the ciliary ligament, or that hard substance to which the posterior layer of the capsule firmly adhered. This little cylinder was covered for the extent of two lines and a half forwards from the entrance of the optic nerve, by a stratum of whitish matter, reflected on itself, like the epiploon, when raised towards the fundus of the stomach. Scarpa conceived that this stratum of whitish matter was the relics of the unorganized retina; for, on pouring rectified spirits of wine on the whole inner surface of the choroides, and the little cylindrical body, he found no vestiges of the retina on this membrane, and that the whitish substance, which was reflected on itself, became very firm, just as the retina does when immersed in spirits of wine. Both the cylinder and the indurated substance, occupying the place of the ciliary body, were manifestly only the membrane of the vitreous humour, destitute of water, and converted, as was described, into a substance partly of a spongy, partly of an adipose nature. It is not easy to determine whether this altered state of the vitreous tunic had preceded, or was a consequence of the dropsy of the eye. However, it may be this fact, in conjunction with several other similar ones, that Scarpa has met with, in which he found no vitreous humour in the posterior cavity of the eye, but only water, or a bloody lymph, tends very much to establish the fact, that this disease principally consists of a morbid secretion of the vitreous humour, and occasionally, also, of a strange degeneration of the alveolar membrane, by which this humour is formed. Scarpa refers to a similar case. (See *Med. Obs. and Inquiries*, Vol. 3, art. 14.)

The augmentation in the secretion of the aqueous fluid, both in the cells of the vitreous humour and out of them, after they have been ruptured from excessive distention, together with a debilitated action of the absorbent system of the eye affected; Scarpa regards as the probable cause of the morbid accumulation of humours in the eye. From such a lodgment, and successive increase of the vitreous and aqueous humours, the eyeball at first necessarily assumes an oval shape, ending at the point of the cornea; the organ enlarges in all dimensions; and in the end, it projects from the orbit in such a manner that it cannot be covered by the eyelids, disfiguring the patient's face as

much as if an ox's eye were placed in the orbit.

This disease (says Scarpa) is sometimes preceded by blows on the eye, or adjoining temple; sometimes by an obstinate internal ophthalmia. In other instances it is preceded by no inconvenience, except an uneasy sensation of tumefaction and distention in the orbit, a difficulty of moving the eyeball, and a considerable impairment of sight. Lastly, it is sometimes preceded by none of these causes, or no other obvious one whatever, especially when the complaint occurs in children of very tender age, from whom no information can be obtained. As soon as the eye has assumed an oval form, and the anterior chamber has become preternaturally capacious, the iris seems situated further backward than usual, and tremulates in a very singular way on the slightest motion of the eyeball. The pupil remains dilated in every degree of light, while the crystalline is sometimes brownish from the very beginning of the disease; and sometimes it does not become cloudy till the affection has arrived at its highest pitch. The complaint then becomes stationary; and as the crystalline is not deeply opaque, the patient can distinguish light from darkness, and, in some degree, the contour of objects, and brilliant colours. But when the eye has acquired a larger volume, and the whole crystalline has become opaque, the retina at last remains in a state of complete paralysis.

In the last stage of the disease, to which the term bupthalmos, or ox-eye, is properly applicable, when the dropsical eye projects from the orbit, so as not to admit of being covered by the eyelids with the inconveniences already enumerated, says Scarpa, others associate themselves, arising from the friction of the ciliae, the secretion of gum, the flux of tears, the ulceration of the lower eyelid, on which the eye rests, and the excoriation of the eye itself. Hence the dropsical eye is gradually attacked with violent ophthalmies, attended with intolerable pain in the part affected, and the whole head. The ulceration, also, does not always confine itself within certain limits; but continues to spread, first depriving the cornea of its transparency, next consuming the sclerotic, and lastly, destroying progressively the other component parts of the eyeball.

At the first appearance of dropsy of the eye, many surgeons recommend mercurials, the extract of cicuta, and of pulsatilla nigricans; and astringent and corroborant collyria, a seton in the nape of the neck, and compression of the projecting eye. However, Scarpa has never yet met with a single well-detailed history of a dropsy of the eye, cured by means of the above-mentioned internal medicines. With regard to externals he has learnt, from his own experience, that when the disorder is manifest, astringent and corroborant collyria, as well as compression of the protuberant eye, are highly prejudicial. In such circumstances,

making a seton in the nape of the neck, frequently bathing the eye in a lotion of mallows, and applying to it a poultice composed of the same plant, have enabled him to calm, for a time, that disagreeable sense of distention in the orbit, and over the forehead and temple of the same side, of which patients in this state make so much complaint, especially when they are affected with a recurrence of ophthalmia. But as soon as the eyeball begins to protrude from the orbit, and project beyond the eyelids, he thinks there is no means of opposing the very grievous dangers which the dropsy of the eye threatens, except an operation which consists in evacuating, by an incision, the superabundant humours, then exciting gentle inflammation of the membranes, and suppuration within this organ, so as to make it contract, and shrink into the bottom of the orbit. To defer the operation any longer, would be abandoning the patient to the constant inconvenience of an habitual ophthalmia, the danger of an ulceration of the eyeball and subjacent eyelid, and what is worse, of carcinoma of the whole eye, with great peril to the patient.

Beer's prognosis in the third species of hydrophthalmia is at least as discouraging as that made by Scarpa; for the rapidity of the disease is said to be such as leaves scarcely a possibility of benefit being effected by any mode of treatment, and the case usually terminates in a carcinomatous exophthalmia, and death. These melancholy events are said, by Beer, to be accelerated by paracentesis of the eye, however executed; and he thinks that the sole chance of stopping the progress of the disease depends upon an endeavour being made in its very commencement to improve the general health, though he owns that success is to be regarded as a very rare and fortunate occurrence. The same author has no faith in any local treatment, and, when the disease is advanced, he considers the extirpation of the eye the only rational expedient, though very precarious in its result. (*Lehre von den Augenkr. B. 2, p. 628, 629.*)

The main point, on which Scarpa differs from Beer, is that respecting the effects of discharging the humours of the eye: a practice, which the former represents as useful, even in cases where the hydrophthalmia continues an accumulation both of the aqueous and vitreous humours. In former times, says Scarpa, paracentesis of the eye-ball was greatly extolled. Nuck one of the promoters of this operation, punctured the eye with a trocar, exactly in the centre of the cornea. (*De Duct. Ocul. Aquos, p. 120.*) It has since been thought better to puncture the sclerótica about two lines from the junction of this membrane with the cornea, that such a small quantity of the vitreous humour may be more easily discharged at the same time with the aqueous, as may be deemed adequate to effect a diminution in the morbid enlargement of the eye-ball.

According to Scarpa, paracentesis of the eye, done so as merely to discharge the hu-

mours, can never be a means of curing dropsy of the eye, unless the puncture, made with the trocar, excite inflammation and suppuration, and afterward a concretion of the membranes composing the eye-ball. Indeed Nuck relates, that in a young man at Breda, he was obliged to puncture the eye five several times; that, on the fifth time of doing this, it was necessary to suck through the cannula of the trocar, in order to evacuate the greatest possible quantity of the vitreous humour; and lastly, that it seemed proper to introduce a plate of lead between the eyelids and eye-ball, for the purpose of making continual pressure on the eye, in its empty shrivelled state. In a woman at the Hague, he twice punctured the eye in vain; and she submitted two or three times afterward, to the same operation, but with what degree of success is not specified. Scarpa has no difficulty in believing, that a radical cure of the dropsy has sometimes been accomplished by means of the puncture, after the trocar, and other similar hard substances, have been repeatedly introduced into the eye, through the cannula of that instrument; but this success can never be attributed to the mere evacuation of the superabundance of the vitreous and aqueous humour; though it may be referred to that circumstance, conjoined with the irritation produced by the cannula, or the tents with which Mauchart kept open the wound.

Scarpa condemns the plan of making a circular incision through the sclerótica, as disadvantageous, and even dangerous. In fact, this circular recision, is constantly followed by the most aggravated symptoms, particularly frequent hemorrhages, an accumulation of grumous blood at the bottom of the eye-ball, vehement inflammation of the eye, eyelids, and head, obstinate vomitings, convulsions, delirium, and the most imminent danger to the patient's life. Such modern surgeons, as have faithfully published the results of their practice on this point, among whom, after M. Louis, (*Mém. de l'Acad. de Chir. T. 13 p. 289, 290*) Morehan, (*Journal de Méd. de Paris, Janvier, 1770: Sur deux Exophthalmies, ou grosseurs contre nature du Globe de l'Œil*;) and Terras, (*Ibidem, Mars, 1776; Sur l'Hydrophthalmie*;) having ingenuously declared that, after performing the circular recision of dropsical eyes in the sclerótica, they had the greatest motives for repenting of what they had done. Scarpa prefers making a circular section, about three lines in breadth, at the summit or centre of the cornea of the dropsical eye, as directed by Celsus, in cases of staphyloma.

Whether the cornea be transparent or not, as sight is irrevocably lost, the surgeon must introduce a small bistoury across the apex, or middle of the cornea, at one line and a half from its central point; and then by pushing the instrument from one towards the other canthus of the eye, he will cut the lower part of the cornea in a semicircular manner. The segment of the cornea being next elevated with the forceps, the operator is to turn the edge of the knife upward, and complete the

work by a circular removal of as much of the centre of the cornea as is equal to three lines in diameter. Through this circular opening, made in the centre of the cornea, the surgeon may, by means of gentle pressure, discharge as much of the superabundant humours in the eye, as is requisite to make the eye-ball diminish, and return into the orbit, so as to be covered by the eyelids. As for the rest of the humour lodged in the eye, it will gradually escape of itself, through the circular opening in the cornea, without any more pressure being made.

Until the appearance of the inflammation, that is, until the third or fifth day after the operation, the dressings are to consist of the application of a compress of dry lint, supported by a bandage. As soon as the inflammation and tumefaction invade the eye operated on, and the eyelids, the surgeon is to employ such internal remedies as are calculated to moderate the progress of inflammation; and he is to cover the eyelids with a bread and milk poultice, which must be renewed at least once every two hours. It is a very frequent result, both in the staphyloma and dropsy of the eye, that, on the first appearance of inflammation, the eye-ball, on which the operation has been done, augments and protrudes again from the eyelids, in the same way as before the operation. In this circumstance, Scarpa directs the projecting part of the eye-ball to be covered with a piece of fine linen, smeared with a liniment of oil and wax, or the yolk of an egg and oleum hyperici; the application of the bread and milk poultice being continued over this other dressing. Scarpa next states, that when the interior of the eye begins to suppurate, the swelling of the eye-lids decreases, and the eye-ball diminishes in size, and returns gradually into the orbit. This state of suppuration may be known by observing, that the dressings are smeared with a viscid lymph, blended with a portion of the humours of the eye, which incessantly issue from the centre of the cornea; and by noticing the appearance of the margin of the incision, which is changed into a circle of a whitish substance, resembling the rind of bacon, which is afterward detached, like a slough, so as to leave a small ulcer, of a very healthy colour. This ulcer, as well as the whole eye-ball, contracts, and becomes entirely cicatrized, leaving every opportunity for the placing of an artificial eye between the eyelids and the stump of the eyeball.

If a mild inflammation and suppuration in the interior of the eye should not take place on the fifth day, Scarpa exposes the eye to the air, or removes a circular portion of the cornea, half a line in breadth, or little more, by means of the forceps and curved scissors. The foregoing practice is certainly preferable to that advised by Richter, who, when the eyesight is lost, and the object is merely to discharge the humours, and let the eye collapse, sometimes makes a crucial division of the cornea, and removes the four flaps or angles, or even cuts away the whole of the anterior part of the eye-ball through the

sclerotica. (*Anfangsgr. B. 3, p. 404.*) In order to lessen the bulk of the eye, the late Mr. Ford, in one instance, passed a seton through the front of the organ with apparent success. (See *Med. Communications, Vol. 1.*) Consult *Mauchart, De Paracentesi Oculi, Tab. 1744.* *Conradi, Handbuch der Pathol. HYDROPS. (from *ὕδωρ*, water.) A dropsy, or morbid accumulation of water. *Hydrops articuli*, refer to *Joints, diseases of*; *hydrops oculi*, see the foregoing article. We regard to *hydrops pectoris, hydrothorax, dropsy of the chest*, as it is altogether a medical case, an account of its symptoms and treatment will hardly be required in this Dictionary. The only concern, which a surgeon has with the disease, is being occasionally required to make an opening for the discharge of the water. (See *Paracentesis Thoracis*.)

HYDROSARCOCELE. (from *ὕδωρ*, water; *σαρκῆς*, flesh; and *κύστις*, a tumour.) A sarcocele attended with a collection of fluid in the tunica vaginalis.

HYMEN IMPERFORATE. The inconveniences brought on by such a cause, and the mode of relief, are explained in the article *Vagina*.

A continuation of the hymen over a part of the orifice of the meatus urinarius may produce great pain and difficulty in making water, and symptoms, which may give rise to suspicion of there being a stone in the bladder. For a case illustrating the truth of this observation, see *Warner's Cases in Surgery, p. 276, Edit. 4.*

HYPOPIUM, or HYPOPYON. (from *ὑπο*, under; and *πύον*, pus.)

By hypopium (says Scarpa) I imply with all surgeons, that accumulation of a glutinous, yellowish fluid, like pus, which takes place in the anterior chamber of aqueous humour, and, frequently, also in the posterior one, in consequence of severe, acute ophthalmia, particularly the internal species. Though severe, acute ophthalmia mostly affects particularly the external parts of the eye; yet, it occasionally invades, with equal violence, both the external and internal coats of this organ, especially the chorioides and uvea. If such inflammation be not promptly checked

ed, by chirurgical means, coagulating lymph is extravasated from the highly inflamed choroides and uvea, and gradually, as it is effused into the cavity of the eye, it passes through the pupil into the chambers of the aqueous humour, and descends to the bottom of the anterior one, so as to fill sometimes one-third, sometimes one-half of this space; and occasionally, to occupy it to such a height, as totally to conceal the iris and pupil.

This viscid matter of hypopium, though commonly called pus, Scarpa regards as coagulating lymph. The symptoms, portending an extravasation of coagulating lymph in the eye, or an hypopium, are the same as those which occur in the highest stage of violent acute ophthalmia: viz. prodigious tumefaction of the eyelids; the same redness and swelling of the conjunctiva, as in chemosis; burning heat and pain in the eye; pains in the eyebrow and nape of the neck; fever, restlessness, aversion to the faintest light, and a contracted state of the pupil.

As soon as the hypopium begins to form, (says Scarpa) a yellowish semi-lunar streak makes its appearance at the bottom of the anterior chamber, and, regularly, as the glutinous fluid is secreted from the inflamed internal membranes of the eye, so as to pass through the pupil, and fall into the aqueous humour, it increases in all dimensions, and gradually obscures the iris, first at its inferior part, next where it forms the pupil, and lastly the whole circumference of this membrane. As long as the inflammatory stage of violent ophthalmia lasts, the hypopium never fails to enlarge; but, immediately this stage ceases, and the ophthalmia enters its second period, or that dependent on local weakness, the quantity of coagulating lymph, forming the hypopium, leaves off increasing, and, from that moment, is disposed to diminish.

This fact sufficiently evinces (continues this eminent Professor) how important it is, in order to check the progress of the hypopium, to employ, with the utmost care, the most effectual means for checking the attack of violent ophthalmia in its first stage. Copious evacuations of blood, both generally and topically, ought to be speedily put in practice; and when chemosis exists, the conjunctiva should be divided; mild aperients given, blisters applied to the nape of the neck, little bags of emollient herbs to the eye, and other measures employed. It will be known that they have fulfilled the indication, by noticing that, some days after the adoption of such treatment, though there may still be redness of the conjunctiva and eyelids, the lancinating pains in the eye abate, the heat considerably diminishes, the fever subsides, quietude and sleep are restored, the motion of the eye becomes free, and, lastly, the collection of viscid matter forming the hypopium, becomes stationary. It is not unfrequent to see, especially among the lower orders of the people, persons affected with the second stage of severe acute ophthalmia, bearing this collection of coagulating lymph, in the chambers of the

aqueous humour, with the greatest indifference, and without complaining of any of those symptoms which characterize the acute stage of ophthalmia. It is only at this crisis, or at the termination of the acute stage of violent inflammation of the eye, that the enlargement of the hypopium ceases, and the coagulating lymph begins to be absorbed, provided this salutary operation of nature be not impeded, nor retarded, by any injudicious regimen. However, if Scarpa had also been aware of the great efficacy of mercury, in arresting the effusion of lymph, I can hardly doubt, that he would have modified some of the preceding observations, as well as his practice; a subject to which I shall presently advert again.

Scarpa states, that persons, little versed in the treatment of diseases of the eyes, would fancy that the most expeditious and efficacious mode of curing an hypopium, after it has become stationary in the second stage of severe acute ophthalmia, would be that of opening the cornea at its most depending part, in order to procure a speedy exit for the matter collected in the chambers of the aqueous humour; especially as this was once the common doctrine. But experience shows, that dividing the cornea, in such circumstances, is seldom successful, and most frequently gives rise to evils, worse than the hypopium itself, notwithstanding the modification suggested by Richter, (*Obs. Chir. Fasc. 1, Chap. 12.*) not to evacuate the whole of the matter at once, nor to promote its discharge by repeated pressure and injections, but to allow it to flow slowly out of itself. The wound made at the lower part of the cornea, for evacuating the matter of the hypopium, small as the incision may be, most commonly reproduces severe acute ophthalmia, and a greater effusion of coagulating lymph into the chambers of the aqueous humour. Besides, after opening the cornea, if the matter of the hypopium were allowed to escape gradually of itself, it would be several days in being completely discharged, on account of its viscosity. During this time, the glutinous lymph would keep the edges of the wound of the cornea dilated, and make them suppurate. Thus, the incision would be converted into an ulcer, through which the aqueous humour would escape, and even a fold of the iris. Opening the cornea, therefore, only converts the hypopium into an ulcer of that membrane, attended with a prolapsus of the iris, and occasionally of the crystalline itself. Nor can any inference be drawn, in favour of making an artificial opening, during the stationary state of an hypopium in the second stage of severe acute ophthalmia, from the matter of the hypopium having sometimes made its way spontaneously through a narrow aperture in the cornea, with a successful result. For, there is a wide difference, between the effects of a spontaneous opening in a natural, or preternatural cavity of the animal body, or of one made with caustic, and the consequences of an opening, made with a cutting instru-

ment. In the two first methods, the subsequent symptoms are constantly milder than in the last. Besides, even in the instance in which a spontaneous discharge of the hypopium takes place through the cornea, an escape of the aqueous humour, and a prolapsus of the iris, not unfrequently ensues; consequently, the spontaneous evacuation of the hypopium cannot justly form a rule for the treatment of the disease. There is only one case, in which dividing the cornea, in order to discharge an hypopium, is not only useful, but indispensable; this is, when there is such an immense quantity of coagulating lymph extravasated in the eye, that the excessive distention, which it produces of all the coats of this organ, occasions symptoms so vehement, as not only threaten the entire destruction of the eye, but even endanger the life of the patient. But this particular case cannot serve (says Scarpa) as a model for the treatment of ordinary cases.

The dispersion of the hypopium, by means of absorption, forms the primary indication, at which the surgeon should aim. In order to stop its progress, the most efficacious method is to subdue the first violence of the inflammation, and to shorten its acute stage, by the free employment of antiphlogistic treatment, and the use of mild emollient, topical remedies. And, in conjunction with these means, there can now be no doubt, that the practice of Bruel, published in 1809, as will be mentioned at the close of this article, ought to be followed: I mean, the quick exhibition of the submuriate of mercury, which has been also found at the London Eye Infirmary the most powerful means of checking the effusion of lymph in the eye. (See *Saunders's Work on the Eye*, Ed. 2, and a *Synopsis of the Diseases of the Eye*, by B. Travers, p. 135.)

If this treatment answer, the incipient collection of coagulating lymph, at the bottom of the anterior chamber of the aqueous humour, not only ceases to augment, but, also, in proportion as the severe ophthalmia disappears, the absorbent system takes up the heterogeneous fluid extravasated in the eye, and the white, or yellow speck, shaped like a crescent, situated at the bottom of the anterior chamber, gradually diminishes, and is at last entirely dispersed. Janin considered an infusion of the flowers of mallows, applied to the eye that is inflamed and affected with this disease, as a specific resolvent in these circumstances, (*Mém. et Obs. sur l'Œil*, p. 405,) but it is now known, that every topical emollient application, provided it be conjoined with such internal antiphlogistic treatment, as is the most proper for repelling the acute stage of the severe ophthalmia, produces quite as good an effect as this infusion. Simple warm water produces the same benefit. "A young girl (says Nannoni) was struck in the eye by an ear of corn. An inflammation was the consequence, which produced a white pus of a semi-lunar shape, apparently behind the cornea, without a possibility

of judging whether the matter was actually situated between the laminae of that membrane, or in the anterior chamber. Hence, I was asked, whether it might not be evacuated by an incision, particularly as the patient complained of great pain in the eye, and eyebrow. She was in the hospital; and in the presence of Dr. Lulli, and several students in surgery, I said that the pain of which the patient complained, was not occasioned by the pus itself, but the cause which produced it. This cause was inflammation, which probably would be increased by making a larger opening for the external air, than what it has to the internal parts, while the external ones remain entire. By fomenting the eye and forehead with warm water, the inflammation subsided, and the pus disappeared. We have so often witnessed the fact subsequently, that we can also extol the simplicity of the treatment." Such, in short, is the successful termination of an hypopium, whenever the disease is properly treated at its commencement, and the acute stage of severe ophthalmia is promptly checked by internal antiphlogistic means, and emollient applications. But, in consequence of the inflammatory period of the severe ophthalmia having resisted, in an uncommon manner, the best means, or because such means have been employed too late, it sometimes happens, that the coagulating lymph, collected in the anterior chamber, is so abundant, even after the acute stage of ophthalmia, that it continues for a long time to cloud the eye, and intercept vision. Scarpa has often seen patients, especially paupers, who from indolence, negligence, or ill treatment, remained a long time after the cessation of the inflammatory stage of ophthalmia, with the anterior chamber almost entirely filled with the glutinous matter of hypopium. When the inflammation had ceased, these unhappy persons wandered about the streets almost quite indifferent, and without complaining of pain, or any other inconvenience, than the difficulty of seeing with the eye affected. In this second stage of the ophthalmia, the resolution of hypopium obviously cannot be accomplished by the same means, nor with equal celerity, as in the first. At this crisis, the great quantity and density of the glutinous matter extravasated, and the atony of the vascular system of the eye, make it necessary to give nature sufficient time to dissipate the thick, tenacious matter, and, at length, to dispose it to be insensibly absorbed with the aqueous humour which is continually undergoing a renovation. Hence it is right, (says Scarpa) to adopt those means, which are best calculated to invigorate the vascular system of the eye, more especially the lymphatics. This requires more or less time, according as the patient is advanced in years, of a relaxed fibre and weak; or a young man of good constitution.

However, according to Scarpa, in the second stage of violent acute ophthalmia, complicated with hypopium, the surgeon should limit his efforts to the removal of

very thing, which may irritate the eye, or be likely to renew the inflammation; and he should only employ such means, as are conducive to the resolution of the second inflammatory stage, depending on relaxation of the conjunctiva and its vessels, and such remedies as tend, at the same time, to invigorate the action of the absorbents. Therefore, in this state, he ought first to examine carefully the degree of irritability in the eye affected with the hypopium, by introducing, between the eye and eyelids, a few drops of vitriolic collyrium, containing the mucilage of quince seeds. Should the eye seem too strongly stimulated by this application, it must not be used, and little bags of warm mallows with a few grains of camphor are to be substituted for it. In the intervals, the vapours of the liquor ammon. comp. may be applied, and recourse had again to a blister on the nape of the neck. When the extreme sensibility of the eye is overcome, the zinc collyrium must be used again, afterward strengthened with a few drops of camphorated spirit. Under such treatment, proceeds Scarpa, the surgeon may observe, that, in proportion as the chronic ophthalmia disappears, and the action of the absorbents is re-excited, the tenacious matter of the hypopium divides first into several small masses; then dissolves still further; and, afterward, decreases in quantity: descending towards the inferior segment of the cornea; and, finally, vanishing altogether. But Scarpa accurately observes, that the surgeon cannot always expect to be equally successful, whether the disease occur during the first, or second stage of violent acute ophthalmia, if the tenacious lymph, suddenly extravasated in the interior of the eye, prevail in such quantity, as not only to fill, but strongly distend, the two chambers of the aqueous humour, and the cornea in particular. In this state, notwithstanding the most skilful treatment, the unpleasant complication is often followed by another inconvenience, still worse than the hypopium itself; viz. ulceration, opacity, and bursting of the cornea.

The ulceration of the cornea ordinarily takes place with such celerity, that the surgeon seldom has time to prevent it. As soon as an aperture has formed, the excessive abundance of coagulating lymph, contained in the eye, (sometimes named empyema oculi) begins to escape through it, and a degree of relief is experienced. But, this melioration is not of long continuance; for, scarcely is the glutinous fluid evacuated, that distended the whole eye, and especially the cornea, when it is followed by a portion of the iris, which glides through the ulcerated aperture, protrudes externally, and constitutes the disease termed prolapsus of the iris. (See *Iris, Prolapsus of.*) But, if in such an emergency, the cornea already ulcerated, opaque, and greatly deranged in its organization, should not immediately burst, the surgeon is then constrained by the violence of the symptoms, depending on the prodigious distention of the eyeball, to

make an opening in this membrane, in order to relieve the immense constriction, and even the danger in which life is placed.

Were there the least chance of restoring, in any degree, the transparency of the cornea, and the functions of the organs of vision, after opening the cornea, Scarpa acknowledges that it would certainly be more prudent to make the opening at the lower part of this membrane. But in the case of empyema of the eye, now considered, in which the cornea is universally menaced with ulceration and opacity, and seems ready to slough, there can be no hope of its resuming its transparency at any point, and he therefore deems it the best and most expeditious method of relief to divide its centre with a small bistoury to the extent of a line and a half; and then to raise with a pair of forceps the little flap, and cut it away all round with one stroke of the scissors, so as to let the humours escape without any pressure.

The eye is to be covered with a bread and milk poultice, which is to be renewed every two hours, the use of such general remedies, as are calculated to check the progress of acute inflammation, and to quiet the nervous system, not being omitted. In proportion as the interior of the eye suppurates, the eyeball gradually diminishes, shrinks into the orbit, and at length cicatrizes, leaving things in a favourable state for the application of an artificial eye.

When Scarpa delivers his opinion, that in the above aggravated form of hypopium, there can be no chance of the cornea resuming its transparency at any point, I think his assertion rather impudent. Nor admitting its general truth, does it follow as a matter of course, that it is necessary and right to cut away a piece of the centre of the cornea, and absolutely destroy whatever little chance may yet be left of saving the eye. In support of this remark, let me contrast what Mr. Travers has said with the advice of Scarpa. "When the hypopium is so large as to rise towards the pupil, and the ulceration of the cornea is extending, I think its discharge by section near its margin advisable. If not too long delayed, the ulcerative process is checked by it, which would otherwise run into sloughing, and the cornea recover with only partial opacity and disfigurement." (*Synopsis of the Diseases of the Eye*, p. 280.)

Mauchart de Hypopyo. Tubinge, 1742. C. P. Leporin, de Hypopyo. Ato. Goett. 1778. Goeldlin, Diss. de Hypopyo. Erlang. 1810. Wolther Merkwürdige Heilung eines Eiterauges, &c. Sto. Landshut, 1819. I observe, that in Hufeland and Himley's Journal for Octob. 1809, p. 93, there is an account of the treatment of an hypopium, or case of effused lymph in the chambers of the eye, by exhibiting from 12 to 18 grains of the submuriate of mercury, in the space of 12 hours, and then giving bark, while as an external application the tinct. opii crocat. was employed. Thus we see that the efficacy of mercury in checking the effusion of lymph in the eye, and promoting an absorption, has been known many years in

Germany. *A. Scarpa Saggio di Osservazioni e d'Esperienze, sulle Principali Malattie degli Occhi*; Venezia, 1802. Richter *Anfangsgründe der Wundarzneykunst*, B. 3. 1795. J. Wardrop, *Essays on the morbid*

HYSTEROTOMIA. (from *hystera*, the womb, and *tomos*, to cut.) See *Cæsarean Operation*.

I.

IMPERFORATE HYMEN. (See *Vagina*.)

INCARCERATION. This term is usually applied to cases of hernia in the same sense as strangulation. When the viscera are pressed upon either by the opening through which they protrude, or by the parts themselves within the hernial sac, in such a degree, that the course of the intestinal matter to the anus is obstructed, and nausea, sickness, pain, and tension of the swelling and abdomen, &c. are occasioned, the rupture is said to be in a state of incarceration or strangulation.

According to Professor Scarpa, however, an *incarcerated*, and a *strangulated* hernia, do not imply exactly the same thing. In the first case, says he, the course of the intestinal matter is interrupted, without any considerable impairment of the texture, or vitality of the bowel. On the contrary, in the *strangulated* hernia, besides the obstruction to the course of the fecal matter, there is organic injury of the coats of the intestine, with loss of its vitality. The bowel that is merely incarcerated, resumes its functions immediately it is replaced in the abdomen; while that which is truly strangulated never returns to its natural state. (*Traité des Hernies*, p. 251.)

This distinction, however, is by no means generally adopted.

INCONTINENCE OF URINE. (See *Urine*, *Incontinence of*.)

INFLAMMATION. (from *inflammo*, to burn.) By the term, *inflammation*, is generally understood the state of a part in which it is painful, hotter, redder, and somewhat more turgid than it naturally is: which topical symptoms, when present in any considerable degree, or when they affect very sensible parts, are attended with fever, or a general disturbance of the system. (*Burns*.)

The susceptibility of the body for inflammation is of two kinds; the one *original*, constituting a part of the animal economy, and beyond the reach of human investigation; the other *acquired* from the influence of climate, habits of life, and state of the mind over the constitution. (*Hunter*.) The first kind of susceptibility being innate, cannot be diminished by art; the second may be lessened by the mere avoidance of the particular causes upon which it depends.

Inflammation may, with great propriety, be divided into *healthy* and *unhealthy*. Of the first, there can only be one kind, though divisible into different stages; of the second, there must be an infinite number of species, according to the peculiarities of different constitutions, and the nature of diseases

which are numberless. (*Hunter*.) Another general division is into *common* and *specific* inflammation, the latter term implying, that the affection has some strongly marked particularity about it, rendering it in some degree independent of such circumstances as would control and regulate the progress of common inflammation. Such are *venereal*, *variolous*, *vaccine*, *erysipelatous*, *gouty*, and *rheumatic* inflammations, &c. Inflammation may also be divided into the *acute* and *chronic*. This division of the subject is one of the most ancient, and seems to have obtained the sanction of all the best surgical writers. Healthy inflammation is invariably quick in its progress, for which reason, it must always rank as an *acute* species of the affection. However, there are numerous inflammations, controlled by a diseased principle, which are quick in their progress, and are, therefore, to be considered as *acute*. Chronic inflammation, which will be treated of when I come to the subject of *tumours*, is always accompanied with diseased action.

My friend, Mr. James of Exeter, justly impressed with the utility which would result from a good no-ological arrangement of inflammation, has lately attempted to supply what must generally be allowed to be a great desideratum. To the division of inflammation into the *acute*, *subacute*, or *chronic*, he objects, that in many instances, these are merely different stages of the same disease. The arrangement into the *adhesive*, *suppurative*, *ulcerative*, or *gangrenous* inflammation, he does not altogether approve, because it is merely founded on the modes in which either different, or in some instances, the same kinds of inflammation terminate. Under the heads of *phlegmonous*, *erysipelatous*, and *gangrenous* inflammation, he argues, that diseases of the most opposite nature have been indiscriminately brought together. The disposition to terminate in gangrene, he admits, will afford a basis for subdivision, but not for primary separation. Mr. James makes some judicious observations on the arrangement of the kinds of inflammation, according to the elementary tissue in which they occur, as proposed by Dr. Carmichael Smith, Pinel, and Bichat. The tissues in question are five, and the doctrine supposes, that the inflammation of each is essentially different. The first is *phlegmonous* inflammation, which affects the cellular membrane, including the parenchyma of the several viscera. The second is inflammation of serous membranes. The third, of mucous membranes. The fourth, which is named *erysipelatous*, is of the skin. And the fifth, term-

ed rheumatic, belongs to fibrous structure. That inflammations differ materially from the circumstance of their affecting one of these elementary tissues, rather than another, Mr. James freely admits: but the following objections appear to him fatal to this system, if they are true. 1. Different kinds of inflammation are liable to occur in the same tissue. 2. The same kind of inflammation is often met with in different tissues. 3. The same inflammation may be transferred from one to another; an argument, however, on which he lays less stress, as being difficult of direct proof. (See *Obs. on the different Species of Inflammation*, p. 3—7. 8vo. Lond. 1821.) Although difference of structure unquestionably accounts for some of the varieties in the appearance and character of inflammation, it will not sufficiently explain the principal diversities of this affection to be taken as the foundation of a nosological arrangement, not only for the reasons pointed out by Mr. James, but because the common distinctions of inflammation at present in vogue, and some of which at least are obvious and striking, cannot be at all solved by any reference merely to texture. Nor did this theory satisfy Mr. Hunter, who observed, that if it were true, "we should soon be made acquainted with all the different inflammations in the same person at the same time, and even in the same wound. For instance, in an amputation of a leg, where we cut through the skin, cellular membrane, muscle, tendon, periosteum, bone, and marrow, the skin should give us inflammation of its kind, the cellular membrane of its kind; the muscles of theirs, &c. &c. but we find it is the same inflammation in them all. However, though Mr. Hunter did not admit the possibility of referring the different kinds of inflammation to peculiarities of texture, his doctrines assign to this cause considerable influence over every form of the disorder, as will be presently explained.

The mode of reasoning adopted by Mr. James, leads him to propose; 1st. The division of inflammations into two great classes, according to their disposition either to be limited by the effusion of organizable coagulable lymph, or to spread. 2dly. The orders are established on the principle of the degree of connexion of the organ with the vital functions of the animal; another cause, which exerts a predominant influence over the character of the inflammation; acts invariably, and *cæteris paribus*, in the same degree; the constitutional sympathy being in proportion to the danger, the difficulty of resisting that danger, and of repairing the mischief done. 3dly. The genera are founded on the original disposition of inflammations to have particular modes of termination: thus, says Mr. James, in boil and whitlow, it is to suppurate; in carbuncle, to slough; and in mumps to resolve: and this disposition is so strong, that it is very difficult to procure any other termination. It may happen, however, that there shall be more than one mode, in which it (the inflammation) is disposed to terminate, as in either resolution, or suppuration, in

sphacelus, or ulceration, &c. (*Op. cit.* p. 13—16.) Mr. James conceives, "that these general principles will perhaps afford a sufficient basis for such an arrangement, as shall be both natural and useful in its application to all kinds of common inflammation; gout, rheumatism, and scrotula having peculiarities which require them to be separated." Also with respect to inflammations arising from external injuries, as they are more simple in their nature, may take place in sound constitutions, and are accompanied with disorganizations, which do not exist in other cases, Mr. James considers them as materially different. This author purposely excludes from his classification inflammations of the organs of sense, and of the bones, the peculiarities in their structure and functions rendering them fit subjects for separate description. With respect to Mr. James's nosological table of inflammation, I consider it very ingenious, and well deserving of the attention of the profession: I may say this without at all involving myself in the hypothesis, that the limitation, or spreading of the generality of inflammations, is a circumstance entirely dependent upon their disposition or indisposition to effuse organizable lymph. Mr. Hunter was well acquainted with the frequent usefulness of the adhesive inflammation in setting limits to disease, yet he did not venture to refer the circumscription of every inflammation to this cause, or the spreading of the disorder entirely to its absence. Nor, indeed, does it seem essential to Mr. James's classification, that any cause should be assigned for the disposition of one class of inflammations to be limited, and of another to spread; the two facts themselves being sufficient for the basis of the division.

There is much foundation for believing that healthy inflammation is invariably an homogeneous process obedient to ordained principles, and, in similar structures, similar situations, and in constitutions of equal strength, uniformly assuming the same features. If experience reveals to us, that *here* it is commonly productive of certain effects, and *there* it ordinarily produces different ones, the same unbounded source of wisdom communicates to the mind a knowledge, that there is some difference in the tone of the constitution, or in the structure or situation of the parts affected, assignable as the cause of this variety. A modern author (*D. Smith, in Med. Communications, Vol. 2.*) makes the nature of the exciting cause one principal ground of the specific distinctions in inflammation, and with good reason, when he takes into the account the action of morbid poisons, and the qualities of disease in general.

The doctrine also receives confirmation from what is observed in cases of burns, and chilblains, where the inflammation is unquestionably attended with great peculiarity, requiring different treatment from that of common inflammation in general. But, when the exciting cause is strictly mechanical, its violence and extent may cause differences in the degree and quantity of in-

flammation; but, with respect to its quality, this must be accounted for by constitution, or other circumstances.

The attentive observation of experience, the only solid basis of all medical, as well as other knowledge, has informed the practitioner, that parts, which from their vicinity to the source of the circulation, enjoy a vigorous circulation of blood through them, undergo inflammation more favourably, and resist disease better than other parts, of similar structure, more remote from the heart. The lower extremities are more prone to inflammation and disease in general, than parts about the chest; when inflamed, they are longer in getting well; and the circumstance of their being depending parts, which retards the return of blood through the veins, must also increase the backwardness of such parts in any salutary process. (*Hunter*) Healthy inflammation is of a pale red when less healthy, it is of a darker colour; but, in every constitution, the inflamed parts will partake more of the healthy red, the nearer they are to the source of the circulation. (*Hunter*.)

Inflammation when situated in highly organized and very vascular parts, is generally more disposed to take a prosperous course, and is more governable by art, than in parts of an opposite texture. The nearer also such vascular parts are to the heart, the greater will be their tendency to do well in inflammation. (*Hunter*.) Hence, inflammation of the skin, cellular substance, muscles, &c. more frequently ends favourably, than the same affection of bones, tendons, fasciæ, ligaments, &c. It is also more manageable by surgery; for those parts of the body, which are not what anatomists term *vascular*, seem to enjoy only inferior powers of life, and, consequently, when excited in a preternatural degree, frequently mortify.

But, inflammation of vital parts, though they may be exceedingly vascular, cannot go on so favourably, as in other parts of resembling structure, but, of different functions; because, the natural operations of universal health depend so much upon the sound condition of such organs. (*Hunter*.) The truth of this observation is illustrated in cases of gastritis, peripneumony, &c.

All new-formed parts, not originally entering into the fabric of the body, such as tumours, both of the encysted and sarcomatous kinds, excrescences, &c. cannot endure the disturbance of inflammation long, nor in a great degree. The vital powers of such parts are weak, and when irritated by the presence of inflammation, these adventitious substances are sometimes removed by the lymphatics, but more commonly slough. This remark applies also to substances generated as substitutes for the original matter of the body; for instance, granulations and callus. The knowledge of this fact, leads us to a rational principle of cure in the treatment of several surgical diseases. Do we not here perceive the

cause, why very large wens are occasionally dispersed by the application of urine, brine, and similar things, which are now in great repute, on this account, with almost every one out of the profession? How many verrucae, wrongly suspected to originate from a syphilitic cause, are diminished and cured by a course of mercury! It is the stimulus of this mineral upon the whole system, that accomplishes the destruction of these adventitious substances—not its antivenereal quality. Topical stimulants would fulfil the same object, not only with greater expedition, but with no injury to the general health.

Inflammation, *ceteris paribus*, always proceeds more favourably in strong, than in weak constitutions; for, when there is much strength, there is little irritability. In weak constitutions, the operations of inflammation are backward, notwithstanding the part in which it is seated may, comparatively speaking, possess considerable organization, and powers of life. (*Hunter*.)

Healthy inflammation, wherever situated, is always most violent on that side of the point of inflammation, which is next to the external surface of the body. When inflammation attacks the socket of a tooth, it does not take place on the inside of the alveolar process, but towards the cheek. When inflammation attacks the cellular substance, surrounding the rectum, near the anus, the affection usually extends itself to the skin of the buttock, leaving the intestine perfectly sound, though in contact with the inflamed part. (*Hunter*.)

We may observe the influence of this law in the diseases of the lachrymal sac and duct, in those of the frontal sinus and antrum, and particularly in gunshot wounds. Suppose a ball were to pass into the thigh, to within an inch of the opposite side of the limb, we should not find, that inflammation would be excited along the track of the ball, but, on the side next the skin which had not been hurt. If a ball were to pass quite through a limb, and carry into the wound a piece of cloth, which lodged in the middle, equidistant from the two orifices, the skin, immediately over the extraneous body, would inflame, if the passage of the ball were superficial.—(*Hunter*) Mr. Hunter compared this law with the principle, by which vegetables approach the surface of the earth; but, the solution of it was too arduous even for his strong genius and penetration.

We see three very remarkable effects follow the prevalence of inflammation; viz. adhesions of parts of the body to each other; the formation of pus, or suppuration; and ulceration, a process, in which the lymphatics are more concerned, than the blood-vessels. Hence, Mr. Hunter termed the different stages of inflammation, the *adhesive*, the *suppurative*, and the *ulcerative*.

All parts of the body are not equally liable to each of the preceding consequences (*Hunter*.)

In the cellular membrane, and in the circumscribed cavities, the adhesive stage takes place more readily than the others; suppuration may be said to follow next in order of frequency; and lastly ulceration.

In internal canals, on the inner surfaces of the eyelids, nose, mouth, and trachea, in the air-cells of the lungs, in the œsophagus stomach, intestines, pelvis of the kidney, ureters, bladder, urethra, and in all the ducts and outlets of the organs of secretion, being what are termed *mucous membranes*, the suppurative inflammation comes on more readily, than either the adhesive, or the ulcerative stage. Adhesions, which originate from the slightest degree of inflammation in other situations and structures, can only be produced by a violent kind in the above-mentioned parts. Ulceration is more frequently met with upon mucous surfaces, than adhesions. (Hunter.) The cellular membrane appears to be much more susceptible of the adhesive inflammation, than the adipose, and much more readily passes into the suppurative. (Hunter.) Thus we see the cellular substance, connecting the muscles together, and the adipose membrane to the muscles, inflaming, suppurating and the matter separating the muscles, from their lateral connexions, and even the fat from the muscles, while the latter substance and the skin are only highly inflamed. (Hunter.) But, it must be allowed, that in situations where fat abounds, we very frequently meet with abscesses. This is so much the case, that fat has been accounted a more frequent nidus for collections of matter, than the cellular substance. (Bromfield.) Abscesses are particularly liable to form in the neighbourhood of the anus, mamma, &c. With respect to the fat being highly inflamed, however, the expression is not strictly true. Fat has no vessels, principle of life nor action of its own; consequently, we cannot suppose that it can itself either inflame, or suppurate. We know, that it is itself a secretion, and when an abscess forms in it, we understand, that the mode of action in the vessels, naturally destined to deposit fat, has been altered to that adapted to the formation of pus. When therefore the fat is said to be inflamed, it is only meant, that the membranous cells, in which it is contained, and by which it is secreted, are thus affected.

The deeply-situated parts of the body, more especially the vital ones, very readily admit of the adhesive stage of inflammation. The circumstance of deeply-seated parts not so readily taking on the suppurative stage of inflammation, as the superficial ones do, is strikingly illustrated in cases of extraneous bodies, which, if deeply lodged, only produce the adhesive inflammation. By this process, a cyst is formed, in which they lie without much inconvenience, and they may even gradually change their situation, without disturbing the parts, through which they pass. But, no sooner do these same bodies approach the skin, than abscesses immediately arise. (Hunter.)

All inflammations, attended with disease, partake of some specific quality, from which simple inflammation is entirely free. When the constitution allows the true adhesive and suppurative stages to occur, it is to be regarded as the most healthy. Were it in an opposite state, we should see the very same irritation excite some other kind of inflammation, such as the erysipelatous, scrofulous, &c. (Hunter.)

In specific inflammations, the position, structure, and distance of the part affected from the source of the circulation, as well as from the surface of the body, seem also to have as much influence as in cases of common inflammation. Upon this point, I feel conscious of being a little at variance with what Mr. Hunter has stated; but, the undecided manner in which he expresses himself, not less than the following reflections, encourages me not to desert my own ideas. We see, that venereal eruptions sooner make their appearance upon the chest and face, than upon the extremities. No organized part can be deemed exempt from the attack of common inflammation; many appear to be totally insusceptible of the venereal. We know, that scrofulous diseases of the superior extremities take a more favourable course, require amputation less frequently, and get well oftener than when situated in the inferior limbs. (Ford.) The venereal disease makes more rapid advances in the skin and throat, than in the bones and tendons; we often see it producing a specific inflammation, and an enlargement of the superficial parts of the tibia, ulna, clavicle, cranium, &c. while other bones, covered by a considerable quantity of flesh, are very rarely affected. Gouty inflammation is prone to invade the small joints; rheumatic, the large.

SYMPTOMS, NATURE, AND CAUSES OF INFLAMMATION.

Redness, swelling, heat, and pain, the four principal symptoms of phlegmonous inflammation, have been accurately noticed by Celsus: *Nota vero inflammationis sunt quatuor, rubor et tumor, eum calore et dolore. lib. 3, cap. 10.* If we refer to any writer on this interesting part of surgery, we shall find the above symptoms enumerated as characterizing phlegmon. In short, this term is usually applied to a circumscribed tumour, attended with heat, redness, tension, and a throbbing pain. These are the first appearances observed in every case of phlegmon; and when they are slight, and the part affected is of no great extent, they have commonly very little, and sometimes no apparent, influence on the general system. But when they are more considerable, and the inflammation becomes extensive, a full, quick, and generally a hard pulse takes place, and the patient, at the same time, complains of universal heat, thirst, and other symptoms of fever. While the inflamed part becomes red, painful, and swelled, its functions are also impaired. The same degree

of inflammation is said to produce more swelling in soft parts, and less in those of a harder structure. (*Burns.*)

Though the redness, swelling, throbbing, tension, and other symptoms of phlegmonous inflammation, are less manifest, when the affection is deeply situated, yet their existence is undoubted. When persons die of peripneumony, or inflammation of the lungs, the air-cells of these organs are found crowded with a larger number of turgid blood-vessels than in the healthy state, and of course the parts must appear preternaturally red. Coagulating lymph, and even blood, are extravasated in the substance of these viscera, which become heavier, and feel more solid. (*Baillie.*)

The extravasation of coagulating lymph, which is one of the chief causes of the swelling, is also one of the most characteristic signs of phlegmonous inflammation.

Some writers (*Smith, in Med. Commun. Vol. 2.*) have confined the seat of phlegmon to the cellular membrane; but this idea is erroneous. Had such authors duly discriminated the nature of common inflammation, they would have allowed that this affection existed, wherever the capillaries appeared to be more numerous and enlarged than in the natural state, accompanied with an effusion of coagulating lymph, whether upon the surface of a membrane, or a bone, or into the interstices of the cellular substance, and attended with acute pain, and a throbbing pulsation in the part.

As Dr. Thomson has observed, the epithet *remote*, as applied to the *causes of inflammation*, does not appear to be happily chosen; for under this term are comprehended all those agents, events, and states, which contribute immediately, as well as remotely, directly as well as indirectly, to the production of the affection. (*Lectures on Inflammation, p. 50.*)

The remote causes of inflammation are infinite in number, but very easy of comprehension, because only divisible into two general classes. The first includes all such agents as operate by their stimulant or chymical qualities; for instance, cantharides, heat, the action of concentrated acids, alkalis, metallic oxides, and metallic salts, acrid vapours, such as ammoniacal gas, the nitrous, sulphureous, muriatic, oxygenated muriatic gases, &c. alcohol, æther, and all acrid vegetable essential oils, animal poisons, and the whole of that class of substances known by the name of rubefacients. (*Thomson on Inflammation, p. 55.*) The second class of causes are those which act mechanically, such as bruises, wounds, pressure, friction, &c.

Fevers often seem to become the remote causes of local inflammation. In other instances, inflammation appears to arise spontaneously, or, as I should rather say, without any perceptible exciting cause.

The principle on which the application of cold to a part becomes the remote cause of inflammation, is not decidedly known. "No subject (says a distinguished professor)

is more deserving of your study, than the effects which are produced in the human body by the operation of cold applied to its surface; but the subject is, at the same time, exceedingly extensive, complicated, and difficult. These effects differ according to the degree in which the cold is applied, the state of the system, the part of the body to which it is applied, and the mode of its application. So diversified, indeed, are these effects, that it requires no mean confidence in theoretical reasoning to believe, that the operation of cold in producing them is applicable upon any single general principle." (*See Thomson on Inflammation, p. 58.*) And in the preceding page, he observes: "The operation of cold upon the human body affords the best example which I can suggest to you, of the production of inflammation from the operation of a power acting upon a part at a distance from that in which the inflammation takes place. The instances formerly mentioned of inflammation of the throat, chest, or belly, from the application of cold to the feet, are daily occurrences in these climates, of which it is impossible for us, in the present state of our knowledge of the animal economy, to give any thing like a satisfactory explanation."

"In some instances, cold, or a diminution of temperature, seems to act more directly upon the parts, with which it comes into contact. We have examples of this in the inflammation of the mucous membranes of the nose, fauces, trachea, and bronchia, from the inhalation of cold air; and in the production of rheumatic inflammation from the accidental exposure of some part or other of the body to cold. The application of cold, in the instances I have mentioned, seems to have somewhat of a directly exciting effect; and perhaps the same remark is still more applicable to the local effects of cold in the production of the inflammation accompanying the state, which is usually denominated frost-bite. Touching a solid body, as a piece of metal, the temperature of which has been greatly reduced, produces a sensation like that of burning, and may be followed, like the application of fire, with a blister." (*Op. cit.*)

Numerous opinions have been entertained respecting the *proximate cause of Inflammation*; but almost every theory has been built upon the supposition of there being some kind of obstruction in the inflamed part.

While the circulation of the blood was unknown, and the hypothetical notions of the power of the liver, in preparing and sending forth this fluid, continued to prevail, physicians were so fully persuaded of the existence and influence of different humours and spirits, and so little did they know of the regular and constant motion of the blood, that they believed in the possibility of depositions and congestions of the blood, the bile, or lymph; and acknowledged these as the cause of inflammation. Their anatomists taught them, and their professors of physic supported the opinion, that the liver

was the centre of the vascular system, from which the blood went forth by day to the extremities, and returned again by night. If then any peccant matter irritated the liver, the blood was sent out more forcibly; and if, at the same time, any part of the body were weakened, or otherwise disposed to receive a greater quantity of fluid than the rest, then a swelling was produced by the flow of humours to this place. Fluxions, or flows of humour to a place, might happen either from weakness of the part which allowed the humours to enter more abundantly, or from the place attracting the humours, in consequence of the application of heat or other agents. The peculiar nature of the swelling was supposed to depend upon the kind of humour. Blood produced the true phlegmon; bile, erysipelas; &c. An idea was also entertained, that the blood and humours might slowly stagnate in a part, from a want of expulsive power, and this affection was termed a *congestion*, while the expression *fluxion* or *defluxion* was used to denote any swelling arising from the sudden flow of humours from a distant part. (J. Burns, *Dissertations on Inflammation*.)

From the theories of *fluxion* and *congestion*, which were quite incompatible with the laws of the circulation of the blood, we turn our attention to the doctrine of *obstruction*.

Boerhaave inculcated, (*Aph.* 375 *et seq.*) that inflammation was caused by an obstruction to the free circulation of the blood in the minute vessels, and this obstruction, he supposed, might be caused by heat, diarrhoea, too copious flow of urine, and sweat, or whatever could dissipate the thinner parts of the blood, and produce a thickness or viscosity of that fluid. When the lensor did not exist before the production of inflammation, he imagined that the larger globules of the blood passed into the small vessels, and thus plugged them up. This circumstance was termed an *error loci*. The obstruction, whether caused by *viscosity* or an *error loci*, was imagined to occasion a resistance to the circulation in the part affected; and hence, an increase of the flow of the blood in the other vessels, an irritation of the heart, and augmentation of the force, or attraction of the blood in that part of the vessel which was behind the obstruction. This caused heat and pain, while the accumulation of blood produces redness. Boerhaave also brought into the account an *acrimonious state of the fluids*, which rendered resolution out of the question, and gangrene likely to follow. (*Aph.* 388.)

The viscosity of the blood cannot be admitted as the proximate cause of inflammation; because we have no proof that this state ever exists; or, granting that it did, it would not explain the phenomena. Were a viscosity to occur it would exist in the whole mass of blood, would affect every part of the body alike, and could not be supposed to produce only a local disorder. How also could such a lensor be produced by causes which bring on inflammation sud-

denly, without there being time for changes of the fluids to take place?

With regard to the doctrine of *error loci*, or of red globules going into vessels which did not formerly transmit them, the fact must be admitted, at the same time, that the conclusion is denied. When the eye becomes inflamed, the tunica conjunctiva is seen with its vessels full of red blood, which in health is not the case; but this redness never appears until the inflammation has commenced, and must therefore be considered as an effect, not a cause. Nor can this *error loci* occasion any obstruction in these vessels; for if they be divided, the blood flows freely, which shows that they are large enough to allow an easy circulation. (J. Burns.)

Boerhaave's theory of obstruction was too circumscribed, and too mechanical; it reduced all inflammations to one species: the only distinctions which could have arisen, must have proceeded from the nature of the obstruction itself; and it was a doctrine that never could account for the action of many specific diseases and morbid poisons. (Hunter.)

As for the supposition of the co-operation of an *acrimony of the fluids*, the proportion of the saline matter of the blood has never been proved to be greater in this, than in any other state of the body. (Burns.) Even were a general disorder of this kind to be admitted, no rational explanation of the proximate cause of local inflammation could be deduced from it.

The decided impossibility of giving a rational explanation of the immediate cause of inflammation by any supposed state of the blood alone, led pathologists to investigate how far a change in the blood-vessels themselves might account for the process. It belongs more properly to a physiological than a surgical work, to explain the various facts and experiments in support of the opinion, that the arterial tubes, and especially the capillaries, possess a high degree of vital contractility, whereby the motion of the fluids in them, the process of secretion, and other local phenomena may be importantly affected, in a manner not at all explicable, by reference only to the action and power of the heart. For such information, I would particularly advise the reader to consult the publications of Dr. Wilson Philip, and Dr. Hastings. According to the latter gentleman, the actual agency of the capillary vessels, "is not only supported by such experiments as those related, it is also countenanced by an extensive series of phenomena presented during disease in the human subject. Of these may be mentioned, irregular determinations of blood, the growth of tumours, increased pulsation of arteries leading to inflamed parts, of which the following is a well-marked example, the accuracy of which may be entirely relied upon. The carotids, when the person alluded to is in health, beat equally as to strength and frequency; but when he is attacked with inflammation in the right tonsil, to which

he is particularly subject, and which proceeds sometimes so far as nearly to prevent deglutition, each pulsation of the artery gives a throbbing sensation on the right side of the head. On the application of the band at this time to each carotid, the right is found to beat much stronger and fuller than the left. This diversity of action in these two arteries cannot arise from any impulse given by the blood to the heart: it must be derived from some modification of the contractile power of the artery." And Dr. Hastings expresses his belief in this explanation, notwithstanding Dr. C. H. Parry wishes to attribute to the remote influence of the heart some of the phenomena of local congestion and motion, and to show, that the different states of vascular dilatation are still more conspicuously connected with the different degrees of action of the heart, and the consequent momentum of the blood, than with local circumstances; and that the proneness to local dilatation, or, as it is called, action, is a consequence of slowly succeeding, but continued impulse.

The blood-vessels, through every part of the system, possess a considerable share of irritability, by which they contract, and propel forward their contents. Hence, the blood, by the action of the vessels, receives a new impulse in the most minute tubes, and a well-regulated momentum is preserved in every part of its course. But of all parts of the sanguiferous system, the capillaries seem most eminently endowed with this faculty, and are least indebted to the presiding influence of the heart. Yet even in these vessels, the action of the heart is of high importance in sustaining the healthy circulation, inasmuch as it gives the first impulse to the blood, and preserves the harmony of the sanguiferous system.

The vessels are endowed with this vital property, in order that each organ in the body may receive such a supply of blood as will enable it duly to exercise its functions. Hence, a healthy state of this property is absolutely necessary for the preservation of the animal functions; for, if the vital contraction of the blood-vessels be either increased or diminished, irregular distribution of the blood inevitably follows, and from this source numerous diseases arise, and none more frequently than inflammation. However, though these sentiments, delivered by Dr. Hastings, may be generally correct, I am not prepared to join in the opinion, that inflammation is ever produced simply by an inequality in the distribution of the blood; a statement which this gentleman probably does not mean to make himself, as he confesses that some of the phenomena of this disease depend upon sympathy between the sanguiferous and nervous systems. (See *Hastings on Inflammation of the Mucous Membrane of the Lungs*, &c. p. 32, 64, 65. 8vo. Lond. 1820; and *C. H. Parry, Additional Experiments on the Arteries*, &c. p. 112, 114; Also *Whytt, on the Motion of the Fluids in the small Vessels*; *Verschuier de Arteriarum et Venarum vi irri-*

tabili; *Zimmermann de irritabilitate*, p. 24; *Hunter on the Blood*, &c.)

Dr. Cullen attributed the proximate cause of inflammation to a "spasm of the extreme arteries supporting an increased action in the course of them." This theory only differs from that of Boerhaave in the cause which is assigned for the obstruction. Dr. Cullen conceived, however, that some causes of inequality in the distribution of the blood might throw an unusual quantity of it into particular vessels, to which it must necessarily prove a stimulus; and that, in order to relieve the congestion, the vis medicatrix naturæ increases still more the action of the vessels; which, as in all other febrile diseases, it affects by the formation of a spasm on their extremities." "A spasm of the extreme arteries, supporting an increased action in the course of them, may, therefore be considered as the proximate cause of inflammation; at least, in all cases not arising from direct stimuli applied; and even in this case the stimuli may be supposed to produce a spasm of the extreme vessels" (Cullen.)

The inconsistencies in Cullen's theory are very glaring. The congestion or accumulation of blood, which is only an effect or consequence of inflammation, is set down as the cause of the spasm of the vessels to which spasmodic constriction Cullen, strangely enough, assigns the name of proximate cause. The spasmodic contraction of the extremities of the vessels, instead of propelling the accumulated quantity of blood, would render the passage of the blood from the arterial into the venous system still more difficult. (Burns.)

We shall now notice the celebrated and very original opinions promulgated on this subject by John Hunter. According to him, inflammation is to be considered only as a disturbed state of parts, which requires a new but salutary mode of action to restore them to that state wherein a natural mode of action alone is necessary. From such a view of the subject, therefore, inflammation in itself is not to be considered as a disease, but as a salutary operation, consequent either to some violence or some disease. Elsewhere the author remarks, the act of inflammation is to be considered as an *increased action of the vessels, which, at first, consist simply in an increase or distention beyond their natural size. This increase seems to depend upon a diminution of the muscular power of the vessels, at the same time that the elastic power of the artery must be dilated in the same proportion. This is, therefore, something more than simply a common relaxation: we must suppose it an action in the parts to produce an increase of size for particular purposes, and this Mr. Hunter would call an act of dilatation. The whole is to be considered as a necessary operation of nature. Owing to this dilatation, there is a greater quantity of blood circulating in the part, which is according to the common rules of the animal economy; for, whenever a part has more to do than*

simply to support itself, the blood is there collected in larger quantity. The swelling is produced by an extravasation of coagulable lymph, with some serum: but this lymph differs from the common lymph, in consequence of passing through inflamed vessels. It is this lymph which becomes the uniting medium of inflamed parts; vessels shoot into it; and it has even the power of becoming vascular itself. The pain proceeds from spasm. The redness is produced either by the arteries being more dilated than the veins, or because the blood is not changed in the veins. "As the vessels become larger, and the part becomes more of the colour of blood, it is to be supposed there is more blood in the part; and as the true inflammatory colour is scarlet, or that colour which the blood has when in the arteries, one would from hence conclude either that the arteries were principally dilated, or, at least, if the veins are equally distended, that the blood undergoes no change in such inflammation in its passage from the arteries into the veins, which I think (says Mr. Hunter) most probably the case; and this may arise from the quickness of its passage through those vessels." When a part cannot be restored to health, after injury, by inflammation alone, or by adhesion, then suppuration, as a preparatory step to the formation of granulations, and the consequent restoration of the part, takes place. The vessels are nearly in the same state as in inflammation; but they are more quiescent, and have acquired a new mode of action. (Hunter.)

With respect to Mr. Hunter's theory, which has deservedly had vast influence in regulating the judgment of professional men in this country, on the nature of the process called inflammation, it cannot be received in the present state of knowledge without some limitation. The hypothesis, that the blood-vessels possess an active power of dilatation, independently of their elasticity, as Dr. Hastings observes, must as yet be regarded as devoid of proof, and therefore should not be assumed as a basis on which any theory of inflammation is founded. (*On Inflammation of the Mucous Membrane of the Lungs, &c.* p. 70.) And, as another intelligent writer remarks, how different would have been Mr. Hunter's inferences, if, instead of trusting to the unassisted eye, he had viewed the inflamed vessels through the microscope. He would then have seen the blood moving, and found, that, "*instead of its passage being quickened in the inflamed vessels, it is uniformly rendered slower in proportion to the degree of inflammation, and, in the most inflamed parts, stands still altogether.*" (*On the Vital Functions*, p. 288, Ed. 2.) And in another part of his writings, Dr. Philip has endeavoured to prove, from several facts respecting the colour of the blood, that *within certain limits, the accumulation of this fluid in the debilitated vessels of the inflamed part necessarily causes the blood to retain the florid colour.* (*On Fevers, Part 2, Introd.*)

In modern times, the vague, but convenient expression, *increased action of the vessels* has been very generally used as an adequate explanation of the proximate cause of inflammation. The doctrine, it is said, derives support from a review of the several exciting causes of the affection, which, being in general of an irritating nature, must, when applied to any living or sensible parts, occasion such increased action of the vessels; while the method of cure also tends to confirm the opinion. But, before one can judge whether this doctrine is correct, and supported by facts and observation, it is necessary to understand precisely what is implied by increased action of vessels; for it is not every affection of the vessels, capable of being thus denominated, which will of itself constitute inflammation. In gestation, the arteries of the womb are enlarged, and a greater quantity of blood is sent into them; yet this organ is not inflamed. The carotids are in a similar state during the growth of the stag's horn; but no inflammation exists. If then the proximate cause of inflammation is to be called an increased action of the vessels, we must first be informed not only what is meant by the term, but what particular vessels are spoken of, whether the arterial trunks, branches, or capillaries? Because, if the phrase is intended to signify increased alternate expansions and contractions of all the arteries of the inflamed part, it is an hypothesis entirely destitute of foundation. If it be meant to denote an increased velocity of the motion of the blood in the part affected, the doctrine is rather contradicted than confirmed by the latest and most carefully instituted microscopical experiments. But if the expression only refers to the dilated state of the capillaries, the throbbing of the arteries leading to the seat of inflammation, the effusion of lymph, &c. less fault can be found with the language, though yet requiring much further explanation ere it can communicate any very precise information.

"There are (says a learned professor) two hypotheses, which at present divide the opinions of pathologists respecting the state of the capillary vessels affected with inflammation. According to the first of these hypotheses, the inflamed vessels are in a state of increased action; according to the second, they act with less force than the trunks from which they are derived." (See *Thomson on Inflammation*, p. 64.)

The first of these opinions, according to Dr. Thomson, was suggested by the views which Stahl took of the animal economy, and his ideas respecting the tonic or vital action of the capillary vessels. The doctrine, however, was more particularly insisted upon by his disciples and followers, especially Dr. Gorter, who in one place expressly states, "that the proximate cause of inflammation consists in an increased vital action of some particular artery or arteries, by which the blood is propelled with greater force than usual into the communicating lymphatic and colourless ves-

sels." (See his *Compendium Medicinæ* and *Chirurgia Repurgata*.)

The doctrine which supposes the action of the inflamed vessels to be diminished, or to be proportionably less than that of the trunk or trunks from which they are derived, was, as far as Dr. Thomson can learn, first stated by Vacca, an Italian physician, in a small treatise on inflammation, published at Florence in 1765, entitled "*Liber de Inflammationis Morbosæ, quæ in humano corpore fit naturâ, causis, effectibus, et curatione.*"

For an account of the arguments with which Vacca supports his hypothesis, my limits oblige me to refer to the work of Dr. Thomson. (P. 68, &c.)

As this gentleman has observed, there are certain points in which the two doctrines agree, as well as in which they differ.

"The advocates for each hypothesis agree in admitting, 1st, that inflammation has its seat in the capillary vessels; and 2dly, that the redness in inflammation is owing to an unusual quantity of blood in the vessels of the inflamed part, and consequently that the capillary arteries are much dilated during the state of inflammation. The contractions of these vessels, indeed, it has been said, are increased also in a ratio proportional to the dilatations; but, this is an assertion which has not yet been proved, either in the way of experiment or of observation.

"The sense of throbbing, which the advocates for the hypothesis of increased capillary action regard as the strongest proof of that action, Mr. Allen is disposed to attribute to the difficulty, which the blood meets with in passing from the trunk into the capillary branches. This sensation of throbbing, and appearance of increased action, may be produced in an instant, by applying a ligature to an uninflamed finger, so as to obstruct the motion of the blood through its point. Besides, this throbbing, or pulsatory motion, can afford us no criterion, by which to judge of the force, with which the artery contracts, for, it is produced in the dilatation of the artery, and by a power foreign to the artery itself." (Thomson on Inflammation, p. 73.)

Dr. Wilson Philip, many years ago, endeavoured to ascertain, by means of the microscope, the state of the vessels in the various stages of inflammation, both in the warm and cold blooded animal. I have put the epithet warm in Italics, because it has been very recently observed by my friend Mr. James, that "analogies between the higher and lower orders of animals, the chief subjects of these experiments, cannot be deemed conclusive." (On some of the General Principles of Inflammation, p. 29, Soc. Lond. 1821) as if it had escaped attention, that many of the experiments were really made on the more perfect animals. From the valuable observations, to which I here allude, (See Philip on Febrile Diseases, Part 2, Introd.) it appears, that the state of the smaller vessels in an inflamed part is that of preternatural distention and debility.

As for the larger vessels, whose state may be ascertained, without the aid of the microscope, "they do not undergo a similar distention, and the increased pulsation of the arteries sufficiently evinces their increased action. In inflammatory affections of the jaw and the head, for example, a greatly increased action of the maxillary and temporal arteries is readily perceived by the finger. It is to be observed, however, that, although inflammation, as was evident from the foregoing experiments, begins in the capillaries, if it continues, the circulation in the smallest vessels becoming very languid, those immediately preceding them in the course of the circulation begin to be distended, and consequently debilitated." Dr. Philip adds, that such distention and debility of the vessels, which immediately precede the capillaries, cannot go far, because when the former lose their power, the circulation in the latter is not supported, and gangrene soon ensues. "In short, (says Dr. Philip) inflammation seems to consist in the debility of the capillaries, followed by an increased action of the larger arteries," and is terminated by resolution, when the capillaries are so far excited, and the larger arteries so far weakened, by the preternatural action of the latter, that the power of the capillaries is again in due proportion to the *vis à tergo*.

"Thus far, (says Dr. Philip) I cannot help thinking the nature of inflammation appears sufficiently evident. The motion of the blood is retarded in the capillaries, in consequence of the debility induced in them: an unusual obstacle is thus opposed to its motion in the arteries preceding them in the course of the circulation; which are thus excited to increased action. Several difficulties, however, remain, on which the experiments just related throw no light. Why does a failure of power, of small extent in the capillaries of a vital part, strongly excite, not only the larger arteries of the part affected, but those of the whole system; while a more extensive debility of the capillaries of an external part excites less increased action in the larger arteries of that part, and often none at all in those of the system in general? Why does inflammation often move suddenly from one part to another, when we see no cause, either increasing the action of the capillaries of the inflamed part, or weakening those of the part now affected? Why does inflammation often arise in parts only sympathetically affected, and consequently far removed from the offending cause? Why is inflammation often as apt to spread to neighbouring parts, between which and the part first affected, there is no direct communication of vessels, as to parts in continuation with that part?

"These phenomena, it is evident, (says Dr. Philip) are referrible to the agency of the nervous system, and seem readily explained by the experiments, which prove, that the effects of both stimuli and sedatives, acting through this system, are felt by the vessels, and that independently of the intervention of any effect produced on the heart

(Exp. 27, 28.) Thus, the irritation of the nerves of the inflamed part may excite the larger arteries of this part, or of distant parts, or of the whole sanguiferous system. It will of course be most apt to do so, where the irritation excited by the inflammation is greatest and, consequently in the more important vital parts. It cannot appear surprising, that inflammation should suddenly cease in one part and attack another, when we know, that the nerves are capable of exciting to due action the capillaries of the one part, and in the other of impairing the vigour of those, which have not suffered. In the same way, we account for parts only sympathetically affected becoming inflamed, and for inflammation readily spreading to neighbouring parts, which always sympathize, although there is no direct communication between them, either of vessels or nerves." (*On the Vital Functions*, p. 279, &c. Ed. 2.)

Respecting the inference, made by Dr. Philip from his experiments, that the circulation is slower in inflamed, than uninflamed arteries, Dr. J. Thompson conceives, that its truth "is not necessary to the establishment of Mr. Allen's hypothesis; and from a number of experiments which I have at different times made upon frogs, I am inclined to believe, that a diminished velocity of the blood, in the capillary branches, is by no means a necessary, constant, nor even the most common effect of incipient and moderate degrees of inflammation." (P. 75.)

In order to reconcile this difference in the statements made by the only two writers, who have examined this subject by experiment, Dr. Hastings repeated their mode of investigation with the aid of the microscope. His conclusions are, "that certain stimuli, applied to living parts, produce an increased velocity of the blood's motion, and a contraction of the blood-vessels. During this state of excitement, the part affected is so far from giving any thing, like the appearances of inflammation, that the size of the vessels is diminished, and the part paler. But, if the stimulus be long continued, or increased in power, the small vessels, which in the natural state admit only of one series of globules, become so dilated, as to allow an accumulation of a much less fluid and redder blood in them, which loses its globular appearance, and moves much more slowly, than that which previously passed through the vessels. The part now appears inflamed. If the stimulus be removed, the vessels do not soon regain their original state; time is necessary to allow them to recover their contractile power, so as to prevent the impetus, with which the blood is propelled by the heart and larger arteries from keeping up the dilated state of the capillaries. Here then we are obliged to admit, with Boerhaave, that there is an error loci; for, a denser and redder blood passes into small vessels, which before carried much more fluid contents; but the error loci does not cause the inflammation, but results from the previously weakened state of the capilla-

ries. In this manner, the blood may occasionally be extravasated in inflammation, without any actual rupture of a vessel, for the exhalants may be so weakened, and dilated as to allow globules to pass through them.

"If the stimulus, which produces the inflammation, be of a very acrid nature, debility of the vessels is frequently induced without any previous excitement. The blood in all the smaller vessels becomes very red, circulates very slowly, and in some vessels stagnates.

"The application of a stimulus, different from that which produced inflammation, will sometimes bring on resolution. When this occurs, the dilated vessels contract; they no longer contain a red, dense homogeneous fluid, but again receive blood consisting of small, nearly colourless globules, which float in a colourless fluid; and the motion of these globules at length becomes as quick as before the inflammation took place. If, however, the inflammation proceed, the blood becomes nearly stagnant; it continues very red, and the vessels are much dilated.

"When this high degree of inflammation is not relieved, sphacelus ensues. The part then feels softer to the finger, and gives way with less force. The vessels are much dilated, the blood does not move, it loses its red colour, and becomes of a yellowish brown hue. The separation of the dead from the living part takes place soon after this change in the colour of the blood.

"While the ulceration, produced by this separation of the dead from the living part of the web is healing, the capillary vessels, distributed on the ulcerated surface, and the contiguous parts, are much distended with arterial red blood, which is moved very slowly. When the ulceration is healed, the vessels become contracted, and circulate the fluid, with the same degree of velocity as before the inflammation was excited.

"With respect to the seat of inflammation, it may be observed, that the capillaries are first affected; but even the small arteries of the web are also occasionally distended." (*Hastings on Inflammation of the Mucous Membrane of the Lungs*, &c. p. 90—92.)

With respect to the doctrine, espoused by some pathologists, that the smaller branches of veins are the exclusive seat of inflammation, the same author observes, that the microscope shows us, that the most minute arterial branches, though far less numerous, are equally affected with weakness and distention.

In the course of Dr. Hastings's inquiry, it is proved, that the healthy circulation of the blood essentially depends upon a due degree of action in the vessels throughout the system; that the application of stimuli, while it increases the action of the vessels, produces none of the symptoms of inflammation. When, however, the excessive action of these stimuli has impaired the excitability of the small vessels, the phenomena of inflammation are fully manifested; and when their

excitability is restored, the inflammation subsides. It may be logically inferred, therefore, says this writer, that *inflammation consists in a weakened action of the capillaries, by which the equilibrium between the larger and smaller vessels is destroyed, and the latter become distended.* And, with respect to the conclusion, drawn by Dr. Thomson from his experiments, that inflammation, in moderate degrees, consists in an increased action of the vessels, Dr. Hastings argues, that the writer's belief in the excitement of the capillaries, in some cases of inflammation, arises from his having denominated that a state of inflammation, which ought not to be so called. "The application of the salt, (says Dr. Thomson) produced an increased velocity in the dilated larger and smaller arteries and capillary vessels, to which it was more immediately applied. In nine experiments, the phenomena of which I have minutely recorded, the application of the salt was not only followed by a bright red colour, visible to the naked eye, and a sensible enlargement of the arterial and venous branches, but with an increased rapidity of circulation in the capillary vessels; the globules becoming less distinct, than before the application of the salt, and obviously less distinct, from the rapidity of their motion, than the globules in the capillary vessels in the uninflamed part of the web in the same animal. *The repeated application, however, of the salt to the same vessels, was always sooner or later followed by retarded capillary circulation, or even by complete stagnation.*" (See Thomson's Lectures, p. 68.) The results of other experiments, made by this gentleman, and which coincide with the sentiments of Dr. W. Philips and Dr. Hastings, need not here be cited.

Now, with regard to those experiments, which seemed to Dr. Thomson to justify the inference, that moderate degrees of inflammation may be attended with an increased velocity of the blood in the inflamed vessels, Dr. Hastings, as I have already said, objects, that the appearances seen, while such velocity of the circulation presented itself in the vessels affected, ought not to have been denominated inflammation; because "it constantly happened in his own experiments, that when inflammation commenced, no globules could be seen even in the blood of the affected vessels. It was universally converted into a bright red homogeneous fluid. So that *globules could never be seen in the capillaries of a really inflamed part, much less moving with great velocity.* He argues, that the state, alluded to by Dr. Thomson, is only that temporary excitement of the capillaries, generally preceding their debility, which is inseparable from inflammation. (See Hastings on Inflammation, &c. p. 98, 101.)

Of course, such writers as believe, that the blood in the capillaries is not propelled by these vessels themselves, but by the impulse received from the heart, cannot assent to the foregoing view, in which the proximate cause of the inflammation is ascribed to debility of those vessels. Dr. Parry argues,

that the theory, which represents this process as consisting in an increased momentum of the blood in the part affected, is not invalidated, were it even proved, according to the opinion of Dr. Philip, that the velocity of the blood in the vessels of an inflamed part is diminished, unless it be also proved, that the velocity is diminished in a greater proportion, than the quantity is increased. (*Elements of Pathology, Vol. 1, p. 84.*) As far, however, as I can judge, the arguments are in favour of Dr. Philip's view of the subject; for, with respect to quantity making up for loss of velocity, if the supposition were to be adopted, surely it could not be retained after the inflammation has arrived at that state, in which the fluid in the capillaries is seen with the microscope to be nearly or quite stagnant. It must be confessed, at the same time, that the question about the proximate cause of inflammation is still a topic of endless controversy, into which I consider it perfectly absurd to enter any further than can be avoided, without having leisure at present to prosecute the inquiry by experiments. In one sense, both Dr. Philip and Dr. Hastings admit, that an increased action of the vessels may exist in inflammation; but then this excitement or increased action is not in the capillaries, but the larger arteries; and Dr. Philip even suggests, that the presence, or absence of such excitement may make the difference between acute and chronic inflammation. The considerations in support of the side of the question, to which I do not myself incline, may be found in the writings of Dr. Parry, Dr. C. H. Parry and Mr. James of Exeter. From this remark, I would not have it inferred, that I am quite convinced of the propriety of referring the proximate cause of inflammation to *debility* of the capillaries, though the retarded circulation in them, like their dilatation, is now a fact placed out of all doubt. The points, however, on which I should not assent to Dr. Philip's doctrine, will be best understood, when the treatment is considered. In the work of Mr. James may be perused a very good summary of Bichat's doctrine, which I would willingly annex, if the subject were intelligible, without an explanation of some physiological opinions, for which I have not room in this edition. (See J. H. James, *Obs. on some of the general Principles, &c. of Inflammation*, p. 38, 8vo. Lond. 1821.)

Redness.—This is manifestly owing to the increased quantity of blood in the inflamed part. More blood must necessarily be contained there, because the vessels, which previously conveyed this fluid, are preternaturally distended, and the small vessels, which naturally contained only lymph, are now so enlarged as to be capable of receiving red blood. "I froze (says Mr. Hunter) the ear of a rabbit, and thawed it again; this occasioned a considerable inflammation, an increased heat, and thickening of the part. This rabbit was killed when the ear was in the height of inflammation, and the head being injected, the two ears were removed

and dried. The uninflamed ear dried clear, and transparent, the vessels were distinctly seen ramifying through its substance; but, the inflamed ear dried thicker and more opaque, and its arteries were considerably larger."

Many have supposed, that the redness of common inflammation is partly occasioned by the generation of new vessels. This doctrine, however, seems very questionable. When coagulated lymph is extravasated upon the surface of a wound, or an inflamed membrane, unquestionably it often becomes vascular, in other words, furnished with new vessels. But, in the extravasated lymph of a phlegmonous tumour, we have no evidence, that there is any formation of new vessels. Were the lymph to be rendered organized and vascular, the swelling and redness would probably be more permanent, and at least not admit so easily of resolution. When adhesions form between two inflamed surfaces, the organized substance forming the connexion, lives after the subsidence of the inflammation, and is a permanent effect. In the experiments detailed by Dr. Hastings, when the inflammation began and terminated, without any lesion of the part affected, new vessels were never formed. (*On Inflammation, &c. p. 93.*) At the same time, it must be confessed, that great obscurity prevails in this very difficult part of the subject; for when suppuration happens in a phlegmonous tumour, the cavity is lined by a kind of cyst, or membranous layer of lymph, which is unquestionably furnished both with secreting vessels and absorbents; for, otherwise, how could the continued secretion of pus, or its occasional sudden disappearance, be at all explicable. It was probably the enlargement of the small vessels, and the circumstance of their being filled with red blood, that led to the theory of new vessels being usually formed in inflammation. It has, however, been justly observed, that the supposition easily admits of refutation; for heat, and many other causes of inflammation, operate so quickly, that there can be no time for the formation of any new vessels; and, yet the redness is as great, and the inflammation as perfect in a minute as in an hour or a day after the application of the exciting cause. (*Burns*) Mr. Hunter, it is well known, believed, that a coagulum or a layer of lymph might produce vessels within itself.—(*On the Blood, p. 92, &c.*) Others, however, distrust this hypothesis, and incline to the opinion, which refers the derivation of vessels for the organization of deposits to parent branches. (*Travers, Synopsis of Diseases of the Eye, p. 113*) The latter sentiment is corroborated by the appearances noticed by Dr. Hastings, in his experiments, who describes the small vessels first seen in the lymph, upon the surface of a wound, as even then communicating with the inflamed capillaries. (*On Inflammation, p. 94.*) Another reason assigned for the redness of inflammation, is that the blood after it has become venous, retains, more or less, its bright scarlet colour. (*Hunter.*) And, in some late

very carefully conducted experiments, it was remarked, that the weakened action of the smaller vessels was always accompanied with an alteration in the appearance of the blood. In the natural state of this fluid, globules can be distinctly seen; but, after inflammation has commenced, the globular structure disappears, the blood becomes redder, and the most minute capillaries are distended with it. (*Hastings on Inflammation, &c. p. 95.*)

Swelling.—This effect arises from several causes: 1. The increased quantity of blood in the vessels. 2. The effusion of coagulating lymph, and serum, and deposition of new matter. 3. The interruption of absorption, particularly noticed by Soemmering. (*De Morb. Vas. Absorb.*)

Pain.—This is observed to be the greatest during the diastole of the arteries. The affection is probably owing to the unnatural state of the nerves, and not to mere distention, as many have asserted. Were the latter cause a real one, the pain would always be proportioned to it.

"Parts, which in the sound state have little, or no sensibility (as Dr. Thomson remarks) become exquisitely sensible in the inflamed. That this is the case with tendon, ligament, cartilage, bone, and membrane, seems to be fully established by Dr. Whytt in the very instructive controversy carried on between him and Haller, respecting the sensibility and irritability of the different parts of man and other animals.—(*Lectures on Inflammation, p. 45.*)

Heat.—The heat or real increase of temperature in an inflamed part, when judged of by the thermometer, is generally much less, than might be supposed from the patient's sensations. It is said never to exceed the heat of the blood at the heart. This in health is usually about 100°. Fahrenheit's thermometer; but sometimes in diseases it arises to 106°, or even 107°. Mr. Hunter artificially excited inflammation in the chest of a dog, and in the abdomen, rectum, and vagina of an ass, without being able to discover any obvious rise of temperature, in these parts. In a patient, however, on whom he operated for hydrocele, the thermometer, introduced into the tunica vaginalis, and kept for some time close to the side of the testicle, was only 92°; but rose the following day, when inflammation had come on to 98° 3-4. As Dr. Hastings observes, the advocates for excited action of the vessels in an inflamed part have thought, that the increase of temperature favours their hypothesis, and have called to their aid the ingenious calculations of Dr. Crawford. They have even gone so far as to say, what state of the arteries enables the blood to give out most caloric. They tell us, that, in consequence of excitement of the vessels, more blood is transmitted into the minute arteries; the capacity of a greater quantity of this fluid for heat is of course diminished, and more caloric is evolved in the inflamed part. (*Hastings on Inflammation, p. 110.*) Yet, this theory, besides involving the contradicted hypothesis

of an increased and accelerated flow of blood through the vessels of the inflamed part, cannot be reconciled to various other considerations. "Daily experience convinces us, (says the above writer,) that the temperature is not always proportional to the velocity of the circulation. In fevers the author has several times ascertained, with the thermometer, that the heat was 101° , when the pulse beat only 45 times in a minute. In hydrocephalus, with a pulse from 60 to 70, the heat is often above the degree it reaches in health. In these cases, according to the theory of Dr. Crawford, the heat should rather be under, than above, the natural standard." (*Op. cit.* p. 112.) And, as another judicious writer has noticed, although the former mode of explaining the production of animal heat has been held adequate to account for the phenomena by such philosophers as Black, Crawford, Lavoisier, and Laplace, the evidence on which it rests, is not so clear as to have commanded universal assent, or entirely set aside objections. It has indeed been generally allowed, that respiration and the changes it produces in the air and animal fluids, are essential conditions of the evolution of caloric in animals; but, it has been thought, that there are other circumstances, hitherto, perhaps, not well understood, which influence the phenomena. In external appearance, the blood is the same in all the vessels of the fetus: is this any proof, that its temperature is owing to the conversion of oxygen gas into carbonic acid? Is the uniformity of temperature in the higher animals, under varying states of respiration and circulation, and the consumption of various quantities of oxygen, whether in the same, or different individuals, consistent with the theory? And can local variations of temperature be explained by it? (*Rees's Cyclopædia art. Respiration*.) Doubts must also spring from the recollection of the discordance of the experiments, related by Dr. Crawford, Dr. John Davy, De la Roche, and Bernard. In fact, the determinations of the specific heats of oxygen gas and carbonic acid by the two latter experimenters are conceived to be very much against the probability of Dr. Crawford's theory. Other stronger grounds for scepticism in this subject are the results of Mr. Brodie's investigations. Having pithed, or decapitated animals, he kept up artificial respiration, and thus maintained their circulation. The blood continued to be changed in the lungs from venous to arterial, and from arterial to venous, in the general circulation. The respective colours of the two kinds of blood could not be distinguished from those, which they exhibit in living and healthy animals. Yet, the temperature of an animal, thus heated, sunk faster, than that of another animal simply killed and left to itself; and the former was supposed to be more quickly cooled by the air conveyed into its chest. Other experiments, detailed by Mr. Brodie, tend to prove, that the oxygen of the air employed in artificial respiration, underwent its usual con-

version into carbonic acid. A living rabbit formed 50, or 60 cubic inches of carbonic acid in an hour. A decapitated animal, in whom artificial respiration was kept up, emitted 40—48 inches in the same time. The thermometer in the rectum of the latter had fallen from 97° to 90° , while, in another rabbit left to itself, but similarly treated in all other respects, it had fallen only to 91° . In a rabbit, poisoned with woorara, or the essential oil of bitter almonds, not decapitated, and, in which artificial breathing was kept up, 51 cubic inches of carbonic acid were emitted in an hour. The thermometer in the rectum had sunk to 91° in 30 minutes; while it stood at 92° in another animal, treated exactly in the same way, with the omission of the artificial breathing. From these experiments, Mr. Brodie infers "that, in an animal in which the brain has ceased to exercise its functions, although respiration continues to be performed, and the circulation of the blood is kept up to the natural standard, although the usual changes in the sensible qualities of the blood take place in the two capillary systems, and the same quantity of carbonic acid is formed as under ordinary circumstances; no heat is generated, and (in consequence of the cold air thrown into the lungs) the animal cools more rapidly, than one which is actually dead." (*See Phil. Trans. for 1811, p. 38; and for 1812, p. 378.*) It appears certain, therefore, that the generation of animal heat, either in an inflamed, or an uninflamed part, can never be satisfactorily explained by any reference merely to chymical principles, and that the process is essentially connected with and influenced by the state of the functions of the brain and nervous system, and no doubt also by the principle of life itself. At the same time, I think, that any hypothesis, suggested without due reference to the connexion, which respiration has with this curious and interesting process, will never be established. Neither would I venture so far as Dr. Philip, who believes, that animal heat is evolved by the same means, by which the formation of the secreted fluids is effected, viz. the action of nervous influence on the blood, and that the production of such heat is to be regarded as a secretion. (*On the Vital Functions, p. 169.*) However, the influence of the nervous system over this process must be allowed to be very great, and may afford a more probable explanation of the cause of the local change of temperature in inflammation, than Dr. Crawford's theory, combined with the doctrine of increased action, and an accelerated circulation in the vessels of the part affected.

Buffy coat.—The blood, when taken out of the living vessels, spontaneously separates into two distinct parts, the serum and the crassamentum. The last is a compound substance, consisting chiefly of coagulating lymph, and red globules, the most heavy ingredients in the blood. Blood, taken away from persons affected with inflammation, is longer in coagulating, and coagulates more firmly, than in other instances. Hence, the

red globules, not being so soon entangled in the lymph, descend by their gravity, more deeply from its surface, which being more or less divested of the red colouring matter, is from its appearance termed the *buffy coat* or *inflammatory crust*. The firmer and more compact coagulation of the lymph compresses out an unusual quantity of serum from it, and the surface of the size blood is often formed into a hollow, the edges being drawn inward. (Hunter.) In some cases, these changes in the blood are deemed more infallible proof of the existence of inflammation, than the state of the pulse itself. They are however, only a criterion of some unusual operation going on in the system; for, the blood taken from pregnant women is always found to present the same phenomena. In peritoneal inflammation, the patient sometimes seems to be in the most feeble state, and the pulse, abstractedly considered, would rather induce the practitioner to employ tonics, and stimulants, than evacuations; but, should the continuance or exacerbation of the disorder, or any other reason, lead him to use the lancet, then the *buffy coat*, and the *concave surface* of the blood, materially obviate any doubt of the existence of inflammation. Surgeons should never forget, however, that in a few anomalous constitutions, the blood, when drawn, always exhibits the above peculiarities.

Terminations.—Inflammation is said to have three different terminations; or, in more correct language, we may say, that, after this process has continued a certain time, it either subsides entirely, induces a disposition in the vessels to form pus, or completely destroys the vitality of the part.

When the inflammation is to end in the first manner, which is the most favourable, the pain becomes less, the swelling subsides, the fever, and every other symptom gradually abate till at last the part is wholly restored to its natural size and colour. There is no formation of pus, nor any permanent injury of structure; and if Dr. Philip's theory of inflammation be correct, the debilitated capillaries are excited to due action by the increased action of the larger arteries. (*On the Vital Functions*, p. 298.) This termination of inflammation is termed by surgeons *resolution*. It is fortunately the most common, as well as the most desirable manner, in which the affection ends.

If, however, notwithstanding the application of the usual remedies, the several symptoms of heat, pain, and redness, instead of diminishing, rather increase; if the febrile symptoms are likewise augmented, and the tumour gradually acquires a larger size, turns soft, somewhat prominent in the middle, or towards its most depending part; if it should next acquire a clear shining appearance, and become less painful, the different symptoms of fever being at the same time diminished, and a fluctuation perceptible in the tumour; the inflammation has ended in *suppuration*.

The worst, but happily, the least frequent consequence of common inflammation, is

the death, or *mortification*, of the part affected. In the microscopical experiment of Dr. Hastings, it was observed, that, on the approach of gangrene, the blood entirely loses its red colour, and acquires a yellowish brown tinge. (*On Inflammation*, p. 97.) The part, which was of a bright red, becomes of a livid hue; small vesicles, filled with a thin fetid serum, arise on its surface, and air is plainly felt within the cellular membrane. The pain is indeed diminished; but the pulse sinks, while the tumour is gradually changed into a black, fibrous mass.

These are the three common terminations of inflammation. In books, scirrhus is sometimes enumerated as one of the terminations of inflammation. The best modern surgeons, however, do not regard scirrhus as one of the usual effects of ordinary inflammation; "the term scirrhus, as used by the older medical writers, is extremely indefinite, having been sometimes used to express every kind of induration, which remained after an attack of inflammation, as well as the morbid incipient state of parts about to become affected with cancer. Surgeons now usually limit the use of the term to the last of these significations." (*Thomson on Inflammation*, p. 126.)

Common inflammation, particularly when it affects glandular parts, is often followed by induration, which afterward continues for a greater or lesser time. Thus, when the testis has been inflamed, a hardness of the epididymis frequently remains during life. Such induration, however, is not at all malignant, and, consequently, very different from what is implied by a real scirrhus.

TREATMENT OF INFLAMMATION.

One principal difficulty in believing the fact of the retardation of the circulation in the capillaries of an inflamed part, and against the supposition of their being in a state of debility, is, that the most effectual treatment of common inflammation consists of means, which are generally of a debilitating nature, as bleeding, purging, &c. And surgeons are still further attached to the theory of increased velocity of the blood's motion, in the part affected, by the recollection of the local augmentation of temperature, the throbbing, and the instantaneous return of the red colour, after the discontinuance of any pressure, by which the redness has been momentarily removed at some point of the inflamed surface. These too are all so many facts, which, as far as I can judge, are admitted by the generality of reasoners, whatever may be their particular theory. At the same time, it appears equally well proved by careful microscopical experiments, that in the capillaries of the part, which is directly the seat of inflammation, there is a retardation, and sometimes even a stagnation, of the circulation. But, this is not all, it is further manifested, that the capillaries are considerably dilated, the blood in them materially altered, and that these phenomena are followed by an increased action of the lar

ger arteries leading to the part affected. Now, I think, if we remain contented with these obvious circumstances, and dismiss the hypothesis of debility of the capillaries, not only the necessity for venturesome conjectures may be avoided, but a more rational account delivered of the principles of the efficacy of the usual mode of treatment. Thus, I would not presume to offer any supposition, why the capillaries are dilated, and why the motion of the fluid in them is retarded, but would be satisfied with a knowledge of the facts, so as to elude a source of endless controversy, viz. the question, whether these changes proceed from debility of the said vessels, or other causes? In the view, which I take of the nature of phlegmonous inflammation, I consider the following circumstances proved: 1. The dilated state of the capillaries in the immediate seat of inflammation. 2. The retardation, or even stagnation of the circulation in them. 3. The increased action, or excitement of the larger arteries leading to the inflamed part. All these three main points seem to me to be fully established by the investigations and experiments both of Dr. Wilson Philip and Dr. Hastings; and I may make the observation, though aware, that the latter gentleman does not regard increased action of the larger arteries, as a constituent and necessary part of inflammation, because cases occur, in which no such excitement can be detected: (*On Inflammation*, p. 104.) for, I here put out of consideration chronic inflammation, which I believe is entirely a different process, bearing no resemblance to the acute forms of the disorder, either in the state of the capillaries, or of the larger arteries. Assuming the above points as proved, it is to be inquired, whether other facts, such as the heat and throbbing in the inflamed part, the instantaneous return of redness to the spot, which has been touched, and the efficacy of common treatment, are reconcilable with them, or not. I am disposed to think they are; for, it is only asserted, that the passage of the blood is more or less obstructed in the capillaries in the seat of the inflammation; and the larger arteries, leading to them, are, for the most part, obviously in a state of increased action, whereby a greater quantity of blood must be supposed to be determined towards the part. Now, as this augmented quantity of blood cannot pass freely through the smaller vessels, in the immediate place of inflammation, it must be thrown into such arteries in the neighbourhood, as are capable of receiving it, so that, in fact, the theory of obstruction of the capillaries may not be altogether incompatible both with increased action, and quickened circulation, in the arteries directly around the parts, in which there is a retarded circulation in the capillaries. This view of the subject, I think, is not liable to greater perplexity in the explanation of the heat, throbbing, &c. than former doctrines, involving the contracted notion of there being an increased action, and an augmented velocity of the blood's motion, in all the arteries of the part affected.

Resolution being the most favourable termination of common inflammation, it is of course the object at which the surgeon generally aims in the treatment. Dr. Philip's very ingenious view of inflammation leads him to suppose that resolution arises from the debilitated capillaries being excited to the due action by the increased action of the larger arteries. (*On the Vital Functions*, p. 298.) But I am of opinion, that the doctrine of debility of the capillaries, and the hypothesis of their being strengthened by the excitement or increased action of the larger vessels, are by no means satisfactory, and perhaps, not very intelligible. On the contrary, if the capillaries are already so weak as to be distended by the ordinary impulse of the blood, how are they to be restored to their natural dimensions and functions by any increased action of the larger arteries? the effect of which I should conceive, would be to gorge them still more with blood, and produce even a greater dilatation of them. Were the above reasoning correct, it would follow, that a principal indication in the treatment would be to promote the increased action of the larger arteries, whereby so much supposed benefit is communicated to the debilitated capillaries. Yet, such practice is contrary to the dictates of experience, and is even inconsistent with the principles, on which Dr. Philip himself thinks the treatment should be founded. Indeed, the following directions are such, as I imagine, will be perfectly approved of by practitioners, who, far from looking upon the increased action of the arteries, as a means of relief, are accustomed to do every thing in their power to lessen and resist it. "All the local means (says Dr. Philip) are calculated either to lessen the contents of the morbidly distended vessels, or to excite these vessels to expel them. The general means are regulated by the effects, produced by the disease on the more distant vessels, through the medium of the nervous system; the objects of this part of the treatment being, neither to allow the action of these vessels to fall so low, that it is incapable of supporting any degree of circulation in the debilitated vessels, nor to become so powerful, as farther to distend by gorging them with blood. Thus, when the symptoms of active inflammation run high, we lessen the *vis à tergo*; when gangrene is threatened, we increase it." (*W. Philip, on the Vital Functions*, p. 285, Ed. 2.) In short, as soon as the fact is established, that a strong flow of blood towards an inflamed part tends to aggravate the disorder, all difficulty ceases in reconciling the usual means of relief to that theory of inflammation, which takes into the account a retarded state of the circulation in the distended capillaries.

The means employed for the relief of inflammation have been cursorily noticed in a preceding article. (See *Antiphlogistics*.) We shall now devote a few more pages to a more particular consideration of them.

Removal of exciting causes—In all cases the first circumstance to be attended to is, the removal of all such exciting causes as may

happen to present themselves. If the irritation of a splinter were to excite phlegmous inflammation, who would not of his own accord directly take away the extraneous body? In wounds, foreign substances frequently excite inflammation, and ought to be taken away as speedily as possible; splintered pieces of bone often give rise to the affection, and require removal; the head of a bone, being out of its place, may press and inflame the part on which it lies; and who does not immediately see the propriety of putting it back into its natural situation? These and other similar exciting causes may often be detected and removed at once, and this is doing a great deal towards the cure and even the prevention of inflammation. However, many of the exciting causes of this affection are only of momentary application; yet, though they no longer exist, the process of inflammation must follow, as a kind of salutary operation, without which, the injured organization, and tone of the parts, still remaining, could not be rectified again. Hence besides taking away the remote cause, whenever this can be done, it is proper to moderate, by other means, the increased action of the larger arteries, and lessen the velocity of the blood's motion towards the inflamed part.

Bleeding—As there is reason to believe, that, in common inflammation, a greater quantity of blood is impelled towards the inflamed part, than in the natural state, and experience proves, that nothing has a more powerful effect in checking the disorder, than diminishing the determination of blood to the part, bleeding must be a principal means of relieving inflammation: it lessens the action of the whole sanguiferous system, and, of course, of that part of it, which is directly concerned in regulating the quantity of blood transmitted to the part affected. On the principle also of lessening the whole mass of blood in the circulation, it must have a similar effect.

Bleeding, however, is often misemployed, especially when regarded as the only remedy for inflammation, and other steps are neglected. The general obstinacy and vehemence of the process in weak constitutions prove, that bleeding is not invariably proper, and in such individuals it often appears, as if their general irritability and the difficulty of curing the inflammation were in a ratio to their weakness. When inflammation is complicated with disorder of the chylopoietic, blood should be taken away with great circumspection.

A great deal of induration with little pain and heat in the inflamed part; the probability of a long and copious suppuration, as is the case in many compound fractures; and the connexion of the inflammation, with a want of tone in the part; are particular instances, in which the practitioners should be sparing of this evacuation. Bleeding is sometimes quite unnecessary, when the local inflammation and symptomatic fever are trivial, when the patient is feeble or very old, and when the

cause of the affection can be entirely removed. (*Richter.*)

On the other hand, bleeding is highly beneficial when the inflammation is uncomplicated with any previously existing disorder of the gastric system, while it is considerable in extent and degree, and attended with a good deal of febrile disturbance. The same practice is also strongly indicated, when the part affected is very sensible, and highly important, in regard to its office in the system. Thus the lancet must be freely employed in acute ophthalmia, or inflammation of the eye, which is a most sensible part; and in inflammation of the lungs, brain, or stomach; organs, the sound state of which is essential to the regular continuance of all the various operations in the animal machine; and if a successful effort be not promptly made to stop such inflammation by the most vigorous means, death itself will be the result.

In general, bleeding may be said to be indicated, when the patient is young, robust, and plethoric; when the cause of the disorder can neither be removed nor diminished; and when there is a very strong motive for wishing to avoid the formation of matter. Inflammation of the eye is a case, illustrative of the truth of the last observation; for, if suppuration take place in this organ, the common consequence is so serious a destruction of its internal structure and organization that the future restoration of sight is totally impossible. In the examples, falling under the conditions specified as requiring blood to be taken away, it is sometimes necessary frequently to repeat the evacuation.

The efficacy of bleeding is greater, the sooner it is practised, and the more suddenly the blood is evacuated. Bleeding near the part affected is usually more effectual, than when done in a remote situation. Hence, in inflammation of the eye, or brain, it is often considered most advantageous to take blood from the temporal artery.

In many inflammations, particularly those of the parts contained in the three great cavities of the head, chest, and belly, general blood-letting (says a judicious writer) if not the only, is the principal remedy, to which we can trust for a cure. The quantity of blood, which in these inflammations it is necessary to take away, varies according to the violence of the inflammation, the temperament, strength, and habits of the patient, and according to the structure, functions, and situation of the organ in which it occurs. From twelve to twenty ounces, or even more, ought generally to be drawn every time we have occasion to use the lancet in the cure of inflammation, and bleeding to this extent may be repeated two or three times in the course of the first twenty-four hours, according to the effects which it seems to produce, as well as according to the violence and urgency of the symptoms. In inflammation of internal parts, we judge of the effect of bleeding, and of the necessity of a repetition, from the feeling and continuance of pain, from the state of the pulse, and also from the appear-

ance of the blood, which has been last drawn.

"A partial, and in some instances, an almost complete cessation of pain takes place even during the operation of blood-letting. This is always a favourable symptom, and indicates, that the inflammation has made no great, nor very alarming progress. In other instances, the relief from pain, though inconsiderable, at the time of bleeding, becomes afterward more sensible, and the other symptoms of inflammation abate in nearly the same proportion; while, in other instances again, the pain is either not relieved by the bleeding, or, if relieved, the relief is but of short duration. These last are cases, in which the other symptoms of inflammation continuing unabated, recourse must be had again to the use of the lancet, and as much blood drawn, as can be done with safety to the patient.

"The changes, which take place in the state of the pulse, either with regard to its frequency, or strength, during, or soon after the abstraction of blood, though they afford criteria, by which we may judge of the state of the inflammation, and of the effects of the bleeding, are by no means marks so sure of the advantage, which has been obtained, as that derived from the cessation of pain.

"In some inflammations of the head, for example, the pulse is slower than natural, though it beats with its accustomed, or even with an increased degree of strength. In inflammations also of the peritonæum, and of the intestinal canal, we find the pulse not much quicker than natural, small, and contracted. We should deceive ourselves, therefore, were we to infer, that an increase of inflammation had taken place, because, in the first instance, the pulse had become quicker, and in the second, fuller and stronger, during or soon after the abstraction of a quantity of blood.

"The pulse, it may be remarked, has often a contracted, cord-like feel in inflammation, and it may always be regarded as a favourable event, when it becomes softer, fuller, and slower, during or soon after blood-letting." (See Thomson's *Lectures on Inflammation*, p. 166, 168.)

With respect to the buffy coat of the blood, Dr. Thomson states, that it is not by the buffy coat alone, but by the buffy coat, in conjunction with the quantity and firmness of the coagulum, that we must judge of the propriety of any further detraction. When the buffy coat has a firm and tenacious consistence, and when the pain continues unabated, we may conclude, that the inflammation is not subdued. But, when the coagulum is soft and easily broken, and when the colour of the buffy coat is changed from a yellowish to a greenish hue, Dr. Thomson thinks, that little or no benefit can be derived from bleeding. But, as already mentioned, every practitioner should remember, that, in particular constitutions, and in pregnancy, the blood taken away naturally exhibits a buffy appearance, independently of inflammation.

The preceding remarks chiefly relate to

general bleeding; for, in phlegmonous inflammation, topical bleeding is scarcely ever improper. It is always a point highly worthy of the surgeon's consideration, whether bleeding in or near the part will answer better, than taking the blood from the general habit; for, certainly less may be removed in this way, so as to have equal effect upon the part inflamed, and probably, upon every other disease that is relieved by bleeding, with less injury to the constitution. Although, in many cases, the general habit is relieved by bleeding, yet it is the part affected which most requires this evacuation. That local bleeding has very considerable effects on the inflamed part, is proved by the sudden relief which is often produced by the application of leeches in cases of gout. The mere use of leeches, without other measures, will also sometimes remove a tumour in the breast, having all the appearances of a scirrhus, which cannot be considered as inflammatory, so that topical bleeding extends its power further, than the mere checking of inflammation. Some part of its effect has been imputed to sympathy. (Hunter.) There are three modes of performing topical bleeding: by cupping; by leeches; and by dividing or scarifying the dilated vessels leading to the inflamed part. (See *Bleeding*.) Upon the head and face, leeches are commonly employed; upon the chest, either leeches or cupping; upon the abdomen, leeches; and upon the joints, either cupping or leeches. When the eye is inflamed, leeches may either be applied to the adjoining temple; or the dilated vessels of the conjunctiva may be scarified; or both methods may be adopted. When the inflammation extends quite to the surface of the body, leeches are always most eligible, as their bites cause less irritation in inflamed parts, than the punctures of the scarificator, or the pressure of cupping glasses.

Purging. The exhibition of mild laxative medicines, and saline purgatives, is a principal means of diminishing inflammation. Purging does not produce such lasting weakness as is the consequence of bleeding, and, therefore, it is scarcely ever omitted, even when the abstraction of blood is deemed improper. Saline purges must lessen the quantity of circulating blood, inasmuch as they increase the secretion from the intestinal arteries; and therefore, they probably operate beneficially in the cure of local inflammation, much upon the same principle as bleeding. Mr. Hunter was of opinion, that purging lowers action, without diminishing strength, by which we are probably to understand, without producing a very lasting or permanent loss of strength. With respect to mild laxative medicines, none are superior to manna, rhubarb, oleum ricini, and the like; and of the saline purgatives, the best are, the sulphate of soda, tartrate of potass, phosphate of soda, and sulphate of magnesia. It may here be remarked, that, besides the benefit, which the local inflammation derives from the judicious administration of purgatives, the costiveness and heat, which usually attend the sympto-

matic fever, are also removed by the same means.

"Purgatives (says Dr. Thomson) are more or less required in almost every species of inflammation; but they are more peculiarly necessary in those, which are accompanied with a high degree of fever, or with derangement of the digestive, or biliary organs. In cases of inflammation, which have a tendency to spontaneous resolution, they are almost always the best, and often the only remedies that are required." (*Lectures on Inflammation*, p. 171.)

Considering the general approbation of the employment of mild saline purgatives in cases of inflammation, I confess that I was not a little surprised to find merely the following short unfavourable notice taken of them by a celebrated foreign professor, in his account of the treatment of inflammation. "As for purgatives, they must be used with discretion. There are none of them antiphlogistic, as has been pretended. They always produce more or less irritation, and can only be applicable, when the cause of the inflammation is in the intestinal canal. In the beginning of the complaint we ought, therefore, in general to abstain from them, and confine ourselves to emollient clysters" (*Boyer, Traité des Maladies Chirurgicales*, T. 1, p. 39.)

Diaphoretic and nauseating Medicines.

Medicines, which have the power of producing sickness, lessen, for a time, the action, and even the general powers of life. This is in consequence of every part of the body sympathizing with the stomach; and the effect may be very quickly excited. Sickness lowers the pulse, makes the small vessels contract, and rather disposes the skin to perspiration. But, nothing more than nausea should be caused; for vomiting rather rouses than depresses. (*Hunter*) Nauseating medicines, employed after bleeding has been practised once or twice, are often productive of considerable benefit; but there are some affections, in which they cannot be used, such as inflammation of the stomach and intestines. In all superficial inflammations, however, they may be safely and advantageously exhibited, as well as in most inflammatory affections internally situated. In inflammation of the dura mater and brain, and, indeed, in every instance, in which there is an urgent reason for putting as sudden a check as possible to the continuance of the affection, the employment of nauseating doses of antimony is most strongly indicated. The tartrate of antimony (emetic tartar) is the medicine, on which practitioners place the greatest reliance, and it is to be prescribed for the purpose of exciting nausea, as follows:—*R.* Antimonii tartarisi grana duo; Aquæ distillatæ uncias quatuor. Misce et cola. Dosis, Uncia dimidia sextâ quâque horâ.

The safest diaphoretics are citrate of potass, acetate of ammonia, and tartrate of antimony, and James's powder. The two

latter, from their effects in producing nausea, and weakening the pulse, are sometimes most efficacious, as already stated.

"The warm bath seems to act (as a modern writer says) not only by increasing the tendency to perspiration, but also by occasioning a determination of blood to those parts of the body to which it is more immediately applied. It is in this way that bathing the feet seems to relieve inflammatory affections of the head and throat. I have not seen any experiments, nor am I acquainted with any, which have been made with a view to ascertain its use in the inflammations of the chest; but, in all inflammations of the belly, and of the viscera contained within that cavity, there are no other means of cure, blood-letting excepted, which afford such sudden and permanent relief as that which is obtained from hot fomentations and warm bathing." (*See Thomson on Inflammation*, p. 173.)

Opium. The majority of surgeons entertain an insuperable objection to the administration of opiates in almost all cases of inflammation, and the aversion to this practice is for the most part deducible from the recollection of opium being a powerful stimulant. The plan, however, has its advocates. (*B. Bell; Richter, &c.*) One of its strongest partisans tells us, that opium particularly lessens the disturbance of inflammation, and allays pain, which is at once a principal symptom of the process, and a cause of its augmentation, as well as that of the fever. Opium also quiets the inordinate action of the solids, the mental agitation and restlessness so powerfully, that it well deserves the name of the grand *antiphlogistic remedy*. It likewise occasions a moisture on the surface of the body, which experience shows is eminently serviceable in all inflammations affecting the skin. When given with this view, it is usually conjoined with antimony, camphor, calomel, or ipecacuanha. The administration of opium is a general practice in all painful inflammations arising from external causes, and it is attended with perfect safety when evacuations from the bowels and bleeding have been previously put in practice. Care must be taken to give it in sufficient doses; for small quantities not only fail in fulfilling the object, but frequently produce quite an opposite effect. During its employment, the bowels should be kept open with glysters. The efficacy of opium chiefly manifests itself in the early stage of the affection; for, as soon as the inflammatory fever has extended itself to the whole system, it loses its beneficial virtues. Hence, in cases of external injuries, it is to be given the two first days, immediately after bleeding. It is to be given as soon after the accident as possible, in order to tranquillize the mental alarm, and, if convenient, towards the evening, for the sake of procuring a quiet night. (*Richter.*) Evacuations being premised, says the other advocate for this medicine, the next object of importance is to procure ease and quietness to the patient, which, in cases of

inflammation, are often of more real service, than any other circumstance whatever. The most effectual remedy for this purpose is opium, which, when the pain and irritation are considerable, as very frequently happens in extensive inflammations, should never be omitted. In large wounds, especially after amputations, and other capital operations, and in punctures of all kinds, large doses of opium are always attended with remarkably good effects. In all such cases, however, opium, in order to have a proper influence, should be administered in very large doses; otherwise, instead of proving serviceable, it seems rather to have the contrary effect. This circumstance is, perhaps, the chief reason why opiates in general have been very unjustly condemned in every case of inflammation. (*B. Bell.*)

On the contrary, those who are averse to the use of opium, remark, that in acute inflammation daily experience shows, independently of every theory, that the exhibition of this medicine increases the general fever, and aggravates the local action. Even given as a preventive of inflammation, after operations, anodynes are almost uniformly hurtful, producing restlessness, heat, thirst, and afterward headach, sickness and frequently troublesome vomiting. (*Burns.*)

According to Dr. Thomson, "those diaphoretics, into the composition of which opium enters, seem to be better adapted for inflammation attended with fever of a typhoid character, or for cases where the inflammation has existed for a considerable time before diaphoretics are employed. Given at an early period in acute inflammatory diseases, opium never fails to excite vascular action, and to aggravate all the symptoms of fever. Opium, therefore, is not to be used, unless to allay the pain and irritation from a surgical operation, or from the recent infliction of an external injury. Indeed, unless when the patient is very nervous, and complains much of pain, its use, even after chirurgical operations, had, I believe, in general, better be abstained from, as it almost never fails to add to the violence of the symptomatic fever, which is the necessary consequence of the operation. Its effects are often very beneficial, when the period of this fever has passed over." (*See Lectures on Inflammation, p. 172.*) Upon the whole, candour obliges me to own, that the majority of surgeons in this country are decidedly against the general use of opium in inflammation; but, after the performance of severe operations, and in all instances attended with excessive pain, truth, I believe, will justify my saying, that they are in favour of the exhibition of this remedy.

Diet and Regimen.—In all cases, the surgeon is to forbid the use of wine and spirits; and, when the inflammation is at all considerable, the same prohibition is to be made in regard to animal food. Watery, cooling, mucilaginous drinks are proper; for they keep off thirst and heat, promote perspiration, and tend to sooth the increased action

of the whole arterial system. For this purpose, whey, buttermilk, barley-water, decoctions of dried fruits, water-gruel, &c. may be given.

When diluent drinks "are intended to allay thirst, as well as to promote perspiration, the addition of some vegetable acid, such as lemon-juice, or cream of tartar, renders them in general very palatable to patients. In the earlier stages of inflammation, and where the object is to induce a moisture on the skin, the mineral acids, though they might serve to quench thirst, are not to be employed, as they tend rather to check, than promote the flow of sweat." (*Thomson on Inflammation, p. 172.*)

The chamber, in which the patient lies, should not be warmer than his comfort requires; for heat tends powerfully to keep up an increased action of the sanguiferous system. For the same reason, the patient should not be covered with a superfluous quantity of bed-clothes.

The whole body, but more especially the inflamed part, should be preserved in as complete a state of rest as possible. Every one knows, that all motion, exercise, and muscular exertion, accelerate the circulation, and, hence, must have a pernicious effect on inflammation, by determining a larger quantity of blood to the part affected.

Applications. With the exception of what has been stated, concerning topical bleeding, all the foregoing remarks relate to the general treatment of inflammation: the local means remain for consideration.

It has been already observed, that phlegmon is attended with an increase of heat in the part affected, and it is an acknowledged and well-known fact, that the action of the arteries, as well as every other operation in the animal economy, is promoted and increased by the influence of heat. For this reason, an obvious indication arises, viz. to reduce the temperature of the inflamed part, by the topical application of cold, and, in particular, by continually abstracting the heat evolved in the part, by keeping up a constant evaporation from its surface.

"Of the local remedies, applied directly to inflamed parts (says Dr. Thomson) cold is undoubtedly one of the most powerful. In reducing the temperature, cold diminishes the morbid sensibility and pain of inflamed parts; and, probably, in consequence of this, the action also of the vessels, by which the inflamed parts are supplied with blood. The most common mode of employing cold is by the application to the part inflamed of cloths, which have been dipped in cold water. These are to be repeated as often as they become warm, or any relief is experienced by the patient from their use. When the inflammation is seated on the remote parts of either the upper or lower extremities of the body, the inflamed part itself may be immersed in water. This immersion, as I shall afterward have occasion to mention, has often been found useful in superficial burns. In order to increase the effect produced by cold, it

has been proposed, to reduce the temperature of the water below that of the surrounding atmosphere, by a proper mixture of saline bodies, as some of these are known to produce cold during their solution in water, or even in very urgent cases to apply ice or snow. The ice, however, must not be applied too long, nor in too large a quantity; for, it very quickly reduces the temperature of the part to which it is applied, and, in some instances, has been known to occasion gangrene, &c. (*On Inflammation*, p. 180.)

With the cold water applied to phlegmonous inflammation, it is usual to blend some remedies which are astringent, and supposed to have also a sedative quality. The acetite of lead, sulphate of zinc, and vinegar, seem now, indeed, to have acquired permanent celebrity for their efficacy in resolving inflammation.

Extensive experience, and long-established trials, have now fully confirmed the virtue of all those local remedies, in which the acetite of lead is the active ingredient. M. Goulard, and other French surgeons, found, that the objections to the employment of many other sedative applications in the treatment of inflammation, did not exist against the use of this preparation of lead. The universal assent of modern practitioners proves, indeed, that the acetite of lead, as a local application for genuine phlegmonous inflammation, is certainly unsurpassed, if not unrivalled, in point of efficacy.

The preparations of lead are recommended by M. Goulard, as almost equally applicable to every stage of inflammation. When swellings have fully suppurated, the employment, of what he calls, the *extractum Saturni*, will almost always render it unnecessary to open them. Even in gangrene, the solution of lead is represented by this zealous writer, as a remedy deserving of the greatest confidence.

But, notwithstanding the above exaggeration, every man of experience and observation will allow, that, while there is a chance of accomplishing resolution, no local applications to phlegmonous inflammation are in general so proper as cold lotions, containing the acetite of lead.

"The manner in which it operates in curing inflammation (as Dr. Thomson observes) is not known to us, nor is it at all times easy to distinguish between the share, which the lead has in allaying inflammation, and that which is to be attributed to the coldness of the water in which it is dissolved. No one, however, will doubt of the efficacy of this remedy, who has ever felt it in his own body, or witnessed in others the soothing and agreeable effects, which it produces in excoriations of the skin, or in inflammation of mucous membranes. Lead is a remedy, which is often highly useful in excoriations from friction, in punctured wounds with inflammation of absorbent vessels, veins, nerves, &c. in slight burns, in cutaneous heat, eruptions of the face, in fractures and dislocations, in the inflammation

attending scirrhus and cancer, syphilis and gonorrhœa, in wounds accompanied with excoriation from the discharges they emit, and in wounds attended with a burning sensation of pain." (P. 182.)

From the poisonous qualities of lead, when taken into the system, and from the possibility of this mineral being absorbed from the surface of the body, objections have arisen against the free use of its preparations, even as outward remedies in cases of inflammation. Certain it is, however, that though the possibility of such absorption is proved by the occurrence of the disorder called the *colica pictonum*, which originates in painters from the white lead absorbed into the system, yet, any ill effects from the use of lead, as an application to inflamed parts, are so exceedingly rare, that they can hardly form a serious objection to the practice. It is a fact, that, in inflamed parts, there is an impediment to absorption, and this circumstance may tend to render the employment of lead a matter of safety. Mr. B. Bell observes, that in all the experience which he had had of the external application of lead and its preparations, and in many cases, particularly of burns, where he had known the greatest part of the surface of the body covered with applications of this description for days, nay, for weeks together, he did not recollect a single instance of any disagreeable symptom being ever produced by them. Nor has Dr. Thomson ever seen the *colica pictonum* follow the use of Goulard. (See *Lectures on Inflammation*, p. 183.)

A lotion composed of acetite of lead, vinegar, and water, is very commonly employed. R. Plumbi Acetatis \mathfrak{z} ss. Solve in Acet. pur. \mathfrak{z} iv. Et adde Aq. Fontanæ distill. \mathfrak{h} ij. The vinegar makes the solution more complete. In all common cases, a teaspoonful of the liquor plumbi acetatis, blended with a pint of water, will be found an eligible lotion. Occasionally, bread-crumbs is moistened in the fluid, and applied in the form of a poultice; but linen dipped in the lotion, and kept constantly wet with it, is mostly preferred. Thus a continual evaporation is maintained, and of course a regular abstraction of heat.

When the surgeon is afraid of employing a solution of lead, he may try one of the sulphate of zinc. One dram of this substance is to be dissolved in a pint of water, and linen, well wet with the lotion, is to be applied to the inflamed part.

Many practitioners impute very little real efficacy either to the acetite of lead, or sulphate of zinc, contained in the above applications: and they attribute all the good that is produced, entirely to the evaporation kept up from the surface of the inflamed part, and to the coldness of the fluid in which the metallic salts are dissolved. Surgeons, who entertain these sentiments, think the application of simple cold water quite as efficacious as that of any medicated lotions.

There are particular cases of inflammation, in which the extravasation of blood and lymph, in the interstices of the inflamed

part, is exceedingly copious, and the swelling considerable, but the pain and redness not particularly great. In such instances, it is an indication to rouse the action of the absorbents, in order that those vessels may remove the extravasated fluid, and with this view, a more powerful discutient lotion may be employed than in other cases, and sometimes, it is even better to use embrocations and liniments, than any sort of lotion. The following discutient lotions are often employed: \mathcal{R} . Ammoniae Mariatae \mathfrak{z} ss. Aceti; Spiritus Vini rectificati; sing. \mathfrak{lbj} . M. \mathcal{R} . Liq. Ammon. Acet. Spir. Vini rectific.; Aq. Distillatæ; sing. \mathfrak{z} iv. M. The Liq. Ammoniae Acet. also alone answers very well.

When the part affected with inflammation is not very tender, or when it lies deep, applications of the vegetable acid are often had recourse to with considerable advantage; and the most effectual form of using it seems to be a poultice made with vinegar and crumb of bread. In such cases, it has been thought, that an alternate use of this remedy, and the saturnine lotion, has produced more beneficial effects, than are commonly observed from a continued use of one of them. (*B. Bell.*) However, surgeons of the present day seem to think, that vinegar can be as advantageously applied in the form of a lotion, as in that of a poultice, and, certainly, with less trouble.

Alcohol and æther have acquired some celebrity as local remedies for inflammation. No doubt one great reason why they are not more extensively used for this purpose is, the expense attending such treatment, as these fluids evaporate with great rapidity. Alcohol may possibly prove useful from its astringent qualities; but it seems much more rational to impute both its virtue, and that of æther, to the powerful manner, in which their evaporation deprives the inflamed part of its heat.

Warm Applications. The absurdity of attempting to reconcile every useful practice with a philosophical theory, is, in no instance, more strikingly exemplified, than in the opposite sorts of local applications, which are of service in inflammation. The generality of cases undoubtedly receive most relief from the use of cold sedative astringent lotions: but there are constitutions and parts, which derive most service from the local employment of warm emollient remedies.

Were I to endeavour to define the particular instances, in which the latter applications avail most, I should take upon me a task, which has baffled all the most able surgical writers. The first stage of the acute ophthalmy, and the hernia humoralis, or inflamed testicle, may be specified, however, as examples, in which, generally speaking, warm emollient applications are better than cold astringent ones. Yet, even with respect to inflammation of the testis, there is some difference of opinion about the superiority of cold or warm applications. Mr. James's sentiments are as follows: in the treatment it is of importance to consider the differences of the cause: thus, in mumps

and rheumatism, the constitution is chiefly to be attended to, and cold applications are certainly improper. When it (the inflammation of the testis) arises from a blow, after leeches have been freely employed, fomentations are the best remedy. But Mr. James thinks, that this is not the case, in many instances of hernia humoralis from gonorrhœa, where cold applications are preferable; but, he owns, that the feelings of the patient will best determine the point. (*James on Inflammation*, p. 164.)

"Fomentations, or embrocations with warm water, (as a judicious writer has remarked) are often a very powerful means of abating internal inflammation. This effect is very apparent in some of the deeper seated inflammations, as in the inflammation of the urinary bladder, intestines, or other viscera contained within the cavity of the abdomen. The warmth, in this case, may be applied to the surface of the abdomen, by bath or fomentation, or, in the way of injection, by the anus, &c. In some inflammations of the joints, warmth also is found to be very useful. These, however, are inflammations, which have a tendency to the chronic state. (See *Thomson on Inflammation*, p. 188.)

If we may judge by the feelings of certain patients, there are undoubtedly particular constitutions, in which the local use of warm remedies produces greater relief than that of cold ones. This circumstance, however, does not generally happen; and, as warm emollient applications, of all kinds, have the most powerful influence in promoting suppuration, a fact admitted by every experienced practitioner, the use of such remedies, while the resolution of inflammation is practicable, must be highly censurable. But, I am ready to grant, that in all cases of inflammation, which manifestly cannot be cured without suppuration, the emollient plan of treatment ought to be at once adopted; for, the sooner the matter is formed, the sooner the inflammation itself is stopped. The inflammation attending contused and gunshot wounds, and that accompanying boils and carbuncles, are of this description. The inflammation, originating in fevers, commonly ends in suppuration, and, in such instances, perhaps, it might be advantageous, also, to employ at once the emollient treatment.

Warmth and moisture together, in other words fomentations, are commonly had recourse to in cases of inflammation; but, when the warmth is as much as the sensitive principle can bear, it excites action. Whether it is the action of inflammation, or the action of the contraction of the vessels, is unknown. We see that many patients cannot bear warmth, and, therefore, it might be supposed to increase the action of dilatation, and do harm. But, if the pain should arise from the contraction of the inflamed vessels, benefit would be the result; though we must doubt that this change is produced, as making the vessels contract would probably give ease. (*Hunter.*)

From the preceding observations, we must perceive how vain it is to theorize on this subject, which even puzzled the genius and penetration of a Hunter. In addition to what has been already observed, I feel totally incapable of giving any useful practical advice, with respect to those cases, in which warm emollient applications should be used in preference to cold astringent ones. I can, however, with confidence remark, that the surgeon who consults the feelings and comfort of the patient on this point, will seldom commit any serious error. Hence, in all cases, in which the first kind of topical applications seem not to produce the wanted degree of relief, let the second sort be tried. From the opportunity of comparison, a right judgment may then be easily formed.

The poultice made of the powder of linseed is so easily prepared, that the old bread and milk poultice is now seldom employed. As much hot water is to be put into a basin, as the size of the poultice requires, and then the linseed powder is to be gradually mixed with the water, till the mass is of a proper consistence. Frequently, a little sweet oil is also added to keep the application longer soft and moist.

Fomentations are only to be considered as temporary applications, while the emollient poultices are the permanent ones. The former are, at most, never used more than three times a day, for the space of about half an hour each time. Two of the best are the following:—*R. Lini contusi ℥j. Chamæmeli ℥ij. Aq. Distill. ℔vj. Paulisper coque et cola. Or. R. Papaveris albi exsiccati ℥iv. Aq. Puræ ℔vj. Coque usque remaneant ℔ij. et cola.*

Some practitioners, however, are inclined to think warm water alone quite as efficacious as the decoctions of particular herbs. Thus Dr. Thomson observes, "herbs are now seldom used in the way of fomentation, unless in compliance with ancient custom, or with the prejudices of particular individuals. The discutient power of the warm water may be increased by the addition of various substances, such as vinegar, spirits of wine; saline substances, such as common salt, acetite and muriate of ammonia. But, these warm and stimulating embrocations are used chiefly in the passive, chronic, or more indolent species of inflammation." (See *Lectures on Inflammation*, p. 189.)

By pursuing the treatment recommended above, the resolution of the inflammation will in general begin to take place, either in the course of three or four days, or in a shorter space of time. At all events, it may usually be known before the expiration of this period, how the disorder will terminate. If the heat, pain, and other attending symptoms abate; and, especially, if the tumour begins to decrease, without the occurrence of any gangrenous appearances; we may then be almost certain, that, by a continuance of the same plan, a total resolution will in time be effected.

On the other hand, when all the different symptoms increase, and particularly when the tumour becomes larger, and softish, attended with a more violent throbbing pain, we may conclude, that the case will proceed to suppuration. Hence, an immediate change of treatment is indicated, and such applications, as were proper while resolution seemed practicable, are to be left off, and others substituted. This remark relates to the employment of cold astringent remedies, which, when suppuration is inevitable, only do harm, by retarding what cannot be avoided, and affording no relief of the pain and other symptoms. If the inflammation, however, should already be treated with emollients, no alteration of the topical applications is requisite, in consequence of the inevitability of the formation of matter. Indeed, emollient poultices and fomentations are the chief local means both of promoting suppuration, and diminishing the pain, violent throbbing, &c. which always precede this termination of phlegmonous inflammation.

But, besides the substitution of warm emollient applications for cold astringent lotions, practitioners have decided, that it is also prudent, as soon as the certainty is manifest, to relinquish the free employment of evacuations, particularly blood-letting, and to allow the patient a more generous diet. When the system is too much reduced by the injudicious continuance of rigorous antiphlogistic treatment, the progress of the ensuing suppuration is always retarded in a disadvantageous manner, and the patient is rendered too weak to support either a long-continued, or a profuse discharge, which it may not be possible to avoid.

I shall conclude this article with briefly noticing blisters, rubefacients, issues, and synapisms, as means often employed for the relief of particular cases of inflammation. "Blisters (says Dr. Thomson) are never applied to a part which is actually inflamed. They seem to be chiefly useful by exciting inflammation in a contiguous part. It is from this tendency, which blisters have to produce inflammation, and of course a certain degree of fever, that they are seldom to be employed in acute inflammatory cases, till the constitutional symptoms are by other means in some measure subdued."—(P. 187.)

"Of the same nature, though milder in their operation, than blisters, are the whole class of rubefacients. They produce a determination of blood to the parts to which they are applied, and in a manner not yet well understood, occasion a diminution in the action of the vessels, and consequently in the quantity of blood with which the inflamed parts are supplied. This influence is exerted more or less directly in different instances. The extremities of the intercostal arteries may open both on the pleura lining the chest, and on the surface of the skin covering it, and whatever excites an increased flow of blood into one of these textures, may be conceived to be attended

with a proportionally diminished flow into the other texture. But, blisters are found by experience to be efficacious in removing inflammation, where no communication whatever can be traced between the blood-vessels of the inflamed part, and that to which the blister is applied. We have examples of this mode of action in the beneficial effects obtained from the application of blisters in inflammation of the brain and the membranes immediately covering it, of the lungs and intestines, or of any of the viscera contained in the cavity of the abdomen. The nearer in such instances the blister or rubefacient can be applied to the part inflamed, the greater is the relief obtained; and in general, I believe, it may be laid down as a rule, that the relief, which they afford, will be proportional to the degree of inflammation which they excite." (See *Thomson on Inflammation*, p. 187, 189.)

Synapsims, blisters, and issues are in many instances applied to situations, which are so remote from and unconnected by vessels with the inflamed parts, that it is impossible to explain their mode of operation except through the medium of the nervous system. "The irritation of a synapsim applied to the foot (says Dr. Thomson) may relieve an attack of gout in the head, or stomach. Bathing the feet and legs gives relief in inflammation of the bowels; and the application of a blister, or caustic to the neck, may cure an inflammation of the eyes, &c. (P. 189.) Here counter-irritation is the principle by which an explanation is usually attempted. (See *Blisters*.)

INJECTION. A fluid intended to be thrown against, or into a part of the body by means of a syringe. Thus port wine and water form an injection, which is used by surgeons for radically curing the hydrocele, and, for this purpose, it is introduced into the cavity of the tunica vaginalis, where it excites the degree of inflammation necessary to produce an universal adhesion between this membrane and the albuginea.

Thus many fluid remedies are introduced into the urethra and vagina for the cure of gonorrhœa. In the article *Gonorrhœa*, will be found an account of the best injections employed for its relief. A few additional remedies of this class are here subjoined.

INJECTIO ACIDI MURIATICI. R. Aquæ distil. ℥iv. Acid. Mur. gutt. viij. Misce. Useful when the scalding is a very troublesome symptom.

INJECTIO ALUMINIS.—R. Alum. ℥j. Aq. pur. ℥vj. Misce.—Successfully employed by Dr. Cheston, as an injection in affections of the rectum, either when the internal coat is simply relaxed, and disposed to prolapsus, or when it is studded with loose fungated tumours. In such cases, camphor is also of service. The quantity of alum may be increased, if the parts will bear it.

INJECTIO CUPRI AMMONIATI. R. Liquoris Cupri ammon. gutt. xx. Aquæ rosæ ℥iv. Misce. Strongly recommended by Mr. Foot.

INJECTIO QUERCUS. R. Decocti quercus ℔bj. Aluminis purificat. ℥ss. Misce. May be used, when the rectum, or vagina, is disposed to prolapsus from relaxation, or in cases of gleet.

*** INNOMINATA ARTERIA.** By referring to the article *Aneurism*, in the Appendix, will be seen the case at full length, in which professor Mott of this city tied the Arteria Innominata for the purpose of directing the blood from an aneurism of the subclavian artery; together with some remarks upon the criticisms, which have appeared against it. *Am Ed*

INOSULATION denotes, in the language of anatomy and surgery, the union of vessels by conjunction of their extremities. It is generally synonymous with *anastomosis*, though sometimes a distinction is made, *anastomoses* signifying the union of vessels by minute ramifications, and *inoscu-*

lation a direct communication by trunks. The great use of inosculation is to facilitate and ensure the continuance of the circulation, when the large trunks of vessels are obstructed by pressure, disease, &c. Thus, in cases of aneurism, when the main artery of a limb is tied, the inosculation of the branches, given off above the ligature, with other branches arising below it, form at once a channel, through which the lower part of the limb is supplied with blood. Were there no such arrangement in the human body as inosculation, aneurisms could never be cured by a surgical operation. So infinitely numerous indeed are these inosculation, that they do the office of the subclavian, carotid, and external and internal iliac arteries, when these vessels are tied, and upon this fact is founded the success of some of the most brilliant operations in modern surgery. (See *Aneurism*.) Even the aorta itself may be perfectly obstructed, the circulation go on, and every part be fully supplied with blood. (See *Aorta*.) In dogs, the abdominal aorta has been tied, without the circulation in the hinder extremities being stopped. (See the *Experiments of Mr. A. Cooper in Med. Chir. Trans. Vol. 2, p. 258*;) and the operation, performed a few years ago, in Guy's hospital, tends to prove that the same thing is possible in the human subject. (See *Aorta*.) From the observations of the same distinguished surgeon it appears, that the arteries, which form the new circulation in a limb, after the obliteration of the principal artery, are not only enlarged but tortuous. Any great increase, however, in the diameter of the anastomosing vessels is but slowly produced; for Mr. A. Cooper has injected a limb several weeks after the operation for popliteal aneurism, without being able to force the injection through communicating vessels into the parts below. The limb must have active exercise before the vessels enlarge much. On account of the arteries not very readily enlarging, the limbs of persons who have undergone the operation for aneurism, are for a considerable time weaker than natural. They feel the influence of cold more, and are more disposed to ulcerate from slight causes. Hence, the utility of covering them with flannel, or fleecy hosiery. Hence, the rashness of applying cold washes, bandages, &c. (See *A. Cooper's remarks in the above-mentioned Vol. p. 249, et seq.*)

In another place, the same gentleman has published an interesting description of the anastomoses of the arteries of the groin. "Hypothesis (says he) would lead to a belief, that anastomosing vessels would be numerous in proportion to the time which had elapsed from the operation; but, the reverse of this is the fact; for, at first, many vessels convey the blood, originally conducted by the principal artery. But, gradually, the number of these channels becomes diminished and, after a length of time, a few vessels, conveniently situated for the new circulation, become so much

enlarged, as to be capable of conveying an equal portion of blood to that which passed through the original trunk."

The experience of Mr. A. Cooper also tends to confirm the important fact, that "it is desirable in femoral aneurism, if not, indeed, in all others, to perform the operation in an early state of the disease," as the patient then recovers the use of the limb much more quickly, than when the tumour has been suffered to attain a large size. (See *Medico-chirurg. Trans. Vol. 4, p. 425, et seq.*)

INTERRUPTED SUTURES. See *Sutures*.

INTESTINES WOUNDED. See *Wounds of the Abdomen*.

INTROSUSCEPTION. or *Intussusception*, (from *intus*, within, and *suscipio*, to receive.) Called also *Volvulus*. Is a disease produced by the passing of one portion of an intestine into another, and it is commonly from the upper passing into the lower part. (*J. Hunter*.) On this subject, Mr. G. Langstaff has published an interesting paper, in the *Edinb. Surg. Journal. No. XI*; which I shall take the liberty of freely quoting.

This gentleman remarks, that the small intestines of children are so often affected with intussusception in a slight degree, that most practitioners must have had opportunities of observing the form of the complaint. The greatest part of three hundred children who died either of worms, or during dentition, at the Hôpital de la Salpêtrière, and came under the examination of M. Louis, had two, three, four, and even more volvuli, without any inflammation of the parts, or any circumstances leading to a suspicion that these affections had been injurious during life. "These cases (says M. Louis) seem to prove, that intussusception may be formed, and destroyed again by the mere action of the intestines." (*Mém. de l'Acad. de Chirurg. 4to. Tom. 4. p. 222*.) This opinion is confirmed by the authority of Dr. Baillie, (*Morbid Anatomy, 2d Edit. p. 162*) who observes, that, "in opening bodies, particularly of infants, an intussusception is not unfrequently found, which had been attended with no mischief; the parts appear perfectly free from inflammation, and they would probably have been easily disentangled from each other by their natural peristaltic motion."

The disease, continues Mr. Langstaff, assumes a more dangerous, and indeed, generally a fatal form, when it occurs at the termination of the small intestines in the cœcum. A contracted state of the part to be intussuscepted, and a dilatation of that portion of the canal into which this part must pass, are essential conditions to the formation of a volvulus; and those exist nowhere so completely as in the situation here alluded to. The extent to which the affection proceeds in this situation, would appear almost incredible, if it were not proved by well-authenticated facts. A person who considered the natural situation and connexion of the parts, would of course require the strongest evidence before he would believe, that the ile-

um, cæcum, ascending and transverse portions of the colon, may descend into the sigmoid flexure of the latter intestine; nay more, that they may pass through the rectum, and be protruded in the form of a procidentia ani. Such cases, however, are recorded. (*Langstaff, in Edinb. Med. and Surgical Journal, No. XI.*)

This gentleman next relates the case of a child three months old, the body of which he inspected after death, and found to confirm the truth of the preceding account. The example was particular in their being in addition to an extensive introsusception in the usual way, a smaller invagination in the opposite direction, like what probably occurred in the case related by Mr. Spry; *Med. and Physical Journal, No. XI*. Sir E. Home, (*Trans. of a Society for Medical and Chir. Knowledge, Vol. 1.*) mentions an example of a retrograde introsusception, in which a worm was found coiled up round the introsuscepted part. The disease took place in a boy who had swallowed arsenic.

If the following mode of accounting for introsusception be just, it will most frequently happen downwards, although there is no reason why it may not take place in a contrary direction; in which case, the chance of a cure will be increased by the natural actions of the intestinal canal tending to replace the intestine; and probably from this circumstance it may oftener occur than commonly appears.

When the introsusception is downwards, it may be called *progressive*, and when it happens upwards, *retrograde*. The manner in which it may take place is, by one portion of a loose intestine being contracted, and the part immediately below relaxed and dilated; under which circumstances, it might very readily happen by the contracted portion slipping a little way into that which is dilated, not from any action in either portion of intestine, but from some additional weight in the gut above. How far the peristaltic motion, by pushing the contents on to the contracted parts, may force these into the relaxed, Mr. Hunter will not determine, but is inclined to suppose that it will not.

By this mode of accounting for an accidental introsusception, it may take place either upwards or downwards; but if a continuance or an increase of it arises from the action of the intestines, it must be when it is downwards, as we actually find to be the case; yet this does not explain those in which a considerable portion of intestine appears to have been carried into the gut below: to understand these, we must consider the different parts which form the introsusception. It is made up of three folds of intestine; the inner, which passes down, and being reflected upwards, forms the second or inverted portion, which being reflected down again, makes the third or containing part, that is the outermost, which is always in the natural position. (*J. Hunter.*)

The outward fold is the only one which is active, the inverted portion being perfectly passive, and squeezed down by the outer,

which inverts more of itself, so that the angle of inversion in this case is always at the angle of reflection of the outer into the middle portion or inverted one, while the innermost is drawn in. From this we can readily see how an introsusception, once begun, may have any length of gut drawn in.

The external portion acting upon the other folds in the same way as upon any extraneous matter, will by its peristaltic motion urge them further; and if any extraneous substance is detained in the cavity of the inner portion, that part will become a fixed point for the outer or containing intestine to act upon. Thus it will be squeezed on, till at last the mesentery preventing more of the innermost part from being drawn in, will act as a kind of stay, yet without entirely hindering the inverted outer fold from going still further. For it being the middle fold that is acted upon by the outer, and this action continuing after the inner portion becomes fixed, the gut is thrown into folds upon itself; so that a foot in length of intestine shall form an introsusception not more than three inches long.

The outer portion of intestine is alone active in augmenting the disease when once begun; but if the inner one were capable of equal action in its natural direction, the effect would be the same, that of endeavouring to invert itself, as in a prolapsus ani; the outer and inner portions, by their action, would tend to draw in more of the gut, while the intermediate part only would, by its action, have a contrary tendency.

The action of the abdominal muscles cannot assist in either forming or continuing this disease, as it must compress equally both above and below, although it is capable of producing the prolapsus ani.

When an introsusception begins at the valve of the colon, and inverts that intestine, we find the ileum is not at all affected; which proves that the mesentery, by acting as a stay, prevents its inversion. (*J. Hunter.*)

From the natural attachment of the mesentery to the intestines, one would, at the first view of the subject, conceive it impossible for any one portion of gut to get far within another; as the greater extent of mesentery that is carried in along with it would render its further entrance more and more difficult, and we should expect this difficulty to be greater in the large intestines than in the small, as being more closely confined to their situation; yet one of the largest introsusceptions of any known was in the colon, as related by Mr. Whateley. (*Vid. Phil. Trans. Vol. 76, p. 305.*)

The introsusception appeared to have begun at the insertion of the ileum into the colon, and to have carried in the cæcum with its appendix. The ileum passed on into the colon, till the whole of the ascending colon, the transverse arch, and descending colon, were carried into the sigmoid flexure and rectum. The valve of the colon being the leading part, is at last got as low as the anus; and when the person went to

stool he only emptied the ileum, for one half of the large intestines being filled up by the other, the ileum alone, which passed through the centre, discharged its contents. (J. Hunter.)

Two questions of considerable importance present themselves to the mind in considering this subject; whether there are any symptoms by which the existence of the affection can be ascertained during life? And whether we possess any means of relieving it, supposing that its existence could be discovered? The symptoms attending an introsusception are common to inflammation of the intestines, hernia, and obstruction of the canal, from whatever cause, and a volvulus is the least frequent cause of such symptoms. (Langstaff.) In the case published by this gentleman, and in those related by Mr. Hunter and Mr. Spry, the seat of the disease was clearly denoted by a hard tumour on the left side of the abdomen. This circumstance, together with the impossibility of throwing up more than a very small quantity of fluid in clysters, (Hevin, Spry, Langstaff,) and the presence of the other symptoms, would lead us to suspect the nature of the disorder. If the invaginated portion descended so low as to protrude through the anus, and we could ascertain that it was not an inversion of the gut, the case might be considered as clear, and we should have no hesitation in delivering a prognosis, which, by preparing the friends for the fatal termination, would exonerate us from all blame on its occurrence. (Langstaff.)

In the treatment of this disease, bleeding, to lessen the inflammation that might be brought on, and quicksilver to remove the cause, have been recommended.

Quicksilver would have little effect either in one way or the other, if the introsusception were downward; for it is to be supposed that it would easily make its way through the innermost contained gut, and, if it should be stopped in its passage, it would by increasing its size, become a cause (as before observed) of assisting the disease. In cases of the retrograde kind, quicksilver, assisted by the peristaltic motion, might be expected to press the introsusception back; but even under such circumstances it might get between the containing and inverted gut into the angle of reflection, and by pushing it further on, increase the disease it is intended to cure. (J. Hunter.)

Every thing that can increase the action of the intestine downwards, is to be particularly avoided, as tending to increase the peristaltic motion of the outer containing gut, and thus to continue the disease. Medicines can never come into contact with the outer fold, and having passed the inner, can only act on the outer further down, and therefore cannot immediately affect that portion of the outer which contains the introsusception; but we must suppose that whatever affects or comes into contact with the larger portion of the canal, so as to throw it into action, will also affect by sympathy any part that may escape such application. Mr. Hunter there-

fore advises giving vomits, with a view to invert the peristaltic motion of the containing gut, which will have a tendency to bring the intestines into their natural situation.

If this practice should not succeed, it might be proper to consider it as a retrograde introsusception, and by administering purges endeavour to increase the peristaltic motion downwards. (J. Hunter.)

I cannot agree with Mr. Langstaff, that it is to be regretted, Hunter's name should be affixed to the preceding proposal, or that it is an absurd one; for purgatives and emetics were only recommended to increase the peristaltic action, the former downward, the latter upward, according as the supposed nature of the case might require, and this effect they certainly would have, notwithstanding vomiting is an early and constant symptom of the disease, and an insuperable constipation an equally invariable attendant. The method, I allow, however, is not very hopeful, and may sometimes be frustrated by the formation of adhesions. According to Mr. Langstaff, the *Recherches Historiques sur la Gastrotomie dans le cas de Volvulus*, par M. Hevin, (*Mem. de l'Acad. de Chirurgie*, Tom. 4, 4to.) contain many interesting facts and sound reasoning. There we find a very ample discussion of the question, concerning the propriety of opening the abdomen, in order to disentangle the introsuscepted intestine; a proposal which M. Hevin very properly condemns.

If the equivocal and uncertain nature of the symptoms of volvulus were not sufficient to deter us from undertaking an operation, which, under the most favourable circumstances, could not fail to be extremely difficult, and imminently hazardous to the patient, the state of the invaginated parts would entirely banish all thoughts of such an imprudent attempt; for the different folds of the intestine often become agglutinated to each other, so that they can hardly be withdrawn after death; (Simpson, *Edinburgh Med. Essays*, Vol. 6, Hevin's 4th Obs. Malcolm, *Physical and Lit. Essays*, Vol. 2, p. 360. Hunter, *Med. and Chir. Trans.* and Soemmering in *Transl. of Baillie's Morb. Anat.*) Nay, the stricture on the introsuscepted part may cause it to inflame, and even mortify. (Soemmering.) It is very clear that in this state of parts, the operation of gastrotomy would be totally inadmissible, even if the symptoms could clearly indicate the nature of the case, and the affected part could be easily reached and examined. (Langstaff.)

The forcible injection of clysters was found useless by Dr. Monro, and the agglutination of the parts must produce an insuperable obstacle to the bowels being pushed back by this means. (Langstaff.) Some have proposed the employment of a long bougie, or a piece of whalebone, to push back the intestine; and this proposal may be adopted, when we are furnished with an instrument, adapted to follow the windings of the large intestine to its origin in the

right ilium, without any risk of perforating the gut in its course. (*Langst. ff.*)

It must be confessed, that both surgery and medicine are almost totally unavailing in the present disease. Yet, here, as in many other instances, the resources of nature are exhibited in a most wonderful and astonishing manner, while those of art completely fail. The invaginated portion of intestine sometimes sloughs, and is discharged *per anum* while the agglutination of the parts preserves the continuity of the intestinal canal. The annals of medicine furnish numerous instances, in which long pieces of gut have been discharged in this manner, and the patient has recovered. Hence, some hope may be allowed under the most unpromising circumstances. In a case, related in Duncan's Commentaries, eighteen inches of small intestine were voided *per anum*, Vol. 9 p. 278. Three similar instances occur in M. Hevin's Memoir; twenty-three inches of colon came away in one of these, and twenty-eight of small intestines in another. Other cases occur in the Physical and Literary Essays, Vol. 2, p. 361; in Duncan's Annals, Vol. 6 p. 298; in the Medical and Chirurgical Transactions, Vol. 2; where Dr Baillie states, that a yard of intestine was voided. The patients did not, however, ultimately survive in every one of these instances. (*Langstaff in Edinb. Med. and Surgical Journal.*)

Langenbeck has recorded an instance, in which a prolapsus of the large intestines protruded half an ell out of the anus. The disease had lasted thirty weeks. Langenbeck made an incision into, or rather through, the protruded inverted bowel, immediately below the sphincter ani. He first divided the inner vascular coat, then the muscular, and lastly the outer coat with great caution. He now discovered, within the protruded inverted bowel, which he had opened, another part of the intestinal canal, which was not yet inverted. He remarked upon it the appendices epiploicæ, and the white shining peritonæal coat. This last portion would also have become inverted, had the disease continued. He next reduced the latter uninverted part, and afterward succeeded in replacing the rest of the protrusion; which did not fall down again when the boy had stools. No bad symptoms immediately followed; but, the lad being very weak, survived only eight days. (See *Bibl für die Chir.* B. 3 p. 756, Gott. 1811.)

INVERSION OF THE UTERUS. See *Uterus, Inversion of.*

IRIS, PROLAPSUS OF. As long as the humours, which fill the cavity of the eye, and in which the iris is immersed and suspended, remain in perfect equilibrium with respect to each other, that membrane retains its natural position, and a suitable distance from the cornea, and although of a very delicate and yielding texture, it contracts, and relaxes itself, without ever forming any irregular fold. But, when the aqueous humour has escaped through an accidental, or artificial, opening in the cornea, the iris is pressed forward by the humours situated behind it, and is urged gradually towards the cornea until a portion of it protrudes from the eye, at the same opening, through which the aqueous humour made its escape. Thus a small tumour of the same colour as the iris forms on the cornea, sometimes named *staphyloma of the iris*; sometimes *procedentia*, or *prolapsus of the iris*.

The causes of this complaint are such wounds and ulcers of the cornea, as make an opening of a certain extent into the anterior chamber of the aqueous humour, and such violent contusions of the eyeball, as occasion a rupture of the cornea. If the edges of a wound in this situation, whether accidental, made for the purpose of extracting the cataract, or evacuating the matter of hypopium, be not brought immediately afterward into reciprocal contact, or continue not sufficiently agglutinated together to prevent the escape of the aqueous humour from the anterior chamber, regularly as this fluid is reproduced; the iris, drawn by its continual flux towards the cornea, glides between the lips of the wound, becomes elongated, and a portion of it gradually protrudes beyond the cornea, in the form of a small tumour. The same thing takes place, whenever the eyeball unfortunately receives a blow, or is too much compressed by bandages, during the existence of a recent wound of the cornea. Also, if the patient should be affected, in this circumstance, with a spasm of the muscles of the eye, with violent and repeated vomiting, or with strong and frequent coughing, a prolapsus of the iris may be caused. When an ulcer of the cornea penetrates the anterior chamber of the aqueous humour, the same inconvenience happens more frequently, than when there is a recent wound of that membrane; for, the solution of continuity in the cornea, arising from an ulcer, is attended with loss of substance, and in a membrane, so tense and compact as this is, the edges of an ulcer do not admit of being brought into mutual contact.

The little tumour is likewise necessarily of the same colour as the iris, viz. brown, or grayish, being surrounded at its base by an opaque circle of the cornea, on which membrane there is an ulcer, or a wound of not a very recent description.

As it usually happens, that the cornea is only penetrated at one part of its circumfer-

ence by a wound, or ulcer, so in practice, only one prolapsus of the iris is commonly met with in the same eye. But if the cornea should happen to be wounded, or ulcerated at several distinct points, the iris may protrude at several different places of the same eye, forming an equal number of small projecting tumours on the surface of the cornea. Scarpa has seen a patient who had three very distinct protrusions of the iris on the same cornea, in consequence of three separate ulcers penetrating the anterior chamber of the aqueous humour; one in the upper, and two in the lower segment of the cornea.

If, says Scarpa, the delicate structure of the iris; the great quantity of blood-vessels, which enter it; and the numerous nervous filaments, which proceed to be distributed to it, as a common centre; be considered, the nature and severity of those symptoms may be readily accounted for, which are wont to attend this disease, however small the portion of the iris projecting from the cornea may be, even if no larger than a fly's head. The hard and continual frictions to which this delicate membrane is then exposed, in consequence of the motions of the eyelids; together with the access of air, tears, and gum to it; are causes quite adequate to the production of continual irritation; and the blood which tends to the point of the greatest irritation, cannot fail to render the projecting portion of the iris much larger, almost directly after its protrusion, than it was at the moment of its first passing through the cornea. Hence it becomes, soon after the prolapsus, more incarcerated and irritated, than it was at first. In the incipient state of the complaint, the patient complains of a pain, similar to what would arise from a pin penetrating the eye; next he begins to experience, at the same time, an oppressive sensation of tightness, or constriction, over the whole eyeballs. Inflammation of the conjunctiva, and eyelids, a burning effusion of tears, and an absolute inability to endure the light, successively take place. As the protruded portion of the iris drags after it all the rest of this membrane, the pupil assumes of mechanical necessity an oval shape, and deviates from the centre of the iris, towards the seat of the prolapsus. The intensity of the pain, produced by the inflammation, and other symptoms attendant on the prolapsus of the iris, does not, however, always continue to increase.

Indeed, in practice, cases of old protrusions of the iris often occur, where, after the disease has been left to itself, the pain and inflammation spontaneously subside, and the tumour of the iris becomes almost completely insensible. Scarpa met with a man, fifty years of age, who had had a prolapsus of the iris in the right eye ten weeks; it was as large as two grains of millet seed; the patient bore it with the greatest indifference, and without any other inconvenience, than a little chronic redness of the conjunctiva, and a difficulty of moving the eyeball

freely, in consequence of the friction of the lower eyelid against the tumour formed by the iris. When the extremity of the finger was applied, the little tumour felt hard and callous.

In the early stage of this disease, some direct the iris to be replaced in its proper situation by means of a whalebone probe; and in case of difficulty, to make a dilatation of the wound, or ulcer of the cornea, by an incision, proportioned to the exigency of the case, as is done for the return of a strangulated intestinal hernia. Others only recommend stimulating the prolapsed portion of the iris with the view of making it contract and shrink into the eye; or suddenly exposing the eye affected to a very vivid light, in the belief, that as the pupil then forcibly contracts, the piece of the iris, engaged between the lips of the wound, or ulcer of the cornea, will rise to its proper place. However, Scarpa represents all such methods as absolutely useless, and even dangerous. Supposing it were possible, by such attempts, to reduce the iris to its proper situation, without tearing or injuring it, still the aqueous humour would escape again through the wound, or ulcer of the cornea, so that the iris, when replaced, would fall down the moment afterward, and project from the cornea in the same way as before the operation. Hence, though Scarpa admits that the prolapsus of the iris is a serious accident, he argues that as surgery has no means of suppressing at once, or at least, of suspending the escape of the aqueous humour through a wound, much less through an ulcer of the cornea, when either exceeds certain limits, the prolapsus of the iris, far from being an evil in such unfavourable circumstances, is rather useful, and, perhaps, the only means of preventing the total loss of the organ of sight. For the flap of the iris insinuates itself, like a plug, between the edges of the wound, or ulcer of the cornea, and thus completely prevents the exit of the aqueous humour.

Here I ought to observe, that Scarpa's unlimited condemnation of the plan of ever attempting to replace the iris is contrary to the advice delivered by Beer, as may be seen by referring to the article *Cataract*, where the treatment of the protrusion of the iris after the operation of extraction is noticed. And even with respect to the prolapsus of the iris from ulceration making its way through the cornea, Beer distinctly states, that a recent prolapsus of this kind, formed in the second still existing stage of ophthalmia, may not only be lessened by proper treatment, calculated to produce a quick cicatrization of the ulcer, but the iris may be again completely removed from the cornea, without any adhesion to the edge of the ulcer taking place. (*B. 2, P. 63.*) But where the prolapsus of the iris remains, as a consequence of previous inflammation of the eye, Beer confesses that it cannot be cured, without a partial adhesion of the iris to the cornea being left, and a dense scar on

the latter membrane in the situation of the protruded iris. (*Vol. cit. p. 66.*)

In conformity to Scarpa's principles, there are two principal indications in the treatment of the recent prolapsus of the iris. The first is, to diminish, as speedily as possible, the exquisite sensibility in the protruded part of the iris; the other is gradually to destroy the projecting portion of this membrane to such a depth, as shall be sufficient to prevent the little tumour from keeping the edges of the wound, or ulcer of the cornea asunder, and retarding cicatrization. The adhesion, however, which connects the iris with the inside of the cornea, must not be destroyed.

For fulfilling these indications, nothing is more effectual, than touching the portion of the iris projecting from the cornea, with the oxygenated muriate of antimony (*butter of antimony*), or with what is more expeditious and convenient, the *argentum nitratum*, so as to form an eschar of sufficient depth. And, in order that this operation may be effected with quickness and precision, it is necessary that an assistant, standing behind the patient's head, should support the upper eyelid with Pellier's elevator; and that the patient should keep his eye steadily fixed on one subject.

While the assistant gently raises the upper eyelid, the surgeon must depress the lower one, with the index and middle fingers of his left hand; and with the right, he is to be ready to touch the little prominence formed by the iris, with the *argentum nitratum*, scraped to a point like a pencil. This is to be applied to the centre of the little tumour, until an eschar of sufficient depth is formed. The pain which the patient experiences at this moment, is very acute; but, it subsides as soon as the eye is bathed with warm milk. The caustic, in destroying the projecting portion of the iris, destroys the principal organ of sensibility, by covering it with an eschar, of sufficient depth to protect the part affected from the effect of the friction of the eyelids, and from coming into contact with the air and tears. This is the reason, not only why the sense of pricking and constriction in the eye abates after the application of the caustic, but also why the inflammation of the conjunctiva undergoes a considerable diminution, as well as the burning and copious effusion of tears.

As in the case of ulcer of the cornea, these advantages only last while the eschar remains adherent to the little tumour formed by the iris; when it falls off, as it usually does two or three days after the use of the caustic, all the above-mentioned symptoms are rekindled, with this difference, that they are less intense and acute, than they were previously, and the tumour of the iris is not so prominent as it was before the caustic was applied. When these symptoms make their appearance, the surgeon must once more have recourse to the *argentum nitratum*, with the precautions explained above; and he is to employ it a third, and even a fourth time, as occasion may require, until the

prominent portion of the iris is sufficiently reduced to a level with the edges of the wound, or ulcer of the cornea, and no obstacle is left to the granulating process, and complete cicatrization.

There is a certain period, beyond which the application of caustic to the protruded iris becomes exceedingly dangerous, though at first it may have been highly beneficial; beyond which, the eschar, which previously soothed the pain, exasperates it, and reproduces the inflammation of the conjunctiva in almost as vehement a degree as in the beginning of the disease. This appears to Scarpa to be the case, whenever the surgeon continues to employ the caustic, after the little tumour of the iris has been destroyed to a level with the external edges of the wound, or ulcer of the cornea, and the application begins to destroy the granulations just as they are originating. Hence, as soon as the surgeon perceives, that the part of the iris, projecting from the cornea, is sufficiently lowered, and that the application of the *argentum nitratum*, far from allaying, only irritates the disease, he must desist entirely from using the caustic, and be content with introducing between the eye and eyelids, every two hours, the collyrium *zinci sulphatis* with the mucilage of quince-seeds. Every morning and evening, Janin's ophthalmic ointment, weakened with a double, or triple proportion of lard, is to be applied. If the stimulus of such local remedies should not disturb the work of nature, the ulcer gradually diminishes, and heals in the course of a fortnight.

The adhesion, which the projecting part of the iris contracts to the internal margin of the wound, or ulcer of the cornea, during the treatment, continues the same after the perfection of the external cicatrix, and of course during the rest of the patient's life. Hence, even after the most successful treatment of the prolapsus of the iris, the pupil remains a little inclined toward the place of the scar in the cornea, and of an oval figure. The change in the situation and shape of the pupil, however, causes little or no diminution of the patient's faculty of discerning distinctly the smallest objects; and is much less detrimental to the sight, than one, inexperienced in these matters, might conceive; provided the scar on the cornea be not too extensive, nor situated exactly in the centre of this membrane. In the first case, the sight is the less obstructed, as the pupil, which, on the first occurrence of the prolapsus, was narrow, oblong, and drawn considerably toward the wound, or ulcer, gradually enlarges, and forms a less contracted oval. As soon as the wound is completely healed, the pupil tends, in some degree, to occupy its former situation in the centre of the cornea, a fact, also noticed by Richter.

According to Scarpa, the recision of the protrusion with scissors can only be practised with success, when the iris has contracted a firm adhesion to the internal edge of the wound, or ulcer of the cornea; and,

more especially, in that ancient prolapsus of the iris, in which the projecting portion of the iris has become with time almost insensible, hard, and callous, with its base strangulated between the edges of the wound, or ulcer of the cornea, and besides being adherent to them, having also a slender pedicle. Scarpa indeed has seen an incarcerated one fall off of itself.

In such circumstances, the recision of the old prolapsus of the iris is not attended with the least danger; for, after removing with a stroke of the scissors, that prominent portion of the iris, which has already contracted internal adhesions to the ulcerated margin of the cornea, so as to reduce it to a level with the external edges of the ulcer, there is no hazard of renewing the effusion of the aqueous humour, or giving an opportunity for another piece of the iris to be protruded. One or two applications of the *argentum nitratum* suffice afterward for the production of granulations on the ulcer of the cornea, and the formation of a cicatrix. But, it is not so in the treatment of the recent prolapsus of the iris, which has no adhesions to the internal edges of the wound, or ulcer of the cornea.

In four subjects recently affected with prolapsus of the iris, after Scarpa had removed, with a pair of convex-edged scissors, a portion of that membrane projecting beyond the cornea, of about the size of a fly's head, he found, on the ensuing day, that a new portion of the iris, not less than the first, had made its way through the ulcer of the cornea, and that the pupil was very much contracted, and drawn considerably further toward the ulcer of the cornea. These circumstances took place, notwithstanding the wound was touched immediately afterward with the *argentum nitratum*. Hence Scarpa apprehends, that if he were ever to divide such a little tumour again, it would reappear, and always with an additional protrusion of the iris, and a further distortion of the pupil. The advantage of caustic in the recent sensible prolapsus of the iris; and the use of scissors only in old callous cases, agree also with the directions given both by Beer and Mr. Travers. (*Lehrv. von den Augenkr. B. 2, p. 68*; and *Synopsis, p. 280.*)

There is a particular species of prolapsus, much less frequent, indeed, than that of the iris; but, which does occur, and, in Scarpa's opinion, is very improperly termed by modern oculists, "*prolapsus of the tunic of the aqueous humour.*" (*Janin, Pellier, Guérin, Gleize, &c.*) Neither do his sentiments upon this subject agree with those of Beer, whose explanation of the nature of the case is given in Vol. I. of this Dictionary. We shall there see, that it is a case, which he terms *ceratocoele*, and which he thinks arises from a yielding of the inner layers of the cornea, in consequence of the outer ones not having united. And, in his second vol. p. 59, he has given a description of the same kind of disease from the support of the outer layers of the cornea being destroyed by ulceration. This is a point, on which the most experien-

ced men differ so much, that it is difficult to reconcile their statements. Dr. Vetch seems to have full reliance upon the accuracy of the accounts of a protrusion of the membrane of the aqueous humour. (*Treatise on Diseases of the Eye, p. 54, &c.*) Mr. Travers inclines to Beer's view of the subject, and details reasons for doubting, that the vesicle is a distinct texture: "its appearance corresponds accurately to that of the innermost lamella of the cornea." (*Synopsis of the Diseases of the Eye, p. 116.*)

It is, says Scarpa, a transparent vesicle, filled with an aqueous fluid, and composed of a very delicate membrane, projecting from a wound, or ulcer of the cornea, much in the same way as the iris does under similar circumstances. Scarpa has several times seen this transparent vesicle full of water, elongating itself beyond the cornea, shortly after the operation for the extraction of the cataract, and sometimes, also, in consequence of an ulcer of the cornea, especially after rescinding a prolapsed portion of the iris.

The generality of oculists believe that this little transparent tumour consists of the delicate, elastic, diaphanous membrane, which invests the inner surface of the cornea, and is described by Descemet and Demours. "As soon as the membrane lining the cornea (they say) is exposed by the wound, or ulcer of the latter, and the delicate pellicle can no longer resist the impulse of the humours pressing behind it, it is necessitated to yield gradually, to become elongated, and to project from the wound, or ulcer of the cornea, exactly in the form of a pellucid vesicle." But, says Scarpa, how remote this theory is from the truth, must be manifest: 1. The delicate and elastic pellicle, described by Descemet and Demours, is not separable by any artifice from the inner surface of the cornea, except near where the cornea and sclerotica unite. Since these protruded vesicles make their appearance in practice at every point of the cornea, and even at its very centre, where the above pellicle is certainly neither separable, nor distinct from the compact texture of the cornea; it may at least be asserted, that the tunic of the aqueous humour does not in every instance constitute the transparent vesicle in question. 2. It is a well-known fact, that this vesicular, pellucid prolapsus happens more frequently after the extraction of the cataract, than any other occasion. In this case, since the tunic of the aqueous humour has certainly been divided to afford an exit to the crystalline, no one can be of opinion, that the transparent vesicle, which protrudes from the cornea after this operation, ought to be attributed to the distention and protrusion of the tunic of the aqueous humour. 3. If, in cases of ulcers of the cornea, the transparent vesicle should sometimes appear after the recision of the prolapsus of the iris, it is obvious, that if it consisted of the tunic of the aqueous humour, it ought invariably to appear before the prolapsus of the iris. 4. Should the surgeon remove the protruded

vesicle to a level with the cornea by a stroke of the scissors, a small quantity of limpid water is seen to ooze out, at the moment when the incision is made, without any part of the aqueous humour escaping from the anterior chamber. This inconvenience would be inevitable, were the protruded vesicle in question formed by the delicate elastic pellicle, which is said to invest the inner surface of the cornea. Besides, the little transparent tumour disappears when the incision is made; but often another one exactly similar to what was cut off, is found in the very same place the following day. Had the little transparent tumour been composed of the tunic of the aqueous humour, elongated out of the wound, or ulcer of the cornea, it could not at all events have been reproduced at the same part of the cornea.

Actuated by such reflections, it is clear to Scarpa, that the pretended prolapsus of the tunic of the aqueous humour is not what it is imagined to be; but strictly speaking, only a forcible protrusion of a portion of the vitreous humour, which, from too much pressure being made on the eye, either at the time of the operation, or afterward, or from a spasm of the muscles of the eye, insinuates itself between the edges of the wound after the extraction of the cataract, and projects in the form of a transparent vesicle. The same thing also happens after ulcers of the cornea, whenever the aqueous humour has escaped, and a portion of the vitreous humour is urged by forcible pressure towards the ulcer facing the pupil; or whenever an elongated piece of the vitreous humour, after the recision of a prolapsed portion of the iris, passes by a shorter route than through the pupil, between the lips of the ulcer of the cornea. At length, we understand, why in both these instances a transparent vesicle forms, even after the recision of the tunic of the aqueous humour, or ulceration of the cornea; and why it very often reappears in the same place, though it has been cut away to a level with the cornea. It is because one or more cells of the vitreous humour, constituting the transparent vesicle, are succeeded after their removal by other cells of the same humour, which glide between the lips of the wound, or ulcer of the cornea, into the same situation.

The treatment of this species of prolapsus consists in removing the transparent vesicle, projecting from the wound, or ulcer, by means of a pair of curved scissors with convex edges, and bringing the edges of the wound of the cornea immediately afterward into perfect apposition, in order that they may unite together as exactly as possible. But when there is an ulcer of the cornea, as soon as the vesicle is removed, the sore must be touched with the *argentum nitratum*, so that the eschar may resist any new prolapsus of the vitreous humour, and at the same time dispose the ulcer of the cornea to granulate and heal.

If, in some particular cases, the vesicle should not project sufficiently from the

wound, or ulcer of the cornea, to be incised in the scissors, the same object may be accomplished by puncturing the tumour with a lancet, or couching-needle; for when the limpid fluid which it contains is discharged, the membrane forming it shrinks within the edges of the wound, or ulcer of the cornea, and no longer hinders the union of the former, or the cicatrization of the latter.

Should the transparent tumour reappear in the same situation, the day after its recision, or puncture, it is right to repeat one of these operations, and to adopt further measures for maintaining the edges of the wound of the cornea in contact; or if it should be an ulcer, the eschar must be made to adhere more deeply to its bottom and sides, so as to form a greater obstacle to the escape of the vitreous humour. In these circumstances, the surgeon must take all possible care to obviate such causes as have a tendency to propel the vitreous humour towards the wound, or ulcer of the cornea; particularly too much pressure on the eyelids, spasms of the muscles of the eye, coughing, sneezing, efforts at stool, and other similar ones; and care must also be taken to check the progress of inflammation.

The choroid coat is, likewise not exempt from prolapsus. Scarpa has seen this complaint in M. Bressanini, an apothecary at Besençon. A small abscess, formed between the sclerotica and choroid coats, at the distance of two lines from the union of the cornea with the sclerotica, in the inferior hemisphere of the globe of the eye, in consequence of a severe internal and external ophthalmia, which had been treated in its incipient state, with repellent remedies. The abscess burst, and discharged a small quantity of thick viscid lymph; then a small blackish body, composed of the choroid coat, presented itself on the outside of the little ulcer of the sclerotica. The treatment consisted in applying the *argentum nitratum* several times to the projecting portion of the choroides, until it was consumed, and reduced to a level with the bottom of the ulcer of the cornea. The part then healed. The eye remained, however, considerably weakened, and the pupil afterward became nearly closed. Scarpa *sulle Principali Morboliche degli Occhi. IRITIS. Inflammation of the iris. See **OPHTHALMY**.

ISCHURIA. (From *ισχω*, to restrain; and *ουρα*, the urine.) A suppression, or stoppage of the urine.

The distinction between a *suppression* and *retention* of urine, is practical and judicious. The former most properly points out a defect in the secretion of the kidneys; the latter, an inability of expelling the urine when secreted. (*Hey*.)

The first disease is not very common, is named *ischuria renal*, or *suppression of urine*, and belongs to the province of the physician; the second is an exceedingly frequent disorder, is named *ischuria vesical*, or *retention of urine*, and its treatment is altogether surgical. Every thing relative to it will be found in the articles *Catheter*, and *Urine, Retention of*.

ISSUE signifies an ulcer, made designedly by the practitioner, and kept open a certain time, or even the patient's whole life, for the cure, or prevention, of a variety of diseases.

The physician, in his practice, has frequent occasion to recommend the making of an issue, and the surgeon finds it a principal means of relief in several important cases, as, for instance, the white swelling, the disease of the hip-joint, caries of the vertebrae, &c. Many persons are never in health, or, at least, fancy themselves always ill, unless they have an issue formed in some part of their body or another. The making of an issue, indeed, is not unfrequently considered as an imitation of nature, who, of her own accord, often forms ulcers and abscesses in various parts of the body (as is not uncommonly conjectured) for the purpose of discharging pernicious humours, whereby people are supposed to be freed from grievous disorders, and have their health preserved. The humoral pathologists were excessively partial to these notions, which, at the present time, will be found by every experienced practitioner to influence the mass of mankind, and render the formation of issues more common, than perhaps is consistent with the better established principles of medical science. Few old subjects will allow a sore of long standing to be dried up (as the expression is,) without requiring the surgeon immediately afterward to make an issue for them. When an ulcer has existed a great length of time, the constitution may possibly become so habituated to it, that the health may really suffer from its being healed. "I have often (says the experienced Dr. Parry) seen various thoracic affections, as pulmonary consumption, asthma, carditis, or hydrothorax, arise from the

spontaneous, or artificial cure of ulcers, perpetual blisters, or fistulae." (*Elements of Pathology, &c. p. 386.*) Asthmatic complaints, severe headaches, &c. are frequently observed to follow the cicatrization of an old ulcer; but whether they would have happened, if an issue had been made in time, is a question difficult of positive determination; for many persons with old ulcers are not prevented from suffering from asthma and headach. The plan of making an issue, however, is commendable both as rational and exempt from danger. Whatever may be the solidity of the theories, which have been offered by medical writers, in regard to issues, the practitioner, who has his eyes open, cannot fail to see the benefit often derived from such means; and if there be any unquestionable facts in medicine and surgery, we may confidently set down among them the frequent possibility of relieving one disease by exciting another of a less grievous, and more curable nature.

There are two ways of making an issue; one is with a lancet, or scalpel; the other with caustic.

The place for the issue being fixed upon, the surgeon and his assistant are to pinch up a fold of the integuments, and with a lancet or knife, make in them an incision of sufficient size to hold a pea, or as many peas as may be thought proper. The pea, or peas are then to be placed in the cut, and covered with a piece of adhesive plaster, a compress, and bandage. The peas first inserted, need not be removed for three or four days, when suppuration will have begun; but the issue is afterward to be cleaned and dressed every day, and have fresh peas put into it. The preceding is the ordinary method of making such issues as are intended to contain only one or two peas.

When the issue is to be larger, which is generally proper, in cases of diseased vertebrae, white swellings, &c., the best plan is to destroy a portion of the integuments with caustic. The caustic potassa, blended with quicklime, is mostly preferred for this purpose. The situation and size of the issue having been determined, the surgeon is to take care that the caustic does not extend its action to the surrounding parts. With this view, he is to take a piece of adhesive plaster, and having cut a hole in it of the exact shape and size of the issue intended to be made, he is to apply it to the part. Thus the plaster will defend the adjacent skin from the effects of the caustic, while the uncovered portion of integuments, corresponding to the hole in the plaster, is that which is to be destroyed. The caustic is to be taken hold of with a bit of lint, or tow, and its end, having been a little moistened with water, is to be steadily rubbed upon the part of the skin where the issue is to be formed. The frictions are to be continued till the whole surface, intended to be destroyed, assumes a darkish corroded appearance. The caustic matter may now be carefully washed off with some wet tow. The

plaster is to be removed, and a linseed poultice applied. As soon as the eschar is detached, or any part of it is loose enough to be cut away without pain, or bleeding, the peas are to be inserted and confined in their proper place with a piece of adhesive plaster. Some use beans for the purpose; others, beads, which answer very well, and have the advantage of serving for any length of time, when washed and cleaned every day. If the issue is at all of a longitudinal shape, the peas, beans, or beads, may be more easily kept in their places, when a thread is passed through them.

Issues ought always to be made, if possible, in a situation, where the peas will not be much disturbed in the ordinary motions of the body, nor interfere with the actions of muscles. The interspaces between the margins and insertions of muscles, are deemed the most eligible places. Thus, issues in the arm are usually made just at the inferior angle of the deltoid muscle, by the side of the external edge of the biceps. In the lower extremities, issues are often made at the inner side of the thigh, immediately above the knee, in a cavity that may be readily felt there with the fingers. Sometimes, issues are made upon the inside of the leg, just below the knee. For the relief of any affections of the head or eye, the nape of the neck is commonly selected as a good situation. In caries of the vertebræ, they are made on each side of the spinous processes. In cases of diseased hips, they are formed in a depression just behind and below the trochanter major. When the nature of the dis-

order does not particularly indicate the situation for the issue, the arm should be preferred to the leg, as issues upon the upper extremities, especially the left arm, are much less annoying, than upon either of the lower limbs.

The great art of keeping an issue open, for a long while, consists in maintaining an equal and effectual pressure upon the peas, by which means, they are confined in their places, little depressions are made for them, and the granulations hindered from rising. Compresses of pasteboard and sheet-lead will often be found highly useful. This plan is the surest one of preventing the issue from healing, and the most likely to save the patient all the severe and repeated suffering, which the fresh application of the caustic, or the use of stimulating powders, in order to renew the sore and repress the fungous flesh, unavoidably occasions.

There is a method of making issues with the caustic made into a sort of paste, which is laid upon the part left uncovered by the adhesive plaster. It seems to me to be a more tedious and painful plan, and I do not recommend it.

It has been suspected, that the pain, arising from the caustic, might be lessened, by mixing opium with the application; but, the idea seems not at all probable; the destruction of a part of the skin must inevitably cause considerable pain, with whatever substance it is produced, and opium itself, so far from being likely to diminish the agony, is itself a violent stimulus, whenever it comes into contact with the exposed extremities of the nerves.

J.

JOINTS, DISEASES OF. The joints are subject to numerous diseases, which are more or less dangerous, according to their particular nature. Like all other parts, the joints are liable to inflammation and abscesses; their capsules frequently become distended with an aqueous secretion, and the disease termed *hydrops articuli* is produced; but, the most important of all their morbid affections, are the cases, which, a few years ago, were indiscriminately called *white swellings*, *scrophulous joints*, and the *disease of the hip-joint*. Here, as Mr. Brodie remarks, the same name has been frequently applied to different diseases, and the same disease has received different appellations. And confusion, with respect to the diagnosis, always gives rise to a corresponding confusion, with respect to the employment of remedies. Although, says he, diseases in their advanced stage extend to all the dissimilar parts, of which the joints are composed, such is not the case in the beginning. Here, as elsewhere, the morbid actions commence, sometimes in one, and sometimes in another texture, differing in their nature, and, of course, requiring to be differently treated, according to the mechanical organization, and vital properties of

the part, in which they originate. (See *Pathological and Surgical Obs. on Diseases of the Joints*, p. 2, 8vo Lond. 1818.) It was this idea, which led Mr. Brodie to trace by dissection the exact parts, in which several of the principal diseases of the joints commence, and how much light and discrimination his successful investigations have produced, it is needless for me here to insist upon, as his merit will long be appreciated by every surgeon, who recollects the perplexity and ignorance which prevailed only a few years ago in this very interesting branch of surgery.

Wounds.—By the wound of a joint, surgeons mean a case, where the capsular ligament is penetrated, or divided. The injury is often accompanied with a division of the lateral, or other ligaments, and sometimes also with that of the cartilages and bones. That the capsular ligament is wounded may generally be learned by the introduction of a probe, and frequently by a discharge of a transparent viscid fluid, called the synovia. But, as a similar discharge may proceed from mere wounds of the bursæ mucosæ, we might form an erroneous judgment, were we unacquainted with the situation of these little

membranous bags. Boyer has seen several cases, in which a fluid, resembling synovia, was discharged from wounds of the sheaths of tendons. (See *Traité des Maladies Chirurg.* T. 4, p. 408.) Here, the advice which I have given in another place, (See *Wounds of the Abdomen*,) respecting the temerity of being too officious with the probe, is equally important, inasmuch as the rough introduction of this instrument into a large joint, like the knee, would be very likely to excite inflammation of the synovial membrane, and a train of dangerous and even fatal consequences; while the information, gained by such employment of the probe, is of little use; because, whenever a wound is suspected to reach into the capsular ligament, exactly the same treatment should always be followed, as if the joint were positively known to be penetrated.

Notwithstanding simple wounds even of large joints often heal favourably, without any bad symptoms, this is not constantly the case, and the records of surgery furnish many examples, in which the most alarming and fatal consequences ensued. (See *Hunter's Commentaries*, Part, 1, p. 69.) When properly treated, punctured wounds of the joints (says Boyer) are not in general attended with danger; but, as some of these wounds, which were apparently quite simple, have been followed by very bad symptoms, and even death, we should always be extremely circumspect in the prognosis. (See *Traité des Mal. Chir.* T. 4, p. 409.) The treatment consists in endeavouring to heal the injury by the first intention; in applying cold lotions; forbidding all motion of the part; and employing bleeding and other antiphlogistic remedies.

Baron Boyer relates two cases of punctured wounds of the elbow joint, which healed up in a few days, without any unfavourable symptom. He acknowledges, however, that these accidents do not always go on so well, and that the consequences are sometimes perilous.

Simple incised wounds present only one indication; viz. that of healing the part by the first intention. At the moment of the accident, some of the synovia is discharged, indicating that the capsular ligament is wounded. Should this circumstance not have been noticed at first, the surgeon may see the synovia flow out again, if he move, or press upon the joint. But, in making this examination, the greatest gentleness should be used, lest the irritation of the capsular ligament be increased. When the wound is large, and there is no considerable thickness of soft parts, the articular surfaces are exposed to view.

The prognosis of an incised wound of a joint is not generally unfavourable, when the edges have been immediately brought together, the cavity of the joint has not been long exposed, and blood is not extravasated in it. This last danger is also exaggerated, as will be noticed, in speaking of collections of blood in joints. With these exceptions, says Boyer, the wound may heal as readily, as if the joint were not opened, and he has cited several facts in proof of this statement. Its

truth is also confirmed by the success which attends operations, practised for the purpose of extracting cartilaginous substances from the knee. Nay, very bad cases sometimes recover under judicious management, even though the joint be large, and abscesses follow. Thus I have seen in St. Bartholomew's hospital, within the last year (1820) two examples of compound fractures of the patella, where the opening in the capsule was so large, that the finger could readily be passed into the cavity of the joint, yet after large abscesses, a great deal of fever, and separation of bone, the patients recovered with stiff joints. But, I would advise surgeons not to let any facts of this kind prejudice their judgment in the treatment of gunshot wounds of the large joints, where, in the circumstances elsewhere explained (see *Amputation and Gunshot Wounds*) amputation is the safest practice. In a sabre, or cut wound, the principal object is to heal the wound by the first intention. The rest of the treatment consists in using every possible means for the prevention of inflammation, by perfect quietude of the part; the use of cold applications, &c.

We repeat, however, that wounds of the joints do not always heal in the above favourable manner. Even among those cases, which appear the most slight and simple, there are but too many, which are followed by such aggravated symptoms, as either prove fatal, or occasion a necessity for amputation. And, in other instances of a less grievous description, when the patient is cured, the termination of danger is not without an anchylosis, by which the motion and functions of the joint are permanently destroyed.

The experienced Mr. Hey has noticed wounds of the joints, and made some pertinent remarks on the subject. He states, that in these cases, the utmost care should be taken to prevent inflammation. "Upon this circumstance chiefly depends a successful termination. I have seen (says he) many large wounds of the great joints healed without the supervention of any dangerous symptoms, where due care has been taken to prevent inflammation; whilst injuries, apparently trifling, will often be followed by a train of distressing and dangerous consequences, where such care has been neglected. It is, generally, easier to prevent inflammation in the joints, after a wound, than to arrest its progress when once begun. I speak now of inflammation affecting the capsular ligament. A slight degree of redness and tenderness in the integuments only is of little consequence; but, when the capsular ligament becomes inflamed, the formation of abscesses attended with a high degree of fever, and ultimately a stiffness of the joint, are the common consequences, if the life of the patient is preserved." (See *Hey's Practical Observations in Surgery*, p. 354, Edit. 2.)

For facts, in confirmation of the foregoing account, I particularly refer the reader to several cases recorded in this last publication, p. 355, et seq. and by Boyer. (*Traité des Mal. Chir.* T. 4, p. 426, &c.)

When the large joints, particularly the knee, are wounded, the stomach is frequently very much affected. I remember being shown by Mr. Best of Newbury, a man, who, in his occupation as a wheelwright, happened to give himself a wound by which one side of the knee was laid open: a good deal of inflammation and suppuration ensued; but, what particularly struck me, was the manner in which the man complained of the affection of his stomach.

In speaking of cartilaginous substances in the joints, I shall have occasion to advert again to the danger attendant on wounds of these parts; and the same fact is still further considered, in the articles *Ampulation, Dislocations, Fractures, and Gunshot Wounds*, in which last part of the Dictionary, the sentiments of Baron Larrey, and other writers on military surgery, are laid before the reader.

Inflammation of Joints, if we exclude from consideration specific cases, may be said usually to be the consequence of a contusion, sprain, wound, or some other kind of injury: but with respect to the inflammation of the synovial membrane, as described by Mr. Brodie, no cause is so frequent, as the application of cold, and hence he explains the frequency of this disease in the knee, and its rarity in the hip and shoulder, which are covered with a thick mass of flesh. As a late writer observes, the inflammation, arising from a wound, is infinitely the most severe after it has once commenced. (*James on Inflammation*, p. 157.)

The inflamed joint shows the common symptoms of inflammation; viz. preternatural redness, increased heat, throbbing, pain, and swelling, while the constitution is also disturbed by the common symptoms of inflammatory fever. It deserves notice, however, that in these cases, the constitutional symptoms are often exceedingly severe, and the pulse is more frequent, and less full and strong, than when parts, more disposed to return to a state of health, are affected. The inflammation first attacks some part of the capsular ligament, and very quickly spreads over its whole extent, as usually happens in all inflammations of smooth serous membranes.

The capsules of the joints are naturally not very sensible; but, like many other parts similarly circumstanced, they often become acutely painful, when inflamed. The complaint is accompanied with an increased secretion of the synovia, which becomes of a more aqueous, and of a less albuminous quality, than it is in the healthy state. Hence, it is not so well calculated for lubricating the articular surfaces, and preventing the effects of friction, as it is in the natural condition of the joint; a circumstance, which may explain, why a grating sensation is often perceived on making the patele.

The capsular ligaments, like other parts, are frequently thickened by inflammation, and sometimes, coagulating lymph being effused on their internal surfaces, organized cartilaginous, or osseous bodies, are formed within the joints.

It has been explained by Mr. Brodie, that the usual consequences of inflammation of the synovial membrane, or capsular ligament, are; 1. a preternatural secretion of synovia, 2. an effusion of coagulating lymph into the cavity of the joint. 3. a thickening of the synovial membrane, a conversion of it into a substance resembling gristle, and an effusion of coagulable lymph, and probably of serum into the cellular structure, by which it is connected with the external parts. The same gentleman has seen several cases, where, from the appearance of the joint, and the symptoms, there was every reason to believe, that the inflammation had produced adhesions of the reflected fold of the membrane to each other: and, in dissection, he has occasionally observed adhesions which might have arisen from inflammation at some former period. "These effects of inflammation of the synovial, very much resemble those of inflammation of the serous membranes. There are, however, some points of difference. In the former, I have reason to believe, that suppuration rarely takes place independently of ulceration; but, this is a frequent occurrence in the latter. Inflammation of the peritonæum, or pleura, though very slight in degree, and of very short duration, terminates in the effusion of coagulable lymph; but it is only violent or long-continued inflammation, which has this termination in the membranes of joints (*Brodie in Med. Chir. Trans. Vol. 4, p. 216.*)

When the inflammation attains a high pitch, an abscess may occur in the capsular ligament, which at length ulcerates, and the pus makes its way beneath the skin, and is, sooner or later, discharged through ulcerated openings.

An abscess rarely takes place in an important articulation, in consequence of acute inflammation, without the system being also so deranged that life itself is imminently endangered. Severe febrile symptoms always afflict the patient, and occasionally, delirium and coma taking place, death itself ensues. Two rapidly fatal cases of ulceration of the synovial membrane, where matter had formed within it from a sprain of the hip, and a contusion of the shoulder, are recorded by Mr. Brodie. (*See Pathol. Chir. Obs. p. 65.*)

In these cases, the inflammatory fever is very quickly converted into the hectic; indeed, when an abscess has taken place in a large joint, in consequence of acute inflammation, hectic symptoms almost immediately begin to show themselves, and the strong actions of the common inflammatory fever suddenly subside.

Local consequences, even worse than those above described, may follow inflammation of a joint. As the layer of the capsular ligament, reflected over the cartilages of the articulation, is often inflamed, the cartilages themselves may have the inflammation communicated to them. Parts of a cartilaginous structure, being very incapable of bearing the irritation of disease, often

ulcerate, or, in other words, are absorbed, so as to leave a portion, or the whole, of the articular surface of the bones, completely denuded of its natural covering. At length the heads of the bones themselves inflame, and become carious; or the consequence may be ankylosis. Mr. Brodie has seen some cases in which there was extensive destruction of the cartilages, apparently in consequence of neglected inflammation of the synovial membrane; but he believes, that in most cases where ulceration of the cartilage is combined with such inflammation, the former is the primary affection, and the latter takes place subsequently, in consequence of the formation of an abscess within the joint. (*Pathol. and Surg. Obs. &c. p. 17.*) According to Mr. Brodie, who speaks chiefly of the inflammation which begins in the synovial membrane itself, and is not communicated to it from other textures, the disease very seldom attacks young children, but is frequent in adult persons, the reverse of what happens in some other diseases of the joints.

The inflammation of the capsular ligament, or synovial membrane, frequently assumes the chronic form, and is then very often confounded with other more serious maladies, under the general appellation of white swelling. The disease often arises from cold, and hence is more common in the knee and ankle than in the hip or shoulder. It may also arise from the immoderate use of mercury, and, in particular constitutions, from rheumatism and general debility of the system. In these instances it often leaves one joint and attacks another; and it is less severe, and less disposed to produce effusion of coagulating lymph, or a thickened state of the membrane, than when it is apparently a local disease. (*Brodie, in Med. Chir. Trans. Vol. 4. p. 218.*) In the latter case the disorder is more likely to assume a severe character, and may be of long duration, leaving the joint with its functions more or less impaired, and occasionally terminating in its total destruction. The following are the chief symptoms of the complaint, pointed out by Mr. Brodie. At first, although some pain is felt over the whole joint, the patient refers it principally to one spot, and it is not at its height before the end of a week or ten days. Sometimes, even at this period, the pain is trifling, but sometimes it is considerable, and every motion of the joint is distressing. In a day or two after the commencement of the pain, the joint is affected with swelling, which at first arises entirely from a collection of fluid in its cavity, and, in the superficial joints, an undulation may be distinguished. However, after the inflammation has prevailed some time, the fluid is rendered less perceptible, either in consequence of the synovial membrane being thickened, or the effusion of lymph; and the more solid the swelling is, the more is the mobility of the joint impaired. The form of the diseased joint does not correspond to that of the heads of the bones: but, as the swelling is

chiefly caused by the distention of the synovial membrane, "its figure depends in a great measure on the situation of the ligaments and tendons, which resist it in certain directions, and allow it to take place in others. Thus, when the knee is affected, the swelling is principally observable on the anterior and lower part of the thigh," where there is only a yielding cellular structure between the extensor muscles and the bone. "It is also often considerable in the spaces, between the ligament of the patella and the lateral ligaments, because at these points the fatty substance is propelled outward by the collection of fluid. In the elbow, the swelling occurs principally above the olecranon, under the extensor muscles of the forearm; and in the ankle, it is between the lateral ligaments and the tendons in front of the joint. In the hip and shoulder, where the disease is less frequent, the fluid cannot be felt, but the swelling is perceptible through the muscles. In the beginning of this disease in the hip, a fulness both in the groin and nates may be remarked; but afterward the nates become flattened, and the glutæi wasted from want of use. The pain is usually confined to the hip, but Mr. Brodie has seen cases in which it was also referred to the knee. It may be discriminated from the case in which the cartilages of the hip are ulcerated, by observing, that the pain is more severe in the beginning than in the advanced stage of the disease; it never amounts to the excruciating sensation felt in the other disease; and it is aggravated by motion, but not by pressing the cartilaginous surfaces against each other. The wasting of the glutæi is also preceded by a fulness of the nates. After the inflammation has subsided, the fluid is absorbed, and the joint frequently regains its natural figure and mobility; but, in the majority of cases, stiffness and swelling remain, and the patient continues very liable to relapse, the pain returning, and the swelling being augmented, whenever the patient exposes himself to cold, or exercises the limb a great deal. In cases where the synovial membrane is thickened, a slow kind of inflammation sometimes continues in the part, notwithstanding the fluid has been absorbed, and the principal swelling has subsided, the disease at length extending to the cartilages, suppuration taking place, and the articular surfaces being completely destroyed. According to Mr. Brodie, in this advanced stage, the history of the disease, and not its present appearance, is the only thing by which one can learn whether the primary affection was inflammation of the synovial membrane, or ulceration of the cartilages. Though such is the most common character of inflammation of the synovial membrane, it is admitted, that its nature is sometimes more acute, exhibiting the symptoms mentioned at the beginning of this section. (See *Brodie's Pathol. and Surg. Obs. p. 21, &c.*) It is remarked by Mr. Wilson, that, when coagulable lymph is effused, the whole of it does not always adhere to the inflamed sur-

face, but some of it forms flakes which float in the fluid within the joint in masses large enough to be sometimes felt through the capsular ligament. In other instances, the lymph becomes solid, adheres to the inside of the synovial membrane, and becomes vascular. The surface of this adventitious coating is sometimes smooth; but, occasionally, it forms thick projecting masses, of different degrees of thickness and length, and so numerous as to conceal every part of the original smooth surface of the synovial membrane, as exemplified in a preparation in Windmill-street. (*On the Skeleton and Diseases of Bones and Joints*, p. 319.)

When inflammation of the synovial membrane has arisen from a protracted or ill-conducted course of mercury, Mr. Brodie recommends a trial of sarsaparilla; and when the disorder is connected with rheumatism, the medicines advised are opium with diaphoretics, preparations of colchicum autumnale, and other usual remedies for rheumatic complaints. In some instances, however, in which several joints were affected, this gentleman has known benefit derived from moderate doses of mercury, (p. 31.) But whether the disease be local, or dependent on the state of the constitution, Mr. Brodie considers topical remedies of most importance.

It will considerably shorten what we have to say concerning the treatment of inflamed joints, to observe, that, in the acute form of inflammation of the synovial membrane, the antiphlogistic plan, in the full sense of the expression, is to be strictly adopted. But, as there is a variety of means often adapted to the same purpose, it seems necessary to offer a few remarks on those which lay the greatest claim to our commendations.

There are few other surgical cases in which general, and especially topical, bleeding is more strongly indicated. The violence of the inflammation, and the strength, age, and pulse of the patient, must determine with regard to the use of the lancet; but the application of leeches may be said to be invariably proper. When the leeches fall off, the bleeding is to be promoted by fomenting the part. The surgeon should daily persist in this practice, until the acute stage of the inflammation has subsided. As Mr. Brodie observes, attention should also be paid to the state of the bowels, and saline draughts and diaphoretic medicines be exhibited. (*Pathol. and Surgical Obs.* p. 32.) In conjunction with this treatment, the lotio plumbi acetatis must be employed.

In a few instances, however, the patient seems to derive more ease and benefit from the employment of fomentations and emollient poultices, which, according to Mr. Brodie, is the case when the swelling has been produced rapidly, and is attended with considerable tension. But, on this point, as I have remarked in speaking of *Inflammation*, the feelings of the afflicted should always be consulted; for, if the pain be materially alleviated by this or that application, its employment will hardly ever be wrong.

Nothing more need be said concerning the rest of the treatment, proper during the vehemence of the inflammation, as the duty of the surgeon is not materially different from what it is in other inflammatory cases.

As soon as the acute stage of the affection has subsided, the grand object is to remove the effects which have been left. These are a thickened state of the capsular ligament, and parts surrounding the articulation; a stiffness of the joint, and pain when it is moved; fluid in the capsule, &c.

At first, as Mr. Brodie has observed, the joint should be kept perfectly quiet, and blood should be several times taken from the part, by means of leeches and cupping. The latter is the method to which the preceding writer expresses the preference. The use of cold evaporating lotions is also to be continued until the inflammation has further abated, when a blister may be applied, and kept open with the savin cerate, or a repetition of blisters kept up, as preferred by Mr. Brodie. "The blisters (he says) should be of considerable size; and if the joint be deep-seated, they may be applied as near to it as possible; but, otherwise, at a little distance. Thus, when the synovial membrane of the hip is affected, they may be placed on the groin and nates; but, when that of the wrist is inflamed, they should be applied to the lower part of the forearm. Mr. Brodie thinks blisters have more effect than any other means, in removing the swelling; but, excepting in very slight cases, he very rightly condemns their use, unpreceded by the abstraction of blood. After the subsidence of the inflammation, moderate exercise of the joint, and stimulating liniments are recommended. The camphor liniment is to be strengthened with the addition of liquor ammoniæ or tinctura lyttæ, or the following formula, adopted as that to which the above gentleman seems to give the preference. *R. Olei olivæ ʒiiss. acid. sulph. ʒss. M.* He speaks also favourably of the effects of the antimonial ointment, in the proportion of ʒj. of the antim. tart. to ʒj. ung. cetacei. Plasters of gum ammoniac he regards as sometimes useful in preventing relapsus. Issues and setons are never serviceable, unless ulceration of the cartilages has begun. For the removal of the remains of the swelling and stiffness, Mr. Brodie joins other writers in praising the efficacy of friction and exercise. The friction may be made with camphorated mercurial ointment, or with powdered starch; but the friction is to be employed with caution, as otherwise it may produce a return of the inflammation. When this happens, it is to be discontinued, and blood taken from the part. On the whole, Mr. Brodie appears to consider friction better adopted to cases, where the stiffness depends upon the state of the external parts, than in others, where it arises from disease in the joint itself. With respect to the plan of allowing a column of warm water to fall on the part, as suggested by Le Dran, and practised at the watering-places.

he allows, that it is beneficial, but that it requires the same caution as the employment of friction. (*Pathol. and Surg. Obs.* p. 30, &c.)

I have met with several instances, in which lotions, composed of vinegar and muriate of ammonia, sufficed for the removal of the chronic complaints, left after the acute stage of the disorder.

The severity of the constitutional symptoms is mostly, if not always, greater, when the inflammation of a large joint arises from a wound, than when it is the consequence of a bruise or sprain.

Loose cartilages in joints.—Hard, roundish, or flattened bodies, mostly of a cartilaginous nature, are sometimes formed within the capsular ligaments, occasioning more or less pain in the affected joints, and a considerable impediment to the freedom of their movements. The disorder, though not noticed by any of the very ancient writers, is far from being uncommon. Paré is the first who speaks of it: he says, that a *hard, polished, white body, of the size of an almond*, was discharged from the knee of a patient, in the year 1558, in which he had made an incision for an *aqueous apostume*, (without doubt an hydrops articuli.) (*Liv.* 25, *chap.* 15, p. 772.) A hundred and thirty-three years afterward, viz. in 1691, Pechlin published the full details of another case, in which a cartilaginous body was successfully extracted from the knee. (*Observat. Physico-Med.* *Obs.* 38, p. 306.) Dr. Alexander Monro in 1728, dissected the knee-joint of a woman, who had been hung, and found in the articulation a cartilaginous body, of the shape and size of a small bean. These were the only examples of the disease known before the year 1736, at which period Mr. Simson cut out of the knee a similar substance, which he supposed at the time of the operation was only beneath the skin. (See *Edinb. Med. Essays*, Vol. 4.)

Since the publication of this last case, the disease has been several times met with in England by Bromfield, Hewit, Middleton, Gooch, Ford, Home, Bell, Abernethy, &c.; in Germany, by Henckel, Theden, Loeffler, &c.; and in France by Desault, Sabatier, and many other practitioners. Hence, as Boyer remarks, this disorder is now as well known, as most others, to which the joints are subject. (*Traité des Mal. Chir.* T. 4, p. 434.)

Such detached and moveable cartilages are not peculiar to the knee, as they occur in other joints; yet they are most frequently met with in the knee, and it is in this joint that they produce symptoms, which render them the object of a surgical operation. Morgagni and B. Bell met with them in the ankle; Haller in the joint of the jaw; and Hey in the elbow.

According to Sir Everard Home, these substances are analogous in their structure to bone; but in their external appearance, they bear a greater resemblance to cartilage. They are not, however, always exactly of the same structure, being in some instances

softer than in others. Their external surface is smooth and polished, and, being lubricated by the synovia, allows them to be moved readily from one part of the joint to another. They seldom remain long at rest, while the limb is in motion; and when they happen to be in situations where they are pressed upon with force by the different parts of the joint, they occasion considerable pain, and materially interfere with its necessary motions.

The circumstance of their being loose, and having no visible attachment, made it difficult to offer good conjectures respecting their formation; and, according to Sir E. Home, no satisfactory account of their origin had been given, when Mr. Hunter made his observations. In the course of his experiments, instituted with a view to establish a living principle in the blood, Mr. Hunter was naturally induced to attend to the phenomena, which took place, when that fluid was extravasated, whether in consequence of accidental violence, or other circumstances. The first change he found to be coagulation; and the coagulum thus formed, if in contact with living parts, did not produce an irritation similar to extraneous matter, nor was it absorbed and taken back into the constitution, but in many instances preserved its living principle, and became vascular, receiving branches from the neighbouring blood-vessels for its support; it afterward underwent changes, rendering it similar to the parts to which it was attached, and which supplied it with nourishment. When a coagulum adhered to a surface, which varied its position, the attachment was rendered in some instances pendulous, and in others it was entirely broken.

Hence, it was easy to explain the mode, in which those pendulous bodies are formed, which are sometimes attached to the inside of circumscribed cavities, and the principle being established, it became equally easy for Mr. Hunter, to apply it under other circumstances, since it is evident from a known law in the animal economy, that extravasated blood, when rendered an organized part of the body, can assume the nature of the parts into which it is effused, and consequently, the same coagulum, which, in another situation might form a soft tumour, would when situated on a bone, or in the neighbourhood of bone, often form a hard one. The cartilages, found in the knee-joint, therefore, appeared to him to originate from a deposit of coagulated blood upon the end of one of the bones, which had acquired the nature of cartilage, and had afterward been separated. This opinion was further confirmed by the examination of joints which had been violently strained, or otherwise injured, where the patients had died at different periods after the accident. In some of these cases, there were small projecting parts, preternaturally formed, as hard as cartilage, and so situated, as to be readily knocked off by any sudden or violent motion of the joint. (*Trans. for the*

Improvement of Med. and Chir. Knowledge, Vol. 1.)

Mr. Brodie met with two cases, however, in which the loose bodies were of a different nature, and had a different origin from that referred to by Sir. E. Home. Sometimes disease causes a bony ridge to be formed, like a small exostosis, round the margin of the cartilaginous surfaces of the joint. In the two examples alluded to, this preternatural growth of bone had taken place, and in consequence of the motion of the parts, portions of it had been broken off, and lay loose in the cavity of the joint. (*Brodie in Med. and Chir. Trans. Vol. 4 p. 276.*) And, in a more recent publication, he remarks, that, in the majority of cases, which he has met with, no inflammation preceded the formation of these preternatural substances, and, therefore, he thinks it probable, that, in some instances, they are generated, like other tumours, by some different process. He further observes, that they appear to be situated originally either on the external surface or in the substance of the synovial membrane, since, before they become detached, a thin layer of the latter may be traced over them. (*Pathological and Surgical Obs. p. 298.*)

One or more of these preternatural bodies may be formed in the same joint. Sir E. Home mentions one instance, in which there were three; they are commonly about the size of a horsebean, often much smaller, and sometimes considerably larger; when very large, they do not give so much trouble to the patient as the smaller kind. A soldier of the 56th regiment had one nearly as big as the patella, which occasioned little uneasiness, being too large to insinuate itself into the moving parts of the joint. Morgagni saw twenty-five in the left knee of an old woman, who died of apoplexy; and Haller met with no less than twenty in the articulation of the lower jaw. When there are several in the same joint, it is observed, that their size is generally small. (*Boyer, Traité des Mal. Chir. T. 4, p. 436.*)

The diagnosis of this disease, as Boyer observes, is seldom attended with any difficulty. When the formation of the extraneous substances follows a fall, or blow upon the joint, the complaint begins with a swelling of the surrounding soft parts, and upon the subsidence of this swelling, which lasts for a time more or less long, the presence of the little cartilaginous tumours is indicated by certain symptoms which are peculiar to them. In persons who have had no blow, nor fall upon the knee, the disease sometimes commences with a more or less acute pain in the joint, with or without swelling of the surrounding soft parts, and which affection is usually regarded as rheumatism. To these first symptoms, which are common both to cases of foreign bodies in the joints, and other diseases of these parts, are soon added other particular signs, by which the nature of the case is evinced.

As the extraneous bodies are in general free and moveable in the joint, they can

easily be made to slip about from one part of the articulation to another: a circumstance, which is facilitated by the smoothness of their surface, as well as by the synovial fluid, which is mostly in larger quantity than natural. According to the situation, which they happen to occupy, sometimes they produce acute pain; sometimes no pain whatever. When they lodge in a depression, where they are not compressed, they cause no pain; and if they could be always kept in this position, their presence would not be likely to excite any inconveniences. But, when they get between the articular surfaces, which in certain postures of the limb come into contact with each other, the following are the effects of the compression. Sometimes, the extraneous substance suddenly glides between the condyles of the thigh bone and head of the tibia, and while it lodges there, excites acute pain in certain directions of the limb, and instantaneous loss of the power of moving the knee. But, when it shifts its place again, either naturally, or accidentally, during an examination of the affected part, the compression is removed, the pain all at once ceases, and the functions of the joint are as suddenly restored. Most frequently, when the extraneous body gets behind the patella, or the ligament of the patella, as the patient is walking, he is compelled to make a sudden stop, and would fall down from the acuteness of the pain, if nothing were at hand to save him. Some patients have been observed, however, who experienced no pain in these circumstances. Reimarus mentions a man, who suffered great pain, and could not move his leg, when the extraneous body was at the side of the joint; but was immediately relieved by pushing it under the patella. B. Bell met with cases, in which the pain was so violent at the instant when the patients put their legs in certain postures, that fainting was brought on, and they were so afraid of a return of the suffering, that they preferred remaining perfectly quiet to running any risk of causing the pain again. He even asserts, that he had known some persons, in whom the least motion of the limb would cause such pain as awoke them out of the deepest sleep. The pain, excited by the situation of the extraneous body betwixt the articular surfaces, recurs at intervals more or less long, and always in consequence of some motion, or exertion. Sometimes it ceases directly by the effect of a movement, contrary to that which produced it; but most frequently it continues, and then the surrounding soft parts are affected with swelling, which obliges the patient to keep his bed, and have recourse to emollient anodyne applications. Sometimes, as I have already noticed, the foreign body lies at a part of the joint, where it causes no inconvenience, and makes no pressure on the articular surfaces. In this case, all the symptoms have been known to cease for several months, so that the patient imagined himself cured, when suddenly, the foreign body was urged by some effort into another situation, where it

occasioned a renewal of all the former pain.

The foregoing circumstances afford strong presumptive evidence of the presence of extraneous cartilaginous substances in the joint; but, they do not amount to certainty: this can only be acquired by the touch. In handling the knee of the patient, the surgeon feels a hard, prominent substance, which slips about under his fingers, and glides under the patella, or the ligament of this bone, and sometimes under the tendon of the extensor muscles of the leg, from one side of the joint to the other. The extraneous body may make its appearance either at the inside or the outside of the articulation; but, it most frequently presents itself at the former part, which is the broadest and most sloping, while the capsular ligament there is loosest. Desault met with one instance, in which the capsular ligament and soft parts were so loose, that the patient could turn the extraneous substance round and round.

In general, the complaint is not dangerous; but, as it is painful, and obstructs, or often prevents walking; and usually can be cured only by an operation, which has sometimes had fatal consequences; we cannot be too much upon our guard in delivering a prognosis.

It is only in the knee, that the disease ever becomes so troublesome as to require an operation, or, indeed, any surgical treatment.

If we except making an incision into the joint, for the purpose of extracting the cartilaginous tumours, we are not acquainted with any certain means of freeing a patient from the inconvenience of the complaint. To this plan, the danger attendant on all wounds of so large an articulation as the knee, is a very serious objection. Middleton and Gooch endeavoured to conduct the extraneous body into a situation, where it produced no pain, and to retain it in that position a long time by bandages, under the idea, that the cartilaginous substance would adhere to the contiguous parts, and occasion no future trouble. Some will be inclined to think, that no positive conclusion ought to be drawn from the cases brought forward by these gentlemen, because they had no opportunity of seeing their patients again at the end of a reasonable length of time, and we know, that loose cartilages in the joints sometimes disappear for half a year, and then make their appearance again. Yet, perhaps, the very circumstance of the patients not applying again, may justify the inference, that sufficient relief had been obtained.

However, it should not be concealed, that this method was also tried in St. George's Hospital without benefit, and that in one case, the pain was increased by it. (See *Reimarus de Fungo Articulorum*, §27, 54, &c.)

Mr. Hey, aware of the dangerous symptoms, which have occasionally resulted from the most simple wounds penetrating the knee-joint, was induced to try the efficacy of a laced knee-cap, and the cases, which

he has adduced, clearly demonstrate, that the benefit thus obtained, is not temporary, at least, as long as the patient continues to wear the bandage. In one case, the method had been tried for ten years, with all the success which the patient could desire. Boyer also made one patient use a knee-cap for a year; after which it was left off, the patient appearing cured. And, in a second instance, the same practitioner tried the plan, which put a stop to the pain, and enabled the patient to walk with ease; but it was not known whether the method was properly continued, as the patient had not latterly been seen. (*Boyer, Traité des Mal. Chir. T. 4, p. 444.*)

Contemplating the evidence upon this point, and the perilous symptoms, sometimes following wounds of the knee-joint, I am decidedly of opinion, that the effect of a knee-cap, or of a roller and compress, applied over the loose cartilage, ought generally to be tried, before having recourse to excision. I say generally, because the conduct of the surgeon ought, in such cases, to be adapted to the condition and inclination of the patient. If a man be deprived of his livelihood, by not being able to use his knee; if he cannot, or will not take the trouble of wearing a bandage; if he be urgently desirous of running the risk of the operation after things have been impartially explained to him; if a bandage should not be productive of sufficient relief; and lastly, if excessive pain, severe inflammation of the joint, a great deal of symptomatic fever, and lameness, should frequently be produced by the complaint, (See *Brodie's Pathological and Surg. Obs. p. 299.*) I think it is the duty of a surgeon to operate. It is very certain, that success has generally attended the operation; but, small as the chance is of losing the limb, and even life, in the attempt to get rid of the disease, since the inconveniences of the complaint are, in most cases, very bearable, and are even capable of palliation by means of a bandage, endangering the limb and life in any degree, must seem to many persons contrary to the dictates of prudence. At all events, we must agree with Boyer, that, as a laced knee-cap can do no harm, we ought always to make trial of it, and never perform the operation, except when pressure does not answer, and the return of frequent and violent pain makes the employment of the knife necessary. (See *Traité des Mal. Chir. T. 4, p. 445.*)

I am ready to allow, with M. Brochier, that the danger attendant on wounds of the large joints, has always been exaggerated in consequence of ancient prejudices. (*Desault's Journ. Vol. 2.*) But, making every allowance for the influence of prejudice, a man must be very sceptical indeed, who does not consider the wound of so large a joint as the knee, attended with real cause for the apprehension of danger. See Case 2, in my *Treatise on the Diseases of the Joints*. At the end of Mr. Ford's case, (*Med. Obs. and Inquiries, Vol. 5.*) we read on the subject of cutting loose cartilages out of the knee:

"The society have been informed of several cases, in which the operation has been performed; some, like this, have healed up without any trouble; others have been followed by violent inflammation, fever, and death itself." The history of a case has lately been published, in which the patient very nearly lost his life from suppuration in the knee-joint after this operation. (See *Kirby's Cases*, p. 75.) In the same work, reference is also made to two other cases, which actually had a fatal termination; (p. 82:) and even in Mr. Kirby's own instance, the recovery was not effected, without the entire loss of the motions of the knee.

As the disorder is often attended with a degree of heat and tenderness in the articulation; as the danger of the operation is, in a great measure, proportioned to the subsequent inflammation; and, as much of the danger is at once removed, if the wound unite by the first intention; the advice to keep the patient in bed a few days before operating, to apply leeches and cold saturnine lotions to the knee during the same time, and to exhibit beforehand a saline purgative, is highly prudent.

I shall next introduce an account of the plan of operating, as described by several of the best modern surgeons.

"As these loose bodies cannot always be found, no time can be fixed for the operation; but the patient, who will soon become familiar with his own complaint, must arrest them when in a favourable situation, and retain them there till the surgeon can be sent for.

"Before the operation, the limb should be extended upon a table in an horizontal position, and secured by means of assistants; the loose cartilages are to be pushed into the upper part of the joint above the patella, and then to one side; the inner side is to be preferred, as in that situation only the vastus internus muscle will be divided in the operation. Should there be several of these bodies, they must be all secured, or the operation should be postponed till some more favourable opportunity, since the leaving of one will subject the patient to the repetition of an operation, not only painful, but attended with some degree of danger.

"The loose bodies are to be secured in the situation above-mentioned by an assistant, a task not easily performed while they are cut upon, from their being lubricated by the synovia; and if allowed to escape into the general cavity, they may not readily, if at all, be brought back into the same situation.

"The operation consists in making an incision upon the loose cartilage, which it will be best to do in the direction of the thigh, as the wound will more readily be healed by the first intention. If the skin is drawn to one side, previously to making the incision, the wound through the parts underneath will not correspond with that made in the skin, which circumstance will favour their union. The incision upon the cartilage must be made with caution, as it will with

difficulty be retained in its situation if much force is applied. The assistant is to endeavour to push the loose body through the opening, which must be made sufficiently large for that purpose; but as this cannot always be done, the broad end of an eyed probe may be passed under it, so as to lift it out, or a sharp-pointed instrument may be stuck into it, which will fix it to its situation, and bring it more within the management of the surgeon.

"The cartilages being all extracted, the cut edges of the wound are to be brought together, and, by means of a compress of lint, not only pressed close to one another, but also to the parts underneath, in which situation they are to be retained by sticking plaster, and the uniting bandage.

"As union by the first intention is of the utmost consequence after this operation, to prevent an inflammation of the joint, the patient should remain in bed with the leg extended, till the wound is perfectly united, or at least all chance of inflammation at an end." (*Home, in Trans. for the Improvement of Med. and Chir. Knowledge*, Vol. 1, p. 239, &c.)

In one instance, Desault proceeded in the following manner: the surgeon, after relaxing the capsular ligament by extending the leg, brought the extraneous body on the inside of the articulation against the attachment of the capsular ligament, and secured it in this situation, between the index finger and thumb of the left hand, whilst an assistant drew the integuments forwards towards the patella. The parts, covering this extraneous body, were now divided by an incision one inch in length, and its extraction accomplished by pushing it from above downwards, and raising it inferiorly with the end of the knife. This substance, on examination, was found similar in colour to the cartilages that cover the articular surfaces: it was three-quarters of an inch in length, six lines and a half in width, and three lines in thickness; its surfaces were smooth, one concave and the other convex: its circumference irregular, disseminated with red points, forming small depressions; the inside was ossified, the outside of a cartilaginous texture. As soon as the substance was extracted, the assistant let go the integuments which he had drawn forwards; they consequently returned to their natural situation, on the inner side of the knee-joint, in such a manner, that the external wound in the integuments was situated more inward, than the one in the capsular ligament. Two advantages were procured by this means: on the one hand, air was prevented from penetrating into the articulation; and on the other, the floating portion of capsular ligament, retained inwards by the skin, was more likely to attach itself to the condyle, in case it did not unite to the other portion of the capsule divided near its attachment. The edges of the wound were brought into contact by means of a uniting bandage; dry lint and compresses were applied, and retained on the part by a slight bandage; and the limb

was kept in a state of extension. (*Desault's Journal*, T. 2.) According to Mr. Abernethy, the inner surface of the internal condyle of the os femoris presents an extensive and nearly a plain surface, which terminates in front and at its upper part by an edge which forms a portion of a circle. If the points of the finger be firmly pressed upon this edge so as to form a kind of line of circumvallation round these (cartilaginous) bodies, they cannot pass into the joint in this direction, nor can they recede in any other, on account of the tense state of the internal lateral ligament. Here these substances are near the surface, and may be distinctly felt: and they may be exposed by simply dividing the integuments, fascia, and the capsule of the joint.

In an interesting case, which Mr. Abernethy relates, the integuments of the knee were gently pressed towards the internal condyle, and the fingers of an assistant applied round the circular edge of the bone. The integuments were gently drawn towards the inner ham-string, and longitudinally divided, immediately over the loose substance, to the extent of an inch and an half. This withdrawing of the integuments from their natural situation was designed to prevent a direct correspondence of the external wound to that in the capsule of the joint: for, when the integuments were suffered to regain their natural position, the wound in them was nearer to the patella, than the wound in the capsule. The fascia, which covers the joint, having been exposed by the division of the integuments, it was divided in a similar direction, and nearly to the same extent. The capsule was now laid bare, and gently divided to the extent of half an inch, where it covered one of the hard substances, which suddenly slipped through the opening, and by pressing gently upon the other, it was also discharged. The bodies, thus removed, were about three-quarters of an inch in length, and half an inch in breadth. They had a highly polished surface, and were hard like cartilage. The fluid contained in the joint was pressed toward the wound, and about two ounces of synovia were discharged. The wound of the integuments was then gently drawn towards the patella, and accurately closed with sticking plaster. (*Surgical Observations*, 1804.)

When there are several extraneous cartilaginous bodies in the joint operated upon, the surgeon ought to extract them all through the same wound, if it can be done without producing too much irritation of the capsular ligament, and they will admit of it. But, frequently, only one can be made to present itself at a time, or can be easily extracted. Each little tumour will then require a separate operation, which is a far safer plan, than disturbing the part by long and repeated attempts to extract them all at once. (*Boyer, Traité des Mal. Chir.* T. 4, p. 448.) The surgeon is also often obliged to make his incision at a particular point, because at no other can the extraneous sub-

stance be fixed. A case confirming all these latter observations was lately published by Dr. Clarke. (*See Med. Chir. Trans.* Vol. 5, p. 67.) In this instance, the operation was thrice performed upon the same knee-joint, with perfect success. Mr. Brodie also extracted five loose cartilages, by three different operations, without any subsequent unpleasant symptoms, although the patient appears to have been previously subject to repeated attacks of severe inflammation of the joint. (*Pathological and Surg. Obs.* p. 299.)

On the preceding subject some observations and two successful operations have been lately published by Baron Larrey. (*See Mémoires de Chir. Militaire*, T. 2, p. 421, &c.) With the exception of a few wrong theories, he appears to have given a fair account of the disease.

Hydrops Articuli signifies a collection of serous fluid in the capsular ligament of a joint. The knee is more subject, than other joints, to dropsical disease, which has been known, however, to affect the wrist, ankle, and shoulder joints. (*Boyer, Traité des Mal. Chir.* T. 4, p. 456.)

Mr. Russel adopted the opinion, that some cases of this kind are venereal, and others scrofulous; but, he has not supported the doctrine on any solid foundation. *Hydrops articuli* generally arises from contusions, rheumatism, sprains, exposure to severe cold, the presence of extraneous cartilaginous bodies in the joint, and in general from any thing, which irritates the capsular ligament; and, as already explained, it is a common attendant on inflammation of the synovial membrane; the complaint also sometimes follows fevers; but, in most instances, it is purely a local affection, quite independent of general debility. (*Boyer, T. 4, p. 467.*)

Hydrops articuli presents itself in the form of a soft tumour; circumscribed by the attachments of the capsular ligament; without change of colour in the skin; accompanied with a fluctuation; it is indolent, and very little painful; causing hardly any impediment to the motion of the joint; yielding to the pressure of the finger, but not retaining any impression, as in oedema. The swelling does not occupy equally every side of the joint, being most conspicuous where the capsular ligament is loose and superficial. In the wrist it occurs at the anterior and posterior parts of the joint, but, especially, in the former situation, while it is scarcely perceptible at the sides. In the ankle, it is more apparent in front of the malleoli, than any where else; and, in the shoulder, it does not surround the joint, but is almost always confined to the forepart of it, and can only be seen in the interspace between the deltoid and great pectoral muscles.

In the knee joint, which is the common situation of *hydrops articuli*, the tumour does not occur behind the articulation; but at the front and sides. Behind, the capsular ligament is too narrow to admit of being

much distended with the synovia; while, in front, and laterally, it is broad, so that it can there yield considerably in proportion as the quantity of fluid increases. The swelling is at first circumscribed by the attachments of the capsular ligament; but, in consequence of the accumulation of fluid, it afterward exceeds these limits above, and spreads more or less upward between the thigh bone and the extensor muscles of the leg, which are lifted up by it. Boyer has seen it reach to the upper third of the thigh. The swelling is irregular in shape: it is most prominent where the capsular ligament is wide and loose, and it is in some measure divided longitudinally into two lateral portions, by the patella, the ligament of the patella, and the tendon of the extensor muscles of the leg, all which parts the synovia raises, and pushes forward, though in a much less degree than the capsular ligament. Of these lateral portions, the internal is broadest and most prominent, because the part of the capsule between the patella and edge of the internal condyle being larger than that situated between the patella and edge of the external condyle, yields in a greater degree to the distending fluid. The motions of the leg, which are generally little interrupted by this disease, make a difference in the shape and consistence of the swelling. In flexion, the tumour becomes harder, tenser, and broader, and more prominent at the sides of the knee-pan, which is somewhat depressed by its ligament. In extension, the tumour is softer, and the fluctuation plainer.

In order to feel distinctly the fluctuation, which is one of the best symptoms of the disease, the ends of two or three fingers should be placed on one side of the swelling, while the opposite side is to be struck with the end of the middle finger of the other hand.

The patella, being pushed forward, away from the articular pulley, is very moveable, and, as it were, floating. When it is pressed backward, while the leg is extended, it can be felt to move a certain way before it meets with the resistance of the articular pulley. And on the pressure being discontinued, it immediately separates from this part again.

By such symptoms, hydrops articuli may easily be distinguished from other diseases of the joints, from tumours of the bursa mucosa under the extensor tendons of the leg; from ganglions in front of the knee-pan; from rheumatism; œdema, &c.

The prognosis is most favourable, when the swelling is recent and small, and has been quick in its progress. On the contrary, when the tumour is of long standing and large; the effused fluid thick and viscid; and the synovial membrane thickened; the removal of the fluid by absorption, and the restoration of the parts to their natural state, will be more slow and difficult. The worst case is that which is complicated with disease of the capsular ligament, cartilages, and bones.

The cure of the above-described dropsical affection of the joints, depends upon the

absorption of the effused fluid. And, when the case is combined with acute or chronic inflammation of the synovial membrane, the treatment is the same as that already recommended for those particular forms of disease. When inflammation subsides, the absorption of the fluid is sometimes altogether spontaneous, and it may always be promoted, by mere friction, by rubbing the joint with camphorated mercurial ointment, and particularly, by the employment of blisters.

The operation of a blister may be very materially assisted with a moderately tight bandage. Among other effectual means of cure, we may enumerate frictions with flannel impregnated with the fumes of vinegar; electricity; and the exhibition of mercurial purgatives. When hydrops articuli occurs during the debility, consequent to typhoid, and other fevers, the complaint can hardly be expected to get well, before the patient has regained some degree of strength.

As, however, hydrops articuli is generally quite a local disease, Boyer contends, that it should be chiefly treated with topical remedies; and he sets down diuretics, sudorifics, hydragogues, &c. as improper or inefficient. (*Op. cit.* p. 467.) He is strongly in favour of repeated blisters, both for the prevention and cure of the disease.

Circumstances do not often justify making an opening into the joint: but, excessive distention, in some neglected cases, might certainly be an urgent reason for performing such an operation. Also, if the complaint should resist all other plans of treatment, and the irritation of the tumour greatly impair a week constitution, the practice would be justifiable. An interesting example of this kind is related by Mr. Latta. (*System of Surgery*, Vol. 2, p. 490.)

It is best to make the opening in such a way, that the wound in the capsular ligament after the operation, will not remain directly opposite the wound in the skin. For this purpose, the integuments are to be pushed to one side, before the surgeon divides them. (*Encyclopédie Méthod. Part. Chir. Art. Hydropsie des Jointures.*)

The operation is not always successful, being sometimes followed by alarming symptoms, which either end fatally, or occasion a necessity for amputation. The fluid also generally collects again, and as the synovial membrane is mostly thickened, it often inflames, and suppuration in the joint ensues. Hence, when hydrops articuli originates from rheumatism; when it is recent, indolent, and not large; and when it does not seriously impair the functions of the joint; Boyer recommends the operation not to be done. But, he sanctions its performance, when the disease is combined with extraneous cartilaginous bodies in the joint: or when it is very considerable, attended with severe pain, and impairment of the functions of the joint. (*Op. cit.* T. 4, p. 473.)

Collections of Blood in Joints.—Most systematic writers speak of this kind of case,

though it must be uncommon. Tumours about the joints, composed of blood, and set down in numerous surgical works, as extravasations within the capsular ligaments are generally on the outside of them.

Certainly, if a collection of fluid were to take place in a joint immediately after a sprain, or contusion, and to continue to increase gradually for some time afterward, there would be reason to believe most of the contents of the tumour to be blood. The production of an abscess, and the secretion of any fluid, would have required a longer time.

Were blood known to be undoubtedly effused in a large articulation, however, no man would be justified in making an opening for its discharge. No bad symptoms are likely to result from its mere presence, and the absorbents will, in the end, take it away. If an incision were made into the joint, the coagulated state of the extravasated blood would not allow such blood to be easily discharged.

The best plan is to apply discutient remedies; a lotion of vinegar, spirits of wine, and muriate of ammonia for the first three or four days; and afterward, friction with camphorated liniments may be safely adopted.

Mr. Hey relates a case, in which the knee-joint was wounded, and blood insinuated itself into the capsular ligament; yet though the occurrence could not be hindered, no harm resulted from the extravasation, which was absorbed, without having created the smallest inconvenience. (*Practical Obs. in Surgery*, p. 354.)

White Swelling.—The white swelling, or spina ventosa, as it was at one time not unfrequently called, in imitation of the Arabian writers, Rhazes and Avicenna, has been a name indiscriminately applied to many diseases, which differ widely in their nature, curability, and treatment. Wiseman was the first who used the term White-Swelling; and if the expression did not confuse together complaints of very different kinds, not much fault could be found with it, because it unquestionably conveys an idea of one mark of some of these distempers, which is, that notwithstanding the increase of size in the joint, the skin is generally not inflamed, but retains its natural colour. (*Pott*.)

The name, therefore, appears objectionable, only inasmuch, as it has tended to prevent the introduction of a sufficient number of well-founded and necessary distinctions. Systematic writers have generally been content with a distinction into two kinds, viz. *rheumatic*, and *scrofulous*.

The last species of the disease they also distinguish into such tumours, as primarily affect the bones, and then the ligaments and soft parts; and into other cases, in which the cartilages, ligaments, and soft parts become diseased before there is any morbid affection of the bones.

Mr. Brodie has endeavoured to form a more correct classification of the different complaints, to which the term white-swelling

is applied; and his descriptions are valuable, because confirmed by extensive observation, and numerous dissections. With respect to the disease beginning in the ligaments, if the capsular ligaments be put out of consideration, it is, as this gentleman observes, a rare occurrence, and he has never met with a case, in which the fact was proved by dissection. (*Pathol. and Surgical Obs.* p. 7.)

1. The first case is inflammation of the synovial membrane, as described in the foregoing pages, especially that form of the disease which often arises from cold, and constitutes the disease formerly often termed a rheumatic white swelling.

2. Another form of disease, ordinarily comprised under the general name of white-swelling, has been particularly described by Mr. Brodie: the disease originates in the synovial membrane, which loses its natural organization, and becomes converted into a thick, pulpy substance, of a light brown, and sometimes of a reddish brown colour, intersected by white membranous lines, and from 1-4 to 1-2 of an inch, or even more than an inch in thickness. As this disease advances, it involves all the parts of which the joint is composed, producing ulceration of the cartilages, caries of the bones, wasting of the ligaments, and abscesses in different places. The complaint has invariably proved slow in its progress, and sometimes has remained nearly in an indolent state for many months, or even for one or two years; but (says Mr. Brodie) "I have never met with an instance, in which a real amendment was produced; much less have I known any in which a cure was effected." (*See Medico-Chir. Trans. Vol. 4, p. 220, &c.*) The whole, or nearly the whole of the synovial membrane has always been found affected; though if a very early examination were made, Mr. Brodie conceives that this might not be the case, and in one example, he found only a half of the membrane thus altered, while the rest was of its natural structure. (*Pathol. and Surg. Obs.* p. 94.) This gentleman further acquaints us, that the preceding affection of the synovial membrane is rarely met with, except in the knee, that he has never known an instance of it in the hip or shoulder; that it is peculiar to the synovial membrane of the joints; that he has never known an instance of it in other serous membranes, nor even in the synovial membranes, which constitute the bursæ mucosæ and sheaths of tendons; and that it generally takes place in young persons, under, or not much above the age of puberty. In fact, Mr. Brodie has not met with more than one instance, in which it occurred after the middle period of life. "In the origin of this disease, there is a slight degree of stiffness and tumefaction, without pain, and producing only the most trifling inconvenience. These symptoms gradually increase: at last, the joint scarcely admits of the smallest motion, the stiffness being greater than where it is the consequence of simple inflammation. The form of the swelling bears some resemblance to that in cases of inflammation of the synovial

membrane, but it is less regular. The swelling is soft and elastic, and gives to the hand a sensation as if it contained fluid. If only one hand be employed in making the examination, the deception may be complete, and the most experienced surgeon may be led to suppose, there is a fluid in the joint when there is none; but if both hands be employed, one on each side, the absence of fluid is distinguished by the want of fluctuation.

"The patient experiences little or no pain, until abscesses begin to form, and the cartilages ulcerate; and even then the pain is not so severe, as where the ulceration of the cartilages occurs as a primary disease, and the abscesses heal more readily, and discharge a smaller quantity of pus, than in cases of this last description. At this period, the patient becomes affected with hectic fever, loses his flesh, and gradually sinks, unless the limb be removed by an operation." (Brodie, in *Med. Chir. Trans. Vol. 5, p. 251, 252.*) In the majority of cases, this gentleman believes that the gradual progress of the enlargement, the stiffness of the joint without pain, and the soft elastic swelling without fluctuation, will enable the practitioner readily to distinguish this from all other diseases of the joints. However, when the diseased synovial membrane happens to be distended with a quantity of turbid serum and flakes of coagulable lymph, the complaint somewhat resembles in its feel and appearance that stage of common inflammation of the synovial membrane, where this part is left thickened, and more or less distended with coagulable lymph, but the impossibility of relieving the former case by the same means which cure the latter, and due attention to the history of the disease, will prove the difference between them. (Brodie, *Pathol. and Surg. Obs. p. 96.*)

3. Ulceration of the articular cartilages takes place in the advanced stage of several diseases of the joints, and it also exists in many instances as a primary affection, in the early stage of which, the bones, synovial membrane, and ligaments, are in a natural state. If neglected, it ultimately occasions the entire destruction of the articulation. It may be the consequence of inflammation of the cartilage itself, or of the bony surface, with which it is connected; but as Mr. Brodie further observes, in many instances, there are no evident marks of the disorder being preceded by any inflammatory action in one part or the other, and the inflammation, which afterward takes place, appears rather to be the attendant upon, than the cause of the ulcerative process. One striking peculiarity of ulceration of the articular cartilages is, that the process may take place without the formation of pus; for the disease often proceeds so far as to cause caries of the bones, and yet no purulent matter is found within the joint. (See Brodie's *Pathol. and Surgical Obs. &c. p. 102.*) The investigations of the same author dispose him to believe, that a conversion of these cartilages into a soft fibrous structure, is a frequent though not constant forerunner of ulceration. (P. 105.) When the ulceration of the cartilage occurs

in the superficial joints, it constitutes one of the diseases which have been known by the name of white-swelling. From cases which Mr. Brodie has met with, he is led to conclude, that when it takes place in the hip, it is this disease, which has been variously designated by writers, the "*morbis coxarius*," the "Disease of the Hip," the "Scrofulous Hip," the "Scrofulous Caries of the Hip Joint." At least, says Mr. Brodie, it is to this disease, that these names have been principally applied, though probably other morbid affections have been occasionally confounded with it. (*Med. Chir. Trans. Vol. 4, p. 236.*) The ulceration of the articular cartilages takes place as a primary disease, chiefly in children, or adults under the middle age. "Of sixty-eight persons affected with this disease, fifty-six (according to Mr. Brodie) were under thirty years of age: the youngest was an infant of about twelve months; the oldest was a woman of sixty. As the knee is more frequently affected by inflammation of the synovial membrane, so is the hip more liable, than other joints, to the ulceration of the cartilaginous surfaces. In general the disease is confined to a single joint; but it is not very unusual to find two or three joints affected in the same individual, either at the same time, or in succession. Sometimes the patient traces the beginning of his symptoms to a local injury, or to his having been exposed to cold, but for the most part, no cause can be assigned for the complaint." (See *Med. Chir. Trans. Vol. 6, p. 319.*)

The symptoms of the disease of the hip-joint will be described in the ensuing section, and we shall here confine our remarks to the symptoms characterizing ulceration of the cartilages of the knee, as pointed out by Mr. Brodie. They differ from those of inflammation of the synovial membrane, by the pain being slight in the beginning, and gradually becoming very intense, which is the reverse of what happens in the latter affection. The pain in the commencement is also unattended with any evident swelling, which never comes on in less than four or five weeks, and often not till after several months. It is not to be inferred, however, that every slight pain of the joint, unaccompanied with swelling, must of course arise from ulceration of the cartilages. But, says Mr. Brodie, when the pain continues to increase, and at last is very severe; when it is aggravated by the motion of the bones on each other, and when, after a time, a slight tumefaction of the joint takes place, we may conclude that the disease consists in such ulceration. The swelling arises from a slight inflammation of the cellular membrane on the outside of the joint: it has the form of the articulating ends of the bones; and for the most part it appears greater than it really is, in consequence of the muscles being wasted. No fluctuation is perceptible, as where the synovial membrane is inflamed; nor is there the peculiar elasticity, which exists where the synovial membrane has undergone a morbid alteration of its structure.

Mr. Brodie has explained, however, that

in some cases, the swelling has a different shape, and communicates the feel of a fluctuation. This happens when inflammation of the synovial membrane, attended with a collection of the synovia of the joint, or abscesses in the surrounding soft parts, or in the articulation itself, occur as secondary diseases. When there has been considerable destruction of the soft parts from abscesses and ulceration, the head of the tibia may become dislocated and drawn towards the ham. (*See Med. Chir. Trans. Vol. 6, p. 326, &c.*)

4. I shall pass over ulceration of the synovial membrane, which Mr. Brodie considers in a separate section, and now proceed to scrofulous white-swelling. In the scrofulous disease of the joints, the bones are primarily affected, in consequence of which, ulceration takes place in the cartilages covering their articular extremities. The cartilages being ulcerated, the subsequent progress of the disease (says Mr. Brodie) is the same as where this ulceration takes place in the first instance. (*Medico-Chir. Trans. Vol. 4, p. 266.*)

By Mr. Lloyd, scrofulous white swellings are divided into three stages; the first being that in which the affection is confined to the bone; the second, that in which the external parts become thickened and swelled; and the third being what he names the suppurative stage, attended with ulceration of the cartilages, inflammation of the synovial membrane, and abscesses. (*On Scrofula, p. 121.*) It was formerly a common notion, that in white-swellings, the heads of the bones were always enlarged. Mr. Russel, I believe, is the first writer who expressed an opposite sentiment, and he distinctly declares, that he had never heard, nor known of an instance in which the tibia was enlarged from an attack of white-swelling. (*P. 37.*) The inaccuracy of the opinion was afterward pointed out by Mr. Lawrence, to the late Mr. Crowthey, and the subject was mentioned in the earliest edition of the "First Lines of the Practice of Surgery."

Deceived by the feel of many diseased joints, and influenced by general opinion, I once supposed, that there was generally a regular expansion of the heads of scrofulous bones. But excepting an occasional enlargement, which arises from spiculae of bony matter, deposited on the outside of the tibia, ulna, &c. and which alteration cannot be called an expansion of those bones, I never until lately saw the head of a bone enlarged, in consequence of the disease known by the name of white-swelling. I was formerly much in the habit of inspecting the state of the numerous diseased joints, which were every year amputated at St. Bartholomew's Hospital, and though I was long attentive to this point, my searches after a really enlarged scrofulous bone always proved in vain. Nor was there at that period any specimen of an expanded head of a scrofulous bone in Mr. Abernethy's museum. Within the last few years, however, a speci-

men of an enlargement of the upper head of the ulna has been found, and it was some time ago shown to me by Mr. Stanley. My friend, Mr. Langstaff, is said to have in his possession a knee-joint, in which the femur and tibia are much expanded, "the external laminae of the bones not being thicker than when the bones are of their natural size, and the cancelli healthy, though of rather greater solidity than natural." (*Lloyd on Scrofula, p. 148.*) However, this last form of disease evidently does not resemble the common scrofulous affection of the heads of the bones. I may add, that Mr. Wilson, whose dissections have been very numerous, concurs with the best modern writers, concerning the rarity of an actual expansion of the substance of the heads of the bones. (*On the Skeleton, &c. p. 336.*) I have also heard of a few other instances in which the heads of the bones were actually enlarged in cases of white-swelling. However, I believe the occurrence is far from being usual, and doubts may yet be entertained, whether such enlargement is combined with the following alteration of structure. The change which the head of the tibia undergoes in many cases, is first a partial absorption of the phosphate of lime throughout its texture, while at first a transparent fluid, and afterward a yellow cheesy substance are deposited in the cancelli. In a more advanced stage, and indeed, in that stage, which most frequently takes place before a joint is amputated, the head of the bone has deep excavations in consequence of caries, and its structure is now so softened, that when an instrument is pushed against the carious part, it easily penetrates deeply into the bone. Occasionally, as my friend Mr. Lloyd has observed, all the bones of a joint are affected in this way; but frequently only one of them. (*On Scrofula, p. 120.*)

According to a modern writer, "The morbid affection appears to have its origin in the bones, which become preternaturally vascular, and contain a less than usual quantity of earthy matter, while, at first, a transparent fluid, and afterward a yellow cheesy substance, is deposited in their cancelli. From the diseased bone, vessels, carrying red blood, shoot into the cartilage, which afterward ulcerates in spots, the ulceration beginning on that surface, which is connected to the bone. As the caries of the bones advances, pus is collected in the joint. At last, the abscess bursts externally, having formed numerous and circuitous sinuses." (*Brodie, in Med. Chir. Trans. Vol. 4, p. 272, and Pathol. Obs. p. 227.*) The above-described alteration of the structure of the bones, this author has never seen in the cranium, nor in the middle of the cylindrical bones; but, it is asserted by another late writer, that the cheesy matter sometimes pervades the cancelli of the whole bone, and is deposited in innumerable portions of the most minute size. (*E. A. Lloyd on Scrofula, p. 120.*) Also, with respect to the increased vascularity of the diseased part of the bone, although Mr. Lloyd assents to the truth

of this statement, as applied to the early stage of the disorder, he represents the vascularity as afterward being diminished, in proportion as the quantity of cheeselike deposit increases. (*Vol. cit. p. 122, 123.*)

A cursory examination of a diseased joint, even when it is cut open, will not suffice to show, that the heads of the bones have not acquired an increase of size. In making a dissection of this kind, in the presence of a medical friend, I found that, even after the joint had been opened, the swelling had every appearance of arising from an actual expansion of the bones. The gentleman with me felt the ends of the bones after the integuments had been removed, and he coincided with me, that the feel, which was even now communicated, seemed to be caused by a swelling of the bones themselves. But, on cleaning them the enlargement was demonstrated to arise entirely from a thickening of the soft parts. So unusual, indeed, is the expansion of the heads of the bones, that the late Mr. Crowther, who paid great attention to these cases, joined Mr. Russel in believing, that such a change never happened: a conclusion not entirely correct. (See *Practical Obs. on White-Swelling, &c. Edit. 2, p. 14, 1808.*)

Mr. Russel has particularly noticed how much the soft parts frequently contribute to the swelling. He describes the appearances on dissection thus: "The great mass of the swelling appears to arise from an affection of the parts, exterior to the cavity of the joint, and which, besides an enlargement in size, seem also to have undergone a material change in structure. There is a larger, than natural, proportion of a viscid fluid, intermixed with the cellular substance; and the cellular substance itself has become thicker, softer, and of a less firm consistence, than in a state of health." (*On the Morbid Affections of the Knee, p. 30.*) The manner, in which the soft parts are affected, is also described by Mr. Brodie: "Inflammation takes place of the cellular membrane, external to the joint. Serum, and afterward coagulable lymph, are effused, and hence arises a puffy elastic swelling in the early, and an œdematous swelling in the advanced stage of the disease."

"Scrofula attacks only those bones, or portions of bones, which have a spongy texture, as the extremities of the cylindrical bones, and the bones of the carpus and tarsus; and hence, the joints become affected from their contiguity to the parts, which are the original seat of the disease." (See *Medico-Chir. Trans. Vol. 4, p. 273.*)

In the cavity of the joint, we sometimes find a quantity of curdy matter, and the cartilages absorbed in various places, but more particularly round the edges of the articular surfaces.

As the name of the disease implies, the skin is not at all altered in colour. According to Mr. Lloyd, the first decided symptom of disease going on in the articulating extremity of a bone, is an occasional deep-seated, dull, heavy pain, unattended by swelling, and not increased by motion; and if it be the hip,

knee, or ankle, which is affected, the patient keeps the knee rather bent, and never fully extends it in progression. (*On Scrofula, p. 138.*) In some instances, the swelling yields in a certain degree to pressure; but it never pits, and is almost always sufficiently firm to make an uninformed examiner believe, that the bones contribute to the tumour. It is remarked by Mr. Brodie, that while the disease is going on in the cancellous structure of the bones, before its effects have extended to the other textures, and while there is still no evident swelling, the patient experiences some degree of pain, which however, is never very severe, and often is so slight, that it is scarcely noticed. After a time, varying from a few weeks to several months, the external parts begin to swell, and serum and coagulable lymph to be effused in the cellular membrane so as to form a puffy, elastic swelling. (*Pathol. Obs. p. 231.*) In the majority of scrofulous white-swelling, let the pain be trivial, or more severe, it is particularly situated in one part of the joint: viz. either the centre of the articulation, or the head of the tibia. Sometimes, the pain continues without interruption; sometimes there are intermissions; and in other instances, the pain recurs at regular times, so as to have been called by some writers, periodical. Almost all authors describe the patient, as suffering more uneasiness in the diseased part, when he is warm, and particularly, when he is in this condition in bed.

In the early stage of the disease, the swelling is mostly very inconsiderable, or there is even no visible enlargement whatever, excepting perhaps after exercise. In the little depressions, naturally situated on each side of the patella, a fullness generally first shows itself, and gradually spreads all over the affected joint. According to Mr. Lloyd, however, when the soft parts on the outside of the knee-joint, permanently swell, the swelling often commences on each side, just behind the condyles, so that the joint appears wider, and he says, that he has often seen the enlargement commence by the swelling of a gland, immediately above the inner condyle. He observes, however, that there is no point of the joint, where the swelling may not begin. (*Op. cit. p. 139.*)

The patient, unable to bear the weight of his body on the disordered joint, in consequence of the great increase of pain thus created, gets into the habit of only touching the ground with his toes, and the knee being generally kept a little bent in this manner, soon loses the capacity of being completely extended again. When white-swelling has lasted a good while, the knee is almost always found in a permanent state of flexion. In scrofulous cases, the pain constantly precedes any appearance of swelling; but the interval between the two symptoms differs very much in different subjects.

The morbid joint, in the course of time, acquires a vast magnitude. Still the integuments retain their natural colour, and remain unaffected. The enlargement, however, always seems greater than it really is, in con-

sequence of the emaciation of the limb both above and below the disease.

An appearance of blue distended veins, and a shining smoothness, are the only alterations to be noticed in the skin covering the enlarged joint. The shining smoothness seems attributable to the distention, which obliterates the natural furrows and wrinkles of the cutis. When the joint is thus swollen, the integuments cannot be pinched up into a fold, as they could in the state of health, and even in the beginning of the disease.

As the distemper of the articulation advances, the cartilages ulcerate, and collections of matter form around the part, and at length burst. Their progress, as Mr. Brodie has stated, is slow, and when they burst, or are opened, they discharge a thin pus, with portions of a curdy substance floating in it. The discharge afterward becomes less copious, and thicker. (*Pathol. Obs. p. 234.*) The ulcerated openings sometimes heal up; but, such abscesses are generally followed by other collections, which pursue the same course. In some cases, these abscesses form a few months after the first affection of the joint; on other occasions, several years elapse, and no suppuration of this kind makes its appearance. They sometimes communicate with the cavity of the diseased joint, or lead down to diseased bone, portions of which occasionally exfoliate. In the generality of cases, several abscesses take place in succession, some healing up, and others ending in sinuses.

As the cartilages continue to ulcerate, Mr. Brodie has observed, that the pain becomes aggravated, though not in a very great degree, and, he says, that it is not severe, until an abscess has formed, and the parts over it are distended and inflamed. (*Pathol. Obs. p. 234.*)

The local mischief must necessarily produce more or less constitutional disturbance. The patient's health becomes gradually impaired, he loses his appetite and natural rest and sleep; his pulse is small and frequent; and obstinate debilitating diarrhoea, and profuse nocturnal sweats ensue. These complaints are, sooner or later, followed by dissolution, unless the constitution be relieved in time, either by the amendment or removal of the diseased part. In different patients, however, the course of the disease, and its effects upon the system, vary considerably, in relation to the rapidity with which they occur.

Rheumatic white-swollings, or inflammations and thickenings of the synovial membrane from cold, or other causes, are very distinct diseases from the scrofulous distemper of the large joints. In the first, the pain is said never to occur without being attended with swelling. Scrofulous white-swollings, on the other hand, are always preceded by a pain, which is particularly confined to one point of the articulation. In rheumatic cases, the pain is more general, and diffused over the whole joint.

Mr. Lloyd thinks, that the scrofulous white-swelling may be distinguished from all other diseases of the joints, by its being at-

tended with less pain, by the great degree of external swelling often existing for a long time before matter forms in the cavity of the articulation, and by the swelling being but little diminished by any discharge of matter, which may take place. In its first stage, before the interior of the joint is affected, it may be distinguished from primary ulceration of the cartilages, by the pain not being much increased by motion. The grating, produced by moving the joint, is also commonly less in this disease, than in ordinary ulceration of the cartilages. (*Lloyd on Scrofula, p. 142.*) And, according to Mr. Brodie, the principal criterion between scrofulous diseases of joints and the primary ulceration of cartilages, is the little degree of pain in the former cases, which is never much complained of before an abscess forms, not particularly severe, "except in a very few instances, and in the most advanced stage of the disease, when a portion of ulcerated bone has died, and having exfoliated, so as to lie loose in the cavity of the joint, irritates the parts, with which it is in contact, and thus becomes a source of constant torment." (*Brodie's Pathol. Obs. p. 236.*)

It seems probable, that cases, in which the cancellous structure of the bones is found quite undiseased, and in which the mass of disease is confined to the soft parts, are not scrofulous white-swollings. Few persons, who have attained the age of five and twenty, without having had the least symptom of scrofula, ever experience, after this period of life, a first attack of the white-swelling of the strumous kind. The general correctness of this observation, I believe, is universally admitted, and that there are but few exceptions to it is confirmed by the statements of Volpi, of Pavia. However, Mr. Lloyd attended a man, who, at the age of between forty and fifty, died of phthisis and had at the time a scrofulous ankle, besides several abscesses about his hip and groin. And the same gentleman met with another patient upwards of forty years old, with a similar disease. (*On Scrofula, p. 137.*) But, if these patients had had no marks of scrofula in their younger days, a circumstance not specified, they form deviations from what is usual, as indeed Mr. Lloyd seems to admit. My own observations lead me fully to concur with Mr. Brodie, that the scrofulous affections of the joints, so frequent in children, are rare after the age of thirty. (*Pathol. Obs. p. 229.*) All cases, in which the internal structure of the heads of the bones becomes softened, previously to the affection of the cartilages, and soft parts, are probably scrofulous.

Mr. Russel has noticed the frequent enlargement of the lymphatic glands in the groin, in consequence of the irritation of the disease in the knee; but he justly adds, that this secondary affection never proves long troublesome.

When the bones are diseased, the head of the tibia always suffers more than the condyles of the thigh bone. (*Russel.*) The articular surface of the femur sometimes has

not a single rough or carious point, notwithstanding that of the tibia may have suffered a great deal. The cartilaginous coverings of the heads of the bones are generally eroded first at their edges; and, in the knee, the cartilage of the tibia is always more affected, than that covering the condyles of the thigh-bone. Indeed, when white-swellings have their origin in the bones, and the knee is the seat of the disorder, there is some ground for supposing, that it is in the tibia, that the morbid mischief usually first commences.

The ligaments of the knee are occasionally so weakened, or destroyed, that the tibia and fibula become, more or less, dislocated backward, and drawn towards the tuberosity of the ischium, by the powerful action of the flexor muscles of the leg. It is observed by Mr. Brodie, that, just as ulceration of the cartilages is sometimes followed by dislocation of the hip, so we find, that dislocation of the knee occasionally takes place from the same cause. Where there has been considerable distention of the soft parts, in consequence of ulceration extending to them, the head of the tibia is gradually drawn backward by the action of the flexor muscles; and Mr. Brodie has even known this happen, previously to the formation of any abscesses. (*Pathol. Obs.* p. 159.)

I have seen a curious species of white-swellings, in which the leg could be bent to each side to a very considerable distance, both when the knee was extended and bent: a state implying a preternatural looseness, or perhaps a destruction, of the ligaments of the articulation.

Scrofulous white-swellings, no doubt, are under the influence of a particular kind of constitution, termed a *scrofulous* or *strumous habit*, in which every cause, capable of exciting inflammation, or any morbid and irritable state of a large joint, may bring on the present severe disease. On the other hand, in a man of a sound constitution, a similar irritation would only induce common healthy inflammation of the joint. In scrofulous habits, it also seems as if irritation of a joint is much more easily produced, than in other constitutions; and no one can doubt, that when once excited in the former class of subjects, it is much more dangerous, and difficult of removal, than in other patients.

The doctrine of particular white-swellings being scrofulous diseases, is supported by many weighty reasons, the opinions of the most accurate observers, and the evidence of daily experience. Wiseman (*Book 4, chap. 4*) calls the *spina ventosa* a species of scrofula, and tells us, that infants and children are generally the subjects of this disease. The disorder is said by Severinus to be exceedingly frequent in young subjects. Petrus de Marchettis has observed both male and female subjects affected with what are called strumous diseases of the joints, as late as the age of five and twenty; but not afterward, unless they had suffered from scrofula before that period of life, and

had not been completely cured. R. Lowerus also maintains a similar opinion. Even though a few persons have scrofulous diseases of the joints, for the first time, after the age of twenty-five, this occurrence, like the first attack of scrofula after this period, must be considered as extremely uncommon.

Another argument, in favour of the doctrine, which sets down particular kinds of white-swellings as scrofulous, is founded on the hereditary nature of such forms of disease.

Numerous continental surgeons, particularly Petit and Brambilla, have noticed how very subject the English are both to scrofula and white-swellings of the joints. We every day see, that young persons afflicted with the present disease, are generally manifestly scrofulous or have once been so. Frequently enlarged lymphatic glands in the neck denote this fatal peculiarity of constitution; and very often the patients are known to have descended from parent- who had strumous disorders. (*Crother.*) The disease is also frequently combined with swelled mesenteric glands, or tuberculated lungs. (*Brodie's Pathol. Obs.* p. 221.) As the same author remarks, since the disease depends upon a certain morbid condition of the general system, it is not surprising, that we should sometimes find it affecting several joints at the same time, or that it should show itself in different joints in succession; attacking a second joint after it has been cured in the first, or after the first has been removed by amputation. (*P.* 230.)

Besides the general emblems of a scrofulous constitution, which will be noticed in the article *Scrofula*, we may often observe a shining, coagulated, flaky substance, like white of egg, blended with the contents of such abscesses as occur in the progress of the disease. This kind of matter is almost peculiar to scrofulous abscesses, and forms another argument in support of the foregoing observations, relative to the share, which scrofula frequently has in the origin and course of many white-swellings.

Mr. Brodie's experience leads him to believe, that in scrofulous cases, the chance of ultimate recovery is much less, where the disease attacks the complicated joints of the foot and hand, than when it is situated in larger articulations of a more simple structure. (*Pathol. and Surg. Obs.* p. 235.)

Treatment of White-swellings—In practice we meet with all these cases both scrofulous and rheumatic, in two very opposite states; sometimes the diseased joint is affected with a degree of acute inflammation; in other instances, the malady is entirely chronic.

The imprudence of patients in walking about, and disturbing the diseased part, is very often the occasion of a degree of acute inflammation, which is denoted by the tenderness of the joint when handled by the surgeon, and also by the integuments feeling hotter than those of the healthy knee. When such state exists, there can be no

doubt, that topical bleeding, fomentations, emollient poultices, or cold saturnine lotions, are means which may be eminently serviceable. The antiphlogistic regimen is now strongly indicated. Cooling purges of the saline kind should also be exhibited. Blood may be taken from the arm, and also from the diseased part, either by means of leeches or cupping. Mr. Latta gives the preference to the latter method, whenever it can be employed; and he very properly remarks, that little advantage can be expected from topical bleeding of any kind, unless the quantity of blood taken away be considerable. Ten or twelve ounces by cupping should be taken away at a time, and the operation should be repeated at proper intervals, till the tenderness and heat of the skin have entirely subsided. When leeches are used, the number ought to be considerable, and Mr. Latta recommends the application of at least sixteen or twenty. (*System of Surgery, Vol. 1, Chap. 6.*)

Although antiphlogistic means are judicious when acute inflammation prevails; yet such practitioners as lose weeks and months in the adoption of this treatment, are highly censurable. While the skin is hot and tender, while the joint is affected with very acute and general pain, and while the patient is indisposed with the usual symptoms of inflammatory fever, great benefit may be rationally expected from the above plan. When, however, the disease is truly chronic, different plans are indicated. In ordinary cases of scrofulous disease of the joints, Mr. Brodie considers topical bleeding as usually unnecessary. (*Pathol. and Surgical Obs. p. 240.*)

It is quite unnecessary to expatiate on the mode of treating white-swellings, complicated with acute inflammation, particularly as the treatment of those cases, which consist of inflammation of the synovial membrane, has been already noticed, and may be said to be applicable to other forms of white-swelling, when they are attended with heat and inflammation of the soft parts. The most eligible plan of arresting the morbid process in the bones, cartilages, and soft parts surrounding the articulation, and the most successful method of lessening the chronic enlargement of the joint, are the subjects at present demanding our earnest investigation.

The works of Hippocrates, Celsus, Rhazes, Hieron, Fabricius, &c. compared with modern surgical books, will soon convince us, that the practice of the ancients, in the treatment of diseased joints, does not differ much from the plan now pursued by the best modern surgeons. Mr. Crowther remarks, that the ancients used local and general blood-letting, the actual and potential cautery, with vesicating and stimulating applications to the skin. They further maintained, that sores, produced by these means, should have their discharge promoted, and continued for a considerable length of time.

With regard to the cases which Mr. Brodie describes as depending upon a total loss of

the natural structure of the synovial membrane, which is converted into a pulpy substance, one quarter or one half of an inch in thickness, though the progress of the disease may be somewhat checked by rest and cold lotions, it is, according to this gentleman, incurable, and at length it ends in ulceration of the cartilages, abscesses, &c. When there is considerable pain, in consequence of the cartilages beginning to ulcerate, partial relief may be derived from fomentations and poultices: but nothing will effect a cure. Hence, when the health begins to suffer, he considers amputation to be indicated. (*Med. Chir. Trans. p. 254.*)

When white-swellings are accompanied with ulceration of the cartilages, all motion of the joint is extremely hurtful. Indeed, as Mr. Brodie well observes, keeping the limb in a state of perfect quietude is a very important, if not the most important circumstance, to be attended to in the treatment. According to this gentleman, it is in these cases, in which ulceration of the cartilages occurs as a primary disease, that caustic issues are usually productive of singular benefit; but he deems them of little use in any other diseases of the joints. He thinks setons and blisters, kept open with savine cerate, may also be used with advantage. Bleeding is indicated only when, from improper exercise, the articular surfaces are inflamed, and there is pain and fever. Mr. Brodie asserts, that the warm bath relieves the symptoms in the early stage, if it does not stop the progress of the disease; but he condemns plasters of gum ammoniac, embrocations, liniments, and frictions, as either useless or hurtful. (*See Medico-Chir. Trans. Vol. 6, p. 332—334.*)

Topical applications, consisting of strong astringents of the mineral and vegetable kingdom, are of no service in examples of ulceration of the cartilages, or of the scrofulous form of the disease, though they often suffice for the cure of some mild descriptions of white-swelling, depending upon a thickening of the synovial membrane. A decoction of oak bark, containing alum, was recommended by Mr. Russel.

My own experience will not allow me to say any thing in favour of electricity, as an application for the relief of white-swelling; and it must be more likely to do harm than good, whenever the indication is to lessen irritation.

"If the tumour is quite indolent, (says Richerand) the application of galvanism may be proposed; it is not, however, exempt from danger, and, on one occasion, where I employed it, lancinating pains and swelling of the joint were brought on by it." (*Nosogr. Chir. T. 3, p. 174, Ed. 2.*)

Mr. John Hunter had confidence in cicuta and sea-bathing, as possessing power over many scrofulous diseases; and that such diseases of the joints are often materially benefited by the patient's going to the seaside and bathing, is a fact which cannot be doubted, whatever may be the mode of explaining the benefit thus obtained. I fully

believe that sea-air and sea-bathing have a beneficial influence over scrofulous diseases of the joints; but probably their effects are produced on the part through the medium of the constitution, and they should only be recommended as an auxiliary plan, to be adopted in conjunction with other still more efficacious measures.

Every one is well acquainted with the efficacy of friction in exciting the action of the absorbents. To this principle we are to impute the great benefit which arises from what is termed *dry rubbing*, in cases of white-swelling. This kind of friction is performed by the mere hands of an attendant, without using at the same time any kind of liniment, or other application whatsoever, excepting sometimes a little flour, or powdered starch, and the rubbing is continued several hours every day. At Oxford many poor persons earn their livelihood by devoting themselves to this species of labour, for which they are paid a stipulated sum per hour. This practice, however, is chiefly advantageous in the chronic stage of white-swelling, arising from inflammation of the synovial membrane.

I look upon all mere emollient applications, such as fomentations and poultices, as quite destitute of real efficacy, except when great pain or active inflammation is present, and, though they serve to amuse the patient, they ought not to be recommended. That surgeon, who merely strives to please his patient's fancy, without doing any real good to him, in regard to his affliction, may be considered as doing harm, because the semblance of something being done too often hinders other really useful steps from being pursued. The French surgeons are particularly liberal in the praises which they bestow on warm emollient remedies, poultices, steam of hot water, fomentations, &c. and they adduce instances of white-swelling being cured in this manner. But the cases to which they refer were no doubt mere inflammations, and thickening of the synovial membrane; a disease which in general readily yields to several other plans.

The only method of treatment which my own personal experience enables me to recommend for scrofulous white-swelling in a chronic state, consists in keeping up a discharge from the surface of the diseased joints. The opportunities which I have had of observing the effects of blisters, and caustic issues, rather incline me, however, to prefer the former to the latter. I have seen great good derived from both; but more from blisters than the other kind of issue. There are instances in which I should employ vesicating applications; there are others in which I should prefer making an eschar with caustic. In particular individuals blisters create so much irritation, heat, fever, and suffering, that a perseverance in them would be rashness.

The blister should always be large. Many surgeons, instead of following Mr. Crowther's plan, prefer blistering, first one

side of the joint, and then the other, alternately, for a considerable length of time. "Blisters (says Mr. Latta) may be put upon each side of the patella, and ought to be of such a size and shape as to cover the whole of the swelling on the inside, from the hinder part of the joint, at the edge of the hollow of the thigh, to the edge of the patella, over the whole extent of the swelling above and below. As soon as the blister is taken off from one side, it ought to be applied to the other, and thus repeated, alternately, until both swelling and pain be completely removed. When this is the case, the patient ought to be directed to rub the joint well with a liniment, composed of half an ounce of camphor, dissolved in two ounces of oil, with the addition of half an ounce of spir. sal-ammon. caust. or, as it is now called, liquor ammoniac. This is to be used three times a day; and in this way, (continues Mr. Latta) I have successfully treated many cases of white-swelling." (*Syst. of Surgery, Vol. 1, chap. 6.*)

In the beginning, caustic issues are even more painful than blisters; but they afterward become more like indolent sores, and are more easily kept open for a length of time than blisters. Such issues are commonly made on each side of the diseased joint, and of about the size of a half crown. The manner of making the eschars, and keeping these issues open, has been already explained. (See *Issue.*)

The question has been contested, among surgical writers and practitioners, whether blisters and issues produce benefit upon the principle of counter irritation, or in consequence of the discharge which they occasion. They probably operate efficaciously in both ways; for there is no doubt that mere rubefacients possess the power of rousing the action of the absorbents, and they may also modify the vascular action in diseased parts. These applications can obviously only act upon the principle of counter irritation, and they have not been here recommended particularly for white-swelling, because, it seems to me, that whenever some good might be derived from their employment, much more benefit might always be obtained from blisters and issues. This sentiment is confirmed by experience, and we must, therefore, impute a great degree of efficacy to the maintenance of a purulent discharge from the vicinity of the diseased part.

Though my own observations have led me to think issues and blisters as efficient as any means hitherto devised for stopping the progress of scrofulous disease of the heads of the bones, I am far from meaning to say, that such disease can generally be stopped by these or any other remedies, local or general. Mr. Brodie has seldom known any benefit derived from blisters or stimulating liniments; nor has he seen the same degree of good produced by issues in scrofulous cases, as in examples of primary ulceration of the cartilages. Cold evaporating lotions in the early stage of the com-

plaint; perfect quietude of the joint; attention to the patient's health; and riding in a carriage in the fresh air; are the means which this gentleman particularly recommends in scrofulous diseases of the joints. During the formation of abscesses, he approves of fomentations and poultices. (*Pathol. Obs.* p. 242.)

We have noticed the efficacy of friction in exciting the action of the absorbents, by which the thickened state of parts around the affected joint may be considerably lessened, and, on this principle, the utility of dry rubbing arises. We have now to notice the method of producing the same effect by pressure, a plan which yet seems to merit a more extensive trial. I have seen in St. Bartholomew's Hospital, a few cases in which the swelling of the joints was materially diminished, by encircling the morbid articulations with strips of adhesive plaster, applied with moderate tightness.

A somewhat similar plan, though its *modus operandi* is differently accounted for, appears also to have been tried in France. "J'ai dans quelques occasions (says Richerand) obtenu les plus grands avantages de l'application d'un taffetas ciré autour de l'articulation tuméfiée. On coupe un morceau de cette étoffe, assez large pour envelopper la totalité de la tumeur; on enduit les bords d'une gomme dissoute dans le vinaigre, et susceptible de la faire adhérer intimement à la peau; on l'applique ensuite de manière que toute l'accès soit interdit à l'air entre lui et les teguments. Lorsqu'au bout de quelques jours on lève cet appareil, on trouve la peau humide, ramollie par l'humidité de la transpiration condensée en gouttelettes à la surface intérieure du taffetas. Dans ce procédé, on établit un espèce de bain de vapeur autour de l'articulation malade." (*Nosogr. Chir.* T. 3, p. 175, Edit. 2.)

My friend, the late Mr. Clement Wilson Cruttwell, of Bath, sent me a very excellent case, illustrative of the efficacy of treatment by pressure. He remarks that, "After cupping the part, and endeavouring to quiet the inflammation, I used blisters; but they excited such intolerable pain, and produced so great a degree of swelling and inflammation, that I was under the necessity of healing them immediately. After two months strict confinement to bed, and the use of leeches and refrigerant washes, the inflammation having again subsided, and the pain being removed, I again ventured to apply one small blister, and again a similar attack of pain, swelling, and inflammation was produced. The joint became distended with fluid, of which it had always contained a large quantity, and the irritation of the constitution was excessive. By the liberal use of opium I once more succeeded in quieting the disturbance, and, convinced of the hazard of using blisters in such a subject, I applied moderate pressure, by means of a roller, together with a wash, containing a large proportion of spirit, in order to keep up a constant evaporation. The skin, which

was before much inflamed, and hard, has become natural and flaccid, the pain has ceased, the swelling has diminished, and I have every prospect of effecting a cure, with the preservation of tolerably free motion in the joint."

Mr. Cruttwell, in a subsequent letter, informed me, that this case got completely well by the treatment with pressure, and had remained so for upwards of six months, under full and free exercise.

This example clearly evinces the impropriety of using blisters in certain constitutions. In some remarks, annexed to the above case, Mr. Cruttwell expresses his conviction, that absolute rest, cold applications, and pressure, would succeed in very many cases, without local counter irritation. Pressure, he adds, succeeds best when fluid is effused, and the disease is indolent; but he is convinced that it may be used with advantage in later stages, when abscesses have formed, and sinuses already exist; and he reminds me how very serviceable continued pressure is to the scrofulous finger-joints of children.

The good effects of pressure in scrofulous cases are confirmed by the observations of Mr. Brodie: when, says he, after several abscesses have taken place, the tendency to suppuration has ceased, and the swollen joint has become diminished, ankylosis is probably disposed to take place. At this period, pressure, by means of strips of linen, spread with soap-cerate, or some other moderately adhesive plaster, and applied in a circular manner round the limb, will be productive of benefit. (*Pathol. and Surg. Obs.* p. 243.)

When the knee is affected, the limb has a tendency to become permanently bent. It must undoubtedly be judicious to prevent this position, by means of splints, which will also serve to prevent all motion of the diseased joint, an object of the very highest importance. Were the disease to end in ankylosis, the advantage of having the limb in a state of extension need scarcely be mentioned.

In cases which commence in the cancellous structure of the heads of the bones, it seems rational to combine, with the local treatment, the employment of such internal remedies as have been known to do good in other scrofulous diseases. "It is to be supposed, (as Mr. Brodie observes) that the air of a crowded city must be more or less unfavourable; and that a residence on the seacoast is likely to be more beneficial than a residence in the country elsewhere. The patient should live on a nourishing, but plain diet; he should be in the open air in summer, as much as he can, without exercising the joint. His mode of life should, in all respects, be regular and uniform." Mr. Brodie has found more benefit derived from the long use of steel medicines than any others, suspending their use, however, and substituting the mineral acids for them, when the formation of abscesses excites febrile action. With such means, in child-

ren, he combines the occasional exhibition of mercurial purgatives. (*Pathol. Obs.* p. 245.) In a work, which Mr. Lloyd has just published, it is assumed as a fact, that, in scrofula, there always is more or less disorder of the functions of the digestive organs, and primarily of no other important function. Hence, the regulation of diet, the state of the bowels, and the hepatic secretions, is with this gentleman a principal object; and, with the latter views, he employs, after Mr. Abernethy's plan, five grains of the blue pill every night, and half a pint of decoct. sars. twice a day, with opening medicines, if necessary, to procure regular daily evacuations. When acidity of the stomach is present, he gives soda, and, when the stomach is weak, cinchona, steel, and mineral acids. (*On Scrofula*, p. 37, &c.) However, no doubt can be entertained, that these means, like many others, have no specific power over scrofulous diseases, and, like sea-air and sea-bathing, only answer by sometimes improving the state of the constitution. In the local treatment of scrofulous joints, Mr. Lloyd commends quietude of the limb, which is to be confined in a sling, or in splints, the occasional resistance of inflammatory action by leeches, and a diminution of temperature; poultices when abscesses form; opening such collections of matter early; and, after all irritation has ceased, issues, setons, blisters, or the antimonial ointment; or compression upon Mr. Baynton's plan. (*P.* 152, &c.) With respect to opening these abscesses early, Mr. Lloyd differs from many excellent surgeons, especially Dr. Albers, who distinctly states, that it is generally best to allow them to burst of themselves. On this subject, however, great diversity of opinion prevails, and Langenbeck is among the advocates for making an early opening. (*Bibl. B.* 2, p. 39.) Hectic symptoms are those which we commonly have to palliate in these cases. When the appetite is impaired, and the stomach will bear bark, this medicine should be given with the aromatic confection. Above all internal remedies, opium claims the highest recommendation, as it at once tends to keep off and relieve a debilitating diarrhoea, which too frequently prevails, at the same time that it alleviates pain and procures sleep. The objection, made against its exhibition on the ground that it increases perspiration, seems exceedingly frivolous, when the above important benefits are taken into consideration.

Too often, however, the terrible disease of which we are now treating, baffles all human skill and judgment, and the unhappy patient's health having declined to the lowest state, he is necessitated to submit to amputation, as the only chance of preserving life. It has been explained in speaking of *Amputation*, that the condition of the patient's health, and not of the diseased joint, forms the principal reason for recurring to the severe operation of removing the limb. If the patient's constitution be equal to a longer struggle, no man can pronounce that every

prospect of saving the limb is at an end. Many diseased joints, apparently in the most hopeless condition, frequently take a favourable turn, and, after all, allow the limb to be saved.

The proposal of cutting out diseased joints, has been considered in the article *Amputation*.

Disease of the Hip-joint.—This complaint is very analogous in its nature to the white-swelling of other articulations. In the same way as the latter disorder, it seems probable, that the disease of the hip has its varieties, some of which may be connected with scrofula, while others cannot be suspected to have any concern with it. Mr. Brodie's investigations lead him to believe, however, that the disease is of that nature, in which the first change is disease and ulceration of the cartilages. The present complaint is most frequently seen in children under the age of fourteen; but, no age, no sex, no rank, nor condition of life is exempt from the possibility of being afflicted, so that though children form a large proportion of those subjects, who are attacked; yet the number of adults, and even of old persons, is considerable.

The approach of the disease of the hip-joint is much more insidious, than that of a white-swelling. Some degree of pain always precedes the latter affection; but, the only forerunner of the former is frequently a slight weakness, and limping of the affected limb. These trivial symptoms are very often not sufficiently urgent to excite much notice, and, when observed by superficial practitioners, are commonly neither understood, nor treated according to the dictates of surgical science. As there is, also, sometimes an uneasiness in the knee, when the hip is affected, careless practitioners frequently mistake the seat of disease, and I have many times seen patients, on their entrance into an hospital, having a poultice on their knee, while the wrong state of the hip was not at all suspected.

This mistake is extremely detrimental to the patient, not on account of any bad effect, resulting from the applications so employed; but, because it is only in the incipient period of the complaint, that a favourable prognosis can be made. In this stage of the disease, mere rest and repeated topical bleeding, will do more good in the course of a fortnight, than large painful issues will afterward generally accomplish in the long space of a twelvemonth.

The symptoms of the disease of the hip-joint, when only looked for in the situation of that articulation, are not very obvious to the surgical examiner. Though, in some instances, the attention of the surgeon is soon called to the right situation of the disease, by the existence of a fixed pain behind the trochanter major; yet, it is too often the case, that mere pain about an articulation, entirely destitute of visible enlargement and external alteration of colour, is quite disregarded, as a complaint of no importance in young subjects, and as a mere

rheumatic, or gouty affection, in adults. Patients frequently complain of their most painful sensations being in the groin, and all accurate observers have remarked, that, in the hip disease, the pain is not confined to the real seat of disease, but shoots down the limb, in the course of the vastus externus muscle to the knee.

The pain, says Mr. Brodie, is at first trifling, and only occasional; but, it afterwards becomes severe and constant. It resembles a good deal the pain of rheumatism, since it often has no certain seat. As the disease advances, the pain becomes exceedingly severe, particularly at night, when the patient is continually roused from his sleep by painful startings of the limb. Sometimes he experiences a degree of relief in a particular position of the joint, and no other. As the pain increases in intensity, it becomes more fixed. In the greater number of instances, it is referred both to the hip and knee, and the pain in the latter joint is generally the most severe. At other times, there is pain in the knee, and none in the hip. A boy, in St. George's hospital, complained of pain in the inside of the thigh near the middle; and another patient referred the pain to the sole of the foot. Wherever the pain is situated, it is aggravated by the motion of the joint, and especially by whatever occasions pressure of the ulcerated cartilaginous surfaces against each other. (*Brodie's Pathol. Obs. p. 139.*)

The early symptoms of disease in the hip-joint are only strongly delineated to such practitioners, as have acquired the necessary information relative to this part of surgery, from careful study and extensive experience.

We shall next trace those characters of the present disease, which serve to denote its existence.

It is a curious circumstance, that when the functions of a limb are obstructed by disease, the bulk of the member generally diminishes, and the muscles become emaciated. Nearly as soon as the least degree of lameness can be perceived, the leg and thigh have actually wasted, and their circumference has diminished.

If the surgeon make pressure on the front of the joint, a little on the outside of the femoral artery, after it has descended below the os pubis, great pain will be experienced.

"Soon after the commencement of the complaint, (as Mr. Brodie remarks,) the hip-joint is found to be tender, whenever pressure is made on it either before or behind. The absorbent glands become enlarged, and occasionally there is a slight degree of general tumefaction in the groin." The same gentleman has also adverted to the curious circumstance of there being in some cases a tenderness of the parts, to which, though not diseased themselves, the pain is referred from sympathy with the disease of the hip. This occurrence he has observed in the knee several times, and in one instance in the course of the peroneal nerve. He has also seen a slight degree of puffy swelling of the

knee in a case, in which pain was referred to this joint, in consequence of disease of the hip. (*P. 142, 143.*)

The limping of the patient is a clear proof, that something about the limb is wrong, and, if such limping cannot be imputed to diseased vertebræ, or some recent accident, and if, at the same time, the above-mentioned emaciation of the limb exists, there is great cause to suspect, that the hip is diseased, particularly when the pain is augmented by pressing the front of the acetabulum.

Diseased vertebræ, perhaps, always produce paralytic affection of both legs at once, and they do not cause painful sensations about the knee, as the hip disease does.

The increased length of the limb, a symptom that has been noticed by all practitioners since De Haen, is a very remarkable and curious occurrence, in the early stage of the present disease. This symptom is easily detected by a comparison of the condyles of the os femoris, the trochanter major, and malleoli, of the diseased limb, with those parts of the opposite member, taking care that the patient's pelvis is evenly situated. The thing is the more striking, as the increased length of the member is frequently as much as four inches. The rationale of this fact, John Hunter used to explain by the diseased side of the pelvis becoming lower than the other. (*Crowther, p. 266.*) The same thing had also been noticed by Falconer, (*On Ischias, p. 9*) long before the period, when Mr. Crowther printed his second edition.

It is easy (says Mr. Brodie,) to understand how the crista of one ilium becomes visibly depressed below the level of the other, when the position is remembered, in which the patient places himself when he stands erect. "He supports the weight of his body upon the sound limb, the hip and knee of which are in consequence maintained in the state of extension. At the same time, the opposite limb is inclined forward, and the foot on the side of the disease is placed on the ground considerably anterior to the other, not for the purpose of supporting the superincumbent weight, but for that of keeping the person steady, and preserving the equilibrium. Of course, this cannot be done, without the pelvis on the same side being depressed. The inclination of the pelvis is necessarily attended with a lateral curvature of the spine, and hence one shoulder is higher than the other, and the whole figure in some degree distorted." (*Pathol. Obs. p. 146.*) These effects, says Mr. Brodie, are in general all removed by the patient's lying in bed a few weeks, except when the deformity has continued a long time in a young growing subject.

In justice to the memory of the late respected Dr. Albers, of Bremen, I ought here to mention, that he appears in his work on Coxalgia, to have first pointed out the deformity of the spine in this disease, and the reason of such change, the tenor of his observations upon this point agreeing with those subsequently made by Mr. Brodie.

An appearance of elongation of the limb is not exclusively confined to the early stage of the morbus coxarius: it may attend other cases. I remember seeing in one of the wards of St. Bartholomew's Hospital, a little girl, with a diseased knee, whose pelvis was considerably distorted in this manner, so that the limb of the same side appeared much elongated. Her hip-joint was quite sound. This case was pointed out to Mr. Lawrence and myself by Mr. Cother, of Gloucester.

Volpi, Albers, and several other foreign writers, point out the fact, that the early stage of this disease is sometimes attended with an appearance of elongation, sometimes with that of a shortening of the limb. An explanation of the circumstance is given by Mr. Brodie, as follows: "In a few cases, where the patient is in the erect position, it may be observed, that the foot, which belongs to the affected limb, is not inclined more forward than the other, but the toes only are in contact with the ground, and the heel raised, at the same time that the hip and knee are a little bent. This answers to the patient the same purpose of enabling him to throw the weight of his body on the other foot; but it produces an inclination of the pelvis in the opposite direction. The crista of the ilium is higher than natural, and there is an apparent shortening, instead of elongation of the limb on the side of the disease." (*Pathol. and Surg. Obs.* p. 147.)

Mr. Ford has very accurately called the attention of surgeons to the alteration, with respect to the natural fulness and convexity of the nates, that part appearing flattened, which is usually most prominent. The glutæus magnus becomes emaciated, and its edge no longer forms so bold a line, as it naturally does at the upper and back part of the thigh, in the sound state of the limb.

Although this symptom, in combination with others, is of importance to be attended to, it has been explained by Mr. Brodie, that "it is not in itself to be regarded, as a certain diagnostic mark of disease in the hip; since, in its early stage, this symptom is wanting; and it is met with in other diseases, in which the muscles in the neighbourhood of the hip are not called into action, although the joint itself is unaffected. (See *Medico-Chir. Trans.* Vol. 6, p. 322.)

Though there may be more pain about the knee than the hip, at some periods of the malady in its incipient state, yet the former articulation may be bent and extended, without any increase of uneasiness; but, the os femoris cannot be moved about, without putting the patient to immense torture.

The patient soon gets into the habit of bearing the weight of his body chiefly upon the opposite limb, while the thigh of the affected side is bent a little forward, that the ground may only be partially touched with the foot. This position is found to be the most comfortable, and every attempt to extend the limb occasions an increase of pain.

This is the first stage of the disease, or that which is unaccompanied with suppuration.

The symptoms which precede the formation of pus, vary in different cases, according as there is acute, or chronic inflammation present. When the diseased joint is affected with acute inflammation, as generally happens, the surrounding parts become tense and extremely painful; the skin is even reddish; and symptoms of inflammatory fever prevail. When the severity of the pain abates, a swelling occurs in the vicinity of the joint, and a pointing quickly follows. In this stage startings and catchings during sleep are said to be among the most certain signs of the formation of matter. "The shortening of the limb," says Mr. Brodie, "which usually takes place in the advanced stage of the disease, is usually, but not always the precursor of abscess. The formation of matter is also indicated by an aggravation of the pain; by more frequent spasms of the muscles, by a greater wasting of the whole limb, and by the circumstance of the thigh becoming bent forward, and being incapable of extension," and by the pulse becoming quick, the tongue furred, and the whole system being in a state of preternatural excitement. "The abscess usually shows itself in the form of a large tumour over the vastus externus muscle; sometimes on the inside of the thigh, near the middle; and occasionally two or three abscesses appear in different parts, and burst in succession" (*Brodie's Pathol. Obs.* p. 152.)

We have noticed the commonly lengthened state of the limb, in the first periods of the hip disease. This condition is not of very long duration, and is sooner or later succeeded by a real shortening of the affected member. The foot may be turned inwards; but, as Mr. Brodie observes, if left to itself, it is generally turned outwards. In other cases, the limb is shortened; the thigh is bent forwards; the toes are turned inwards, and do not admit of being turned outwards; (*Pathol. Obs.* p. 148;) and all the symptoms of a luxation of the thigh upwards and outwards may be observed, the head of the bone, indeed, being actually drawn into the external iliac fossa, and carried betwixt the os innominatum and glutæus minimus, which is raised up by it. (See *Richerand Nosogr. Chir. T.* 3, p. 171, 172, Ed. 2.)

When the retraction is very considerable, it arises from nothing less than an actual dislocation of the head of the thigh-bone, in consequence of the destruction of the cartilages, ligaments, and articular cavity. This retraction sometimes comes on long before any suppuration takes place. The head of the bone is sometimes dislocated, and the disease terminates in ankylosis, without any abscess whatever. However, if suppuration has not taken place, Mr. Brodie believes, it rarely happens, that the limb, after the cure, does not regain its natural degree of mobility. (See *Med. Chir. Trans.* Vol. 6, p. 325.)

It is worthy of particular notice, that the

head of the bone is always luxated upwards and outwards; and the only exception to this observation, upon record, is a case related by Cocchi, in which a spontaneous dislocation of the thigh-bone, as it is termed, happened upwards, forwards, and a little inwards. (See *Levéillé, Nouvelle Doctrine Chir. T. 3, p. 595.*) On a également vu la tête du fémur luxée en dedans et en bas, et placée sur le trou obturateur, mais cette mode de déplacement consécutif, dans lequel le membre est allongé, est infiniment rare. (*Richerand, Nosogr. Chir. T. 3, p. 172.*)

The hip disease generally induces hectic symptoms, after it has existed a certain time. In some subjects, such symptoms soon come on; in others, the health remains unaffected a very considerable time.

"The health of the patient (says Mr. Brodie) usually suffers, even before abscesses have formed, from the want of exercise, pain, and particularly from the continued disturbance of his natural rest. I recollect no instance of an adult, in whom abscesses had formed, and who did not ultimately sink exhausted by the hectic symptoms which these induced. Children may recover in this ultimate stage of the disease; but, seldom without a complete ankylosis of the joint." (*Med. Chir. Trans. Vol. 6, loco cit.*)

When abscesses of the above description burst, they continue, in general, to emit an unhealthy thin kind of matter for a long time afterward.

With respect to the morbid anatomy of the disease in its incipient state, until lately little was known. A few years ago two dissections related by Mr. Ford were, perhaps, the only ones throwing light upon this point. In one, there was a tea-spoonful of matter in the cavity of the hip joint. The head of the thigh-bone was a little inflamed, the capsular ligament a little thickened, and the ligamentum teres united in its natural way to the acetabulum. The cartilage lining the cotyloid cavity was eroded in one place, with a small aperture, through which a probe might be passed, underneath the cartilage, into the internal surface of the os pubis on one side, and on the other, into the os ischii; the opposite, or external part of the os innominatum showing more appearance of disease, than the cotyloid cavity. In the other instance, the disease was more advanced. These examples are important, inasmuch as they prove that what is commonly called the disease of the hip joint, primarily affects the cartilages, ligaments, and bones, and not the surrounding soft parts, as De Haen and some others would lead one to believe.

As the disorder advances, the portions of the os ischium, os ilium, and os pubis, composing the acetabulum, together with the investing cartilage, and synovial gland, are destroyed. The cartilage covering the head of the os femoris, the ligamentum teres, and capsule of the joint, suffer the same fate, and caries frequently affects not only the adjacent parts of the ossa innominata, but also the head and neck of the thigh-

bone. The bones of the pelvis, however, are always more diseased than the thigh-bone, a fact which displays the absurdity of ever thinking of amputation in these cases. Mr. Ford observes, "In every case of disease of the hip joint, which has terminated fatally, I have remarked, that the os innominatum has been affected by the caries in a more extensive degree, than the thigh bone itself" (*Observations on the Disease of the Hip joint, p. 107.*)

Sometimes however, the head and neck of the thigh-bone are annihilated, as well as the acetabulum.

Mr. Brodie has had opportunities of dissecting some diseased hip joints both in the incipient and advanced stage of the complaint. From his observations, it appears; 1st. That the disease commences with ulceration of the cartilages, generally that of the acetabulum first, and that of the femur afterward. 2. That the ulceration extends to the bones, which become carious; the head of the femur diminishing in size, and the acetabulum becoming deeper and wider. 3. That an abscess forms in the joint, which after some time makes its way by ulceration, through the synovial membrane and capsular ligament, into the thigh and nates, or even through the bottom of the acetabulum into the pelvis. Mr. A. Cooper showed Mr. Brodie two specimens, in which the abscess had burst into the rectum. 4. In consequence of the abscess, the synovial membrane and capsular ligament become inflamed and thickened. The muscles are altered in structure; sinuses are formed in various parts, and, at last, all the soft parts are blended together in one confused mass, resembling the parietes of an ordinary abscess. (*Brodie, in Medico-Chir. Trans. Vol. 4, p. 246, 247.*)

Such are the beginning and progress of the ordinary disease of the hip joint; but, it is admitted by Mr. Brodie, that there are other scrofulous cases, in which the mischief begins in the cancellous structure of the bones, and also other instances, which consist in chronic inflammation and abscesses of the soft parts in the neighbourhood of the hip. (*Op. cit. Vol. 6, p. 326.*)

External violence; lying down on the damp ground in summer time; and all kinds of exposure to damp and cold; are the causes to which the disease has sometimes been referred. No doubt, scrofula has, frequently, some concern in its origin; but, often, no rational cause is assignable for the complaint.

Treatment of the disease of the Hip Joint.

—The writings of Hippocrates, Celsus, Cælius Aurelianus, &c. prove, that the ancients treated the present disease much in the same way, as it is treated by the moderns. Forming an eschar, and keeping the sore open; topical bleeding; cupping; fomenting the part, &c. were all proceedings adopted in the earliest periods of surgery. Drs. Charlton, Oliver, and Falconer, have extolled Bath water, as a most efficacious application to diseased hip joints, previous to the suppura-

tive stage. However, had not their accounts been exaggerated, all patients of this kind would long ago have flocked to Bath, and the surgeons in other places would never have had further occasion to adopt a more painful mode of treatment. The plan pursued at Bath, is to put the patient in a warm bath, two or three times a week, for fifteen or twenty-five minutes.

In the first stage of coxalgia, the late Dr. Albers, however, had a very high opinion of warm bathing, fomentations with decoctions of herbs, and of bathing in mineral waters and the sea. But though he commenced the treatment with the frequent use of the warm bath, and continued the plan a long while, it is to be remarked, that he also combined with it an issue. After the patient had been in the bath a period not exceeding half an hour, he was taken out, and his whole body well rubbed with flannel. It appears to me, that one objection to this practice must be the considerable disturbance occasioned by moving the patient in this manner every morning; for if it be true, that most of these diseases commence in the cartilages of the joint, all motion of the limb must be particularly injurious.

In the early period of the disease, entire rest, the application of fomentations, and the employment of topical bleeding, particularly cupping, are highly proper. Such practice, also, is invariably judicious, whenever the case is attended with symptoms of acute inflammation. When the fomentations are not applied, the *lotio aquæ lithargyri acetati* may be used.

This method of treatment ought never to be employed, unless manifest signs of active inflammation be present. When no such state exists, this plan can only be regarded as preventing the adoption of a more efficacious one, and, therefore, censurable.

"Where the cartilages of the hip are ulcerated (says Mr. Brodie,) the patient should in the first instance, be confined to a couch, if not to his bed: and if the disease is far advanced, the limb should be supported by pillows properly disposed, so as to favour the production of an ankylosis, by allowing it to vary as little as possible from one position." (See *Medico-Chir. Transs.* Vol. 6, p. 335.)

Quibus diuturno dolore, says Hippocrates, ischiadico vexalis coxa excidit, iis femur contabescit et claudicant, nisi urantur. Forming an eschar, or issue, is the most efficacious plan of treating the disease even now known. A caustic issue seems to me more beneficial than a blister. The depression, just behind and below the trochanter major, is the situation in which surgeons usually make the issue, and the size of the eschar should be nearly as large as a crown-piece. It is generally necessary to keep the issue open a very long time. When the thigh-bone is dislocated, and the patient survives, the case mostly ends in ankylosis.

For the cure of the disease in adults, Mr. Brodie and Dr. Albers have also expressed a preference to caustic issues; but

in children, and even in grown-up persons, when the complaint is recent, they agree in thinking blisters capable of affording complete relief. Mr. Brodie states, that in these cases they are more efficacious when kept open with the savine ointment, than repeatedly applied. With respect to issues, he acknowledges, that behind the great trochanter is the most convenient place for them; but he believes that they have more effect, when made on the outside of the joint on the front edge of the tensor vaginae femoris muscle. Instead of keeping the issue open with beans, Mr. Brodie has found it a more effectual practice to rub the sore, two or three times a week, with the *potassa fusa*, or sulphate of copper. In particular cases, where the pain was very severe, this gentleman made a seton in the groin over the trunk of the anterior crural nerve, which plan, he says, affords quicker relief, though in the end it is less to be depended upon for a cure, than caustic issues.

In Dr. Albers's work, the great efficacy of issues and blisters in giving immediate relief to the severe pain in the knee, is illustrated by some valuable observations. He speaks also very favourably of the moxa, the employment of which he says is not very painful; a remark, in which Langenbeck concurs. (See *Bibl. B.* 2, p. 27.) Dr. Albers, in the hectic stages, recommends opium as highly useful, especially when combined with musk, or camphor.

The occurrence of suppuration makes a vast difference in the prognosis. "The formation of even the smallest quantity of pus in the joint in cases of this disease, in the young person, considerably diminishes, and in the adult almost precludes the hope of ultimate recovery." (Brodie, in *Medico-Chir. Trans.* Vol. 6, p. 347.) This gentleman is not much in favour of opening the abscesses early, at least before the joint has been kept for some time perfectly at rest. He has seen no ill consequences arise from the puncture of the lancet remaining open, and he has not found, that in cases of carious joints, the method of evacuating the matter, recommended by Mr. Abernethy (see *Lumbar Abscess*), is attended with any particular advantage.

Mr. J. Burns, in the second vol. of his "Dissertations on Inflammation," p. 344, has recorded a remarkable instance, in which this joint was affected with that intractable and fatal distemper, the fungus hæmatodes. The case was at first supposed to be the disease, of which we have just been treating in the preceding columns. The limb seemed to be elongated, and issues were employed, without any material benefit. The upper part of the thigh swelled, while the lower wasted away. The patient lost his appetite, had a quick pulse, and passed sleepless nights. The part was rubbed with anodyne balsam and laudanum given every night; but, these means were only productive of temporary benefit. After some months, a difficulty of making water came on, which ended in a complete retention. It being

found impracticable to introduce a catheter, and a large elastic tumour, supposed to be the distended bladder, being felt within the rectum, a trocar was pushed into the swelling. A good deal of bloody fluid was thus discharged. Afterward a considerable quantity of high-coloured fetid urine continued to escape from the urethra. In about a week after this operation, the patient died.

On dissection, Mr. Burns found the hip-joint completely surrounded with a soft matter resembling brain, enclosed in thin cells, and here and there other cavities, full of thin bloody water, presented themselves. The acetabulum and head of the os femoris were both carious. The muscles were quite pale, and almost like boiled liver, having lost their fibrous appearance. The same kind of substance was found in the pelvis, and most of the inside of the affected bones was carious. Large cells, containing bloody water, were observed in the diseased substance, and it was into one of these cavities that the trocar had entered, when the attempt was made to tap the bladder. *Gil. JUGULAR VEIN, how to bleed in. See *Bleeding*.

JUGULAR VEIN, INTERNAL, WOUNDED. *Dr. Giraud* cursorily mentions a case, in which a French surgeon, at the military hospital of Toulouse, early in the year 1814, passed a ligature round the trunks of the common carotid artery and internal jugular vein. Both these vessels had been wounded by a musket-shot. On the sixth day from the application of the ligature, nothing unfavourable had occurred; but the final result of the case is not related. KALI See *Potassa*.

KERATONYXIS. The term, *keratonyxis*, derived from *κερας*, a horn, and *νυξις*, a puncture, is employed by the professors in Germany to denote the operation of couching performed through the cornea, or horny coat of the eye, the opaque lens being in this manner sometimes depressed, some-

times broken piecemeal, and in other instances, merely turned, so as to place its anterior and posterior surface in the horizontal position. The latter method is what the German surgeons particularly imply by the phrase *reclination*. See *Cataract*.

KNEE, DISEASES, AND INJURIES OF THE. See *Dislocations; Fractures; Gunshot Wounds; Joints, &c.*

L.

LACHRYMAL ORGANS, *Diseases of the.* The lachrymal gland cannot be said to be a part which is frequently the seat of disease. Richerand has seen no instance of an inflammation of this gland, unless by this expression he implied cases in which all the contents of the orbit are more or less affected. (*Nosogr. Chir. T. 2, p. 32.*) I believe that the surrounding cellular substance is more frequently attacked with inflammation and suppuration, than the gland itself. According to Professor Beer, (*Lehre von den Augenkr. B. 1, p. 349.*) true idiopathic inflammations of the lachrymal gland are very rare, and he declares, that in the course of a practice of twenty-seven years, he has but seldom met with them. On this point he differs from Schmidt, who fancied that he had often had under his care cases of this description in gouty and scrofulous subjects. (*Ueber die Krankh. des Thränenorgans, p. 134.*) When the lachrymal gland is attacked with inflammation, its secretion, far from being augmented, as Richerand describes, is always considerably lessened, and therefore one of the earliest symptoms is an uneasy dry state of the eye, the secretion from the meibomian glands, and mucous membrane of the eyelids, not being alone sufficient for keeping the eye duly moist and lubricated. This state is succeeded by a throbbing acute pain in the temple, shooting to the eyeball, forehead, upper and lower jaws, and back of the head. In the mean while, the temporal portion of the upper eyelid becomes swelled, tense, red, and exceedingly tender, the tunica conjunctiva being scarcely at all affected, and merely exhibiting a slight degree of redness and tumefaction towards the outer canthus. However, as the swelling of the gland increases, the eyeball becomes pushed more or less downwards, and inwards towards the nose. But though there is little or no redness, nor any mark of inflammation about the eye, this organ is tense, and extremely tender. The freedom of its movements towards the temple is much lessened in the beginning of the complaint, and, when the tumour has acquired a very large size, is quite destroyed. The impairment of vision is always proportionate to the protrusion of the eyeball, the pupil being diminished, and the iris motionless. The second, or suppurative stage, Beer describes as ushered in by fiery appearances before the eye: an increased displacement of the eyeball; throbbing pain; great increase of the swelling of the upper eyelid, and of the conjunctiva, towards the temple; an annoying sensation of cold, and heaviness in the eye and orbit. Now, under febrile symptoms, rigours, &c. a yellowish point presents itself, either on the reddened portion of the conjunctiva or on the outside of the eyelid, and a fluctuation becomes distinguishable. (*Beer, Lehre, &c. B. 1, p. 350.*) Beer speaks of abscesses

sometimes forming in the vicinity of the lachrymal gland, and terminating in a small sinus, which communicates with one of the principal excretory tubes, and discharges occasionally a thin limpid fluid. (*Lehre von den Augenkr. B. 2, p. 184.*) The experience of this author leads him to consider these sinuses either as a consequence of an unskillfully treated abscess of the upper eyelid, or of a similar neglected affection of the cellular membrane, near the lachrymal gland; or, lastly, of the presence of a portion of the sac of a burst encysted tumour. According to Mr. Travers, the lachrymal gland often suppurates in children, and occasions an excessive swelling above the upper eyelid, depressing the tarsus so as completely to conceal the eye. The abscess, he says, may be conveniently opened, and discharged beneath the eyelid. (*Synopsis of the Diseases of the Eye, p. 228.*) With respect to the treatment of any local inflammation in and about the lachrymal gland, the best means of relief would be leeches, fomentations, emollient poultices, and other common antiphlogistic remedies. In the suppurative stage, Beer recommends mixing with the poultice a good deal of hemlock.

The lachrymal gland is subject to scirrhus enlargement, and, in cases of carcinoma of the eye, it is one of the parts in which a return of the disease is apt to occur. Hence, it is now generally considered right to remove it as soon as the eyeball has been taken away. (*See Eye.*) Sometimes the gland is primarily affected, and Guerin removed one in the state of scirrhus, and so much enlarged, that the eye was entirely covered by it. This operation was performed with such dexterity, that the external straight muscle was not at all injured. Mr. Travers has also removed a scirrhus and enlarged lachrymal gland. The vision of the eye had suffered considerably during the growth of the tumour. The only deformity after the operation, was a slight prolapsus of the eyelid. This gentleman recommends operations of this kind to be always done, if possible, beneath the eyelid. (*Synopsis, &c. p. 228.*)

The caruncula lacrymalis is liable to chronic induration and enlargement, constituting the disease already spoken of in a foregoing part of this work, under the name of *Encanthis*, of which there is also a scirrhus, carcinomatous, or malignant form, quickly extending its effects to the eyeball, and the adjacent thin bones of the orbit. (*Beer, Lehre von den Augenkr. B. 2, p. 188.*)

From these subjects, I proceed to consider the diseases of the excreting parts of the lachrymal organs; cases which, though of the most various natures, were formerly all confounded together under the title of *fistula lacrymalis*, and it is only within the last few years, that these complaints have been subjected to the same principles and distinctions, which are conceived to be highly use-

ful in other branches of surgery. As Mr. McKenzie has judiciously remarked, the consequence of not distinguishing the different diseases of the excreting parts of the lachrymal organs from each other, has been an attempt to discover some single successful method of curing them all. "Now, there is no one method of treatment by which this can be accomplished; and hence it is, that the several remedies which have been proposed, being eminently successful in one or other of these diseases, but not adapted to all the rest, have at different times been held in such various degrees of estimation." (*On Diseases of the Lachrymal Organs*, p. 10, 8vo. Lond. 1819.) And an intelligent critic observes, that in lachrymal diseases, obstruction of the nasal duct appears to be almost the only circumstance against which the treatment recommended by the surgeons of France and England, has been directed. "On sait qu'au rétrécissement ou à l'oblitération du canal nasal produits par une cause quelconque, est due, dans presque tous les cas, la maladie qui nous occupe; soit que, restées intactes, les parois du sac présentent une tumeur lachrymale, d'où les larmes refluent continuellement sur les joues, à travers les points lachrymaux: soit qu'en partie détruites et ulcérées, ces parois présentent une fistule, qui offre aux larmes un passage contre nature, sans cesse entretenue par elles; en sorte que ces deux états, la tumeur et la fistule, sont presque toujours des degrés différens d'une même affection, et que le traitement qui convient à l'une repose sur les mêmes bases que celui indiqué dans l'autre." (*Œuvres Chir. de Desault*, T. 2, p. 120.) It is evident from the writings of Pott and Ware, that even these authors considered the obstruction of the nasal duct, as the foundation of all the train of varied symptoms presented by the excreting lachrymal organs. "An obstruction in the nasal duct is most frequently the primary and original cause of the complaint." "The seat of this disease is the same in almost every subject," says Mr. Pott (*Obs. on the Fistula Lachrymalis*;) and Mr. Ware, in his observations on the same disease, sets out with the same assumption. Now, obstruction of the nasal duct is an occasional consequence merely of inflammation of the excreting lachrymal organs; in most of their diseases, obstruction of the nasal duct has no part; and one might, with as much propriety, treat all the affections of the bladder and urethra, by the dilatation of the latter part, as treat all the diseases of the excreting lachrymal organs, by dilating the nasal duct. The false assumption in question has led to most erroneous treatment. For instance, in blennorrhœa of the sac, and in hernia of the sac, though in both these diseases the nasal duct is patent, the common treatment in this country is to open the sac by the knife, and thrust down a style, or some other instrument into the nose: thus destroying the organization of the parts which are affected merely with a gleet secretion in the one case, and with extreme relaxation in the other. Sup-

pose (says the same critical writer) that some charlatan should make oath at the Man-ion-House, that he had cured fifty or a hundred cases of gonorrhœa by opening the urethra in the perinæum, and passing a bougie through that tube, from behind forwards, who would approve of such an operation? Yet the laying open of the lachrymal sac, and thrusting a probe down into the nose, when the nasal duct is either perfectly patent, or at the most, slightly tumid from inflammation, is neither less preposterous, nor less cruel. (*See Quarterly Journ. of Foreign Medicine*, Vol. 1, p. 293.) Indeed, it is somewhat surprising, that errors of this kind should have prevailed so long, particularly as experience had taught Mr. Pott, that slight cases might be benefited by the simple employment of a vitriolic collyrium; a fact which ought to have convinced him, that the disease did not always depend upon obstruction of the nasal duct. It is curious, therefore, that he did not fully see this mistake; for, that he knew of these diseases having great variety, is evident from the following remark: As the state and circumstances of this disease are really various, and differ very essentially from each other, the general custom of calling them all by the one name of fistula lachrymalis is absurd." I believe, that one great cause of deception has been the fact, that, though laying open the lachrymal sac, and the introduction of instruments down the nasal duct, have been frequently practised, when milder plans would have answered every purpose, yet a cure has often followed the practice, and thus confirmed the supposition of relief having been effected by the removal of the imaginary obstruction in the nasal duct. Thus the late Mr. Ramsden, of St. Bartholomew's, with whom I served my apprenticeship, always followed the common plan of passing a probe down the nasal duct, and letting the patient keep a piece of bougie, or a style, in the part for two or three months afterward; and I scarcely recollect an instance in which he failed to accomplish a cure, though I have no doubt that the same benefit might sometimes have been obtained without any operation at all. And a discerning practitioner should never forget that, if no permanent obstruction exist in the nasal duct, a cure will generally follow, on the subsidence of inflammation, and a change taking place in the action of the parts, whether a probe, style, cannula, bougie, or seton, be employed, or not.

Erysipelas of the Parts covering the Lachrymal Sac.—Beer considers it highly necessary that this case should be discriminated from inflammation of the sac itself, which is often but little affected, and this even when an abscess forms. Unless the true nature of the disease be comprehended, the surgeon is apt to suppose, that the matter is in the sac itself, and believes that, when he makes an opening, he is puncturing that receptacle, whereas he is in reality, merely dealing with a superficial abscess of the integuments. Nor, as Beer has observed, is the mistake free from ill consequences; for, imagining

that the wound is made into the sac, the surgeon pokes about with his probe so long, that a good deal of unnecessary pain and inflammation is produced. According to the same author, the case is not very frequent, and is mostly met with in scrofulous subjects, who have had for a considerable time a blennorrhœa of the lachrymal sac. The inflammation partakes of the usual characters of erysipelas, and commonly extends to the eyelids, particularly the upper one. The absorption and conveyance of the tears into the lachrymal sac are interrupted, because the inflammation constantly affects the lachrymal ducts and papillæ, the latter appearing considerably shrunk. When the inflammation spreads over the side of the face, Beer says there is usually a discharge of thin mucus from the nose; and when the affection extends more deeply to the anterior portion of the lachrymal sac, as may easily happen when the case is neglected, or treated in its first stage with stimulating applications, a bean-shaped, circumscribed, hard, painful tumour may be felt, or is even denoted by its very red appearance. The puncta lachrymalia are now completely closed, the papillæ shrivelled up, and the nostril on the affected side very dry and tender.

If in the first stage of the disorder, the lachrymal papillæ and canals have not been too violently affected, the former parts expand again, and the absorption of the tears recommences with the second stage. But, at this period, according to the observations of Professor Beer, a good deal of mucus is secreted from the caruncula lachrymalis and Meibomian glands, and collects and glues the eyelids together, especially during sleep. At the same time, mucus generally accumulates in the lachrymal sac itself, and may be voided both through the puncta lachrymalia and nasal duct, by gentle pressure. The mucous discharge from the nostril also acquires a thicker consistence. Should the lachrymal papillæ and ducts have suffered more severely in the first stage of the disease, the due absorption of the tears does not begin after the subsidence of the inflammation, and a dropping of them over the cheek, a *stillicidium lachrymarum* frequently continues a long while after the termination of the other symptoms. It depends upon the atony of the lachrymal puncta and ducts, and is very troublesome in cold wet weather. And, when the lachrymal sac itself has been a good deal inflamed in the first stage of the complaint, a large quantity of mucus collects within it in the second stage, and may be discharged by pressure. Sometimes the subcutaneous abscess actually communicates with the cavity of the sac; a case, which Beer terms a spurious fistula of the lachrymal sac, the matter not being formed in that receptacle itself, but getting into it from the external abscess. As the skin is generally rendered very thin, these abscesses near the bridge of the nose usually burst by several openings. Beer remarks, that it is easy to learn, whether the ulceration extends through the lachrymal sac; for when this has hap-

pened, the slightest pressure upon the superior part of the sac produces a discharge of pus and mucus from the external opening, and, if the lachrymal canals have already recommenced their functions, the discharge will also be mixed with tears. (See *McKenzie on Diseases of the Lachrymal Organs*, p. 22.) The quantity of matter, which flows out, is likewise so copious, that it is evident it could not have been all lodged between the skin and orbicularis palpebrarum muscle, but must have come partly out of the lachrymal sac. The use of a fine probe will remove any doubt which may be left. (*Beer, Lehre von den Augenkr. B. 1, p. 332—35.*)

On the subject of the causes of this complaint, the preceding author delivers no remark worthy of notice. In speaking of the prognosis, he observes, that when the case is not neglected, nor wrongly treated in its first stage, and the inflammation has not extended to the lachrymal sac, the prognosis is very favourable; for, after the subsidence of the inflammation, a temporary atony of the lachrymal puncta and ducts, an imperfect conveyance of the tears into the nose, and of course a slight oozing of them over the cheek, most troublesome in cold, wet weather, are the chief inconveniences which remain. But, when the lachrymal sac participates in the inflammation, the prognosis is much less favourable; because, when suppuration takes place, ulceration is apt to form an opening in the front part of the sac, or else, during the second stage, a large quantity of mucus may collect in the sac, and, if not skilfully treated, it frequently ends in a very obstinate blennorrhœa of that part. As Beer observes, this is a case which is often, though quite erroneously, named a fistula lachrymalis. (*B. 1, p. 336.*)

The prognosis is also very favourable in the second stage of the complaint, as long as the suppuration is restricted to the integuments, and it is characterized by desquamation and scabbing; but, the case is more serious, when a large collection of matter forms, and particularly when the abscess makes its way into the lachrymal sac. In these last circumstances, an obstinate blennorrhœa from the sac often follows, notwithstanding the fistulous sore be treated in the most skilful manner, and sometimes the matter spreads so far around, as to spoil, and even annihilate, the lachrymal canals, and cause an irremediable dropping of tears over the cheek, during the rest of the patient's life. (*Beer.*)

The suppuration (says Mr. McKenzie) may destroy the ligamentous layer of the lower eyelid, and end in the total obliteration of the cavity of the sac. But when the sac is not thus annihilated, and the lachrymal canals are destroyed, it is necessary that the cavity of the sac should be obliterated by artificial means; for otherwise a form of disease will follow, which Beer denominates *hydrops sacci lachrymalis*, and Mr. McKenzie, *mucocœle*, as will be hereafter noticed.

"In common cases, a piece of folded linen, dipped in cold water, and applied to

the parts affected, and the administration of gentle doses of sulphate of magnesia, make up the treatment. In severe cases, it will be found necessary, not only to continue the cold applications, and to open the bowels, but to administer an emetic of tartrate of antimony, to purge freely, and even sometimes to take away blood from the arm." (*McKenzie, p. 24.*)

In the second stage, a warm dry air, and a linen compress, are commended, with the exhibition of diaphoretics. In the two first of these means, I confess, that I should place little or no confidence. When the formation of matter cannot be prevented, poultices are to be used. Beer particularly cautions us not to leave the abscess to burst of itself, but to open it immediately a fluctuation can be felt, so as to prevent an ulcerated opening from taking place in the anterior part of the lachrymal sac. And, if the surgeon has not been consulted before such a communication has been established between the sac and subcutaneous abscess, he should avoid all unnecessary disturbance of the parts with probes and syringes, and at most, only wash out the abscess once a day with Anel's syringe, filled with lukewarm water and a little of the vinous tincture of opium. Beer also recommends introducing into the superficial abscess, but not into the sac, a small quantity of lint, dipped in the tincture. If the blennorrhœa of the sac continue, it is to be treated as will be explained in considering the second stage of inflammation of that part.

Inflammation of the Lachrymal Sac.—According to Beer, the symptoms of the first stage of this complaint are as follows: in the corner of the eye, precisely in the situation of the lachrymal sac, a circumscribed, very hard, tender swelling arises, of the shape of a bean, producing a lancinating pain when it is touched, and gradually acquiring considerable redness. The absorption and conveyance of the tears into the lachrymal sac, and thence into the nose, are completely interrupted; the lachrymal papillæ are shrunk; the puncta cannot be seen; and of course the tears fall over the cheek. The nostril on the affected side is at first very moist, but soon becomes perfectly dry, the mucous membrane being a good deal affected. As the inflammation also constantly spreads to the orbicular muscle and integuments in the corner of the eye, the complaint often presents an erysipelatous appearance, extending to the eyelids and down the cheek; but, the circumscribed swelling, caused by the inflamed sac, is still not only capable of being distinctly felt, but even seen. It rarely happens, in cases of common inflammation, that on the change of the first stage into the second, the nasal duct is rendered impervious by an effusion of lymph; but such an occurrence is more frequent where the inflammation is not of a healthy description, and the patient is scrofulous. Under these circumstances, the lachrymal canals may also be permanently obliterated.

In weak, irritable constitutions, towards the end of the first stage of the inflammation, a degree of symptomatic fever prevails, with severe headach, great redness and swelling of the whole inner canthus, involving the caruncula lachrymalis, the semilunar fold, the conjunctiva, the edges of the eyelids, and the lachrymal puncta.

Here as in inflammation of every mucous membrane, at the very commencement of the second stage, a copious morbid secretion takes place, and accumulates in large quantity; for, either in consequence of the thickening of the mucous membrane, the adhesion of the sides of the nasal duct together, or there being no mixture of the tears, the secretion within the sac cannot escape either into the nostril, or out of the lachrymal puncta, and consequently it distends in a prodigious degree the anterior side of the sac, where it is uncovered by bone. Hence, the swelling is here very manifest, and a fluctuation may be felt in it, even before the suppurative stage has actually begun. According to Beer, whoever is induced by the fluctuation to open the lachrymal sac at this period, will certainly bring on a very hurtful suppuration of the part, exceedingly likely to render the excreting parts of the lachrymal organs completely unserviceable. At the beginning of the second stage, there is also a morbid secretion from the mucous membrane of the nostril and caruncula lachrymalis. Now not only the swelling of the lachrymal sac increases more and more, the redness acquires a deeper colour, the skin becomes more shining, the fluctuation still more evident; and, at length, in the centre of the tumour formed by the lachrymal sac, a yellowish, soft point presents itself. In this state of things, in order to prevent a true fistula, the surgeon should make an opening in the lachrymal sac, without the least delay; for, if the abscess be left to itself, the pus will at last make a passage for itself through the orbicular muscle and integuments; but it will only be a small fistulous opening, surrounded with callous hardness, and merely capable of letting some of the pus and mucus of the sac escape, so that the thicker part of the matter remains behind, and, consequently, though the swelling diminishes after the formation of a spontaneous opening, it does not entirely subside. A quantity of blood is also remarked to be blended with the discharge from the sac. This last is the case, which Beer denominates a *true fistula of lachrymal sac*. When the abscess bursts of itself, the fistulous opening in the sac is not always exactly opposite the aperture in the skin, and, though there is commonly but one communication with the sac, it sometimes happens, that several small external openings are produced more or less distant from the sac. The diagnosis is easy enough; for, on pressing upon the upper portion of that receptacle, mucus and pus, blended together, are immediately discharged from all the fistulous apertures. After the disease has lasted a good while, it not unfrequently happens,

that tears are also voided from the fistulous opening; a circumstance, indicating the restored action of the lachrymal puncta and canals; but, according to Beer, such tears are never duly blended with the mucous and purulent matter. He further remarks, that, when the second period of the second stage, or the suppurative process is over, a morbid secretion of mucus still continues in the third period of the second stage, that secretion becoming whitish, thick, opaque, and only partly resembling pus. As, in consequence of its thickness, and the swelling of the mucous membrane of the nasal duct, the secretion cannot descend into the nose, it collects in the sac, and sometimes pushes off any piece of lint, or plaster, with which the external opening in the sac has been closed. At length, by means of judicious treatment, this third period of the second stage is also brought to a termination; the mucus is secreted again in due quantity; it becomes transparent like white-of-egg, and viscid; but white streaks may be for some time perceived in it. Afterward the mucus becomes thinner, and, if the functions of the lachrymal puncta and ducts are not destroyed, it is thoroughly mixed with the tears. The opening in the lachrymal sac now either heals up of itself, or under skilful treatment; but, in general, a minute fistulous aperture still remains, from which the tears and mucus are occasionally voided, if the passage through the nasal duct be not free. However, if the small fistulous aperture should happen to heal up completely, the mucus and tears accumulate in the sac, and the patient is obliged to press them out through the puncta lachrymalia several times a day.

When the surgeon is consulted early enough, and proper treatment is adopted, Beer sets down the prognosis in the first stage of the inflammation as very favourable. But, if the practitioner be called in later, it will not be in his power completely to disperse the inflammation, and prevent the morbid secretion, and accumulation of mucus in the lachrymal sac; the *blennorrhœa* of this part, of professor Beer, or the *dacryops blennoideus*, of Schmidt; a state, however, which soon gives way to judicious treatment. But, when the case is neglected, or wrongly managed at the period, when the lachrymal sac is violently inflamed, a complete, or partial closure of the nasal duct by adhesive inflammation is apt to be the consequence. And, the same effect may also be produced in the lachrymal canals, in which event, the absorption of the tears is for ever impeded, and the patient must remain the rest of his life afflicted with a *stillicidium lachrymarum*.

With regard to the prognosis in the second stage of inflammation of the lachrymal sac, Beer considers it as very dubious, on account of the impairment of the functions of the excreting parts of the lachrymal organs; for, says he, no surgeon can exactly know, what may have been the result of the first stage, in relation to the perviousness of the nasal duct and lachrymal canals, and an officious examination of the parts with a probe, for

the purpose of obtaining information, would be attended with considerable mischief. However, generally speaking, the prognosis is most hopeful at the first period of the second stage, just when the morbid secretion of mucus is beginning; the suppuration may yet be moderated by right treatment, and the excreting parts of the lachrymal organs preserved. But, if the suppurative stage has already come on, much will depend upon the consideration, whether the matter has been originally formed in the lachrymal sac, has lodged there a good while, and the sac is ready to burst, or whether there is actually an opening in the sac opposite that in the skin, or, lastly, whether the openings do not correspond. In the first case, the suppuration yet admits of being regulated by judicious treatment, and the lachrymal sac can be punctured; but, in the other circumstances, the management of the case is far more difficult, especially when the patient's constitution is not good. However, the surgeon should be careful not to disfigure the patient with a large scar; and the aim should be to prevent atony of the lachrymal puncta and ducts, and a consequent *stillicidium lachrymarum*. These are the least serious evils to be apprehended from mismanagement; for, if the case be ill-treated, or neglected, in the latter stage of the suppurative process, necessarily attending a fistulous state of the sac, the lachrymal organs may be rendered quite useless, or even entirely destroyed, and the nasal duct obliterated, or obstructed by the effects of caries. In some few instances, indeed, the whole lachrymal sac is destroyed, or will require to be so by art, as will be presently explained. It is always a favourable circumstance when the tears are seen to issue from the fistulous opening with the mucus and pus, as it is a proof that the absorption and conveyance of the tears into the lachrymal sac are established again, and that now the only question is about the state of the nasal duct, which point cannot be determined before the fistula is completely healed, and the third period of the second stage is entirely obviated. (Beer, *Lehre von den Augenkr. B. 1, p. 356—367.*)

In the first stage, the indication is to endeavour to resolve the inflammation. "It is, (as Mr. McKenzie observes) by combating the inflammation, that we are to cure this disease, and not by attacking merely one, or even several of the symptoms. Dilatation, for instance, by the introduction of probes through the canals into the sac and even into the nose, would only be subjecting the inflamed parts to a new cause of irritation, and might thus produce effects which would render a complete cure difficult, if not impossible." On the contrary, in the first stage, Mr. McKenzie joins Beer in praise of antiphlogistic measures; the application of cold lotions to the part; and, in severe cases, venesection and leeches are set down as proper, together with opening and diaphoretic medicines. (*On Diseases of the Lachrymal Organs, p. 33, 34.*)

In the second stage, when resolution

no longer practicable, emollient applications are the most beneficial, and all debilitating means are to be stopped, by the further use of which an incurable blennorrhœa of the lachrymal sac would be likely to be induced. And, as soon as the sac is so distended with mucus and matter, that the centre of the swelling begins to be soft, and a fluctuation is perceptible, the sac should be freely opened, so as to let its contents have a ready outlet. If, after this evacuation, there should be any deep-seated hardness of the lachrymal sac, Beer recommends the application of a camphorated hemlock poultice. Afterward, the wound in the skin and sac is to have introduced into it a little bit of lint, dipped in the vinous tincture of opium, over which dressing a piece of diachylon plaster may be placed. When, under such treatment, the suppuration diminishes, but a preternatural secretion of mucus yet continues, Beer introduces into the wound every day a piece of lint, on which is spread a little bit of the following ointment: *R. Butyri recentis insulsi, 3ss. Hydrargyri Nitrico-Oxydi, gr. x. tutiæ, ppt. gr. vj. M.* And, on changing the dressings, some of the following lotion may be dropped into the inner canthus, and injected lukewarm into the sac itself: *R. Subacetatis Cupri, Potassæ Nitratis, aluminis, ā a gr. iij.—vj. Camphoræ tritæ grij.—iv. Aquæ distillatæ 3ss. Solve et cola. Liquori colato adde Vini Opii 3j.—3ij. Aquæ Rosæ 3iv. M.* Professor Beer makes a mass of the three first articles melted together in equal proportions, and terms it the *lapis divinus*, of which he makes the lotion, and then adds the other ingredients. When, by means of such treatment, the mucous secretion from the sac has been brought into a healthy state, and all the induration has subsided, the period has arrived for the surgeon to think of taking measures for the re-establishment of the passage through the nasal duct, if it should not already have become pervious of itself, which, when the inflammation has been of a healthy kind, and the treatment judicious, very frequently happens. (*Beer, Lehre, &c. B. 1. p. 369—371.*)

Chronic Blennorrhœa of the excreting Parts of the Lachrymal Organs.—Mr. M'Kenzie, whose Essay contains a faithful account of Beer's opinions upon the present subject, describes the inflammation, with which this form of disease commences, as seldom considerable, and in scrofulous patients, it is said to be not unfrequently quite disregarded, no advice being taken until the lachrymal sac is much distended with mucus. By means of pressure upon the bean-shaped tumour, caused by such distention of the sac, a quantity of puriform mucus is forced out of the puncta lachrymalia, and overflows the eye; and so far are the lachrymal canals from being obstructed, that, excepting when any return of inflammation happens, they even absorb, and convey the tears into the sac. Pressure, however, will rarely make the contents of the sac pass through the nasal duct, on account of the thickened

state of the mucous membrane, and therefore the nostril is generally very dry. "In the course of this tedious disease, the accumulated mucus varies much both in quantity and quality. For instance, the mucus accumulates more rapidly, and is much thicker after a good meal, than at other times. The secretion of it is very plentiful, but thinner than usual, when the patient continues long in a moist cold atmosphere. In this case, the overfilling of the sac takes place so rapidly, that the compression of the orbicularis palpebrarum in the action of winking is sufficient to evacuate the sac through the canals to such a degree, that the whole surface of the eyeball is suddenly overflowed, and the puriform fluid runs down upon the cheek. After the patient remains for a short time in a warm and dry atmosphere, the morbid secretion becomes sparing and ropy. We find, that this chronic blennorrhœa almost completely disappears in many individuals during warm weather, upon which the yet unexperienced patient and the unexperienced surgeon are apt to express a great, but a premature joy, for, on the very first change to cold and wet weather, the disease most frequently returns."

During chronic blennorrhœa, the lachrymal sac is extremely liable to repeated attacks of inflammation, and sometimes a fistula, with a good deal of induration of the surrounding cellular substance, is produced. Mr. M'Kenzie represents this disease as the most frequent of all those to which the excreting parts of the lachrymal organs are liable, and as consisting in inflammation of these organs, modified by scrofula, general debility, disorder of the digestive organs, or other constitutional causes which prolong its second stage. "Even regarded locally, the present disease is seldom a primary affection, but is most frequently excited by catarrhal inflammation of the Schneiderian membrane, or by a long-continued disorder of the Meibomian glands." (*M'Kenzie on Diseases of the Lachrymal Organs, p. 37—40.*)

Scarpa's opinions on the present subject are in some degree peculiar to himself; for he considers the affection of the Meibomian glands and inside of the eyelids, the *puriform palpebral discharge*, as he terms it, as constituting the first degree of all those complaints which have usually gone under the name of fistula lachrymalis; the second degree, or effect, being the tumour of the lachrymal sac; and the third, the fistula, or ulcerated opening in the latter part. Scarpa asserts, that the chief part of the yellow viscid matter, which accumulates in the lachrymal sac, is secreted by the lining of the eyelids, and by the little glands of Meibomius; and that the altered quality of this secretion has a principal share in the cause of the disease. He states, that the truth of this fact may at once be ascertained by everting the eyelids, and especially the lower one of the affected side; and by comparing them with those of the opposite eye.

The former will always exhibit an unnatural redness of the internal membrane, which has a villous appearance all over the extent of the tarsus; while the edge of the lid is swollen, and numerous varicose vessels are distinguishable on it. The follicles of Meibomius are also turgid and prominent, and when examined with a magnifying glass, not unfrequently appear to be slightly ulcerated.

"The villous structure then, which the surface of the internal membrane of the palpebra assumes in these cases, becomes an organ secreting a larger quantity of fluid than usual, resembling viscid lymph, which, as before stated, being mixed with the sebaceous matter, copiously effused from the glands of Meibomius, constitutes the whole of the viscid fluid, with which the eyelids are imbued, and which is continually carried by the puncta lachrymalia into the sac, so as to fill and also frequently distend it, until it forms a tumour.

"If, indeed, the lachrymal sac is emptied of this matter, by means of compression, and the eye and internal surface of the palpebræ are carefully washed, so that none of the glutinous humour, pressed from the sac, may remain upon them, and the eyelids are everted half an hour afterward, the internal surface, especially of the lower one, will be found covered with a fresh effusion of mucus mixed with sebaceous matter, which has evidently not flowed back from the lachrymal sac to the eye, but has been generated between the eye and the palpebræ." Another argument, brought forward by Scarpa, in support of his theory, is, that, if the morbid secretion of the eyelids be retarded, or suppressed, either accidentally or by means of astringent applications, little or none of the viscid secretion collects in the lachrymal sac, or can be forced out of the puncta lachrymalia. He has also constantly observed, that the puriform discharge may be radically cured at its commencement, and before it has induced any flaccidity of the sac by a timely correction of the morbid secretion from the inside of the eyelids, and keeping the lachrymal passages cleansed, by means of injections of simple water through the puncta lachrymalia into the nose. As for the internal membrane of the sac itself, he argues, that its structure does not qualify it for secreting a tenacious unctuous matter, like what is chiefly discharged from it, as it is entirely destitute of sebaceous glands, and can in reality only furnish a thin mucus. However, he admits, that if the sac happen to be inflamed and ulcerated, a turbid matter may issue from it with the tears; but, says he, this matter is true pus, and quite different from the curdy unctuous fluid which takes place in the puriform palpebral discharge. (*On the Principal Diseases of the Eyes*, Transl. by Briggs, Ed. 2. p. 3—7.)

The foregoing opinions of Scarpa have not met with universal assent, and though there is probably much truth in them, he may have overlooked too much the possible

simultaneous affection of the mucous membrane of the lachrymal sac and nasal duct. To Scarpa's hypothesis, Himly and Flajani have made the following objections: First, that they have observed the fistula lachrymalis, without the least morbid alteration of the eyelids and Meibomian glands. Secondly, that every puriform discharge of the eyelids is not succeeded by a fistula lachrymalis. Lastly, that the fistula lachrymalis is cured by means of the operation alone, without any attention being paid to the morbid state of the eyelids, when it exists. And Mr. Travers also regards Scarpa's account of the origin of the disease, independently of a permanent stricture, as hypothetical; for if founded in fact, the distention of the lachrymal sac, and the regurgitation of the fluid on pressure, would attend every severe lippitudo, or ophthalmia with puriform discharge, which is not the case. If Scarpa's account were correct, Mr. Travers sees no reason why the fluid, once admitted, should be arrested, or regurgitate, instead of passing into the nose, (see also *Nicod. in Revue Med. T. 1, p. 155*.) and he thinks there is every reason to believe that the fluid, so discharged, is the proper secretion of the sac, and cases are frequent, in which it is retained and cannot be expressed, owing to strictures both of the lachrymal and nasal ducts. (*Synopsis of the Diseases of the Eye*, p. 360.) Some of the arguments with which Scarpa meets this reasoning, are already anticipated, especially that which refers to the difference between the secretion of the sac itself, and that of the sebaceous glands of the eyelids. Also, in asserting that the origin of the fistula lachrymalis generally manifests itself on the eyelids, before the lachrymal passages are affected, Scarpa declares, that he does not pretend thereby to exclude altogether the possibility of a case, in which the membranes of the nasal duct and lachrymal sac may not be thickened and ulcerated, independently of the disease of the eyelids. That this is the case, I think is evident from the account already delivered in the two first sections of this article, of Beer's opinions, respecting the consequences of inflammation of the integuments and other parts about the inner angle of the eye, as well as respecting the effects of acute inflammation of the lachrymal sac itself. However, Scarpa admits the fact, and the question left is, whether he is right in assigning the morbid secretion from the inside of the eyelids, as the most common cause of the swelling, ulceration, &c. of the lachrymal sac? That every puriform discharge from the eyelids is not followed by fistula lachrymalis, he allows, is unquestionable; and this, he conceives, most probably happens, because the lippitudo has not been entirely neglected, or because the secretion being less dense and viscid than usual, descends freely with the tears into the nose through the lachrymal canals, which are large and pervious. But in the acute stage of the purulent ophthalmia, he asserts that the reason why the discharge is not conveyed into the

sac is, that the inflammation and swelling actually close the puncta lachrymalia, and change their direction, so that both the puriform matter and the tears fall over the cheek, and cannot descend into the sac.

As for the instances of cure, without any remedies being applied for the correction of the state of the eyelids, Scarpa deems the argument inconclusive, because particular vices of the constitution, under the use of appropriate internal remedies and a well-regulated diet, disappear, or are transferred to other parts, without the use of topical remedies.

For my own part, I am disposed to believe, that, whether the disease begin in the eyelids, or elsewhere, generally both their lining, and that of the sac and nasal duct are also more or less affected; and, consequently, though Scarpa's theory may not be in every respect satisfactory, nor at all applicable to certain disorders of the excreting parts of the lachrymal organs, the practice, to which his sentiments lead, will, in the generality of cases, which Beer denominates *chronic blennorrhœa*, be highly advantageous.

According to Mr. McKenzie, the local treatment of chronic blennorrhœa does not differ essentially from that of inflammation of the excreting parts of the lachrymal organs. But, every possible means must also be employed for improving the general health; for, otherwise all local remedies will be unavailing. In scrofulous cases, particular attention must be paid to diet and mode of living. In weakly persons, the preparations of iron will be highly beneficial; and, when the disease is connected with disorder of the digestive organs, the treatment recommended by Mr. Abernethy is that to which Mr. McKenzie expresses a preference. The employment of Anel's syringe and probe are strongly reprobated. "I grant, (says this author,) that the application of certain substances to the mucous membrane affected, is one of the most powerful means, which we possess, of correcting its disposition to chronic blennorrhœa. But, he who believes, that the best manner of applying these substances, is to inject them with Anel's syringe, introduced through the puncta, is lamentably mistaken. He is, in fact, closing his eyes upon what he must know of the functions of the several parts of the lachrymal organs, and is doing that very thing, which is calculated to prolong and exasperate the disease. Except at the time of a smart renewal of the inflammation, the puncta and canals, during this disease, continue in the exercise of their functions. Whatever fluid, therefore, is dropped into the lacus lachrymarum, will be taken up by the puncta, conveyed through the canals, and applied to the whole internal surface of the sac. Even ointments, placed within reach of the puncta, will be absorbed in the same manner. "We ought then first of all to empty the sac by pressure, and, if possible, through the nasal duct into the nose. Having placed the patient upon his back, we drop into the lacus lachrymarum a small quantity of a weak so-

lution of corrosive sublimate. *R. aq. ros. ʒiv. hydrarg. oxy. muriatis grss. grj. Mucil. ʒj. vini opii ʒj. ʒi.* After remaining for a quarter of an hour in that position, he ought to rise, but without wiping away any of the collyrium, which may remain. After another quarter of an hour, the eyelids are to be carefully dried, and a little of Janins's ophthalmic ointment applied with a camel-hair pen to the caruncula lachrymalis and edges of the eyelids. All this is to be carefully repeated twice a day." Protesor Schmidt recommends the following collyrium. *R. Aq. rosæ ʒvj. acid. nitrici ʒj. alcoholis ʒj. M.* For the removal of the induration over the sac gentle friction, with camphorated mercurial ointment is recommended. And, says Mr. McKenzie, if the blennorrhœa depend upon chronic inflammation of the Meibomian glands, the diluted citrin ointment is to be applied every evening at bed-time. (*On Diseases of the Lachrymal Organs, p. 43, &c.*) In the first stage of what Scarpa terms the puriform discharge of the palpebræ, when the weeping is incipient, this author states, that a cure may be effected, without dividing the sac, or any other painful operation. His practice consists in restraining the immoderate secretion from the Meibomian glands and internal membrane of the palpebræ, and in cleansing the viæ lachrymales through their whole extent by means of injections of warm water, rendered more active by the addition of a little spirit of wine, and thrown into the puncta lachrymalia every morning and evening; a measure, which, as already stated, is disapproved of by Mr. McKenzie, Schmidt, &c. Scarpa considers Janins's ophthalmic ointment, weakened with lard, or fresh butter, as the best application for correcting the morbid secretion of the eyelids. A portion, equal to the size of a barley corn, is to be introduced upon the point of a blunt probe, every morning and evening, between the eye and eyelids, near the external angle, and the edges of the eyelids are to be smeared with it. The eye is then to be shut, and the eyelids gently rubbed, so that the ointment may be distributed upon the whole of their internal surface. A compress and bandage should be applied, and the eyelids kept closed for two hours. At the end of this time, the eye should be washed with the zinc collyrium. When there are superficial ulcerations at the edges of the eyelids, Scarpa applies to them either Janins's ointment, or the unguentum hydrarg. nitrat., and in very obstinate cases, the argentum nitratum itself. If the vessels of the conjunctiva are varicose, he drops into the eye the tinctura thebaica. (*Scarpa, Ed. 2, by Briggs, chap. 1.*)

The late Mr. Ware was earlier than Scarpa in pointing out the advantage of making applications to the inside of the eyelids, for the relief of certain forms of disease, usually classed with fistula lachrymalis.

"When an epiphora (says he) is occasioned by an acrimonious discharge from the sebaceous glands on the edges of the eyelids, it must be evident, that injections into the sac

will be very insufficient to accomplish a cure, because the sac is not the seat of the disorder. The remedies that are employed must be directed, on the contrary, to the ciliary glands themselves, in order to correct the morbid secretion that is made by them; and for this purpose, I do not know any application that is so likely to prove so effectual as the unguentum hydrargyri nitratri, of the new London Dispensatory, which should be used here in the same manner, in which it is applied in common cases of the psorophthalmia. It will be proper to cleanse the eyelids every morning, from the gum that collects on their edges during the night, with some soft unctuous applications; and I usually advise to apply to them, two or three times, in the course of the day, a lotion composed of three grains of white vitriol, in two ounces of rose or elder-flower water." (*Additional Remarks on the Epiphora.*)

In a modern periodical work may be perused some interesting remarks by M. Nicod, which perfectly accord with the sentiment already expressed, that whatever may be its primary seat, the chronic inflammation is not generally limited to the inside of the eyelids, but extends throughout the membranous lining of the sac and nasal duct, and that this circumstance, in conjunction with the altered and viscid nature of the secretions, accounts for their not readily descending into the nose, but regurgitating through the puncta. M. Nicod also relates cases exemplifying that the ointment applied to the inside of the eyelids actually passes with the matter into the lachrymal sac, and thence into the nose, so as to act upon and cure the chronic inflammation of the sac and nasal duct, as well as that of the Meibomian glands and lining of the eyelids. (*See Revue Medicale Historique, &c. T. 1, p. 156, 8vo. Paris, 1820.*) The proceedings for adoption, when the nasal duct is obstructed, will now be considered.

Obstruction of the Nasal Duct.—That a permanent closure of this canal does not so frequently attend diseases of the lachrymal organs, as writers have generally imagined, must be evident from the remarks already delivered; and also that its perviousness, when interrupted partly by inflammation and thickening of its lining, and partly by the viscid curdy nature of the matter, may generally be restored, without thrusting any probes, tubes, or other instruments down the passage, (measures, more likely, under these circumstances, to do harm than good,) is a fact, which is no longer questionable. The treatment, necessary in such cases, must be already intelligible from what has been said in the preceding sections, the indication being the diminution of the thickened state of the mucous membrane, by means adapted to the acute, or chronic form of the inflammation, and, in many cases, the correction also of the morbid state of the Meibomian glands and internal membrane of the eyelids. It is only when the treatment, conducted upon these mild principles, is found ineffectual, that the surgeon should think of examining the state of the nasal duct, and learning, by the intro-

duction of a fine probe into the passage, whether any permanent stricture, or obstruction, is present. It does not appear to me, that it is a matter of much importance, whether the probe be made of whalebone, as Beer recommends, or of silver; but, that it should not be too thick is a thing certainly deserving greater attention. Supposing there is no direct opening through the skin into the lachrymal sac, one should be made with a lancet. However, a mere puncture will suffice, as a large incision, beginning just below the tendon of the orbicularis palpebrarum muscle, and extending in a semilunar form, nearly an inch downwards and outwards, as used to be the old practice, can here answer no rational object, the surgeon merely having occasion for a small direct opening, through which he may conveniently pass a small probe, for the purpose of ascertaining the state of the nasal duct. "The probe, (as Mr. McKenzie observes,) is to be introduced horizontally till it touches the nasal side of the sac; it should then be raised into a vertical position, and its point directed downwards and a little backwards. Turning the probe upon its axis, we pass it from the sac into the duct; and as we continue to press it gently downwards, the instrument, if the sac is pervious, enters the nose. If its point meets with some obstruction, we must not immediately conclude, that there is an obliteration of the duct. We must press down the probe a little more strongly, yet without violence, turning it round between the fingers, and giving it different directions. By these means, the obstacle is frequently overcome, and the probe suddenly descends. If the obstacle remains as before, and is extremely firm, still this is not sufficient ground for us to conclude, that there is a real obliteration," because, as the author proceeds to point out, the difficulty may arise from a mere thickening of the mucous membrane and swelling and induration of its cryptæ. (*McKenzie on the Lachrymal Organs, p. 78.*)

When the probe has entered a good way down the nasal duct, and becomes, as it were, wedged, Beer leaves the instrument in this position, until the next time of dressing, taking care, however, to fix it to the forehead, so that it may not slip out again. At the same time, he introduces into the lachrymal sac a tent, which he keeps in with a piece of sticking plaster. (*Lehre von den Augenkr. B. 2, p. 168;*) a measure which I conceive may be advantageously dispensed with. When, at length, the probe can be made to pass with some trouble into the nostril, Beer recommends introducing the instrument regularly every day, until the increased diameter of the passage allows it to be put in and withdrawn without the slightest difficulty. The period is now arrived, when Beer conceives, that some measure should be taken for rendering the perviousness of the nasal duct complete and permanent, and thus entirely re-establishing the efficiency of the excreting parts of the lachrymal organs. But, says this author, whoever merely aims at restoring the natural diameter of the nasal

duct by mechanical means, fulfils only one, and that not the most essential indication. And in order that the duct may retain its natural diameter, and the tears and mucus descend freely into the nose, it is necessary, that the morbid state of the mucous membrane be first removed, and the action of the excreting parts of the lachrymal organs rectified again; objects which cannot be performed by any mechanical means. Hence, Beer places considerable stress upon the necessity of obviating every unfavourable state of the health, likely to affect the mucous membrane of the lachrymal sac. For the purpose of restoring the natural diameter of the nasal duct, the experience of many years has convinced him, that pieces of violin catgut, which are to be gradually increased in size, are the best. The end of the piece, which is to be introduced, is to be first softened a little between the teeth, straightened, and dipped in sweet oil. Then at least six inches of it are to be introduced, so that its lower end may be easily drawn out of the nostril; a business, which Beer always lets the patient do himself. The upper portion of the catgut is coiled up, and kept within a little linen compress, on the patient's forehead. Beer also places in the opening of the sac a small dossil of lint, and covers it with a bit of sticking plaster. In two hours, the patient is to try to force the lower end of the catgut out of the nostril, by driving the air through the opening, while the mouth and opposite nostril are shut. As soon as the end of the catgut is secured, it is to be turned over the side of the nose, and fixed there with a piece of sticking plaster. The next day, the bit of plaster over the sac is to be loosened with warm water, and together with the dossil of lint, taken away, and one of the lotions, hereafter specified, injected down the passage. The upper end of the catgut on the forehead is next to be unfastened, and a fresh portion of it covered with some of the applications, presently mentioned, when the patient is to draw it into the sac and duct, by gently pulling the end, which hangs out of the nostril. The superfluous lower piece of catgut is now cut away, and the new piece turned up, and fixed to the side of the nose. The injection is again repeated, and the dressings applied, as before. The same method is to be continued, until the whole of the first piece of catgut is expended. Some water, coloured with the vinous tincture of opium, is now to be thrown down the sac, in order to see, whether any part of the fluid will pass into the nose, and what progress has been made. Then a larger piece of catgut is to be employed, exactly in the manner of the first, and when it is all exhausted, the coloured injection is to be used again, in order to learn what advance has been made in the re-establishment of the natural diameter of the passage. Lastly, a catgut of still larger size is to be used, after which the coloured injection will be found, when the patient inclines his head forwards, to run freely out of the nostril, and not merely drop into it, as it did previously. When this is the state of

things, all further dilatation becomes unnecessary. (*Beer. Lehre von den Augenkr. B. 2, p. 169—172.*)

This author then repeats his decided opinion, that the mechanical treatment with catgut, bougies, cannulae, &c., will only answer, when attention is paid to rectifying the morbid state of the mucous membrane of the lachrymal sac by means of suitable applications, the use of which, he thinks, ought to commence with the first employment of the catgut. And, he adds, that even such treatment will only succeed, when the diseased state of the membrane of the sac is entirely a local complaint, and uncomplicated with any unfavourable condition of the health. In the beginning, if the probe can be introduced without any great trouble, and the lining of the duct is only trivially thickened, Beer moistens the catgut, on its daily introduction into the passage, with the vinous tincture of opium, and injects into the sac a lukewarm lotion, containing the proportions of subacetate of copper, nitrate of potass, alum, camphor, and vinum opii, specified in one of the preceding columns. The lint, which Beer places in the orifice of the sac, is also dipped in the vinum opii. When the probe meets with more resistance, the catgut is smeared with the unguentum hydrargyri nitrati, which is to be at first weakened, and afterward gradually increased in strength. The wound is also to be dressed with the same application, and some of the following lotion injected down the sac twice a day: *R. Aq. Ros. ℥iv. Hydrarg. Oxymur. grj. ss. gr. j. Mucil pur. ℥j. Vini opii ℥j. M.* When any irregularities and indurated points are felt with the probe in the course of the nasal duct, Beer smears the catgut with an ointment, containing a small quantity of red precipitate, and directs frictions with a little camphorated mercurial ointment to be employed every day round the external opening.

Beer joins the generality of writers in believing, that a long perseverance in the mechanical means is necessary, in order to remove all disposition in the nasal duct to close again. (*P. 176.*) And, as the use of the probes, syringe, catgut, and dossils of lint, may be supposed to have done more or less injury to the lachrymal ducts, so as to cause some impediment to the due conveyance of the tears into the lachrymal sac, Beer advises a trial to be made, whether a couple of drops of some coloured fluid, introduced into the inner canthus, while the patient is lying upon his back, will pass into the lachrymal sac; and, if they will not do so, the same author thinks, that an attempt should be immediately made to clear the lachrymal ducts, by means of Anel's probe. (*P. 177.*)

According to Beer, the foregoing treatment is perfectly useless, whenever the lachrymal puncta and ducts are obliterated; because, even if it were practicable to restore their perviousness, it would yet be impossible to communicate to the new-formed apertures and canals the power of absorbing

the tears and conveying them into the lachrymal sac. He thinks, that, in this state of things, the practitioner need not trouble himself about the condition of the nasal duct; because, even if it were rendered duly pervious, this improvement would not continue long, as Beer's experience has fully convinced him, that, when the mucous secretion of the lachrymal sac is not blended with the tears, a closure of the nasal duct sooner or later ensues, and of course an accumulation of the mucus of the sac, a disease sometimes termed, under such circumstances, *hydrops sacculi lachrymalis*. And in order to prevent this complaint in the state of things just now described, Beer is an advocate for the total obliteration of the cavity of the sac with escharotics. (B. 2, p. 181.)

Such is the practice of Beer, with the view of clearing away obstruction in the nasal duct, and restoring its natural diameter. Let us now consider what methods have been suggested by others. Beginning then with the screw, invented by Fabricius ab Aquapendente, for compressing the distended lachrymal sac, I need only remark with M. Nicod, that, as this plan was not directed against the cause of the disease, it is not surprising, that it should have been unavailing, and ultimately banished from practice. In the year 1716, Anel invented a probe of so small a size, that it was capable of passing from the upper punctum lachrymale into the lachrymal sac, and nasal duct, the obstructions in which latter passage it was intended to remove. Anel also invented a syringe, whose pipe was small enough to enter one of the puncta, and by that means to furnish an opportunity of injecting a liquor into the sac and duct; and with these two instruments he pretended to be able to cure the disease whenever it consisted in obstruction merely, and the discharge was not much discoloured. "The first of these, viz. the passage of a small probe through the puncta, (says Mr. Pott) has a plausible appearance, but will, upon trial, be found very unequal to the task assigned; the very small size of it, its necessary flexibility, and the very little resistance it is capable of making, are manifest deficiencies in the instrument; the quick sensation in the lining of the sac and duct, and its diseased state, are great objections on the side of the parts, supposing that it was capable of answering any valuable end, which it most certainly is not." (Pott.)

It must be at once obvious, that Anel's instruments were devised with the view of avoiding a puncture in the lachrymal sac; but the principle has been strongly objected to by Beer, there being no comparison between the inconveniences of a small opening made in the sac, and the injury done to the lachrymal puncta and canals by the long and repeated introduction of instruments through them, whereby their functions are likely to be for ever ruined, of which Beer has seen some sad examples. (Lehre, &c. B. 2, p. 169.)

The next practice deserving notice, is that

of Laforest, who used to introduce into the termination of the nasal duct in the nostril a probe, with which he cleared away the obstruction in the passage. He also introduced into the same orifice a curved tube, which was left in the part three or four months, for the purpose of employing injections. The method, however, was found not only troublesome and difficult, on account of the anatomical varieties to which the termination of the nasal canal was liable, but also on account of the treatment, when practised, being subject to frequent failures.

Following up the principles of Anel, another French surgeon, Mejean, dilated the nasal duct with a seton, which was drawn up into the lachrymal sac by means of a thread first introduced from the upper punctum lachrymale. But it was soon discovered, that what was gained on one side, was lost on the other; the lodgment of the thread in the lachrymal duct for several months, and the irritation of its orifice in changing the seton every day, not only causing inflammation of the punctum lachrymale, but even such ulceration and cicatrices, as sometimes destroyed the functions of the parts.

J. L. Petit, sensible of the inconveniences of Mejean's practice, and disgusted with the barbarous imitation of the ancients in cauterizing the fistula, sac, and os unguis, conceived that, instead of these plans, or that of perforating the os unguis, as proposed by Woolhouse, it would be better to endeavour to restore the natural passage, by removing the obstruction in the nasal duct, which obstruction Petit regarded as the cause of the disease. His method consisted in opening the lachrymal sac with a small bistoury, introducing through the wound, sac, and nasal duct a probe, down into the nostril, and then using bougies for the dilatation of the passage. This method may be said to be the model of that which has been most extensively followed even down to the present time. Pellier and Wathen recommended introducing a metallic tube down the ductus nasalis, and leaving it for a time in that situation, with a view of preventing the duct from closing again; and the use of a cannula is even now preferred by Dupuytren, the greatest surgeon of France.

The desire of avoiding any puncture of the sac has influenced many practitioners besides Anel, and given rise to various ingenious inventions. Thus, in 1780, Sir William Blizard proposed, instead of injecting water, to introduce quicksilver through a small pipe, communicating with a long tube full of this fluid. The specific gravity of the quicksilver, when the sac was distended with it, he believed would have more power than water propelled through a syringe, to remove the lachrymal obstruction.

The late Mr. Ware, after trying Sir William Blizard's plan, gave the preference to Anel's syringe, with which he generally injected warm water, through the lower punctum lachrymale, into the lachrymal sac, and put a finger over the superior punctum to

prevent the fluid from escaping through it. With his finger he also occasionally compressed the lachrymal sac, in order to assist in propelling the water down into the nose. Mr. Ware sometimes used the injection thrice a day, though, in general, much less frequently. (See *Ware on the Epiphora*.)

"I in general begin the treatment by injecting some warm water through the inferior punctum lachrymale, and I repeat the operation four or five days in succession. If in this space of time, none of the water pass through the duct into the nose, and if the watering of the eye continue as troublesome as it was before the injection was employed, I usually open the angular vein, or direct a leech to be applied near the lachrymal sac; adding here a caution, that the leech be not suffered to fix on either of the eyelids, lest it produce an extravasation of blood in the adjacent cells. About the same time that blood is taken away in the neighbourhood of the eye, I usually vary the injection, and try the effects either of a weak vitriolic, or anodyne lotion. In some instances also, when I have found it impossible, after several attempts, to inject any part of the liquid through the duct, I have introduced a golden probe, about the size of a bristle, through the superior punctum lachrymale, and, attending to the direction of the duct, have insinuated its extremity through the obstruction, and conveyed it fully into the nose; immediately after which I have found that a liquid, injected through the inferior punctum, has passed without any difficulty; and by repeating these operations for a few successive days, I have at length established the freedom of the passage, and completed the cure. In other instances, I have recommenced a strongly stimulating sternutatory to be snuffed up the nose, about an hour before the time of the patient's going to rest, which, by exciting a large discharge from the schneiderian membrane, has sometimes also greatly contributed to open the obstruction in the nasal duct.

"Cases occur very rarely which may not be relieved by some of the means above related." (*Ware's Additional Remarks on the Epiphora*.)

When the discharge was fetid, Mr. Ware sometimes found, that a vitriolic lotion injected into the sac, quickly corrected the quality of the matter.

In a subsequent tract, Mr. Ware observes, that if, after "about a week or ten days, there be not some perceptible advance towards a cure, or, if, from the long continuance of the obstruction, there be reason to fear, that it is too firmly fixed to yield to this easy mode of treatment, I do not hesitate to propose the operation which is now to be described. The only persons, with respect to whom I entertain any doubts as to the propriety of this opinion, are infants. In such subjects, I always think it advisable to postpone the operation, unless the symptoms be particularly urgent, until they are eight or nine years old.

"If the disease has not occasioned an aperture in the lachrymal sac, or if this aperture be not situated in a right line with the longitudinal direction of the nasal duct, a puncture should be made into the sac, at a small distance from the internal juncture of the palpebræ, and nearly in a line drawn horizontally from this juncture toward the nose, with a very narrow spear-pointed lancet. The blunt end of a silver probe, of a size rather smaller than the probes, that are commonly used by surgeons, should then be introduced through the wound, and gently, but steadily, be pushed on in the direction of the nasal duct, with a force sufficient to overcome the obstruction in this canal, and until there is reason to believe, that it has freely entered into the cavity of the nose. The position of the probe, when thus introduced, will be nearly perpendicular; its side will touch the upper edge of the orbit; and the space between its bulbous end in the nose and the wound in the skin will usually be found, in a full-grown person, to be about an inch and a quarter, or an inch and three-eighths. The probe is then to be withdrawn, and a silver style of a size nearly similar to that of the probe, but rather smaller, about an inch and three-eighths in length, with a flat head like that of a nail, but placed obliquely, that it may sit close on the skin, is to be introduced through the duct, in place of the probe, and to be left constantly in it. For the first day or two after the style has been introduced, it is sometimes advisable to wash the eye with a weak saturnine lotion, in order to obviate any tendency to inflammation which may have been excited by the operation; but this in general is so slight, that I have rarely had occasion to use any application to remove it. The style should be withdrawn once every day for about a week, and afterward every second or third day. Some warm water should each time be injected through the duct into the nose, and the instrument be afterward replaced in the same manner as before. I formerly used to cover the head of the style with a piece of dyachylon plaster spread on black silk; but have of late obviated the necessity for applying any plaster by blackening the head of the style with sealing wax."

Mr. Ware did not, on first trying this method, expect any relief, till the style was left off. However, he found, that the watering of the eye ceased, as soon as the style was introduced, and the sight became proportionably more useful and strong.

The wound, which Mr. Ware makes in the sac, when there is no suitable ulcerated aperture, is only just large enough to admit the end of the probe, or style; and this soon becomes a fistulous orifice, through which the style may be passed without the least pain. In short, in about a week or ten days, the treatment becomes so easy, that the patient, or any friend, is fully competent to do what is necessary. It merely consists in withdrawing the style, two, or three times a week, occasionally injecting some warm

water, and then replacing the instrument as before.

Some, finding no inconvenience from the style, and being afraid to leave it off, wear it for years; many others disuse it in about a month, or six weeks, and continue quite well. The ulcerations, sometimes existing over the lachrymal sac, commonly heal, as soon as the tears can pass down into the nose; but Mr. Ware mentions two instances, in which such sores did not heal until a weak solution of the hydrargyrus murialis, and bark, were administered. (See *Ware on the Fistula Lachrymalis*.)

Great as the recommendation of the foregoing practice is, as delivered by Mr. Ware, Mr. Travers is strongly disposed to doubt, whether any permanent benefit was ever derived from letting the style remain in the passage. When an abscess over the sac has been opened, this gentleman, instead of the introduction of a style into the ductus nasalis, recommends simply the examination of the duct with a fine probe. "If the probe passes without resistance into the nose, the case requires no further operative treatment, the integument recovers its healthy condition under an emollient application, the discharge gradually diminishes, and the wound heals. If, on the other hand, upon examination with the probe, introduced through the wound, into the sac, resistance is offered to its passage into the nose, no more favourable opportunity will be presented for overcoming such resistance. This, therefore, should be accomplished, but to this the operative process should be limited, and the wound should be suffered to heal without further disturbance." When there is what Mr. Travers terms a stricture in the nasal duct, and the passage of the probe is more firmly resisted, he admits that some means must be employed for keeping the duct pervious, after it has been reopened. He never interferes with the integuments, except in the case of abscess discolouring the skin, and threatening to produce a fistula; and for the purpose of restoring the passage, he uses a set of silver probes, of about five inches long, of various sizes, flattened at one end, and slightly bulbous at the point. When there is no obstruction, these, he says, may be introduced with perfect facility from either of the puncta lachrymalia into the nostril. "If the punctum be constricted, it is readily entered, and dilated by a common pin; and, upon withdrawing it, by one of the smaller probes. The direction and relative situation of the lachrymal ducts, the sac, and nasal canal, point out the proper course of the instrument. It is confirmed by its advance, without the employment of force, and the sensation conveyed by the free and unincumbered motion of its point. Until the point is fairly within the sac, it is necessary to keep the eyelid gently stretched and slightly everted; the upper lid being drawn a little upward toward the brow; the lower, as much downward toward the zygoma. The point carried home to the sac, and touching lightly its

nasal side, the lids may be left at liberty, while a half circular motion is performed by the instrument; the surgeon neither suffering the point to recede, nor, on the other hand, allowing it to become entangled in the membrane. The probe now rests, in a perpendicular direction, upon the eyebrow, toward its inner angle, and, in this direction, it is to be gently depressed, until it strikes upon the floor of the nostril, where its presence is readily ascertained by a common probe passed beneath the inferior turbinated bone. The probe, of smallest dimensions, is of sufficient firmness to preserve its figure in its passage through the healthy duct, but it is too flexible to oppose any considerable obstruction. For the stricture of the lachrymal ducts, it is of sufficient strength. Very many cases of recent origin, and in which the stricture has no great degree of firmness, (Mr. Travers says) are completely cured by three or four introductions of the probe into the nostril, at intervals of one, or two days. I have seldom met with a stricture so firm as not to yield to the full-sized probe." When the resistance is not altogether removed, after this plan has been tried some days, Mr. Travers introduces a style, having a small flat head, a little sloped, through the punctum lachrymale into the nose, and leave it in the nasal duct for twenty-four hours. If worn longer, he says, that it causes ulceration of the orifice. A day or two is to elapse, before the style is again introduced, which must now be passed through the other lachrymal duct. On the intervening days, tepid water should be injected with Anel's syringe. (*Synopsis of the Diseases of the Eye*, p. 360, 370, 372, 374.)

Thus, we see, that Mr. Travers's practice bears a considerable resemblance to that of Anel, inasmuch as the sac is never opened, except when likely to ulcerate, and nearly every thing is done with probes and injections, introduced through the lachrymal puncta and ducts. I wish that my views of the nature of these diseases, and of the parts concerned, would allow me to think the latter proceedings, in the case of stricture of the nasal duct, as commendable as another part of Mr. Travers's practice, where, in cases of slighter obstruction, he contents himself with opening the sac, clearing away the stoppage of the nasal duct with a probe, and healing up the wound, without leaving any style, cannula, or seton in the passage. Where the obstruction is very slight, such practice must be judicious. But if, in other cases, it be deemed right for the prevention of a relapse, that the nasal duct should be either filled with some dilating instrument a certain time, or repeatedly probed, I am decidedly of opinion with Professor Beer, M. Nicod, &c. that the object of not making a small opening in the sac is attended with no advantage, at all likely to counterbalance the mischief, which must be done to the lachrymal puncta and ducts, not only by the repeated introduction of probes and of syringes, but by the lodgment of the former in them for the space of twenty-four hours.

together. If there be an opening in the sac, its convenience in permitting the easy use of a probe is generally acknowledged; and, in order to gain this advantage, and avoid the evils, which are inseparable from taking too much liberty with the lachrymal pucta and ducts, surely a slight puncture in the sac, if there be no opening already, must be the most rational, simple, and successful practice.

When the perviousness of the nasal duct cannot be restored by any use of the probe, and the obstructed part has a very elastic feel, is of inconsiderable extent, and, near the termination of the duct in the nostril, Beer recommends a perforation to be made with a trocar-shaped probe, the point of which is to be covered with a bit of wax, in order that it may not hurt the parts in its passage downward. Some discharge of blood from the nose indicates, that the perforation is made. The sharp-pointed probe is then to be withdrawn, a blunt one used for the purpose of dilating the passage, and, at length, the catgut, as already explained. (*Beer, B. 2, p. 181.*)

Supposing the nasal duct to be obliterated for a considerable part of its extent, by a firmer substance, what practice should then be followed? Ought the formation of an artificial passage to be attempted? On this point, modern practitioners differ, but, as the expedients adopted for this purpose cannot be judged of previously to their description, it will be better in the first place briefly to notice them. As Mr. Pott has remarked, the upper and hinder part of the lachrymal sac is firmly attached to the os unguis, a small, and very thin bone, just within the orbit, which bone is so situated, that, if it be by any means broken through, the two cavities of the nose and orbit communicate with each other: consequently, the os unguis forms the partition between the hinder part of the lachrymal sac, and the upper part of the cavity of the nose; and it is by making a breach in this partition, that the formation of an artificial passage has been attempted. In Mr. Pott's time, the cautery had long been disused for making an aperture in the os unguis, and various instruments were recommended for this object, such as a large strong probe, a kind of gimblet, a curved trocar, &c. each of which, says this practical writer, if dexterously and properly applied, will do the business very well; the one necessary caution is, so to apply whatever instrument is used, that it may pierce through that part of the bone which lies immediately behind the sacculus lachrymalis, and not to push too far up into the nose, for fear of injuring the os spongiosum behind, while it breaks its way. Mr. Pott adds, that he himself has always used a curved trocar, the point of which should be turned obliquely downward, from the angle of the eye, toward the inside of the nose. The accomplishment of the breach will be known by the discharge of blood from the nostril, and of air from the wound, upon blowing the nose. Care must

be taken to apply the instrument to the part of the bone, anterior to the perpendicular ridge, which divides it.

As soon as the perforation is made, a tent of lint should be introduced, of such size as to fill the aperture, and so long as to pass through it into the cavity of the nose: this should be permitted to remain in two, three, or four days, and afterward a fresh one should be passed every day, until the clean granulating appearance of the sore makes it probable, that the edges of the divided membrane are in the same state. The business now is to prevent the incarnation from closing the orifice; for which purpose, the end of the tent may be moistened with diluted vitriolic acid, or a piece of lunar caustic, so included in a quill, as to leave little more than the extremity naked, may at each dressing, or every other, or every third day, be introduced; by which the granulations will be repressed, and the opening maintained: and when this has been done for some little time, a piece of bougie of proper size, or a leaden cannula, may be introduced instead of the tent; and leaving off all other dressings, the sore may be suffered to contract as much as the bougie will permit; which should be of such length, that one extremity of it may lie level with the skin in the corner of the eye, and the other be within the nose.

The longer time the patient can be prevailed upon to wear the bougie, the more likely will be the continuance of the opening: and when it is withdrawn, the external orifice should be covered only by a superficial pledget, or plaster, and suffered to heal under moderate pressure. (*Pott.*)

After the perforating instrument was withdrawn, Mr. Ware recommended a nail-headed style, about an inch long, to be introduced through the aperture, in the same way in which it is introduced through the nasal duct, in cases in which the obstruction is not so great as to prevent its passing in this direction; and it may remain here with as much safety as in this last-mentioned instance, for as long a time as its continuance may be thought necessary to establish the freedom of the communication.

Unfortunately for the scheme of making an artificial passage, nature was generally so busy, that she completely frustrated the aim of the surgeon by gradually filling up the new aperture again. Hence, some practitioners were not content with drilling a hole through the os unguis, but actually removed a portion of this bone either with the forceps proposed by Lamorier in 1729. (*See Mém. de l'Acad. des Sciences.*) or with cutting instruments, among which the most celebrated is the sharp-edged kind of cannula devised by Hunter. While this was being applied, however, it was necessary to support the os unguis with something passed up the nose, and a piece of horn was found to answer very well. Instead of these methods, Scarpa prefers destroying a portion of the os unguis with the actual cautery passed through a cannula; a practice, long ago ba-

nished from good surgery, and most justly condemned by Richter.

I do not feel it necessary to enter very particularly into the details of these methods of forming an artificial passage between the lachrymal sac and nostril. I have never seen a case, in which I should have deemed such practice advisable, and that the necessity for it must be rare must be inferred from what Mr. Travers has observed, viz. that he does not believe the perforation of the os unguis ever really required. (Synopsis, p. 379.) Beer's remarks are also decidedly against the practice; for, he states that, in order that the new opening may not be closed with lymph, it must be made too high up to serve the purpose of a drain, through which the mucus can descend by its own gravity. He has not met with a single case, either in his own practice, or among the patients whom he has had opportunities of seeing under other practitioners, where the perforation of the os unguis had a successful result. On the contrary, in one healthy lad, the operation, which had been done by an experienced surgeon, was followed by the destruction of the nasal process of the upper maxillary bone, one of the ossa nasi, and all the bones contributing to the formation of the passage from the orbit into the nose. (See *Lehre von den Augenkr. B. 2, p. 182.*) Hence, Beer thinks, that the patient had better either submit to the inconvenience of being obliged to empty the distended sac by pressure several times a day, or let the cavity of the sac be obliterated by means, calculated to excite the adhesive inflammation in it. But, if the lachrymal puncta and ducts, as well as the nasal duct, are obliterated, Beer conceives that there is no alternative, because, if the cavity of the sac be left, the case, which he terms *hydrops sacculi lachrymalis*, will ensue, whenever the fistula is closed.

Of Hernia and Hydrops of the Lachrymal Sac.—The diseases, described by Beer under these appellations, are not discriminated in this country, although they are characterized by widely different symptoms, and require opposite methods of treatment. In the case of hernia, or simple relaxation, the lachrymal sac forms a tumour, which never surpasses the size of a common horse-bean, the integuments are of their natural colour, the tumour is soft and yielding to pressure, by which the contents of the sac are readily discharged through the puncta, or nasal duct. Hydrops grows to the size of a pigeon's egg, is purplish from the beginning, very hard and incapable of being emptied by the strongest pressure. Hernia is cured by compression, and the application of astringents to the relaxed parts; hydrops requires the incision of the sac. In hernia, the nasal duct is natural; in hydrops, it and sometimes the puncta are obstructed.

Stillicidium Lachrymarum.—According to Beer, the valuable treatise of Schmidt is the only work, in which the important practical distinction is drawn between stillicidium

lachrymarum and epiphora; the immediate cause of the first complaint being some impediment to the passage of the tears from the lacus lachrymarum into the lachrymal sac; while the other affection consists in a redundant and extraordinary secretion of the tears. The curable form of stillicidium, here to be noticed, arises from relaxation of the lachrymal puncta and canals, in consequence of previous inflammation of the parts. The puncta are widely open; but in other respects, have quite a natural appearance. When touched with Anel's probe, they do not contract, as in the healthy state. The tears, which from time to time fall over the cheek, are not in considerable quantity, only trickling from the inner canthus by drops at intervals; and the nostril on the affected side is found to be rather drier than natural.

Erysipelatous inflammation of the eyelids and parts over the lachrymal sac, and the purulent kinds of ophthalmia, frequently cause this sort of stillicidium. The latter cases indeed the more readily produce the disorder, inasmuch as the semilunar fold of the conjunctiva is relaxed and swelled, so as to push the puncta out of their right position for the due performance of the absorption of the tears, and obstruct this function more than would be the case, if the diminished action of those orifices and the lachrymal ducts were the only thing concerned.

Beer delivers an exceedingly favourable prognosis, observing, that the complaint often disappears of itself on the approach of warm dry weather, and may almost always be readily cured, by means of astringents. Among other remedies specified by this author, I need only mention a solution of the sulphate of iron, to which a small quantity of camphorated spirit, or tincture of opium, has been added. It is to be dropped out of a pen into the inner angle frequently in the course of the day, the patient lying upon his back for some time after each application, so as to let the medicine have more effect upon the parts. (See *Lehre von den Augenkr. B. 2, p. 41—43.*)

Mr. Travers mentions a constricted state of the lachrymal puncta and canals, which is curable by the introduction of a small probe. (Synopsis, &c. p. 366.) All modern writers agree, that the obliterated puncta and canals can never be restored. (See *Mémoires de l'Académie de Chirurgie, T. 5, Edit. 12mo. in which are several essays on fistula lachrymalis viz. one by M. Bordenave, entitled, "Examen des Réflexions critiques de M. Molinelli, insérées dans les Mémoires de l'Institut de Bologne, contre le Mémoire de M. Petit, sur la Fistule Lachrymale, inséré parmi ceux de l'Acad. Royale des Sciences de Paris. Année 1734. LAGOPHTHALMIA, or **LAGOPHTHALMOS**. (from *λαγος*, a hare; and *οφθαλμος*, an eye.) *The Hare's Eye. Oculi Leporinus*. A disease, in which the eye cannot be completely shut. The following complaints may arise from it; a constant weeping of the organ, in consequence of the interruption of the alternate closure and opening of the eyelids, which motions so materially contribute to the propulsion of the tears into the nose; blindness in a strong light, in consequence of the inability to moderate the rays, which enter the eye; on the same account, the sight becomes gradually very much weakened; incapacity to sleep where there is any light; irritation, pain, and redness of the eye, from this organ being exposed to the extraneous substances in the atmosphere.

An enlargement, or protrusion of the whole eye, or a staphyloma, may obviously produce lagophthalmos. But, affections of the upper eyelids are the common causes. Heister has seen the complaint originate from a disease of the lower one. Now and then lagophthalmos depends on paralysis of the orbicularis muscle. A cicatrix, after a wound, ulcer, or burn, is the most frequent cause.

When lagophthalmos arises from a paralytic affection of the orbicularis palpebrarum, the eyelids may be rubbed with a liniment containing the tinctura lyttæ, or the linimentum camphoræ. Electricity and cold bathing are also considered principal means of cure, (Chandler) together with the exhibition of bark, the use of the shower-bath, &c.

When the affection arises from spasm of the levator palpebræ superioris, electricity, a small blister on the neighbouring temple, and rubbing the eyelid and eyebrow with the tinctura opii, are recommended, together with antispasmodic medicines.

When lagophthalmos arises from the contraction of a cicatrix, its relief is to be attempted precisely on the same principles as the ectropium. (See *Ectropium*.) However, when the eyelid is shortened as well as everted, nothing will remove the deformity.

The inconveniences, depending on the eye being unable to shelter itself from the light, are to be obviated by wearing a green shade.

Whoever is acquainted with German, and is desirous of more minute information on this subject, may find an excellent account of lagophthalmos in Richter's *Anfangsgr. der Wundarzn.* B. 2. *Von dem Hasenaugen*. See also Beer's *Lehre von den Augenkr.* B. 2, p. 239, &c. Svo. Wien, 1817.

LARYNGOTOMY. (from *λαρυγξ*, the larynx; and *τομεω*, to cut.) The operation of making an opening into the larynx. (See *Bronchotomy*.)

LATERAL OPERATION. One mode of cutting for the stone. (See *Lithotomy*.)

LENTICULAR. (from *lenticulaire*, doubly

convex.) An instrument, contained in every trephining case, and employed for removing the irregularities of bone from the edge of the perforation, made in the cranium with the trephine. One side of its blade is convex, the other concave; and one of its edges is sharp. On the end of the blade is fixed a little shallow cup, with its concavity towards the handle of the instrument. This part serves the purposes of receiving the little pieces of bone, when detached, keeping the end of the blade from hurting the dura mater, and, when applied under the margin of the opening, enables the operator to guide the edge of the instrument all round it, with steadiness and security.

LEUCOMA. (from λευκος, white.) Leucoma and albugo are often used synonymously, to denote a white opacity of the cornea. Both of them, as Scarpa remarks, are essentially different from the nebula of the cornea; for, they are not the consequence of chronic ophthalmia, with varicose veins, and an effusion of a milky serum into the texture of the delicate continuation of the conjunctiva over the cornea; but, are the result of violent acute ophthalmia. In this state, a dense coagulating lymph is extravasated from the arteries; sometimes superficially, at other times deeply into the substance of the cornea. On other occasions, the disease consists of a firm callous cicatrix on this membrane, the effect of an ulcer, or wound, with loss of substance. The term *albugo*, strictly belongs to the first form of the disease; *leucoma* to the last, more particularly when the opacity occupies the whole, or the chief part, of the cornea.

The recent albugo, remaining after the cure of severe acute ophthalmia, is of a clear milky colour; but, when of ancient date, it becomes pearl-coloured. Some cases, which have existed a considerable time, do not seem to have any connexion with the vascularity of the cornea; for they continue insulated in the middle of the transparent portion of this membrane, without occasioning the least uneasiness to the patient, the least disturbance of the rest of the eye, or any attempt of the absorbents to remove them.

The recent albugo, provided the organization of the cornea be not destroyed, may generally be dispersed by the means employed for the relief of the first and second stages of acute ophthalmia; viz. general and topical blood-letting with internal antiphlogistic medicines, and topical emollients for the first; slightly irritating and corroborant applications for the second. As soon as the inflammation has subsided, the latter should be employed; for, by making the absorbents remove the coagulating lymph, deposited in the cornea, they restore the transparency of this membrane.

But, though this may often be accomplished in the recent state of albugo, it is more difficult when the long duration of the disease has paralyzed the absorbents of the affected part; or when the deposition of a dense tenacious substance into the cornea has subverted its organization. (*Scarpa*.)

The recent condition of the disease, without disorganization of the structure of the cornea; its occurrence in young subjects, whose absorbents are readily excited by external stimulants; are circumstances favourable to the cure. In children, the albugo, arising from severe ophthalmia after the small pox, and insulated in the centre of the cornea, very often disappears of itself in the course of a few months. Heister, Langguth, and Richter, make the same observation. The event can only be imputed to the vigorous action of the lymphatics in children, and to the organization of the cornea not being destroyed. For promoting the absorption, Scarpa recommends the following collyrium: \mathcal{R} . Ammon. muriatæ. \mathfrak{z} ij. Cupri acetati gr. iv. Aquæ Calcis \mathfrak{z} vij. Misce. The fluid is to be filtered, after standing twenty-four hours. He praises also this ointment: \mathcal{R} . Tutin præpar. \mathfrak{z} j. Aloes. s. p. gr. ij. Hydrargyri submur. gr. ij. Adipis suillæ. \mathfrak{z} ss. Misce. And the unguentum ophthalmicum of Janin. He mentions the gall of the ox, sheep, pike, and barbel, applied to the cornea, two or three times a day, with a small hair pencil, if too much irritation should not be produced. In some subjects, when the eyes are very irritable, and cannot bear the latter applications, Scarpa has found the oil of walnuts an useful application. But it is generally necessary to persevere, at least three or four months, before the case can be reckoned incurable.

All the expedients, proposed for the inveterate albugo or leucoma from a cicatrix, consisting of scraping or perforating the layers of the cornea, and exciting ulceration there, are unavailing. For, though the enlargement of the cornea should be lessened by such means, its diaphanous state could not be restored; or should the patient perceive a ray or two of light immediately after the operation, the benefit would only be transient; for, as soon as the wound had healed, the opacity would recur. The formation of an artificial ulcer might prove useful, if leucoma depended on a mere extravasation of lymph; but, the fact is, the disease arises from the deposition of an opaque substance, and the disorganization of the texture of the cornea, conjointly: in this lies the difference between albugo and leucoma.

See *Scarpa sulle Malattie degli Occhi*; *Sco. Venezia*, 1802. *Richter, Anfangsgrunde der Wundarzn. B. 3. Essays on the Morbid Anatomy of the Eye*, by J. Wardrop; *Edinb.* 1808: chap. 11.

LIGATURE. In the article *Hemorrhage*, it has been explained, that the immediate effect of a tight ligature on an artery, is to cut through its middle and internal coats, a circumstance that tends very much to promote the adhesion of the opposite sides of the vessel to each other. Hence, I think with Dr. Jones, in opposition to Scarpa, that the form and mode of applying a ligature to an artery should be such, as are most certain of dividing the above coats of the vessel, in a regular manner. A broad flat ligature does not seem likely to answer this

purpose well ; because it is scarcely possible to tie it smoothly round the artery, which is apt to be thrown into folds, or to be puckered by it, and, consequently, to have an irregular bruised wound made in its middle and internal coats. (Jones.) A ligature of an irregular form is likely to cut through these coats more completely at some parts, than others ; and if it does not perfectly divide them, though adhesion may yet take place, it is a slower and less certain event, and secondary hemorrhage more likely to follow. The fear of tying a ligature too tight may often lead to the same disadvantages. These, and many other important circumstances, are noticed in the article *Hemorrhage*.

Ligatures are commonly made of inkle, and rubbed with white wax. They should be round, and very firm, so as to allow being tied with some force, without risk of breaking. (See Jones on Hemorrhage, p. 172.)

The principles, which should guide the surgeon in the use of the ligature, were not known until the late Dr. Jones published his valuable treatise on hemorrhage. As an able surgeon has observed, "he has banished (at least in this country) the use of thick and broad threads, of tapes, of reserve ligatures, of cylinders of cork and wood, linen compresses, and all the contrivances, which, employed as a security against bleeding, only served to multiply the chances of its occurrence." (Lawrence, in *Med. Chir. Trans.* Vol. 6, p. 162.)

In the article *Amputation*, I have noticed the method of cutting off both ends of the ligature close to the knot, on the face of the stump, with the view of lessening the quantity of extraneous matter in the wound, and promoting a complete union of the divided parts, without suppuration.

This plan has been tried by Mr. Lawrence : "The method I have adopted (says this gentleman) consists in tying the vessels with fine silk ligatures, and cutting off the ends as close to the knot as is consistent with its security. Thus the foreign matter is reduced to the insignificant quantity, which forms the noose actually surrounding the vessel, and the knot, by which that noose is fastened. Of the silk, which I commonly employ, a portion sufficient to tie a large artery, when the ends are cut off, weighs between one-fiftieth and one-sixtieth of a grain : a similar portion of the thickest kind I have tried, weighs one-twentieth of a grain, and of the slenderest one-eightieth."

Mr. Lawrence states, that the kind of silk twist which is commonly known in the shops by the name of dentist's silk, and which is used in making fishing lines, is the strongest material, in proportion to its size, and therefore the best calculated for our purpose, which requires considerable force in drawing the thread tight enough to divide the fibrous and internal coats of the arteries. This twist is rendered very hard and stiff by means of gum, which may be removed by boiling it in soap and water ; but the twist then loses a part of its strength.

The stoutest twist which Mr. Lawrence has used, is a very small thread comp red with ligatures made of inkle. The quantity of such a thread, necessary for the noose and knot on the iliac artery, weighs one-twentieth of a grain ; or, if the gum has been removed, about one-twenty-sixth. But the finest twist, kept in the silk shops, is strong enough in its hard state for any surgical purpose ; and the noose and knot, according to Mr. Lawrence's statement, would not weigh one-fortieth of a grain.

It further appears, from the report of this gentleman on the subject, that there is no danger of these ligatures cutting completely through the vessel, as some surgeons have apprehended ; and that, although he has not yet ascertained what becomes of the piece of ligature after the wound is united, he has never seen abscess nor any other bad symptom occasioned by them. At the time when Mr. Lawrence wrote, he had employed this method of securing the arteries in ten or eleven amputations, in six operations on the breast, and in the removal of two testicles. The cases all did well, excepting a man who lost his thigh, and who died of an affection of the lungs. (See Lawrence on a New Method of Tying the Arteries in Aneurism, &c. in *Medico-Chir. Trans.* Vol. 6, p. 156, &c.)

The foregoing method was tried by myself in several amputations, which I performed in 1815 at Brussels, and in a larger number of cases by my friend, Mr. Collier. Our ligatures, however, though small, were not so small as those judiciously recommended by Mr. Lawrence ; and, on this account, no accurate inferences can be drawn from our examples, which, however, as far as I could learn, were not unfavourable to the practice.

This subject was mentioned by Mr. Guthrie, as follows :—Some military surgeons, both French and English, have lately adopted the practice of cutting off both ends of the ligatures close to the knot on the artery, uniting the parts, if possible, over them, and allowing the knots to find their way out as they can. The edges of the wound, in some instances, have united thoroughly in a few days, and when the knots have come off the ends of the arteries, they have caused small abscesses to be formed, which point at the nearest external surface, and are discharged with little uneasiness. I know that many cases, treated in this manner, in the campaign of 1813, ended successfully, and healed in as short a time as the most favourable ones by the usual method ; and at Montpellier, in June, 1814, Mons. Delpech, Professor of Surgery in that university, showed me at least twenty cases in which he had, and was still practising this method with success. I have seen, however, in two or three instances, some ill-looking abscesses formed by them, and I suspect some disagreeable consequences will ensue, if this practice be continued.

"I consider this improvement as very valuable in all cases, that will not unite by the first intention. The ligatures, if there be

many, form into ropes, are the cause of much irritation, and are frequently pulled away with the dressings; by cutting them off, these evils are avoided, and the knots will come away with the discharge." (See *Guthrie on Gunshot Wounds of the Extremities*, p. 93, 94.)

With respect to the abscesses, which this gentleman saw produced by the method, it is properly observed by Mr. Lawrence, that as this statement is not accompanied by any description of the materials, or size of the ligature, nor by any details of the unfavourable cases, we cannot judge, whether the events alluded to are to be attributed to the method itself, or to the way in which it was executed. (See *Méd. Chir. Trans.* Vol. 6, p. 171.)

M. Roux has tried the plan in three operations on the breast; the cases did well; and no ill consequences arose from the presence of the bits of thread under the cicatrix. (See *Relation d'un Voyage fait à Londres en 1814, ou Parallele de la Chirurgie Angloise avec la Chirurgie Française*; Paris, 1815, p. 134—136.) For other remarks, connected with the foregoing topics, see *Amputation, Aneurism, and Hemorrhage*.

LINIMENTUM ACIDI SULPHURICI.—R. Olei Olivæ \mathfrak{z} i.s. Acid. Sulph. \mathfrak{z} s.s. M. Recommended by Mr. Brodie, for the removal of the effects left by inflammation of the synovial membrane. (See *Joints*.)

LINIMENTUM AMMONIÆ FORTIUS.—R. Liq. ammon. \mathfrak{z} j. Olei olivæ \mathfrak{z} ij. Misce. Properties stimulating.

LINIMENTUM CALCIS.—R. Aq. calcis, Olei olivæ, sing. \mathfrak{z} vij. Spirit. vinosi rectificati \mathfrak{z} i. Misce. A common application to burns and scalds.

LINIMENTUM CAMPHORÆ COMPOSITUM. R. Camph. \mathfrak{z} ij. Aq. ammon. \mathfrak{z} vj. Spirit. lavend. \mathfrak{z} xvj. Sixteen ounces are to be distilled of the two last ingredients, from a glass retort, and the camphor then dissolved in the distilled fluid. For bruises, sprains, rigidities of the joints, incipient chilblains, &c.

LINIMENTUM CAMPHORÆ ÆTHEREUM.—R. Camphoræ drach. j. Ætheris unc. ss. Olei. viperarum drach. ij. Misce. The camphor is to be dissolved in the æther, and the oil afterward incorporated with it. The late Mr. Ware sometimes used this application, in certain obscure affections of the eye, in which it was not easy to determine, whether the imperfection of the sight proceeded from an incipient cataract, or a defect of sensibility in the optic nerve. The mode of applying it is to moisten the finger with it, and to rub it for two or three minutes together, morning and evening, on the outside and edges of the eyelids. (*Pharm. Chirurgica*.)

LINIMENTUM HYDRARGYRI COMPOSITUM.—R. Ung. hydrargyri fortioris, Adipis suillæ, sing. \mathfrak{z} i. Camph. \mathfrak{z} j. Spirit. vinos. rectific. \mathfrak{z} ij. Liq. ammon. \mathfrak{z} j. The camphor being dissolved in the spirit of wine, add the liq. ammon. and the ointment previously blended with the hog's lard. (*Pharm. Sancti. Barthol.*) An excellent formula for all surgical cases, in which the object is to

quicken the action of the absorbents, and gently stimulate the surfaces of parts. It is a capital application for diminishing a chronic indurated state of particular muscles, every now and then met with in practice; and it is particularly well calculated for lessening the stiffness and chronic thickening often noticed in the joints.

LINIMENTUM POTASSÆ SULPHURETI.—R. Saponis Albi. \mathfrak{z} iv. Olei Amygdalæ \mathfrak{z} vij. Potassæ Sulphureti \mathfrak{z} vj. Olei Thymi gr. xv. vel \mathfrak{z} j. This liniment, used twice a day, will cure the itch in five days, or, at latest, in eight. It has very little unpleasant smell, and would be preferable to sulphur ointment, if equally efficacious. (See *London Medical Repository*, Vol. 3, p. 242 and *Cross's Sketches of the Medical Schools of Paris*, p. 176.)

LINIMENTUM SAPONIS COMPOSITUM.—R. Sapon. \mathfrak{z} ij. Camph. \mathfrak{z} j. Spirit. rosmar. \mathfrak{z} ij. Dissolve the soap in the spirit, and then add the camphor. Uses the same as those of the linimentum camph.

LINIMENTUM SAPONIS CUM OPIO. R. Lin. sapon. comp. \mathfrak{z} vj. Tinct. opi. \mathfrak{z} ij. Misce. For dispersing indurations and swellings attended with pain, but no acute inflammation.

LINIMENTUM TEREBINTHINÆ.—R. Ung. resinæ flavæ \mathfrak{z} iv. Ol. terebinthinæ, q. s. Misce. The well-known application for burns, recommended by Kentish. (See *Burns*.)

LINIMENTUM TEREBINTHINÆ SULPHURICUM.—R. Olei olivæ \mathfrak{z} x. Ol. terebinth. \mathfrak{z} iv. Acidi Sulph. \mathfrak{z} ij. Misce. Said to be efficacious in chronic affections of the joints, and in the removal of the old effects of sprains and bruises. (*Pharm. Chirurgica*.)

LIP, CANCER OF. The lips are subject to ulcers, which put on a very malignant aspect, although some of them are not in reality malignant; and many occurring just on the inside of these parts, will be found to depend on the bad state of the constitution, and the irritation and disturbance which the sores are continually suffering from the incessant motion of the parts, and their rubbing against a projecting, or rough tooth.

Arsenic is frequently useful in subduing the obstinacy and malignity of certain ulcers and diseases of the lip, reputed to be cancerous. (*Stark, De Cancro Labii Inferioris*.) Of this essay, Professor Langenbeck speaks in high terms. The following formula is recommended. "R. Arsenici Albi drachm. dimid. Aq. comm. stillaticiæ unc. sex. M. Digerantur vase vitreo clauso in balneo arenæ justî caloris ope per horas sex, tum adde Potassæ Carbontis puræ drachm. dimid. antea solut. in aq. Cinnamon. simpl. unc. duab. M. Digerantur denovo per aliquot horas in loco temperato. Hac solutione bis terve quotidie ad guttas 8—10—15, utimur."

When cancer takes place, it is usually in the lower, and very seldom in the upper lip.

The disease sometimes puts on the appearance of an ulcerated, wart-like excrescence, occasionally acquiring a considerable size. Sometimes it is seen in the form of a very destructive ulcer, which consumes the sur-

rounding substance of the lip; and, in other examples, the disease resembles a hard lump, which, at length, ulcerates. The disease, in its infancy, is often no more than a pimple, which gradually becomes malignant. Whenever there is reason to believe, that the disease is of an unyielding cancerous nature, and it does not soon give way to arsenic, hemlock, and mercurials, the sooner it is extirpated the better. For this purpose, some surgeons admit the propriety of using caustic, when the whole disease can be completely destroyed by one application. But as the action of caustic is not capable of being regulated with so much precision as the extent of a wound can be, and as caustic will not allow the parts to be united again, the knife is the only justifiable means, especially as it occasions also less pain. Two incisions are to be made, meeting at an angle below (supposing it to be the lower lip,) and including the whole of the disease. The sides of the wound are then to be united by the twisted suture. (See *Hare-lip*.) When the affection is extensive, however, the surgeon is frequently necessitated to remove the whole of the lip, or too much of it to admit of the above plan being followed. This circumstance is particularly unpleasant, as the patient's spittle can only be prevented from continually running over his chin by some artificial contrivance. The deformity also is very great, and pronunciation and swallowing can only be imperfectly performed.

LIPPITUDO. (from *lippus*, blear-eyed.) *Blearedness.* The ciliary glands, and lining of the eyelids, only secrete, in the sound state, a mere sufficiency of a sebaceous fluid to lubricate the parts in their continual motions. But, it sometimes happens, from disease, that this sebaceous matter is secreted in too great a quantity, and glues the eyelids together during sleep, so that, on waking, they cannot be easily separated. Hence, the margin of the eyelids becomes red all round, and the sight itself even weakened.

The best remedies are the unguentum hydragryri nitrati, smeared, at night, on the edges and inside of the eyelid with a hair pencil, after being melted in a spoon; the unguentum tutiæ, applied in the same way; and a collyrium, composed of ℞j. of the sulphate of zinc in v℥ij. of rosewater.

When alterative medicines are requisite, a grain of calomel may be exhibited daily, or the compound calomel pill, containing one grain of calomel, one of sulphur antimonii præcipitatum, and two of guaiacum, put together with soap.

Persons who have lippitudo and cataracts together, bear couching much better than one would expect from the appearance of the eyes in that disease; and Mr. Hey never rejects a patient on this account, provided such state is habitual. (*Practical Observations*, p. 51.) Scarpa, however, recommends the lippitudo to be removed before the operation is undertaken.

LIQUOR AMMON. ACET. (L. P.)—This is given in the dose of half an ounce in

many surgical cases, in which the object is to keep up a gentle perspiration.

LIQUOR ARSENICALIS.—℞. Arsenici Oxydi præparati in pulverem subtilissimum triti, Potassæ Subcarbonatis ex tartaro, singulorum gr. 64. Aq. distill. ℥j coque simul in vase vitreo, donec arsenicum omne liqueatur. Liquori frigefacto adjice Spiritus Lavandulæ com. ℥iv. Denique adjice insuper Aq. distil. quantum satis sit, ut mensuram octarii accurate impleat. For internal use the dose is iv. drops gradually increased to xx. twice a day. It is frequently given in cases of anomalous ulcers, and cancerous affections of the lip. It is also used as an external application in similar cases, and especially in hospital gangrene. (See *Arsenic*, and *Hospital Gangrene*.)

LIQUOR CALCIS (L. P.)—Sometimes used as an astringent injection, or lotion, in cases of gonorrhœa, gleet, psora, porrigo, abscesses, &c.

LIQUOR CUPRI SULPHATIS CAMPHORATA.—℞. Cupri sulphatis. Boli Gallici sing. unc. ss. Camphoræ drach. j. Aquæ ferventis lib. iv. Boiling water is to be added to the other ingredients, and the liquor filtered when cold. It is chiefly employed in a diluted state, as a collyrium; but it may also prove of service as an application to foul ulcers.

When used for the cure of the purulent ophthalmia, the lotion is to be injected under the eyelids, by means of a blunt syringe, and, if necessary, the application may be repeated once or twice every hour. (See *Ophthalmia*.)

LIQUOR POTASSÆ SUBCARBONATIS (L. P.)—This remedy is principally deserving of notice on account of its having been given with a view of dissolving calculi in the bladder, so as to remove the necessity of performing the dangerous and painful operation of lithotomy. The principle, on which the liquor potassæ subcarbonatis acts, is by the potassa attracting and combining with the uric acid of the calculus. The medicine may be exhibited in doses of 20 or 40 drops, or of a dram, in a basin of gruel. Experience does not seem to justify the indulgence of much hope, with regard to the complete efficacy of the medicine in dissolving urinary calculi, and on some kinds it is not calculated to act at all, even on chymical principles; but, it would appear, from the reports of writers, that it has often materially palliated the pain which attends the presence of a stone in the bladder. Some practitioners place more confidence in the liquor potassæ.

LIQUOR KALI ARSENICATI.—℞. Kali Arsenicati grana duo. Aquæ Menthæ Sativæ uncias quatuor. Spiritus Vinosi tenuioris unciam. Misce et cola. Two drams of this may be given thrice a day in cases of cancer. My friend, Mr. Barnes, of Exeter, when formerly a student at St. Bartholemew's, showed me a case of lupus, or noli me tangere, which was greatly benefited by this remedy externally applied. Mr. Barnes was using the lotion with double the proportion of

arsenic. There are many ulcerations round the roots of the nails of the fingers and toes, to which Plunket's caustic is sometimes applied; but, the liquor kali arsenicatus would, in all probability, be quite as efficacious, and, certainly, it is a neater application.

LIQUOR POTASSÆ (L. P.) This has been given with a view of dissolving urinary calculi, in considerable doses, for a length of time. The trials, however, have not proved so successful as could have been wished, nor is the exhibition of so active a remedy unattended with disadvantageous consequences to the system; for which reason, soda water and other alkaline waters, supersaturated with fixed air, have of late been much substituted.

The proper dose of the liquor potassæ at first, is from ten to twenty drops twice a day, in some linseed tea. At St. Thomas's Hospital, the following is the way in which the liquor potassæ is prescribed:—*R. Liq. Potassæ ℥i. Aquæ Distillatæ ℥ij. Misce. Dosis Drachma una bis die ex uncis quatuor infusi lini.*

LIQUOR PLUMBI ACETATIS (L. P.)—Is extensively used, largely diluted with water, as an application to inflamed parts. (See *Inflammation*.) One dram to a quart of water is quite strong enough for common purposes. Mr. Justamond and Dr. Cheston used to apply it, mixed with an equal proportion of a spirit resembling the tinctura terri muriati, to the edges of cancerous sores.

LITHONTRIPTICS. (from *λίθος*, a stone; and *τρύπτω*, to break.) Medicines for dissolving stone in the bladder. (See *Urinary Calculi*.)

***LITHOTOMY.** (from *λίθος*, a stone; and *τομή*, to cut.) The operation of cutting into the bladder, in order to extract a stone.

It has been correctly remarked, that no single operation of surgery has attracted so much notice, or had so much written upon it, as lithotomy. A full and minute account of the sentiments of every writer, who has treated of the subject, and a detail of the infinite variety of particular modes of making an opening into the bladder, would occupy as many pages as are allotted to the whole of this dictionary. It must be my endeavour, therefore, rather to describe what is most interesting and important, than pretend to offer an article which is to comprehend every thing.

May I be allowed to premise, that throughout the following columns, I suppose the reader to be already well informed of all that relates to the anatomy of the bladder and adjacent parts, and that of the perinæum? Without correct knowledge of this kind, a man must be presumptuous indeed, to set himself up for a good lithotomist; and if he were to distinguish himself at all, it would only be by the murders which he committed, while his successful feats, if he achieved any, could redound little to his honour, since every young student would soon find out, that they were not the effect

of science, but of mechanical habit and imitation. I would particularly recommend every one, who wishes to understand well the anatomy of the pelvic viscera and perinæum, with a view to lithotomy, in the first place to dissect those parts himself, and then avail himself of the valuable instructions to be derived on the subject from Winslow's *Anatomy*; Le Dran's *Parallèle de Tailles*; Le Cat's *Deuxième Recueil*, planche 5 et 6; Haller's *Inst. Med. of Boërhaave*, and *Elem. Physiol. T. 5*; Morgagni, *Adversar. Anat. 3*, p. 82, 97; Camper's plates; Sabatier's *Anatomy*; John Bell's *Principles of Surgery*; Deschamps's *Traité Historique, &c. de l'Opération de la Taille*, T. 1, p. 7, &c.; and Langenbeck's description of the parts, and the matchless plate which he has given of them in his valuable work on lithotomy, cited at the end of this article.

A few subjects which are closely connected with the present, will be found in other parts of this dictionary. For instance, the nature of stones in the bladder will be considered under the head of *Urinary Calculi*, where also will be seen some observations on lithontriptics. The manner of searching for the stone, or, as it is now more commonly expressed, of sounding, will be explained in the article *Sounding*.

Here I shall principally confine myself to the symptoms of the disease, and the chief methods of executing the much diversified operation of lithotomy.

SYMPTOMS OF THE STONE.

The symptoms of a stone in the bladder are, a sort of itching along the penis, particularly at the extremity of the glans; and hence the patient often acquires a habit of pulling the prepuce, which becomes very much elongated; frequent propensities to make water, and go to stool; great pain in voiding the urine, and difficulty of retaining it, and often of keeping the feces from being discharged at the same time; the stream of urine is liable to stop suddenly, while flowing in a full current, although the bladder is not empty, so that the fluid is expelled by fits, as it were; the pain is greatest towards the end of, and just after, the evacuation; there is a dull pain about the neck of the bladder, together with a sense of weight, or pressure, at the lower part of the pelvis; and a large quantity of mucus is mixed with the urine; and, sometimes, the latter is tinged with blood, especially after exercise. (*Sharp, Earle, Sabatier.*)

Frequently (says Deschamps) a patient will have a stone in his bladder a long while without the occurrence being indicated by any symptom or accident. Most commonly, however, the presence of the stone is announced by pain in the kidneys, more especially in adults and old persons, children scarcely ever suffering in this way, because in them the stone is hardly at all detained in the kidneys and ureters, but descends immediately into the bladder, the preceding

tubes being in them more dilatable, and the rudiment, or nucleus of the stone smaller.

It seldom happens, that calculous patients void blood with their urine, before the symptoms and accidents, usually caused by the stone, have taken place. It is not till after the foreign body has descended into the bladder, acquired some size, and presented itself at the orifice of that viscus, that pain is occasioned, particularly when the surface of the stone is unequal. The patient then experiences frequent inclination to make water, attended with pain. The jolting of a carriage, riding on horseback, and much walking, render the pain more acute. The urine appears bloody, and its course is frequently interrupted, and sabulous matter and particles of stone are sometimes discharged with it. The want to make water becomes more frequent and more insupportable. The bladder is irritated, and inflamed; its parietes become thickened and indurated; and its diameter is lessened. A viscid, more or less, tenacious matter is observed, in greater or lesser quantity, in the urine, and is precipitated to the bottom of the vessel. The urine becomes black and putrid, and exhales an intolerable alkaliescent smell, which is perceived at the very moment of the evacuation, and is much stronger a little while afterward. The patient can no longer use any exercise, without all his complaints being redoubled. Whenever he walks in the least, the urine becomes bloody; the pain about the hypochondria, which was dull in the beginning, grows more and more acute; the ureters and kidneys participate in the irritation with the bladder; they inflame and suppurate, and very soon the urine brings away with it purulent matter. The fever increases, and changes into one of a slow type; the patient loses his sleep and appetite; becomes emaciated and exhausted; and death at length puts a period to his misery. (See *Traité Historique et Dogmatique de l'Operation de la Taille par J. F. L. Deschamps*, T. 1, p. 163, Paris, 1796.)

It is acknowledged by the most experienced surgeons, that the symptoms of a stone in the bladder are exceedingly equivocal, and may be produced by several other disorders. "Pain in making water, and not being able to discharge the urine without the feces, are common consequences of irritation of parts about the neck of the bladder, from a diseased prostate gland, and other causes. The urine stopping in a full stream is frequently caused by a stone altering its situation, so as to obstruct the passage; but the same thing may happen from a tumour, or fungus in the bladder. I have seen an instance of this, where a tumour, hanging by a small pedicle, would sometimes cause obstruction, and by altering the posture, would retire, and give a free passage. The dull pain at the neck of the bladder, and the sensation of pressure on the rectum, are frequently owing to the weight of the stone, &c.; but these may proceed from a diseased enlargement of the prostate gland. Children generally, and grown persons frequently, are

subject to a prolapsus ani, from the irritation of a stone in the bladder; but it will likewise be produced by any irritation in those parts." (Earle.) The rest of the symptoms are equally fallacious; a scirrhus enlargement of the os tincæ, and disease of the kidneys may occasion a copious quantity of mucus in the urine, with pain, irritation, &c. "The least fallible sign (says Sir James Earle) which I have remarked, is the patient making the first portion of urine with ease, and complaining of great pain coming on when the last drops are expelled. This may readily be accounted for, from the bladder being at first defended from contact with the stone by the urine, and, at last, being pressed naked against it. But, to put the matter out of all doubt, and actually to prove the existence of a stone in the bladder, we must have recourse to the operation of sounding."

A stone in the ureter, or kidneys, or an inflammation in the bladder from any other cause, will sometimes produce the same effects; but if the patient cannot urinate, except in a certain posture, it is almost a sure sign that the orifice of the bladder is obstructed by a stone. If he finds ease by pressing against the perinæum with his fingers, or sitting with that part upon a hard body, there is little doubt the ease is procured by taking off the weight of the stone; or, lastly, if, with the other symptoms, he thinks he can feel it roll in his bladder, it is hardly possible to be mistaken; however, the only sure judgment is to be formed from searching. (*Sharp on the Operations*.)

An enlarged prostate gland is attended with symptoms resembling those of a stone in the bladder; but with this difference, that the motion of a coach, or horse, does not increase the grievances, when the prostate is affected, while it does so in an intolerable degree in cases of stone. It also generally happens, that the fits of the stone come on at intervals; whereas, the pain from a diseased prostate is neither so unequal, nor so acute. (*Sharp in Critical Inquiry*, p. 165, Edit. 4.)

Though, from a consideration of all the circumstances above related, the surgeon may form a *probable* opinion of there being a stone in the bladder, yet he must never presume to deliver a *positive* one, nor ever be so rash as to undertake lithotomy, without having greater reason for being certain that there is a stone to be extracted. Indeed, all prudent surgeons, for centuries past, have laid it down as an invariable maxim, never to deliver a decisive judgment, nor undertake lithotomy, without having previously introduced a metallic instrument called a sound, into the bladder, and plainly felt the stone.

Within the last five years, at least seven cases have come to my knowledge, and at two of them I was present, where the patients were subjected to all the torture and perils of this operation, without there being any calculi in their bladders. The maxim, therefore, cannot be too strictly enforced, that the operation ought never to be at-

tempted, unless the stone can be distinctly felt with the sound or staff. In one of the examples, of which I was a spectator, not only the symptoms, but the feel, which the sound itself communicated when in the bladder, made the surgeons imagine, that there was a calculus, or some extraneous body in this organ. Most of the above cases, I understand, recovered, which may be considered fortunate; because when the stone cannot be found, the disappointed operator is apt to persist in roughly introducing his fingers, and a variety of instruments, so long, in the hope of catching what cannot be got hold of, that inflammation of the bladder and peritoneum is more likely to follow, than when a stone is actually present, soon taken out, and the patient kept only a short time upon the operating table.

In a valuable practical work is recorded an instance, in which what is called a horny cartilaginous state of the bladder, made the sound communicate a sensation, like that arising from the instrument actually touching a stone, and the surgeon attempted lithotomy. This patient unfortunately died in twenty-four hours. (See *Desault's Parisian Chir. Journal*, Vol. 2, p. 125.)

However, were the symptoms most unequivocal, there is one circumstance which would always render it satisfactory to touch the stone with an instrument, just before venturing to operate; I mean the possibility of there actually being a stone in the bladder to-day, and *not to-morrow*. It is said, that stones are occasionally forced, by the violent contractions of the bladder, during fits of the complaint, between the fasciculi of the muscular coat of this viscus, together with a portion of the membranous lining of the part, so as to become what is termed encysted. The opening into the cyst is frequently very narrow, so that the stone is much bigger than the orifice of the cyst, in consequence of which it is impossible to lay hold of the extraneous body with the forceps, and the operation would necessarily become fruitless. (*Sharp's Critical Inquiry*, p. 228, Edit. 4.)

In the article *Urinary Calculi*, I have noticed the probability of this having occurred in some of the instances in which Mrs. Stevens's medicine was supposed to have actually dissolved the stone in the bladder; for an encysted stone is not likely to be hit with the sound, nor to cause any inconvenience, compared with what a calculus, rolling about in the bladder, usually occasions.

It is remarked by Deschamps, that when the stone is lodged in an excavated corner of the bladder, in a particular cyst, or depression; when it projects but very little; when it cannot shift its situation in the bladder, so as to fall against the orifice of this viscus; and when it is also smooth, polished, and light; the patient may then have it a long while without experiencing any afflicting symptoms. He may even live to an advanced age, if not without some degree of suffering, at all events, with such pain as is

very supportable. Daily experience proves, that persons may live a considerable time, with one, two, or even three stones in the bladder, and, during the whole of their lives, have not the least suspicion of the existence of these foreign bodies.

According to Deschamps, this must have been the case of M. Portaliu, a tailor. This individual, eighty years old, was frequently attacked with a retention of urine from paralysis, and Deschamps introduced a sound several times, and distinctly felt a stone in the bladder. The patient, however, never had any symptom of the disorder, nor even at the end of two years from the time when Deschamps was first consulted. Very large and exceedingly rough stones have also been found in the dead bodies of persons who had never complained of the symptoms of the disease. Thus, at the anatomical Theatre of La Charité, Richerand found an enormous mulberry stone in the bladder of a person who died altogether of another disease, and never had any symptoms that led to the suspicion of the stone. (*Nomographie Chir.* T. 3, p. 530, Edit. 4.) But cases of this kind must be rare, because it is well known that the pain, which a stone produces, is less in a ratio to its size than to its shape and situation. A small stone, owing to its situation, may be more painful than an enormous calculus which fills the bladder, as is proved by the following case, by Deschamps.

Pechet, a watchmaker, until the age of forty-five, had never had any infirmity, except that of not being able to retain his water a long while. One day, while he was carrying a very heavy clock, he made some exertions which probably, by changing the situation of the calculus, caused at the instant an acute pain in the hypogastric region. Symptoms of the stone soon came on; the pain became intolerable, and the patient went into the Hôpital de la Charité. He was sounded; the stone was felt, and judged to be of considerable size. The incision in the neck of the bladder not sufficing for its extraction, the patient was put to bed again. The next morning he was operated upon above the pubes by Frère Come, who extracted an oval calculus that weighed twenty-four ounces. The patient died four and twenty hours after this second operation. This case proves, then, that very large stones may lie in the bladder without occasioning any serious complaints, since the preceding patient apparently had had such a calculus a long time without suffering inconvenience from it, and it seems likely that he might have continued well still longer, had it not been for the accidental effort which first excited the symptoms. (*Deschamps, in Traité Historique, &c. de la Traille*, Tom. 1, p. 166, 167.)

A priest, in whom Morand had ascertained the presence of a stone by sounding, could not be persuaded that his case was of this nature. However, he bequeathed his body at his decease to the surgeons, and the examination of the bladder fully justified Mo-

rand's prognosis. The celebrated D'Alembert also died with a stone in his bladder, having always refused to be sounded. (Richerand, *Op. cit.* T. 3, p. 538.)

A question may here suggest itself: ought lithotomy to be practised where calculi are under a certain size? Certainly not, because they frequently admit of being discharged with the urine, without any operation at all, even from the male subject, and how much more likely this is to happen in females, must be plain to every body who recollects the direct course, the shortness, ample size, and dilatibility of the meatus urinarius. On this subject, various facts will be adverted to in considering the operation of lithotomy in women. Sometimes, also, when a calculus is too large to pass completely through the male urethra, it lodges in this passage, where it may be more safely cut upon and removed, than from the bladder; and sometimes it is actually discharged by an ulcerative process. Thus, Dr. R. A. Langenbeck has published an example in which a stone made its way out by ulceration, and was discharged immediately behind the testes. (See *J. C. Langenbeck, Bibl. für die Chir. Gott.* 1809.) And G. Coopmans has recorded an almost incredible case, in which a calculus, weighing five ounces, one drachm and a half, when being dried, was discharged on the left side of the urethra of an elderly man, a little below the glans penis. In fact, without some further explanation, this case would be pronounced impossible; but it should be recollected, that after a small calculus has made its way out of the urethra by ulceration, if the urine have still access to it, it will continue to increase in size in its new situation: and this is what happened in the present example; for the extraneous body, when first felt externally, was not larger than a pea. The calculus is now preserved in Camper's museum. (*G. Coopmans, Neurologia, Svo. Franequeræ*, 1795.) I am not meaning, however, to recommend surgeons to let the patient encounter all the sufferings which must inevitably attend leaving the business to be completed by ulceration, because, as soon as the nature of the case is known, an incision should be made into the swelling, and the foreign body taken out. In many cases, also, small calculi may be voided by dilating the male urethra with elastic gum catheters of very large diameter, and then desiring the patient to expel his urine with considerable force, a plan which Baron Larrey has found repeatedly answer. Of late, Mr. Weiss, surgical instrument maker, in the Strand, has invented a kind of sound, the end of which, when in the bladder, admits of being opened, like a pair of forceps, and closed again, so as to grasp calculi under a certain size, and draw them out through the urethra. The instrument has been tried with great success by Mr. A. Cooper, who removed with it from one patient at different times 84 calculi. And, even when the stone cannot be drawn completely out of the urethra, but only into this

passage, it is a great advantage, because, then it may easily be cut down to, and extracted, without any wound or injury of the bladder. (See *A. Cooper in Med. Chir. Trans. Vol. 11.*)

I shall next describe the various methods of cutting for the stone, beginning with the most ancient, called the *apparatus minor*, and ending with the modern proposal of employing a knife in preference to a gorget.

OF THE APPARATUS MINOR, CUTTING ON THE GRIPE, OR CELSUS'S METHOD.

The most ancient kind of lithotomy was that practised upwards of two thousand years ago by Ammonius, at Alexandria, in the time of Hierophilus and Erasistratus, and by Meges, at Rome, during the reign of Augustus; and being described by Celsus, is named *Lithothomia Celsiana*. From cutting directly on the stone, fixed by the pressure of the fingers in the anus, it has been called *cutting on the gripe*, a knife and a hook being the only instruments used. The appellation of the *lesser apparatus* was given to it by Marianus, to distinguish it from a method which he described, called the *apparatus major*, from the many instruments employed.

The operation was done in the following way. The rectum was emptied by a clyster a few hours previously; and, immediately before cutting, the patient was desired to walk about his chamber, to bring the stone down to the neck of the bladder; he was then placed in the lap of an assistant, or secured in the manner now practised in the lateral operation. The surgeon then introduced the fore and middle fingers of his left hand, well oiled, into the anus; while he pressed with the palm of his right hand on the lower part of the abdomen above the pubes, in order to promote the descent of the stone. With the fingers the calculus was next griped, pushed forward toward the neck of the bladder, and made to protrude, and form a tumour on the left side of the perinæum. The operator then took a scalpel and made a lunated incision through the skin and cellular substance, directly on the stone, near the anus, down to the neck of the bladder, with the horns towards the hip. Then, in the deeper and narrower part of the wound, a second transverse incision was made on the stone into the neck of the bladder itself, till the flowing out of the urine showed that the incision exceeded in some degree the size of the stone. The calculus being strongly pressed upon with the fingers, next started out of itself, or was extracted with a hook for the purpose. (*Celsus, lib. 7, cap. 26. J. Bell's Principles, Vol. 2, p. 42. Allan on Lithotomy, p. 10.*)

The objections to cutting on the gripe, are; the impossibility of always dividing the same parts; for those which are cut will vary, according to the degree of force employed in making the stone project in the perinæum. When little exertion is made, if the incision be begun just behind the scro-

tum, the urethra may be altogether detached from the prostate: if the stone be much pushed out, the bladder may be entered beyond the prostate, and both the vesiculæ seminales and vasa deferentia inevitably suffer. Lastly, if the parts are just sufficiently protruded, the bladder will be cut upon its neck, through the substance of the prostate gland. (*Allan on Lithotomy. Burns, in Edinb. Surg. Journal, No. XIII. J. Bell, Vol. 2, p. 59.*)

The preceding dangers were known to Fabricius Hildanus, who attempted to obviate them by cutting on a staff, introduced through the urethra into the bladder. He began his incision in the perinæum, about half an inch on the side of the raphe; and he continued the cut, inclining the knife as he proceeded towards the hip. He continued to divide the parts till he reached the staff; after which he enlarged the wound to such an extent, as permitted him easily with a hook to extract the stone, which he had previously brought into the neck of the bladder, by pressure with the fingers in the rectum. (*Burns.*) In this way Mr. C. Bell has operated with success. (*J. Bell.*)

The apparatus minor, as practised by Fabricius, with the aid of a staff, is certainly a very simple operation on children, and some judicious surgeons doubt the propriety of its present neglected state. You cut, says an eminent writer, upon the stone, and make of course, with perfect security, an incision exactly proportioned to its size. There is no difficult nor dangerous dissection; no gorget, nor other dangerous instrument, thrust into the bladder, with the risk of its passing betwixt that and the rectum; you are performing, expressly, the lateral incision of Raw and Cheselden, in the most simple and favourable way. The *prisca simplicitas instrumentorum* seems here to have been deserted, for the sake of inventing more ingenious and complicated operations. (*J. Bell.*)

Celsus has delivered one memorable precept in his description of lithotomy, *ut plaga paulo major quam calculus sit*; and he seems to have known very well, that there was more danger from lacerating, than cutting the parts.

The simplicity of the apparatus minor, however, formerly emboldened every quack to undertake its performance; and as this circumstance was necessarily followed by the evils and blunders, unavoidably originating from ignorance, and also diminished the emolument of regular practitioners, it became the grand cause of the downfall of this operation. (*See Heister on this subject.*) It was longer practised, however, than all the other methods, having been continued to the commencement of the 16th century; and it was performed at Bourdeaux, Paris, and other places in France, on patients of all ages, by Raoux, even as late as 150 years ago. Frère Jacques occasionally had recourse to it; and it was successfully executed by Heister. (*Part 2, chap. 140.*) A modern author recommends it always to be

preferred on boys under fourteen. (*Allan, p. 12.*)

APPARATUS MAJOR,

So named from the multiplicity of instruments employed: or the Marian method, from having been first published by Marianus Sanctus, in 1524, as the invention of his master, Johannes de Romanis. (*See Marianus de lapide Vesicæ per incisionem extrahendo.*)

This operation, which came into vogue, as we have noticed, from avaricious causes, was rude and painful in its performance, and very fatal in its consequences. The apology for its introduction was the declaration of Hippocrates, that *wounds of membranous parts are mortal*. It was contended, however, that such parts might be dilated with impunity; and on this principle of dilatation, Romanis invented a complex and dangerous plan of operating; one very incompetent to fulfil the end proposed; one, which, though supposed only to dilate, really lacerated the parts. (*Burns.*)

The operator, kneeling on one knee, made an incision with his razor along the perinæum, on one side of the raphe; and feeling with his little finger for the curve of the staff, he opened the membranous part of the urethra; and fixing the point of the knife in the groove of his staff, gave it to an assistant to hold, while he passed a probe along the knife into the groove of the staff, and thus into the bladder. The urine now flowed out, and the staff was withdrawn. The operator next took two conductors, a sort of strong iron probes; one, named the female conductor, having in it a groove, like one of our common directors; the other the male conductor, having a probe point, corresponding with that groove. The grooved, or female conductor, being introduced along the probe into the bladder, the probe was withdrawn, and the male conductor passed along the groove of the female one, into the bladder. Then commenced the operation of dilating. The lithotomist took a conductor in each hand, and by making their shafts diverge, dilated, or, in plain language, tore open the prostate gland. (*J. Bell.*)

It would be absurd in me to trace the various dilating instruments contrived for the improvement of this barbarous operation, by the Colots, Maréchal, Le Dran, Paré, &c. Among the numerous glaring objections to the apparatus major, we need only notice the cutting the bulb of the urethra, not dividing the membranous part of the urethra, nor the transversalis perinæi muscle, which forms a kind of bar across the place where the stone should be extracted; violent distention of the membranous part of the urethra and neck of the bladder; laceration of these latter parts; large abscesses, extravasation of urine, and gangrene; frequent impotency afterward, and extensive fatality. Bertrandi even saw the urethra and neck of the bladder torn from the prostate by the violence employed in this vile me-

thod of operating. (*Operations de Chir. p. 169.*) Paré, Le Dran, Le Cat, Mery, Morand, Mareschal, Raw, and all the best surgeons in Europe, most strangely practised this rash method, for two hundred years, till Frère Jaques, in 1697, taught at Paris the original model of lithotomy, as commonly adopted at the present day.

OF THE HIGH OPERATION.

This method of cutting for the stone was first published in 1556, by Pierre Franco, who, in his Treatise on Hernia, Ed. 1, says, he once performed it on a child with success, but discourages the farther practice of it. After him, Rossetus recommended it, with great zeal, in his book entitled *Parvus Cæsurus*, printed in 1591; but he never performed the operation himself. Tolet mentions its having been tried in the Hôtel Dieu, but without entering into the particular causes of its discontinuance, merely says, that it was found inconvenient. About the year 1719, it was first done in England, by Mr. Douglas; and after him, practised by others. (*Sharp's Operations.*)

The patient being laid on a square table, with his legs hanging off, and fastened to the sides of it by a ligature, passed above the knee, his head and body lifted up a little by pillows, so as to relax the abdominal muscles, and his hands held steady by some assistants; as much barley-water as he could bear, which was often about eight ounces, and sometimes twelve, was injected through a catheter, into the bladder.

The bladder being filled, an assistant, in order to prevent the reflux of the water, must grasp the penis, the moment the catheter is withdrawn, holding it on one side, in such a manner as not to stretch the skin of the abdomen; then, with a round-edged knife, an incision, about four inches long, was made between the recti and pyramidal muscles, through the membrana adiposa, as deep as the bladder, bringing its extremity almost down to the penis; after this, with a crooked knife, the incision was continued into the bladder, and carried a little under the os pubis; and immediately upon the water's flowing out, the forefinger of the left hand was introduced, which directed the forceps to the stone. (*Sharp's Observations.*) Sabatier condemns making the cut in the bladder from below upward, lest the knife injure the peritonæum. (*Méd. Opératoire*, T. 3, p. 160.)

Although this is one of the easiest, and to all appearance, the safest method of operating, several objections soon brought it into disuse. 1. The irritation of a stone often causes such a thickened and contracted state of the bladder, that this viscus will not admit of being distended so as to rise above the pubes. 2. If the operator should break the stone, the fragments cannot be easily washed away, and remaining behind will form a nucleus for a future stone. 3. Experience has proved, that the high operation is very commonly followed

by extravasation of urine, attended with suppuration and gangrenous mischief in the cellular membrane of the pelvis. This happens because the urine more readily escapes out of the wound in the bladder, than through the urethra; and also because when the bladder contracts, and sinks behind the os pubis, this wound ceases to be parallel to that in the linea alba and integuments, and becomes deeper and deeper. For the prevention of these ill consequences, says Sabatier, it will be in vain to make the patient lie in a horizontal posture, and keep a catheter introduced, as Kousset and Morand recommended: experience evincing, that the bad effects are neither less frequent, nor less fatal. (See *Médecine Opératoire*, T. 3, p. 161, Edit. 2.) And Sir Everard Home confesses, that while the high operation for the stone had no other channel but the wound for carrying off the urine, it seemed to him a method which ought never to be adopted; "the urine almost always insinuating itself into the cellular membrane behind the pubes, producing sloughs, and consequently abscesses." (*On Strictures*, Vol. 3, p. 359, 8vo. Lond. 1821.) 4. The danger of exciting inflammation of the peritonæum. 5. The injection itself is exceedingly painful, and however slow the fluid be injected, the bladder can seldom be dilated enough to make the operation absolutely secure; and when hastily dilated (to say nothing of the possibility of its bursting,) its tone may be destroyed. (See *Sharp, Allan, Sabatier*, &c.)

In many men, however, we know by searching, that the bladder is very large, so that there is no risk of meeting with it in a contracted state, and the objection is of no weight, when the bladder extends a considerable way above the pubes, and will admit a large quantity of injection. Stones are sometimes known to be of large size, and they are less likely to be broken in this, than any other mode of lithotomy, so that the objection of the difficulty of extracting small calculi and fragments is less forcible. Mr. Carpie even declares, that if the stone should break, the particles can be extracted with much greater certainty, in less time, and with considerably less pain, than in the lateral operation. (*History of the High Operation*, p. 154.)

I may add, that some judicious surgeons of the present day are decidedly of opinion, that when a stone in the bladder is known to be very large, no attempt ought ever to be made to extract it from the perinæum. Professor Scarpa also declares, that the lateral operation should not be practised, when the calculus exceeds twenty lines in its small diameter. (See *Memoir on the Cutting Gorget of Hawkins*, p. 8, transl. by Briggs.) In such cases, it is true, the surgeon might do the lateral operation, and try to break the stone. But it is a question whether one ought not to prefer to this unpleasant, unsatisfactory proceeding, the high operation. I speak particularly of cases, in which the stone is known to be of very large dimensions before any operation is begun. Were

the lateral operation commenced, the stone, if too large for extraction, must of course be broken; for, it is then too late to adopt the high operation with advantage. That such things have been done, however, and yet the patients escaped, is a truth, which cannot be denied. Deschamps mentions an instance, in which M. Lassus, after using Hawkins's gorget, could not draw out the calculus, and he therefore immediately did the high operation, and the patient recovered. Indeed, the first example of the high operation on record was done by Franco under similar circumstances, and the patient was saved. I have also heard of a modern French surgeon, who began with the lateral operation, but, finding a large calculus, ended with performing the high operation, without the least delay or hesitation: the patient died.

Mr. Samuel Sharp, an excellent practical surgeon in his time, after noticing with great impartiality the objections which were then urged against the high operation says, that he should not be surprised, if hereafter it were revived and practised with success; an observation, which implied, that Mr. Sharp himself foresaw, that the method was capable of being so improved, as to free it from its most serious inconveniences. In fact, since his time, various attempts have been made to introduce the high operation anew, and upon improved principles. Frère Côme, in particular, knew very well, that there were circumstances, as for instance, a calculus above a certain size, disease of the urethra, or prostate gland, &c., where the lateral operation was liable to great difficulties and disadvantages, and where the high operation, if it could be perfected, would be a fitter and safer mode of proceeding. However, it was only in such cases, and not in all, that Frère Côme thought the method better than the lateral operation. He had also discernment enough to perceive, that it was extremely desirable to invent some means, whereby the painful and hurtful distention of the bladder, for the purpose of making this organ rise behind the pubes, would be rendered unnecessary, at the same time, that some measure was adopted for letting the urine have a more depending outlet, than the wound in the hypogastric region. In the former editions of this dictionary, the error was committed of representing Côme to have cut the neck of the bladder, as well as its fundus; a mistake, which I first became aware of upon the perusal of Mr. Carpue's interesting work on lithotomy. The fact is, that Côme did not wound the bladder in two places; but operated after the following way: he first introduced through the urethra into the bladder a staff, which was then held by an assistant. An incision, an inch in length, was now made in the perinæum in the same direction, as in the lateral operation. Another incision was made in the membranous part of the urethra along the groove of the staff, as far as the prostate gland. A very deeply grooved director was then passed along the

staff into the bladder, and the latter instrument was withdrawn. By means of the director, a *sonde à dard*, or kind of catheter furnished with a stilette, was now introduced into the bladder, and, when this had been done, the director was taken out. An incision was then made, about three or four inches in length, just above the symphysis of the pubes, down to, and in the direction of the linea alba. A trocar, in which there was a concealed bistoury, was next passed into the linea alba, close to the pubes, and the blade of the knife then started from its sheath towards the handle of the instrument, while its other end remained stationary. In this manner, the lower part of the linea alba was cut from below upwards, and an aperture was made, which was now enlarged with a probe-pointed curved knife, behind which a finger was kept so as to push the peritonæum out of the way. Côme then took hold of the *sonde à dard* with his right hand, and elevating its extremity, lifted up the fundus of the bladder, while with the fingers of his left hand he endeavoured to feel its extremity in the wound. As soon as the end of the instrument was perceived, it was taken hold of between the thumb and middle finger, the peritonæum was carefully kept up out of the way, and the stilette was pushed by an assistant from within outwards, through the fundus of the bladder. The bladder being thus pierced, the operator introduced into a groove in the stilette a curved bistoury, with which he divided the front of the bladder from above downwards, nearly to its neck. He then passed his fingers into the opening, and keeping up the bladder with them, withdrew the *sonde à dard* altogether. But, as it was useful that both his hands should be free, the bladder was prevented from slipping away by means of a suspensory hook held by an assistant as soon as the opening was found to be already ample enough, or had been enlarged to the necessary extent. Côme next introduced the forceps, took out the stone, and passed a cannula, or elastic gum catheter through the wound in the perinæum into the bladder, so as to maintain a ready outlet for the urine, and divert this fluid from the wound in the bladder. In women, of course, the catheter was passed through the meatus urinarius. And, I ought here to observe, that Côme thought the high operation especially adviseable for females, because his experience had taught him, that the division, or dilatation, of the meatus urinarius was generally followed by an incontinence of urine. (See *Nouvelle Méthode d'extraire la Pierre de la Vessie par dessus le Pubis*, &c. 8vo. Bruxelles, 1779.)

Another modification of the high operation was suggested by Deschamps, who, instead of opening the membranous part of the urethra as Côme did, perforated the bladder from the rectum, and through the cannula of the trocar effected the same objects, which the latter lithotomist accomplished by means of the incision in the membranous part of the urethra. Of the two plans, that

devised by Côme is unquestionably the best, because not attended with a double wound of the bladder; a thing which, I conceive, must always be highly objectionable.

Dr. Souberbielle, who practices Côme's method, introduces a silver wire through the cannula of the *sonde à dard*, and passes it through the wound made in the *linea alba*. The wire is then held while the *sonde à dard* is withdrawn, and a flexible gum-catheter is passed by means of the wire into the bladder through the wound in the membranous part of the urethra. The wire is now withdrawn, and the catheter is fixed with tapes, passed round the thighs and pelvis, and a bladder is tied to it for the reception of the urine. "A piece of soft linen, half an inch wide, and six or eight inches long, is to be introduced, by means of a pair of forceps into the bottom of the bladder;" the object of which slip of linen is to carry off such urine, as may not escape through the catheter. Lint and light dressings are applied, and a bandage round the abdomen. Great care is to be taken to keep the catheter pervious, and, usually on the third day, the slip of linen may be taken out, and the wound closed with adhesive plaster. (See *Carpue's History of the High Operation*, p. 171, 172.)

Sir Everard Home made trial of Dr. Souberbielle's method in St. George's Hospital, and though some difficulty and delay occurred in the operation, on account of the stone being encysted, the result was successful. Subsequently to this case, however, Sir Everard has invented and practised another method, which, as far as I can judge, is better than that of Côme, or Souberbielle, though its principles are the same. When it is considered, that in the operation of these last lithotomists, the neck of the bladder is not opened, and the catheter enters that receptacle through the prostatic portion of the urethra, it must be immediately obvious, that the incision in the perinæum cannot answer any material object, because a tube may be placed in the same position by passing it through the urethra from the orifice in the glans. The retainer, or bracelet, invented for keeping the catheter in the bladder, in cases of enlargement of the prostate gland, seemed to Sir Everard Home peculiarly applicable to the high operation, since it keeps the tube steadily in the natural canal, and renders the wound in the perinæum unnecessary. Bracelets, for this purpose, extremely elastic, and producing no irritation, are sold by Mr. Weiss, of the Strand. They are furnished with small rings, to which the outer end of the catheter is fixed by means of string.

Sir Everard Home performed his new operation, for the first time, in St. George's Hospital, on the 26th of May, 1820. An incision was made in the direction of the *linea alba*, between the pyramidales muscles, beginning at the pubes, and extending four inches in length: it was continued down to the tendon. The *linea alba* was then pierced close to the pubes, and divided by a probe-pointed bistoury to the extent of three

inches. The pyramidales muscles had a portion of their origin at the symphysis pubis detached to make room. When the finger was passed down under the *linea alba*, the fundus of the bladder was felt covered with loose, fatty, cellular membrane. A silver catheter, open at the end, was now passed along the urethra into the bladder, and when the point was felt by the finger in the wound, pressing up the fundus, a stilet, that had been concealed, was forced through the coats of the bladder, and followed by the end of the catheter. The stilet was then withdrawn, and the opening, through the fundus of the bladder, enlarged towards the pubes, by a probe-pointed bistoury, sufficiently to admit two fingers, and then the catheter was withdrawn. The fundus of the bladder was held up by one finger, and the stone examined by the forefinger of the right hand. A pair of forceps, with a net attached, was passed down into the bladder, and the stone directed into it by the finger: the surface being very rough, the stone stuck upon the opening of the forceps, and being retained there by the finger, was extracted. A slip of linen had one end introduced into the bladder, and the other was left hanging out of the wound, the edges of which were brought together by adhesive plaster. A flexible gum catheter, without the stilet, was passed into the bladder by the urethra, and kept there by an elastic retainer surrounding the penis. The patient was put to bed, and laid upon his side, in which position the urine escaped freely through the catheter." As no blood had been lost in the operation, twelve ounces were taken from the arm. The next day the slip of linen was withdrawn, as useless and irritating, the catheter, while pervious, preventing any urine from escaping by the wound. Sir Everard thinks, that in future the linen need only be left in the external wound, so as to prevent collections of matter, and carry off any urine, which may issue from the opening in the bladder, when the catheter happens to be stopped up. For this operation, Sir Everard particularly recommends catheters, with their insides polished like their outsides, in order that they may better resist the effects of the urine. Suffice it to add, with respect to the above case, that the boy soon recovered, the bladder having resumed its healthy functions in ten days, although the calculus was of the roughest possible kind.

Sir Everard Home has repeated his new method on a gentleman, who went out in his carriage, with the external wound completely healed, on the 14th day after the operation. The only particulars, which need here be noticed, in regard to the latter case, are, that some difficulty was experienced in bringing the point of the catheter forwards toward the pubes, and the slit in the front of the instrument made it so incapable of bearing lateral motion, that the two sides were twisted over one another. (*On Strictures*, Vol. 3, p. 359, 8vo. Lond. 1820.)

Whoever follows this method of operating should always be provided with several

tubes and stilets, of different lengths and curvatures; for, in the only case, in which I have seen the operation attempted, the extremity of the catheter could not be made to project the fundus of the bladder towards the pubes, and, after long-protracted endeavours had been made to bring the end of the instrument upwards and forwards, the tube broke, and the operation was left unfinished. The impression upon my mind was, that no resistance of the bladder could account for what happened, and that the fault lay in the instrument itself, which should have been exchanged for another of more suitable form, as soon as it was found to be inapplicable. And, I believe, that if attention be paid to this suggestion of always having at hand a sufficient number of tubes and stilets of different lengths and curvatures, Sir Everard Home's new method will be the best modification of the high operation yet proposed. The slip of linen, however, I think is more likely to do harm by its irritation, than any good, as a conductor of the urine or matter out the wound. At all events, as Sir Everard has observed, it should never be passed into the bladder itself. Whenever I am asked my opinion, respecting the preference, which should be given to the high operation, as a general practice, I venture no further than to express a favourable opinion of it for cases, in which the calculus is known beforehand to be of very large size, or the urethra and prostate gland are diseased. The reasons urged by Mr. Carpue, in favour of a preference to the high operation in most cases, are: 1. Because, it is generally performed in less time; a point, which may be disputed, though it is perhaps not worth contesting, since the danger of an operation cannot always be truly estimated by the length of time, which the patient remains in the operating room, slow and gentle proceedings sometimes contributing to his safety. 2. There is less pain; a remark, the justness of which must depend, perhaps, upon the manner in which each operation is done. 3. There is no fear of a fatal hemorrhage; a consideration, which I admit is one good reason in favour of the high operation; though the lateral operation is only subject to risk of hemorrhage, when the incisions are directed in a manner not sanctioned in this dictionary. 4. There is no division of the prostate and inferior part of the bladder: no, but there is one of the fundus, so that perhaps on this point the two operations stand upon an equality. As for there being no danger in the high operation of wounding the rectum, it is undoubtedly an advantage, though the accident, as far as I have seen, is not followed by any serious consequences, and can only happen from inattention to rules easily followed. 5. The stone, if of a certain size, cannot be extracted by the lateral operation, but admits of being so by the high operation. Of all the reasons for the latter practice, this appears to me the strongest, with the exception perhaps of disease in the urethra and prostate. 6. A small stone is more readily discovered in this method, than

in the lateral operation: a point which I consider questionable, and at all events, not sufficiently important to form a ground for the high operation. 7. If a stone breaks, the particles can be extracted with more certainty, than in the lateral operation: on this question authors differ. 8. The high operation enables the surgeon to remove encysted calculi with greater ease: a reason which may perhaps be generally true, but which is somewhat weakened by the consideration that encysted calculi are not very frequent. Mr. Carpue allows, that the high operation should not be selected when the patient is corpulent, and the bladder is thickened and diseased, so that its fundus cannot be raised above the pubes. (See *Hist. of the High Operation*, p. 173, 8vo. Lond. 1819.)

As it is not my object to discourage the practice of the high operation, under the particular circumstances which have been specified, I decline entering into any strict consideration of the inconveniences to which this method is exclusively subject, especially, the greater vicinity of the wound to the peritoneum and small intestines, and the division of that membrane and protrusion of the viscera; accidents, which will be found by any body, who chooses to look over the cases on record, not to have been unfrequent. On the contrary, as I believe this method is advantageous in certain cases, the recent attempts to bring it to greater perfection give me sincere pleasure.

In December, 1818, Mr. Kirby, of Dublin, performed the high operation for the extraction of an elastic gum catheter, which had slipped into the bladder through the cannula of a trocar, with which paracentesis had been performed. No contrivance was found necessary for lifting up the fundus of the bladder. The puncture, already made, was enlarged, and after the operation was finished, a catheter was placed in the wound, but was withdrawn on the 4th day, as the urine passed out by the side of it. The case terminated well. (See *Kirby's Cases*, p. 92, &c. 8vo. Dublin, 1819.)

LATERAL OPERATION.

So named from the prostate gland, and neck of the bladder, being laterally cut.

From some quotations made by Mr. Carpue from the works of Franco, it appears clear enough, that the latter was not only the inventor of the lateral operation, but that he placed his patients in the position adopted at the present time, used similar instruments to those now employed, (excepting that his gorget had no sharp side) and made the same incisions. Now, as this claim of Franco to an invention of such importance had been nearly, or quite forgot, when Mr. Carpue's work made its appearance, the latter gentleman deserves much praise for reminding the profession of what may be due to the memory of an old surgeon, whose name must flourish, as long as the history of the rise and progress of surgery is interesting to mankind. But, though Franco appears probably to have practised the lateral operation, or

something very much like it, he never established the method as a permanent improvement of surgery, which measure was left to be completed long afterward by an ecclesiastic, who called himself Frère Jacques: he came to Paris in 1697, bringing with him abundance of certificates of his dexterity in operating; and making his history known to the court and magistrates of the city, he got an order to cut at the Hôtel Dieu, and the Charité, where he performed this operation on about fifty persons. His success did not answer the promises which he had made, and from that time his reputation seems to have declined in the world, if we may give credit to Dionis, who has furnished us with these particulars.—(*Sharp's Operations*.)

Frère Jacques used a large round staff without a groove, and when it was introduced into the bladder, he depressed its handle, with an intention of making the portion of this viscus, which he wished to cut, approach the perinæum. He then plunged a long dagger-shaped knife into the left hip, near the tuber ischii, two finger-breadths from the perinæum, and pushing it towards the bladder, opened it in its body, or as near the neck as he could, directing his incision upward from the anus. He never withdrew his knife, till a sufficient opening had been made for the extraction of the stone. Sometimes he used a conductor to guide the forceps, but more commonly directed them with his finger, which he passed into the wound after withdrawing the knife. When he had hold of the stone, he used to draw it out in a quick rough manner, heedless of the bad consequences. His only object was to get the stone extracted, and he disregarded every thing else; all preparatory means, all dressings, all after-treatment. (*Allan, p. 23.*)

Totally ignorant of anatomy, and thus rude and indiscriminate in practice, Frère Jacques soon sunk into disrepute. However, there were several eminent surgeons, who conceived, from considering the parts which he cut, that his method might be converted into a most useful operation. (*Sharp's Operations*.)

The principal defect in his first manner of cutting, was the want of a groove in his staff, which made it difficult to carry the knife into the bladder. At length, Frère Jacques was prevailed upon to study anatomy, by which his judgment being improved, he readily embraced several improvements, which were suggested to him. Indeed, we are informed that he now succeeded better, and knew more, than is generally imagined. Mr. Sharp says, that when he himself was in France in 1702, he saw a pamphlet, published by this celebrated character, in which his method of operating appeared so much improved, that it scarcely differed from the practice of that time. Frère Jacques had learnt the necessity of dressing the wound after the operation, and had profited so much from the criticisms of Mery, Fagon, Felix, and Hunauld, that he then used a staff with a groove, and what is more extraordinary, had

cut thirty-eight patients successively, without losing one. (*Sharp's Operations*.)

In short, as a modern writer has observed, he lost fewer patients than we do at the present day, in operating with a gorget. He is said to have cut nearly 5000 patients in the course of his life, and though persecuted by the regular lithotomists, he was imitated by Marchal at Paris, Raw in Holland, and by Bamber and Cheselden in England, where his operation was perfected. (*Allan*.)

For a particular history of Frère Jacques, and his operations, Allan refers us to *Bus-siere's Letter to Sir Hans Sloane*, *Philos. Trans.* 1699. *Observations sur la Manière de tailler dans les deux Sexes, pour l'Extraction de la Pierre, pratiquée par F. Jacques, par J. Mery*. *Lister's Journey to Paris in 1698*. *Cours d'Operations de Chirurgie, par Dionis*. *Garengeot Traité des Operations, T. 3, Morand, Opuscule Chirurgie, Part 2.*

Among the many who saw Frère Jacques operate, was the famous Professor Raw, who carried his method into Holland, and practised it with amazing success. He never published any account of it himself, though he admitted several to his operations; but after his death, his successor Albinus, gave the world a very circumstantial detail of all the processes, and mentions, as one of Raw's improvements, that he used to open the bladder, between its neck and the ureter. But either Albinus, in his relation, or Raw himself in his supposition, was mistaken; since it is almost impossible to cut the bladder in that part upon the common staff, without also wounding the neck." (*Sharp in Operations and Critical Inquiry*.)

Raw's method was objectionable, even when accomplished, as the urine could not readily escape, and became extravasated around the rectum, so as to produce terrible mischief. There is little doubt, that Raw's really successful plan was only imitative of Frère Jacques's second improved one, though he was not honourable enough to confess it. (*See Ferrius de Colculo Vesicæ*.)

Dr. Bamber was the first man in England, who made a trial of Raw's method on the living subject, which he did in St. Bartholomew's Hospital. Cheselden, who had been in the habit of practising the high operation, gladly abandoned it, on receiving the account of Raw's plan and success, and a few days after Bamber, he began to cut in this way in St. Thomas's Hospital.

Cheselden used at first to operate in the following manner. The patient being placed, and tied much in the same way, as is done at this day, the operator introduces a hollow grooved steel catheter into the bladder, and with a syringe, mounted with an ox's ureter, injects as much warm water into it, as the patient can bear without pain. The water being kept from running out by a slip of flannel tied round the penis, the end of the catheter is to be held by an assistant, whose principal care is to keep it from rising, but not at all to direct the groove to the place where the incision is to be made.

With a pointed convex-edged knife, the

operator beginning about an inch above the anus, on the left side of the raphe, between the accelerator urinæ, and erector penis, makes an incision downwards, by the side of the sphincter ani, a little obliquely outwards as it descends, from two and a half to four inches in length, according to the age of the patient, or size and structure of the parts. This incision he endeavours to make all at one stroke, so as to cut through the skin, fat, and all, or part of the levator ani, which lies in his way. This done, he passes his left fore-finger into the middle of the wound, in order to press the rectum to one side, that it may be in less danger of being cut; and taking a crooked knife in his other hand, with the edge on the concave side, he thrusts the point of it through the wound, close by his finger, into the bladder, between the vesicula seminalis and os ischium of the same side. This second incision is continued upwards, till the point of the knife comes out at the upper part of the first. The incision being completed, the operator passes his left fore-finger through the wound into the bladder, and having felt, and secured the stone, he introduces the forceps, pulls out his finger, and extracts the stone.

As the bladder was distended, Cheselden thought it unnecessary to cut on the groove of the staff, and that, as this viscus was sufficiently pressed down by the instrument, the forceps could be very well introduced without the use of any director, except the finger. (*Postscript to Douglas's History of the Lateral Operation, 1726.*)

With respect to this first of Cheselden's plans, Sharp says, the operations were exceedingly dexterous; but the wound of the bladder retiring back, when it was empty, did not leave a ready issue for the urine, which insinuated itself among the neighbouring muscles and cellular substance, and four out of the ten patients on whom the operation was done perished, and some of the others narrowly escaped. (*Sharp's Operations.*)

Cheselden, finding that he lost so many patients in imitating Raw, according to the directions given by Albinus, began a new manner of operating, which he thus describes: "I first make as long an incision as I well can, beginning near the place where the old operation ends, and cutting down between the musculus accelerator urinæ and erector penis, and by the side of the intestinum rectum: I then feel for the staff, and cut upon it the length of the prostate gland straight on to the bladder, holding down the gut all the while with one or two fingers of my left hand." (*Anatomy of the Human Body, Edit. 1730.*)

It deserves remark, that it was Cheselden's second manner of cutting, which was described in the *Opusculæ de Chirurgie*, of Morand, who was deputed, and had his expenses defrayed by the Royal Academy of Sciences in Paris, to come over to England, and learn from Mr. Cheselden himself, his way of operating for the stone; and, accordingly, we find, that most French authors, taking their account from Morand, describe Cheselden's se-

cond, not his third operation, as that which he invented, and bears his name. But, that Mr. Cheselden never resumed his second manner of cutting may be inferred from his continuing to describe the third only in all the editions of his anatomy published after 1730. (*See a note by J. Thomson, M. D. annexed to his new edition of Douglas's Appendix, Edinb. 1808.*)

The instruments which Cheselden employed in his third, and most improved mode of cutting for the stone, were a staff, an incision knife, a gorget, a pair of forceps, and a crooked needle carrying a waxed thread. The patient being placed on a table, his wrists are brought down to the outsides of his ankles, and secured there by proper bandages, his knees having first been bent, and his heels brought back near his buttocks.

Cheselden used then to take a catheter, first dipped in oil, and introduce it into the bladder, where having searched for, and discovered the stone, he gave the instrument to one of his colleagues, whom he desired to satisfy himself, whether there was a stone, or not. The assistant, standing on his right hand, held the handle of the staff between his fingers and thumb, inclined it a little towards the patient's right thigh, and drew the concave side close up to the os pubis, in order to remove the urethra as far as possible from the rectum.

The groove of the staff being thus turned outwardly and laterally, Cheselden sat down in a low chair, and keeping the skin of the perinæum steady with the thumb and fore-finger of his left hand, he made the first or outward incision, through the integuments, from above downwards, beginning on the left side of the raphe, between the scrotum and verge of the anus, almost as high up as where the skin of the perinæum begins to form the bag containing the testicles. Thence he continued the wound obliquely outwards, as low down as the middle of the margin of the anus, at about half an inch distant from it, and consequently, beyond the tuberosity of the ischium. He was always careful to make this outward wound as large as he could with safety. Having cut the fat rather deeply, especially near the rectum, he used to put his left fore-finger into the wound, and keep it there till the internal incision was quite finished; first to direct the point of his knife into the groove of the staff, which he now felt with the end of his finger; and secondly, to hold and prevent the rectum from being wounded, by the side of which his knife was to pass. This inward incision Cheselden made with more caution, than the former. His knife first entered the groove of the rostrated, or straight part of the staff, through the side of the bladder, immediately above the prostate, and its point was afterward brought along the same groove in the direction downwards, and forwards, or towards himself. Cheselden thus divided that part of the sphincter of the bladder, which lay upon the prostate gland, of which he next cut the outside of one half obliquely, according to the direction and whole length of the

urethra within it, and finished the internal incision, by dividing the membranous portion of the urethra, on the convex part of his staff.

A sufficient opening being made, Cheselden used to rise from his chair, his finger still remaining in the wound. Next he put the beak of his gorget in the groove of the staff, and then thrust it into the bladder. The staff was now withdrawn, and while he held the gorget with his left hand, he introduced the forceps with the flat side uppermost, with great caution along the concavity of the gorget. When the forceps was in the bladder, he withdrew the gorget, and taking hold of the two handles of the forceps with both his hands, he searched gently for the stone, while the blades were still kept shut. As soon as the calculus was felt, the forceps was opened, and an attempt made to get the lower blade under the stone, in order that it might be more conveniently laid hold of. This being done, the stone was extracted with a very slow motion, in order to give the parts time to dilate, and the forceps was gently turned in all directions.

When the stone was very small, and did not lie well in the forceps, Cheselden used to withdraw this instrument, and introduce his finger into the bladder, for the purpose of turning the stone, and disengaging it from the folds of the lining of the bladder, in which it was sometimes entangled. Then the gorget was passed in again on the upper side of his finger, and turned as soon as the latter was pulled out. Lastly; the forceps was introduced, and the stone extracted. With the view of hindering a soft stone from breaking during its extraction, Cheselden used to put one or more of his fingers between the branches of his forceps, so as to prevent any greater pressure upon it, than what was just necessary to hold it together. But when it did break, or there were more calculi than one, he used to extract the single stones, or fragments, one after another, repeating the introduction of his fingers and forceps, as often as there was occasion. Cheselden took care not to thrust the forceps so far into the bladder as to bruise or wound its opposite side; and he was equally careful not to pinch any folds of its inner coat. In this way, Cheselden saved 50 patients out of 52, whom he cut successively in St. Thomas's Hospital. (*Appendix to the History of the Lateral Operation, by J. Douglas. 1731.*)

Cheselden, with all the enthusiasm of an inventor, believed, that he had discovered an operation, which was not susceptible of improvement; yet, he himself changed the manner of his incision not less than three times, in the course of a few years. 1st, He cut into the body of the bladder, behind the prostate, when he imitated Raw. 2dly, He cut another part of the bladder, viz. the neck and the thick substance of the prostate; this is his lateral mode of incision. 3dly, He changed a third time, not the essential form of the incision, but the direction, in which he moved the knife; for in his first operation, when imitating the sup-

posed operation of Raw and Frère Jacques, he struck his knife into the body of the bladder, betwixt the tuber ischii and the vesiculæ seminales, and all his incision lay behind the prostate gland. In this second operation, he pushed his knife into the membranous part of the urethra, immediately behind the bulb, and ran it down through the substance of the gland; but his incision stopped at the membranous part, or body, of the bladder. But in his third operation, after very large external incisions, he passed his knife deeply into the great hollow under the tuber ischii, entered it into the body of the bladder immediately behind the gland, and drawing it towards himself, cut through the whole substance of the gland, and even a part of the urethra, "cutting the same parts the contrary way." By carrying the fore-finger of the left hand before the knife, in dissecting towards the body of the bladder, he protected the rectum more perfectly, than he could do in running the knife backwards along the groove of the staff; and by striking his knife into the body of the bladder and drawing it towards him, through the whole thickness of the gland, he was sure to make an ample wound. (*J. Bell's Principles of Surgery, Vol. 2, Part 1, p. 152.*)

LATERAL OPERATION AS PERFORMED AT THE PRESENT DAY WITH CUTTING GORGETS.

The gorget has the same kind of form as one of the instruments used by F. Colot and others in the performance of the apparatus major, and the common opinion, that the conductor of Hildanus was the first model of it, is not exactly true; but it differs from the instruments employed by these older surgeons in having a cutting edge. Sir Cesar Hawkins thought that, when its right side was sharpened into a cutting edge, it might be safely pushed into the bladder, guided by the staff, so as to make the true lateral incision in the left side of the prostate gland more easily, and with less risk of injuring the adjacent parts, than Cheselden could do with the knife; and surgeons were pleased with a contrivance, which saved them from the responsibility of dissecting parts, with the anatomy of which all were not equally well acquainted. (*J. Bell. Allan.*)

As Scarpa observes: To render the execution of the lateral operation easier to surgeons of less experience than Cheselden, was the motive which induced Hawkins to propose his gorget. He thought, that two great advantages would be gained by the use of this instrument; one of executing invariably the lateral incision of Cheselden; the other, of constantly guarding the patient through the whole course of the operation, from injury of the rectum, and of the arteria pudica profunda. The utility of the latter object (says Scarpa) cannot be disputed, as it is evident, that the convexity of the director of the instrument defends the rectum from injury, and that its cutting edge not being inclined horizontally,

towards the tuberosity and ramus of the ischium, but turned upwards in the direction of the longitudinal axis of the neck of the urethra, cannot wound the pudic artery. But, with respect to the first advantage, or that of executing precisely the lateral incision of Cheselden, it must be admitted that it does not completely fulfil the intention which he proposed, not only on account of the cutting edge of his instrument not being raised enough above the level of the staff, to penetrate sufficiently the substance of the prostate gland, and consequently to divide it to a proper depth; but, because being too much turned upwards at that part of it, which is to lay open the base of the prostate gland, it does not divide it laterally, but rather at its upper part, towards the summit of the ramus of the ischium, and the arch of the pubes; an opening, of all others in the perinæum, the most confined, and presenting the greatest impediment to the passage of the stone from the bladder. The breadth of the point of the director is, besides, so disproportionate to the diameter of the membranous part of the urethra, that, from the great resistance with which it meets, the instrument may easily slip from the groove of the staff, and pass between the bladder and rectum, a serious accident, which has very often happened even in the hands of experienced surgeons.

Scarpa considers all the modifications of Hawkins's gorget, proposed by B. Bell, Desault, Cline, and Cruikshanks, as deteriorations of the original instrument. B. Bell (he observes) has diminished the breadth of the director, but has given the cutting edge an horizontal direction. The horizontal direction of the cutting edge is also preferred by Desault, Cline, and Cruikshanks; but they have enlarged the director, and flattened the part which was previously concave. Aware of the danger of wounding the pudic artery, by the horizontal direction of the gorget, they direct the handle of the staff to be inclined towards the patient's right groin, and the gorget to be pushed along it, inclined in such a manner, that its obtuse edge may be directed towards the rectum, and its cutting edge placed at a sufficient distance from the tuberosity and ramus of the ischium to avoid wounding the artery. Scarpa contends, however, that it is difficult to give a proper degree of obliquity to the staff, and that such inclination of the instrument must be incommodious, arbitrary, and unstable, in comparison with that position of it, in which the handle of the staff is held in a line perpendicular to the body of the patient, and its concavity placed against the arch of the pubes; on which stability of the instrument (says Scarpa) the safety and precision of the lateral operation depend. According to this eminent professor, the defects of Hawkins's original gorget arise from the excessive breadth of the director, particularly at the point; the want of sufficient elevation of the cutting edge, above the level of the groove of the staff, and the uncertain incli-

nation of the edge to the axis of the urethra and prostate gland. The cervix of the urethra, in a man between thirty and forty years of age, is only three lines in diameter at the apex of the prostate gland, four lines in its centre, and five near the orifice of the bladder. The apex of the prostate gland is rather more than two lines in thickness, the body or centre four, and the base six, and sometimes eight, which surrounds the orifice of the bladder. In an adult of middle stature, from eighteen to twenty years of age, the thickness of the base of the prostate gland is about two lines less, compared with that of a man of forty, and of a large size. The precise line in which the lateral incision of the prostate gland should be made in an adult, (says Scarpa) is found to be inclined to the longitudinal axis of the cervix of the urethra, and of the gland itself, at an angle of 69° . Now, from these data, drawn from the structure of the parts, Scarpa makes the director of his gorget only four lines broad, and two deep; the breadth decreasing at the beak. The cutting edge of the instrument is straight near its point, but gradually rises, and becomes convex above the level of the staff, so that its greatest convexity is seven lines broad. Lastly; the inclination of the cutting edge to the longitudinal axis of the director, is exactly at an angle of 69° ; that is to say, the same as the left side of the prostate gland to the longitudinal axis of the neck of the urethra. (See *Scarpa's Memoir on Hawkins's Gorget*; transl. by Mr. Briggs, p. 12, 17.)

For nearly twenty years past, the instrument-makers in London have been in the habit of selling a gorget, which Mr. Abernethy first had constructed, and which in the particularity of having its cutting edge turned up at an angle of 45° , bears much analogy to the instrument lately recommended by Scarpa. The cutting edge is straight, and that useless and dangerous part of a gorget, sometimes called the shoulder, is removed. Admitting that the principles of the lateral operation as inculcated by Scarpa, are correct, and of which I shall presently speak, it appears to me, that Mr. Abernethy's gorget is far preferable to that very recently proposed by Scarpa. Its edge is not so immoderately turned up, and it will enter with more ease, and less risk of slipping from the staff, because it has not any projecting shoulder, which, while the staff is firmly held with the beak of the gorget in it, can have no other effect but that of obstructing the passage of the last instrument.

Gorgetts, which cut on both sides, have also been sometimes employed in England, and as a larger opening can be obtained by them, even without trespassing the limits of the incision, fixed by Scarpa, that is to say, without cutting any part of the body of the bladder, they appear to promise utility, especially when the stone is suspected to be large. However, they are less used now, than they were some years ago, when Sir Astley Cooper employed them in Guy's Hos-

pital; but I am unacquainted with the particular reasons of this change.

Some criticisms on Scarpa's method of operating, and a few remarks on the size and direction of the lateral incision, will be found in a subsequent section of the present article.

As inflammation of the bladder and peritonæum is the principal danger of this operation, and, under an equal degree of injury and violence, is most likely to happen in a plethoric subject, it has been a question, whether venesection should not be practised a day or two before the patient is operated upon, supposing that his age and weakness form no prohibition. The chief reason, which prevents the common observance of this practice is, that a great deal of blood is sometimes lost in the operation itself. But when this has not happened, and the patient is young and strong, and particularly when the operation has been tedious, and the bladder has suffered a good deal, I am disposed to think very favourable of the rule, which is followed by many surgeons, of bleeding the patient as soon as he is put to bed, and recovered from the first depressing effects of the operation. An opening medicine should also be given the day before the patient is cut, and a clyster injected a couple of hours before the time fixed upon for the operation, in order to empty the rectum, and thus diminish the chance of its being wounded.

As it is advantageous to have the bladder somewhat distended, the patient should be requested to retain his urine a certain time before being cut. Formerly, a jugum penis was sometimes used for confining the urine in the bladder; but, since my entrance into the profession, I have never heard of this contrivance being employed.

Before the operation, the following instruments should all be arranged ready on a table: a staff of as large a diameter as will easily admit of introduction, and the groove of which is very deep, and closed at the extremity. A sharp gorget, with a beak nicely and accurately adapted to the deep groove of the preceding instrument, so as to glide easily and securely. A large scalpel for making the first incisions. Forceps of various sizes, for extracting the stone. A blunt-pointed curved bistoury for enlarging the wound in the prostate, if the incision of the gorget be not sufficiently large, as the parts should never be lacerated. A pair of Le Cat's forceps with teeth for breaking the stone, if too large to come through any wound reasonably dilated. A syringe for washing out clots of blood, or particles of the stone. A scoop for the removal of small calculi or fragments. Two strong garters, or bands, with which the patient's hands and feet are tied together.

The curvature of the staff is a matter of considerable importance; because the direction of the incision through the prostate gland and neck of the bladder is partly determined by it. The French surgeons, convinced of the advantage of introducing the

gorget in the direction of the axis of the bladder, always use a staff, which is much more curved than what English surgeons employ. (See Roux, *Voyage fait à Londres en 1814, ou Parallèle de la Chir. Angloise, &c.* p. 319.) But, I am inclined to believe with Scarpa, that, upon the whole, it is best to let the curvature of the staff correspond exactly to that of the axis of the neck of the urethra and prostate gland. (*Memoir on Hawkins's Gorget, &c.* p. 17.)

After introducing the staff, and feeling that the stone is certainly in the bladder, the patient is to be secured in the same position, as was described in the account of Cheselden's latest method of operating.

The assistant, holding up the scrotum with his left hand, is with his right to hold the staff, inclining its handle towards the right groin, so as to make the grooved convexity of the instrument turn towards the left side of the perinæum. Some operators, also, like the assistant to depress the handle of the staff towards the patient's abdomen, in order to make its convexity project in the perinæum, while others condemn this plan, asserting, that it withdraws the instrument from the bladder. (*Allan, &c.*)

Professor Scarpa disapproves of inclining the handle of the staff towards the patient's right groin, (p. 15.) and he expressly recommends this instrument to be held firmly against the arch of the pubes, in a line perpendicular to the body of the patient, so that the convex part of the director may be placed towards the rectum, and take the exact course of the axis of the neck of the urethra and prostate gland. (P. 20.) This position of the staff is the firmest and most commodious to the surgeon, and Scarpa maintains, that on such stability of the instrument the safety and precision of the lateral operation depend. (P. 15.)

The first incision should always commence below the bulb of the urethra, over the membranous part of this canal, at the place, where the operator means to make his first cut into the groove of the staff, and the cut should extend at least three inches, obliquely downward, to the left of the raphe of the perinæum, at equal distance from the tuberosity of the ischium and the anus. In a large man, the first cut should pass the anus an inch and a half or more; for it is a general rule in surgery to make free external incisions, by which the surgeon is enabled to conduct the remaining steps of his operation with greater facility, and nowhere is it so necessary, as where a stone is to be extracted. (*Allan.*) That excellent surgical writer, Callisen, lays it down as a rule to be observed in the lateral operation, that the incision ought not to extend to such parts as can make no impediment to the extraction of the stone; and therefore, (says he) the bulb, and that part of the urethra, which is surrounded by the corpus spongiosum, should never be cut. Only those parts ought to be divided, which firmly resist the safe introduction of instruments into the bladder, and the extraction of the stone. Hence, the in-

teguments must be opened by an ample incision, and the membranous part of the urethra, transversales perinæi muscles, levator ani, and prostate gland, be properly divided.

(*Callisen Systema Chirurgiæ Hodiernæ, Pars 2, p. 655.*) Like Scarpa, however, he is fearful of making a free cut through the neck of the bladder, and in lieu of doing so, prefers a slow and cautious dilatation of the parts. When the external cut through the integuments has been executed, the next object is to divide the transversales perinæi muscles, which stand, like a bar, across the triangular hollow, out of which alone the stone can be easily extracted. A part of the membranous portion of the urethra, adjoining the prostate gland, is next to be laid open; but an extensive cut through it, as far forward as the bulb, is quite unnecessary, because it will not at all facilitate the passage of the stone outward.

Having placed the beak of the gorget in the groove of the staff, the operator takes firm hold of the latter instrument with his left hand, raises its handle from the abdomen, so that it may form nearly a right angle with the body, and stands up. Before attempting to push the gorget into the bladder, however, he should slide it backwards and forwards, with a wriggling motion, that he may first be sure of its beak being in the groove of the staff. The bringing forward of the handle of the latter instrument, so as to elevate its point, before introducing the gorget into the bladder, is also considered of great importance: for it is by this means, that the gorget is introduced along the groove of the staff in the axis of the bladder, the only direction unattended with risk of wounding the rectum. In fact, the gorget should be introduced nearly in a direction, corresponding to a line drawn from the os coccygis to the umbilicus. It is obvious, however, that the degree in which the handle of the staff should be depressed, must depend very much upon the curvature of the instrument.

The utmost attention to the rule last noticed is especially necessary, when a staff with a groove not closed at the end is employed. The neglect of it in this case might make the operator cut the bladder with the gorget in several places, as has actually happened, as we learn from the observations of Mr. B. Bell. But since the gorget, when introduced as nearly as possible in the axis of the bladder, may transfix and otherwise injure this organ, if introduced either too far, or at all beyond the extremity of the staff, I am decidedly of opinion that every surgeon, who chooses to perform the lateral operation with a gorget, should employ a staff, the groove of which is closed at the extremity, as is invariably done in France, and is expressly enjoined by Professor Scarpa. (See *Sabatier's Médecine Opératoire, T. 3, p. 223. Edit. 2; and Scarpa's Memoir on Hawkins's Gorget, p. 18, &c.*) There can also be no doubt of the prudence of endeavouring to have only a fixed and limited length of the staff in the

bladder. Scarpa specifies an inch and a half as the proper distance to which the end of the staff should enter the bladder. However, as it is known, that this distinguished Professor is an advocate for a very limited incision, and that consequently, he would not require the staff to extend further than an inch and a half into the bladder, I infer that operators, who prefer making a freer opening, must use a staff that reaches into this viscus rather further. Much, however, will depend upon the kind of gorget employed, particularly its breadth.

As soon as the gorget is introduced, the staff is to be withdrawn. Some operators next pass the forceps along the concave surface of the gorget into the bladder; while others, with every appearance of being right, recommend the cutting gorget to be withdrawn immediately it has completed the wound; for then the bladder contracts, and its fundus is liable to be cut. The gorget should be withdrawn in the same line in which it entered, pressing it towards the right side, in order to prevent its making a second wound. If, however, the operator should prefer passing the forceps into the bladder, along the gorget, the latter instrument must be kept quite motionless, lest its sharp edge do mischief; and, at all events, as soon as the forceps is in the bladder, the cutting gorget is to be withdrawn.

Some operators withdraw the cutting gorget, and introduce a blunt one for the guidance of the forceps; a step certainly unnecessary, as the latter instrument will easily pass, when the incision into the bladder is ample and direct, as it ought always to be.

The operator has next to grasp the stone with the blades of the forceps; for which purpose, he is not to expand the instrument as soon as it has arrived in the bladder; but he should first make use of the instrument as a kind of probe, for ascertaining the exact situation of the stone. If this body should be lodged at the lower part of the bladder, just behind its neck, the operator is to open the forceps immediately over the stone, and after depressing the blades a little, is gently to shut them, so as to grasp it. Certainly it is much more scientific to use the forceps at first, merely for ascertaining the position of the stone: for when this is known, the surgeon is much more able to grasp the extraneous body in a skilful manner, than if he were to open the blades of the instrument immediately, without knowing where they ought next to be placed, or when shut. No man of experience can doubt that the injury, which the bladder frequently suffers from rough, reiterated, awkward movements of the forceps, is not an uncommon cause of such inflammation of this viscus, as too often extends to the peritonæum, and occasions death.

If the surgeon cannot readily take hold of the stone with the forceps, he should introduce his fore and middle fingers into the rectum, and raise up the extraneous body, when it may generally be easily grasped. The stone should be held with sufficient

firmness to keep it from slipping away from the blades, but not so forcibly as to incur the risk of its breaking.

Sometimes the extraction of the stone is attended with difficulty, owing to the operator having chanced to grasp it in a transverse position, in which circumstance, it is better to try to change its direction, or let it go altogether, and take hold of it in another manner. When the stone is so large, that it cannot be extracted from the wound without violence and laceration, the surgeon may either break the stone by means of a strong pair of forceps, with teeth constructed for the purpose; or he may enlarge the wound with a probe-pointed crooked bistoury, introduced under the guidance of the fore-finger of the left hand. The latter plan is generally the best of the two; for, breaking the stone is an exceedingly unpleasant circumstance, as it creates serious danger of calculous fragments remaining behind.

However, as nothing can justify the exertion of force in pulling out a stone, if the operator should be afraid of making the wound more ample, (it being already large and direct) he must break the stone as above described. As many of the fragments are then to be extracted with the common lithotomy forceps, as can be taken away in this method, after which the surgeon should introduce his finger, in order to feel whether any pieces of the stone still remain behind. Perhaps some of these may be most conveniently taken out with the scoop; but if they are very small, it is best to inject lukewarm water with moderate force into the wound for the purpose of washing them out.

The surgeon however, cannot be too strongly impressed with the absolute necessity of using the greatest care not to remove the patient from the operating table, while any calculus, or fragment, remains in the bladder. For, the distressing pain of the disorder has been known to recur upon the healing of the wound, and a second operation become necessary. It is a melancholy truth, however, that a fresh calculus may form again in the short space of a few months. I have seen several patients who have been cut for the stone, more than once; and Richerand mentions the case of a surgical instrument maker, resident at the gate of La Charité, in Paris, who has undergone the operation three times in the course of a year and a half, although after each operation several eminent surgeons carefully examined the bladder, and could not find any calculus remaining in it. (See *Nosogr. Chir.* T. 3, p. 549, Edit. 4.)

The stone should always be attentively examined immediately it is extracted; because its appearance conveys some information, though not positive, concerning the existence of others. If the stone is smooth on one surface, the smoothness is generally found to arise from the friction of other stones still in the bladder; but, when it is uniformly rough, it is a presumptive sign, that there is no other one remaining behind. In every

instance, however, the surgeon should gently examine the cavity of the bladder with his fore-finger; for, it would be an inexcusable neglect to put the patient to bed with another stone in his bladder.

After the operation, a simple pledget should be laid on the wound, supported by a T bandage; the patient should lie in bed on his back, with his thighs closed; a piece of oil-cloth, and some folded napkins should be laid under him for the reception of the urine, and, if there be much pain, a large opiate should be administered; but, as the latter medicine is a stimulant, if it can be dispensed with, so much the better.

An occasional embarrassment to lithotomists is the circumstance of stones in the bladder not being always free and detached: some are embraced very tightly by the coats of this viscus; others are partially engaged in the ureters; they are sometimes fixed in the neck of the bladder; and are not unfrequently found lodged in sacculi accidentally formed. These cysts are of different sizes: some are small, and exist in a considerable number; some are deeper, with an orifice smaller than their base. They appear to be formed by a prolongation of the internal coat of the bladder. Other sacculi are occasionally found which seem to be composed of all the tunics of the bladder, and they are sometimes of such magnitude, that the bladder appears as if it were divided into two or more cavities of nearly equal size. Stones, found in these sacculi, sometimes present depressions and irregularities, in which fungi of the bladder have been received. When this happens, a portion of such fungous productions is often extracted with the stone; a circumstance that has deceived some practitioners, and led them to suppose, that the calculi actually adhered to the coat of the bladder. (See *Desault's Parisian Chirurgicale Journal*, Vol. 2, p. 386, 387.)

The extraction of encysted stones requires different modes of proceeding from those which have been related. Littre conceived that they might be removed in two ways. When they made only an inconsiderable projection into the bladder, he recommended the introduction of a probe, with which the membrane, covering the calculus, was to be rubbed, a finger being put into the rectum, in order to keep it down, and facilitate the action of the probe in opening the cyst. When the calculi were very prominent, Littre recommended taking hold of them with a pair of forceps, and contusing and breaking the membranous pouch, with the points and asperities upon the inside of the blades of the instrument. He conceived that suppuration would then destroy the internal parietes of the cyst, and that the stone would fall into the bladder, and admit of being easily extracted. As Sabatier observes, it is plain, that this theory, which is founded on the idea entertained by Littre of the manner in which stones become encysted, is totally inadmissible in practice.

Garengeot ventured to pass a bistoury into the bladder for the purpose of disengaging a calculus lodged in a particular cyst at the fundus of this organ, behind the pubes. The knife had some tape twisted round the greatest part of its length, and was introduced under the guidance of the left index finger, which was passed in as far as it could reach. The patient was not more than ten, or eleven years old, and consequently of a size, which favoured the operation. The stone was loosened and taken out, and the child recovered. However, as Sabatier remarks, there are many instances, in which this mode of proceeding cannot be imitated; for, if the calculus should be in a sort of cul-de-sac, as often happens, the entrance of which is narrower than its bottom, and the stone be of considerable size, the incision cannot be made large enough, without risk of cutting through the whole thickness of the bladder, and producing certain death by the effusion of urine in the abdomen.

Other practitioners fancied, that the calculus might be taken hold of with the forceps, and turned about in different directions so as to lacerate its connexions, or even that it might be forcibly extracted, with any serious ill consequences. Houstet mentions, (See *Mem. de l'Acad. de Chir. T. 2, p. 307, &c. Edit. 12mo.*) that Peyronie adopted this method on a patient, thirty-one years of age. The calculus did not resist long, and its surface was found covered with fleshy substances, which formed the adhesions to the bladder. The operation was painful, followed by considerable hemorrhage, tension of the belly, hiccough, cold extremities, and death.

There are some examples, however, in which this bold practice had better success. In 1730, Le Dran extracted from a woman an enormous stone, adherent to that part of the bladder which lies upon the rectum. The irritation of the inequalities of the stone had produced ulceration of the bladder, and fungous growths, which insinuated themselves into the substance of the extraneous body. The adhesions readily yielded, and the excrescences came away with the calculus. Ten days afterward, some thick membranous sloughs were voided. This calculus is engraved in Le Dran's Treatise on the Operations.

Le Dran afterward extracted similar stones, which adhered by a less extensive surface; and he relates an operation done by Maréchal, who, in 1715, extracted with a pair of forceps a stone shaped like a calabash, and having its narrow part surrounded by a fungus. In one case, the position of the calculus led Le Dran to suspect that it was fixed in the extremity of the ureter; he shook it occasionally with a pair of forceps; and, lastly, it fell into the bladder, whence it was extracted without difficulty. It resembled a cucumber in shape, and its large extremity had been lodged in the ureter, from which it could only be gradually removed. Sabatier believes, that a case of

this description, which must be very uncommon, is the only one in which there is any prospect of removing an encysted stone with success. In other examples, he conceives, that it is more prudent to leave the stone, and let the wound heal, than expose the patient to an almost certain death by repeated attempts to extract it. (*Médecine Opératoire, T. 3, p. 190, 194, Edit. 2.*) Desault employed a sort of concealed knife, called a *coupe-bride*, for opening the cavity or cyst; and he has recorded one example, in which he thus successfully extracted from a woman, aged sixty-two, a stone, lodged at the insertion of the ureter into the bladder. The bistoury, used by Garengeot, Desault did not consider a safe instrument, as the stones are round, and the knife may slip and pierce the bladder; an objection to which, he says, the *coupe-bride* is not liable. No injury can be received from its point, as the blade is concealed, nor can any part be divided, except what the surgeon intends. If the incision should not be completed at first, the blade may be withdrawn, the semicircular notch of the instrument pushed more forward, and the incision prosecuted to any extent. This instrument was invented for the express purpose of dividing membranous bands in the rectum; but it was afterward employed with the greatest success for the excision of diseased tonsils and fungous tumours situated in cavities. The blade is so contrived, that when it passes through the semicircular notch, it firmly fixes the parts which are to be divided: a thing that cannot be done either with the scissors or bistoury, as the moveable parts recede, and render the section difficult. (See *Desault's Parisian Chirurgicale Journal, Vol. 1, p. 33, &c.*)

A stone perfectly encysted would not be expected to produce symptoms equal in severity to those which arise from an extraneous body actually in the cavity of the bladder. And yet, in Houstet's interesting dissertation, several cases are recorded, which prove that encysted stones do sometimes cause the same distressing symptoms which proceed from the presence of a loose calculus in the bladder. Hence, the patients were sounded, and in consequence of the sacs, or pouches, in which the stones lay, not being entirely closed, the calculi were distinctly struck by the instrument, and lithotomy attempted. It deserves particular remark, also, that, in a large proportion of these cases, the pouches, or cysts, were not single, but numerous, occupying different parts of the bladder. In some dissections, referred to by Houstet, cysts of this kind were found, not containing any stones whatever; a circumstance that would rather lead one to suspect, that, in general, the formation of these sacs precedes that of the calculi commonly found in them. (See *Observations sur les Pierres Enkistées et Adhérentes à la Vessie par M. Houstet, in Mem. de l'Acad. de Chir. T. 2, p. 268, Edit. 12mo.*)

OF SOME PARTICULAR METHODS AND INSTRUMENTS.

M. Foubert, a very eminent surgeon at Paris, devised and practised a plan of his own, which, however, has not been considered by others as worthy of being imitated. The patient having retained his urine, so as to distend his bladder, an assistant, with a convenient bolster, presses the abdomen a little below the navel in such a manner, that, by pushing the bladder forwards, he may make that part of it protuberant which lies between the neck and the ureter. The operator, at the same time, introduces the fore-finger of his left hand up the rectum, and drawing it down towards the right buttock, pushes in a trocar on the left side of the perinæum, near the great tuberosity of the ischium, and about an inch above the anus. Then the trocar is to be carried on parallel to the rectum, exactly between the erector penis and accelerator urinæ muscles, so as to enter the bladder on one side of its neck. As soon as the bladder is wounded, the operator withdraws his fore-finger from the anus.

In the upper part of the cannula of the trocar, there is a groove, the use of which is to allow some urine to escape, immediately the instrument enters the bladder, so that the trocar may not be pushed in any further; but its principal use is for guiding the incision. As soon as the urine began to flow, Foubert, retracting the trocar a little, without drawing it quite out of the cannula, introduced the point of a slender knife into the groove in the cannula; and by the guidance of this groove he ran it onwards into the bladder, and was aware of the knife having actually entered this viscus, by the urine flowing still more freely. Then raising the knife from the groove, he made his incision about an inch and a half in length, through the neck of the bladder, by moving the knife from that point at which it had entered upwards towards the pubes. And finally, by moving the handle more largely than the point of the knife, he opened the outer part of the wound to whatever extent the size of the stone seemed to require, and then, withdrawing the knife, he introduced a blunt gorget to guide the forceps.

An effort was made by Thomas to improve this method; but he failed, and it was never much adopted. The inability of many bladders to bear being distended, is an insuperable objection; for, without this, the trocar is liable to pass between the bladder and rectum, and even through the bladder into the pelvis. (*Mémoires de l'Acad. de Chir.* 663, Vol. 1. *Le Dran's Parallèle.* *Sharp's Critical Inquiry.* *J. Bell's Principles,* Vol. 2.)

In the year 1748, Frère Come's method of performing the lateral operation began to attract considerable notice. The operation was done with a particular instrument, called the *lithotome caché*, by means of which the prostate gland and neck of the bladder were divided, from within outwards. The

lithotome caché is entitled to much attention, because it is still generally used in several parts of the continent, and sometimes in this country, especially by the surgeons of the Westminster Hospital. "In France (says M. Roux) if there is any mode of operating more common than others, and preferred by the majority of practitioners, it is that in which the instrument, named the *lithotome caché*, is employed." (See *Parallèle de la Chirurgie Angloise, &c.* p. 318. Frère Come does not ascribe the invention of this instrument to himself; but acknowledges that it resembles the knife for operating upon hernia, said to have been devised by a French surgeon of the name of Bienaise. It consists of a handle and the blade part. The latter is slightly curved, about as thick as a quill, furnished with a beak, and excavated so as to form a sheath for a knife of its own length. By means of a kind of lever, the knife can be made to pass out of the sheath, and the distance to which the blade projects also admits of being regulated with precision. For this purpose, the handle is divided into six sides, numbered 6, 7, 9, 11, 13, and 15, and which, according as they are more or less elevated, allow the lever to be depressed in different degrees, and the knife to move out of its sheath in the same proportion. Thus the surgeon can at his option make an incision through the prostate gland and neck of the bladder of six different lengths.

When the *lithotome caché* is to be used, the patient must be placed in the same posture as in every other mode of practising the lateral operation; and after a staff has been introduced, an oblique incision is to be made from the raphe of the perinæum, to a point situated rather more towards the anus, than the innermost part of the tuberosity of the ischium. The bulb of the urethra should not be cut, and not too much of the membranous part of the urethra. The fat and transverse muscles having been divided, and the urethra opened, exactly as in the common operation, the scalpel is to be put down, and the beak of the *lithotome* introduced into the groove of the staff. Of course, the surgeon, previously to the operation, will have settled the distance, to which the blade of the instrument is to pass out of the sheath, and which must necessarily depend upon the age of the subject, and the presumed size of the calculus. When the beak of the *lithotome* has been inserted in the groove of the staff, the surgeon is to take hold of the handle of the latter instrument with his left hand, and bring it a little towards himself, at the same time pushing the *lithotome* into the bladder, with the handle depressed as much as possible. The staff is now to be withdrawn, and the surgeon is to try to feel the stone with the sheath of the other instrument, in order to be able to judge of the size of the calculus, and whether the distance, to which the blade of the knife is intended to move out of the sheath, is such as is likely to make an opening of due, but not,

unnecessary magnitude. Things being properly determined, the lithotome is to be held in a position calculated to make a division of the parts which is parallel to the cut in the integuments, and, by means of the lever, the cutting blade of the instrument is then to be disengaged from its sheath. The surgeon is next to draw the opened lithotome towards himself, in a perfectly horizontal manner, so as to make the requisite division of the prostate gland and orifice of the bladder.

As Sabatier observes, Frère Come's method undoubtedly possesses all the advantages of the lateral operation, besides being more easy than Cheselden's plan, and most of the other modes, subsequently proposed, for cutting the neck of the bladder with perfect smoothness, and to a sufficient extent to allow the calculus to be removed, without any laceration of the parts. (*Médecine Opératoire*, T. 3, p. 199.)

There have been several objections urged against the use of the lithotome caché.

1. It is said that the size of the incision is not always proportioned to the distance, to which the knife moves out of the sheath, and that the instrument, when opened to No. 13 or 15, sometimes makes a smaller incision, than when opened only to No. 5 or 7. This uncertainty is said to depend upon the greater or less contraction of the bladder in different subjects.

For my own part, I confess, that I am not inclined to put much credit in the accuracy of this last explanation, and suspect the difference sometimes observed must depend upon the operator not taking care to draw out the instrument in a horizontal direction, a thing which is always easy to be done.

2. Frère Come himself made his incision too high, so that an extravasation of urine in the scrotum followed some of his operations; but the above method of operating is free from any objection of this kind.

3. Some surgical writers have exaggerated the danger of cutting the body of the bladder too extensively with the lithotome, and thus producing internal hemorrhage. However, this cannot happen, unless the surgeon raise the handle of the instrument improperly at the moment of withdrawing it, and as Sabatier himself allows, it is rather the fault of the operator than of the operation.

4. The arteria pudica profunda and the rectum, which some authors conceive to be endangered, must always be in absolute safety, if the edge of the knife of the lithotome be turned in the direction above recommended.

I think that for a surgeon, who understands the right principles of lithotomy, this is one of the best ways of performing the operation.

When I was at Paris in 1815, I saw Dr. Souberbielle operate very skilfully with the lithotome caché. A stone of considerable size was extracted from a gentleman, who was, I should think, not less than 70. No apprehensions were entertained of ill suc-

cess, as I understood that this operator hardly ever lost a patient.

M. Roux, when he visited England, seems not to have been informed, that at the Westminster Hospital, the lithotome caché has been commonly employed for many years past. It has also been sometimes used at Guy's Hospital by Sir A. Cooper. When M. Roux likewise finds fault with the bad construction of this instrument, as made in London, I suspect, that he cannot have seen those which are made and sold by Mr. Evans. (*See Voyage fait à Londres, ou Parallèle de la Chirurgie Angloise, &c.* p. 318.)

Le Cat, a surgeon of Rouen, in Normandy, devised a mode of lithotomy which would be too absurd to be described, were it less renowned. He thought the neck of the bladder might be dilated, like the wound, and his operation was deformed with all the cruelty of the Marian method, and every error attendant on the infant state of the lateral operation. He first introduced a long wide staff; he cut forward with a common scalpel, through the skin and fat, till he could distinguish the bulb, the naked urethra, and the prostate gland. Secondly, with another knife, the urethrotome, having a groove on one side, he opened the urethra, just before the prostate, and fixing the urethrotome in the groove of the staff, and holding it steady, rose from the kneeling posture, in which he performed the outward incision. Thirdly, holding the urethrotome in the left hand, he passed another knife, the cystotome, along the groove of the urethrotome, and the beak of the cystotome being lodged in the groove of the urethrotome, it was pushed forwards, through the substance of the prostate gland into the bladder. Fourthly, drawing the cystotome a little backwards, he gave the staff to an assistant to be held steadily, and lifting a blunt gorget in the right hand, he placed the beak of it in the groove of the cystotome, and pushed it onwards, till it glided from the groove of the cystotome, along the groove of the staff into the bladder. Then, true to the principles of the apparatus major, and never forgetting his own peculiar theory, *little incision, and much dilatation*, he forced his fingers along the gorget, dilated the neck of the bladder, and so made way for the forceps. (*J. Bell's Principles*, Vol. 2.)

In 1741, Le Dran described an operation, the introduction of which has been claimed by several since his time. A staff being introduced, and two assistants keeping open the patient's knees, while a third stands on one side of him on a chair, (Le Dran says,) "I then raise up the scrotum, and directing the last assistant to support it with both hands, so as to avoid bruising it, by pressing it either against the staff, or the os pubis, I place his two fore-fingers on each side of the part, where the incision is to be made; one of the fingers being laid exactly along that branch of the ischium, which rises towards the pubes, and the other pressed upon the raphe, that the skin may be kept fixed and tight. While I thus place the fingers of

the assistant, who supports the scrotum, I still keep hold of the handle of the staff, and direct it so as to form a right angle with the patient's body; at the same time taking care that the end of it is in the bladder. This position is the more essential, as all the other instruments are to be conducted along the groove of this. If the handle of the staff were kept inclined towards the belly, the end of it would come out of the bladder, and the gorget, missing its guide, would slip between that and the rectum.

"The staff being rightly placed, I take the knife from the assistant, who holds the instruments, and put it into my mouth; then pressing the beak of the staff against the rectum, I feel the curvature of it through the perinæum. The incision ought to terminate an inch and a half below where we feel the bottom of the curvature. If we do not carry this incision sufficiently low, it may happen not to be of a size to allow the extraction of a large stone, and might lay us under the necessity of extending it further afterward, for the skin will not lacerate here nor easily give way for the passage of the stone. I therefore begin the incision from the lower part of the os pubis, continuing it down to the place that I before directed for its termination; after which I pass the point of the knife into the groove of the staff, and cutting from below upwards, without taking the point out of the groove, I open the anterior part of the urethra as far as the incision that is in the skin.

"The beak of the staff, which was pressed upon the rectum, must now be raised and pressed against the os pubis. At the same time, I turn the handle towards the right groin, that the groove, which is at the beak of the staff, may face the space between the anus and the tuberculum ischii on the left side. Then carrying the point of the knife down the groove, I slide it along the beak, turning the edge, that it may face the space between the anus and tuberosity of the ischium. By this incision, I exactly divide the bulb of the urethra, and by doing this on its side, we are sure to avoid wounding the rectum, which for want of this precaution has been often cut. This first incision being made, I again pass the point of the knife into the curvature of the staff to the part where it bears against the perinæum, and direct it to be held there by the assistant who supports the scrotum. This done, I take a large director, the end of which is made with a beak, like that of a gorget, and conveying this beak upon the blade of the knife, into the groove of the staff, I draw the knife out. I then slide the beak of this director, along the groove of the staff, into the bladder, and I withdraw the staff, by turning the handle towards the patient's belly. The following circumstances will sufficiently satisfy us, that the director is introduced into the bladder: first, if it strikes against the end of the staff, which is closed; secondly, if the urine runs along the groove. I next feel for the stone with this director, and having found it, endeavour to distin-

guish its size and surface, in order to make choice of a proper pair of forceps; that is, one of a stronger or weaker make, or of a large or small size, agreeably to that of the stone; after which I turn the groove towards the space, between the anus and tuberosity of the ischium, and resting it there, convey a bistoury along the groove, the blade of which is half an inch broad, and about three quarters of an inch long. I continue the incision made by the knife in the urethra, and entirely divide the prostate gland laterally, as also the orifice of the bladder; and, I am very certain, that the introducing the use of these two instruments, which are not employed by other lithotomists, does not prolong the operation a quarter of a minute, but rather shortens the time, both by facilitating the dilatation, that is afterward to be made with the finger, and by rendering the extraction of the stone more easy. The bistoury being withdrawn, the groove of the director serves to guide the gorget into the bladder. I then introduce my fore-finger along the gorget, (which is now easily done, as the urethra and prostate, being divided, do not oppose its entrance) and with it I dilate the passage for the stone, in proportion to the size, of which I discover it to be. This dilatation being made, I withdraw my finger, and use the proper forceps." (*Le Dran's Operations*, Edit. 5, 1784, London.)

Professor Pajola, of Venice, was the pupil of Le Cat, and his method resembles that of his master. He is stated to have cut for the stone 550 patients with success; which deserves notice, because his operation has for its principles, dilatation, and no division of any part of the bladder. He makes an incision into the groove of the staff, with a lancet-pointed, double-edged knife, called an urethrotome, the blade of which has upon its centre a groove, that is continued to its very point, and serves to guide the beak of another instrument, called the cystotome, into the groove of the staff. As the professed intention of the cystotome is only to cut the prostate gland, its name is ridiculous. It consists of a handle, and very slender blade, which is not connected with the handle, but with its sheath, by means of a little joint, close to the beak of the instrument. When the cystotome is opened as far as possible, the end of the blade furthest from the beak, is twelve lines from the sheath. In this position, it is held by a transverse piece of steel, which admits of being pushed more or less out at the option of the surgeon, and can be fixed by means of a screw. Pajola, like Scarpa, considers cutting the neck of the bladder dangerous, and he merely divides the prostate, after which he introduces a blunt gorget, and along this a species of forceps for dilating the neck of the bladder in all directions. (*X. F. Rudtorffer über die Operation des Blasensteins nach Pajola's Methode*.) As Langenbeck observes, great as the success of this lithotomist has been, his method of operating has little to recommend it; and every thing must be ascribed to his individual skill, and intimate knowledge of the parts. Lan-

genbeck even prefers Le Cat's method, in which there is no need of such a multiplicity of instruments. The blunt gorget and dilator are perfectly unnecessary, as the finger would do the purpose of both.

In the former editions of this Dictionary, I have not taken any notice of what has been termed by the French, "*Operation à deux temps*," and which was first mentioned by Franco. It, by this plan, it be intended, that the incision should be made at one period, and the extraction of the stone not attempted till a subsequent period, I cannot too strongly reprobate the practice. But, if I am to understand, that the postponement of the completion of the operation is only to be adopted, as a matter of necessity, when the patient cannot bear the longer continuance of the unsuccessful efforts to extract the stone, of course, I can only say, that every endeavour should be used to avoid this very disagreeable dilemma, by making in the first instance an adequate opening, and (if this cannot be done) by breaking the calculus, and carefully removing all the fragments. Some further considerations against delaying the completion of the operation will be found in the 2d vol. of the *First Lines of Surgery*.

The danger of the beak of the gorget slipping out of the groove of the staff, is one of the chief objections urged against the employment of the first of these instruments. In order to obviate this inconvenience, Sir Charles Blicke had the groove of the staff, and the beak of the gorget, so constructed that they locked into each other, and continued fixed till near the extremity of the staff. The contrivance, though plausible and ingenious, is not much used: the point of contact of the beak and body of the instrument is necessarily so small, that it is liable to break. It is allowed, however, that this objection might be removed, but another one is still urged, viz. the beak and groove catching on each other, so as to resist the efforts made to introduce the gorget into the bladder. Every operator knows, that much of the safety of the lateral operation, as performed at present, depends on the ease with which the beak of the gorget slides along the groove of the staff. Le Cat, in 1747, is said to have devised a similar intention.

Some operators have a good deal of trouble in dissecting into the groove of the staff. Sir James Earle invented an instrument to render this part of the operation more easy. It consists of a short staff, with an open groove, connected by a hinge with the handle of another staff, of the usual size, shape, curvature, and length, which may be called the *long staff*. The hinge, by means of a pin, is capable of being disjoined at pleasure. The short staff is sufficiently curved to go over the penis and scrotum, and long enough to reach to that part of the long staff which is just below the beginning of its curvature. The end of the short staff, made somewhat like a pen, with the sides sharpened and finely pointed, is adapted to shut into the groove of the long staff, and its cutting edges are defended from being injured by a proper recep-

tacle which is prepared for it in the groove of the long staff. When the instrument is shut, the groove of the short staff leads into that of the long one, so as to form one connected and continued groove. The short staff is rendered steady by the segment of an arch projecting from the long one through it.

The long staff, separated from the short one, is first introduced in the usual manner, and, the stone having been felt, the short staff is to be put on the other at the hinge. The incision is then to be made in the usual manner, through the skin and cellular membrane, and a second incision through the muscles, so as nearly to lay bare the urethra. The operator then being perfectly convinced that the extremity of the long staff is sufficiently within the bladder, must bring the end of the short staff down, and press it against the urethra, which it will readily pierce, and pass into the cavity prepared for it in the groove of the long staff. The two pieces being now firmly held together by the operator's left hand, nothing remains to be done, except applying the beak of the gorget to the groove of the short staff, and pushing it on till it is received in the groove of the long one; and if this latter be made with a contracted groove, it will just enter where the contraction begins, and thus must be safely conducted into the bladder. (*Earle on the Stone; Appendix; Edit. 2, 1796.*) Deschamps describes an instrument, invented by Jarda, surgeon of Montpellier, which bears a resemblance to Earle's double staff, but was more complicated, being designed to support the scrotum, and also press the rectum out of the way.

The late Mr. Dease, of Dublin, and Mr. Muir, of Glasgow, considering that the gorget was more apt to slip from the staff in consequence of the latter being curved, and that its beak never slips from the groove of the staff in operating on women, proposed, like Le Dran, to convert the male into the female urethra. They introduce, as usual, a curved grooved staff into the bladder, make the common incisions, and open the membranous part of the urethra; but instead of introducing a gorget on the curved staff, they conduct along the groove a straight director, or staff, into the bladder, and immediately withdraw the other. The gorget is then introduced. In this manner the operation may be very well performed with a narrow bitoury, as was advised by Mr. A. Burns.

LITHOTOMY, AS PERFORMED WITH A KNIFE, INSTEAD OF A CUTTING GORGET, BY SEVERAL OF THE MODERNS.

We have already described, how Frère Jacques and Cheselden, used to operate with a knife, without any cutting gorget, in the early state of the lateral operation. The success which attended the excellent practice of the latter surgeon, certainly far exceeds what attends the present employment of the gorget, for, out of 52 patients whom he cut successively for the stone, he only lost two; and out of 213, of all ages, con-

stitutions, &c. only 20. These facts are strongly in favour of abandoning the use of the gorget, and doing its office with a knife.

The objections to the gorget are numerous and well founded. In the hands of many skilful operators, its beak has slipped out of the groove of the staff, and the instrument has been driven either between the rectum and the bladder, or into the intestine instead of the latter viscus. Sir James Earle remarks: "I have more than once known a gorget, though passed in the right direction, pushed on so far, and with such violence, as to go through the opposite side of the bladder." Bromfield, even when operating with a blunt gorget, perforated the bladder and peritonæum, so that the abdominal viscera came out of the wound. (P. 270.) I now know of at least three instances, in which the gorget, slipping from the staff, completely severed the urethra from the bladder; the stone was not taken out; and the patients died.

We will suppose, however, that the preceding dangers of the gorget are surmounted, as they certainly may be, by particular dexterity, seconded by the confidence of experience. The gorget is introduced, but whatever kind of one has been used, the wound is never sufficiently large for the easy passage of any stone, except such as are below the ordinary size. Camper has noticed this fact: "*Hawkinsius solo conductore, cujus margo dexter in aciem assurgit, idem præstat: omnes plagam dilatant, ut calculum extrahant: dilacerentur igitur semper vesicæ ostium et prostata.*" (P. 114.) Dease says: "In all the trials that I have made with the gorget on the dead subject, I have never found the opening into the bladder sufficiently large for the extraction of a stone of a middling size, without a considerable laceration of the parts. I have frequently taken the largest-sized gorget, and could not find, in the adult subject, I ever entirely divided the prostate gland, if it was any way large; and in the operations that were performed here on the living subject, if the stone was large, the extraction was painfully tedious, and effected with great difficulty, and, in some cases, not at all."

I shall dismiss this part of the subject with referring the reader to the spirited and correct remarks on the objections to the gorget in Mr. John Bell's Principles, Vol. 2. Part 2.

The latter author recommends the external incision, in a large man, to commence about an inch behind the scrotum, and to be carried downwards three inches and a half, midway between the anus and tuberosity of the ischium. The fingers of the left hand, which at first kept the skin tense, are now applied to other purposes. The fore-finger now guides the knife, and the operator proceeds to dissect through fat and cellular substance, and muscular and ligamentous fibres, till the wound is free and open, till all sense of stricture is gone; for it is only by feeling opposition and stricture that we recognize the transverse muscle. When this hollow is fairly laid open, the external incision, which relates merely to the free extrac-

tion of the stone, is completed. If it were the surgeon's design to operate only with the knife, he would now push his fingers deeply into the wound, and, by the help of the fore-finger, dissect from the urethra along the body of the gland, till he distinguished its thickness and solidity, and reached its back part. Then, plunging his knife through the posterior portion of the gland, and settling it in the groove of the staff, he would draw it firmly and steadily towards him, at the same time pressing it into the groove of this instrument, and then the free discharge of the urine, assuring him that the prostate and neck of the bladder were divided, he would lay aside his knife, pass the left fore-finger into the bladder, withdraw the staff, and introduce the forceps. (John Bell, p. 197.)

Mr. Charles Bell describes the following method of operating with a knife, instead of a gorget. A staff grooved on the right side, a scalpel with a straight back, and the common lithotomy forceps, are the indispensable instruments. The staff is kept in the centre, and well home into the bladder. The surgeon making his incision under the arch of the pubes, and by the side of the anus, carries it deeper towards the face of the prostate gland: cutting near to the staff, but yet not cutting into it, and avoiding the rectum by pressing it down with the finger. Now carrying the knife along the staff, the prostate gland is felt. The point of the knife is run somewhat obliquely into the urethra, and into the lateral groove of the staff, just before the prostate gland. It is run on, until the urine flows. The fore-finger follows the knife, and it is slipped along the back of it, until it is in the bladder. Having carried the fore-finger into the bladder, it is kept there, and the knife is withdrawn. Then the forceps, directed by the finger, are introduced. (C. Bell's Operative Surgery, Vol. 1, p. 361.)

Mr. Allan Burns, of Glasgow, recommends the following method: "The plan (says he) introduced by Cheselden, and revived by Mr. J. Bell. I would assume, as the basis of the operation; but still, along with their mode, I would blend that of Mr. Dease, by which, I imagine, we may overcome some of the disadvantages attendant on each considered individually.

"For more than twelve months, I have been in the habit of showing such an operation, which is as simple in its performance, as the one in general use, is attended with less danger to the patient, permits of an incision varying in size, according to the wish of the operator, and completely prevents injury of the rectum, or pudic artery. To perform this operation, I introduce into the urethra a common curved staff, then make the usual incision into the perinæum, divide fully and freely the levator ani, so as to expose the whole extent of the membranous part of the urethra, the complete extent of the prostate gland, and a portion of the side of the neck of the bladder. When this part of the operation is finished, I open the membranous part of the urethra, and intro-

duce through the slit a straight or female staff, with which I feel the stone, and then withdraw the curved staff. This done, I grasp the handle of the staff firmly in my left hand, and with the right lay hold of the knife. Having ascertained that the two instruments are in fair contact, I rest the one hand upon the other, pressing them together, and then by a steady extraction, I pull out the knife and staff together, which is preferable to drawing the knife along the staff; it prevents the risk of the one slipping from the other; it guards the bulb of the urethra, and every other part from injury; for, between them and the cutting instrument, the staff is interposed;” &c. “When introducing the knife, the side of the blade must be laid flat along the fore-finger of the right-hand which is to project a little beyond the point. In this state the finger and knife are to enter the wound, opposite the tuber ischii; but, in proportion as they pass along, they are to be inclined forward, till at last, with the point of the finger, the staff is to be felt through the coats of the bladder, a little beyond the prostate, and rather higher than the orifice of the urethra. Here the knife is to be pushed, with the finger, through the bladder, and when the point is fairly fixed in the groove of the staff, the operation is to be finished by the steady extraction of both instruments” (*Allan Burns, in Edinburgh Surgical Journal, No. 13.*)

The knife of Cheselden does not require so much violence to divide the parts as the gorget does; cannot slip in some instances before, in others behind the bladder; and it will make a wound sufficiently ample for the easy extraction of the stone, without the least laceration. The possibility of its wounding the rectum, Dr. Thomson thinks might be obviated by employing it as follows: “After having made the external incisions, and divided the membranous part of the urethra, in the way that it is usually done for the introduction of the beak of the gorget, a straight-grooved staff is to be introduced into the groove of the curved staff, and pushed along it into the bladder. The curved staff is then to be withdrawn, and the surgeon, laying hold of the handle of the straight staff with his left hand, and turning the groove upwards and a little outwards, presses the back of it downwards towards the right tuber ischii, and holds it steadily in that position. The point of a straight-backed scalpel being now introduced into the groove of the staff, with its cutting edge inclined upwards and a little outwards, is to be pushed gently forwards into the bladder. The size of the scalpel need only be such as will make a wound in the prostate gland and neck of the bladder, sufficiently large to admit the fore-finger of the left-hand. The scalpel being removed, this finger is to be introduced into the bladder, through the wound which has been made, and the staff may then be withdrawn. With the finger the surgeon endeavours to ascertain the size and situation of the stone. If, after this examination,

he judges the incision in the neck of the bladder to be too small for the easy extraction of the stone, he next introduces into the bladder a straight probe-pointed bistoury, with its side close to the forepart of his finger, and its cutting edge upwards. By turning this edge towards the left side, and by keeping the point of his finger always beyond the point of the bistoury, he may safely divide, in the direction of the first incision, as much of the prostate gland, and neck of the bladder, as he shall deem necessary.” (*See Observations on Lithotomy, &c. with a Proposal for a new Manner of Cutting for the Stone, by J. Thomson, M. D. one of the Surgeons of the Royal Infirmary, &c. Edinb. 1808.*) In this small work, the reader will find additional particulars.

Mr. Allan, who is a strenuous advocate for using the knife instead of the gorget, directs us, after laying bare the urethra, and bringing the staff so as to form a right angle with the patient's body, to feel that the instrument is fairly lodged in the bladder. The operator is to use the fore-finger of his left-hand as a director in feeling for the groove in the staff, and in distinguishing the prostate gland; and, with this finger, he is to depress the rectum, and direct the deeper part of his dissection. “Feeling the gland, with the point of the fore-finger of the left-hand, and the groove of the staff in the upper part of the wound, the assistant is desired to steady his hand, and the operator, holding his knife as he does a writing pen, his fingers an inch and a half from the point, turns up its edge towards the staff, and strikes its point through the membranous part of the urethra into its groove, half an inch before the prostate gland. He now turns the back of the knife to the staff, slides it a little backwards and forwards in the groove, that he may be sure he has fairly entered; then shifts the fore-finger, with which he guides the incision, places it under the knife, and carries always before the point of it, to prevent the rectum being wounded; he then lateralizes the knife, enters the substance of the prostate, is conscious of running the scalpel through its solid and fleshy substance, and judges, by the finger, of the extent of the incision which he now makes. The urine flows out; he slips his finger into the opening, withdraws the scalpel, and gives it to an assistant, who hands him the forceps, which he passes into the bladder, using the fore-finger of his left-hand, which is still within the wound, as a conductor. The forceps instantly encounter the staff, which serves to conduct them safely into the bladder, while the finger guides them through the wound; &c.” (*Allan on Lithotomy, p. 48, Edinb. 1808.*)

I leave the reader to judge, which of the foregoing modes of operating with a common knife claims the preference. Perhaps Cheselden's manner, which is also Mr. John Bell's, is as deserving of recommendation as any.

The methods of operating with a knife, as practised by Klein and Langenbeck, I shall not here repeat, as they were described in the

last edition of the *First Lines of Surgery*, accompanied with many valuable practical observations made by these judicious and skilful surgeons.

That the performance of lithotomy with a knife, when the operator has the assistance of a proper staff, cannot be difficult, may be inferred from there being no particular difficulty in the method, even when no staff at all is employed. In the spring of the year 1814, when at Oudenbosch in Holland, I was requested by Sergeant Ryan, of the 1st Foreign Veteran Battalion, to see his little boy, about four years old, who was troubled with symptoms, which made me immediately suspect, that there was a stone in the bladder. As I had no sound, I introduced into this viscus a small silver catheter, which distinctly struck against a calculus. Without taking the instrument out again, I determined to perform lithotomy with a common scalpel. Indeed, no other mode could be adopted, as we had neither staff, gorget, nor lithotomy instruments of any kind. After making the external part of the incision in the common way, I found that the catheter afforded me no guidance. I therefore withdrew it, and dissected deeply by the side of the prostate gland, till the fore-finger of my left hand passed rather beyond it. The scalpel was then plunged into the bladder, behind this gland, under the guidance of my left fore-finger, and with the edge turned towards the urethra. The necessary division of the prostate and neck of the bladder was then made by cutting inwards and upwards in the direction of the rest of the wound. With a small pair of ordinary dressing forceps, a calculus, rather larger than the end of the thumb, was easily extracted. This operation was done at the Military Hospital, in the presence of Dr. Shanks of the 56th regiment, and several other medical officers. Not a single bad symptom ensued, although the army unexpectedly moved into the field three days afterward and the child travelled about for some time in a baggage cart, in an exposed and neglected state. The wound was consequently rather longer in healing than usual; but, this was the only ill effect. The little boy in the end completely recovered.

Of late years, many surgeons have chosen to perform lithotomy with several kinds of beaked scalpels. The practice, indeed, is still gaining ground. Mr. Thomas Blizard's knife is one of the best. Its blade is long, straight, and narrow, and, like the gorget, is furnished with a beak, by means of which it admits of being conducted along the groove of the staff into the bladder, after the external incisions have been made. The staff is then withdrawn, and the operator has now the power of making the incision through the prostate and neck of the bladder downwards and outwards to any extent, which the parts will allow, or the case require. This is one of the principal advantages which beaked long narrow knives have over gorgets, which, after their introduction, cannot be further used for the enlargement of the

wound. The narrow knife will also cut more safely downwards and outwards than any gorget; nor is it subject to the serious danger of slipping away from the staff, and going we know not where; because the moment its beak and extremity have entered the bladder, the staff is no longer necessary, as the proper extent of the blade will then readily pass in without the aid of any conductor at all. I need hardly observe, also, that, in this method, we have nothing like the perilous and violent thrust of the gorget, which, in the event of a little unsteadiness in the operator's hand, or of any fault either in the position of the staff, or the direction of the gorget, will do irremediable and fatal mischief.

A FEW GENERAL REMARKS ON THE BEST MODE OF MAKING THE INCISION IN THE LATERAL OPERATION: AND SOME REFLECTIONS ON THE PRINCIPLES INCULCATED BY PROFESSOR SCARPA.

Perhaps of all the great operations in surgery, lithotomy is that, in which great awkwardness, mortifying failures, and dangerous blunders, are most frequently observed. Many a surgeon, who contrives to cut off limbs, extirpate large tumours, and even tie aneurismal arteries, with *cclat*, cannot get through the business of taking a stone out of the bladder in a decent, much less, a masterly style. This fact is so familiarly known in the profession, and its truth so often exemplified, that I may well be excused the unpleasant task of relating in proof of it all the disasters, which have come to my own personal knowledge. But I must take the liberty of remarking, that, in this branch of surgery, a great number of individuals do not profit by these instructive lessons of experience. The more they see of lithotomy, the more they are convinced of its dangers; yet, too often, instead of studying the causes of ill success, they merely derive from the examples before them, a suspicion of the unskilfulness of the operator, or some discouraging conjectures about the difficulties of the operation.

The establishment of certain principles to be observed in lithotomy, appears the most probable way of diminishing the frequency of the accidents and failures of this common operation. If these principles are not violated, it is of less consequence what instrument is employed, for the surgeon may do nearly the same thing with an ordinary dissecting knife, a concealed bistoury, a beaked scalpel, or a well-made gorget.

After the very opposite principles, and different methods of cutting for the stone, which are explained in the preceding columns, as preferred by different surgeons, I think it may be useful to offer a few general observations on the proper direction and size of the incision. These points, which are of the highest practical consequence, in regulating the principles, which ought to be observed in lithotomy, are far from being settled, as must be plain to every body who

recollects that Desault, Mr. John Bell, Klein, and Langdenbeck, have recommended a free opening; Scarpa, Callisen, and others, a small one; that Mr. Abernethy and Scarpa employ gorgets, which cut upwards and outwards, at angles of 45° and 69° from the axis of the urethra; and that the gorgets of Croickshank, B. Bell, Desault, Mr. Cline, and most other surgeons are constructed for cutting either directly outwards, or outwards and inwards.

It appears to me, that the incision, through the whole of the parts cut in lithotomy, should always be made in a straight, regular, direct manner, from the surface of the skin in the perineum to the termination of the wound in the urethra and bladder. In an adult subject, the external wound should commence about an inch above the anus. The impropriety of beginning it higher up has been duly insisted upon by Sharp, Bertrandi, Callisen, and every good writer on the operation. "Il ne faut couper l'urètre que le moins, qu'on peut, parcequ'on obtient par ce moyen une meilleure voie pour pénétrer dans la vessie sous l'angle du pubis. C'est avec raison que Sharp dit que l'incision de l'urètre faite au dessus de cet angle est si peu utile pour l'extraction de la pierre, qu'on n'en retireroit pas plus d'avantage en le coupant presque dans toute sa longueur." (*Bertrandi, Traité des Opérations*, p. 127.) And Callisen lays it down as a maxim: "Ut ex partes haud sectione attingantur, quæ pro calculi egressu nihil faciunt; adeoque bulbus urethrae, et hujus pars corpore spongioso circumdata intacta relinquatur." (*Systema Chirurgiae Hodiernæ; Pars Posterior*; p. 655.)

Extraordinary as it may seem, it is not the less true, that cutting too much of the urethra is one of the most common faults still committed by modern surgeons. The incision in the integuments is to be large, that is to say, at least, three inches in length in an adult subject, because a free opening in the skin is not only exempt from danger, but attended with many advantages, especially those of facilitating the other steps of the operation, and preventing any future lodgment and effusion of urine. The external wound ought to be directed towards a point situated a very little towards the anus, from the innermost part of the tuberosity of the ischium. From the line, thus made, the incision should be carried inward and upward, through all the parts between it and the side of the prostate gland. Another line, extending from the inferior angle of the wound to the termination of the cut in the bladder, forms the precise limits, to which the depth of the incisions should reach, and no further.

The great principle of making the axis of the wound as straight and direct as possible, should always be kept in view, whether the surgeon employ a common scalpel, which cuts into the bladder, from without inwards, or other instruments, which divide the prostate gland, and neck of the bladder, from within outwards, like the bistourie cachée, beaked knives, and every kind of cutting gorget. In the latter circumstance, the only

difference consists in cutting, from the bladder and urethra, downwards and outwards towards a point, situated a little way more inwardly than the tuberosity of the ischium, instead of carrying the incision from this point, upwards and inwards, through the side of the prostate gland and the orifice of the bladder. The following may be enumerated as important advantages of attending to the foregoing principle:

1. The wound is made in that direction, which affords the greatest room for the extraction of large stones; and the axis of the incision being also as nearly straight as possible, the introduction of forceps, and the passage of the calculus outward, are materially facilitated.

That these are important advantages, I think every surgeon will allow, who knows how much the pain and danger of lithotomy depend upon the injury which the parts suffer from the force sometimes used in the extraction of the stone, and the repeated introduction of the forceps. Cheselden, the most successful lithotomist England ever produced, made the incision in the direction here recommended; sometimes inward and upward; sometimes outward and downward. The following remarks of another excellent surgeon merit particular attention:—"J'ai vu plusieurs fois dans les Hôpitaux de Paris, que les Chirurgiens, coupant trop en haut vers l'angle du pubis, sentoient une grande résistance au périnée, quand ils vouloient retirer le calcul avec les tenettes; on voyoit le périnée se tuméfier par la pression, qu'y faisoit la pierre; en ce cas, quelques opérateurs plussages abandonnoient la pierre, introduisoient de nouveau le gorgeret, et en tournant en dessous la cannelure de celui-ci, prolongeoient l'incision obliquement vers la tubérosité de l'os ischion; et enfin à la faveur de cette plus grande ouverture, retiroient la pierre sans causer de déchiremens." (*Bertrandi, Traité des Opérations*, p. 133.) Larger stones may likewise be thus extracted, without being broken, than in any other mode of making the lateral incision, as must be obvious to every practitioner, who recollects the very limited room, afforded at the upper part of the triangular space, between the arch of the pubes, the ramus of the ischium, and the neck of the bladder. This consideration cannot fail to have great weight with all surgeons, who feel duly convinced, how unsatisfactory a method it is to break a calculus, in order to get it out of the bladder. The measures necessary for the removal of all the fragments protract the completion of the operation, and seriously increase its danger; while the continuance of a single part of the stone behind may cause a renewal of all the grievances, for the cure of which the patient submitted to the operation. By these remarks, however, I am far from meaning to say, that large calculi should not be broken; on the contrary, my only wish is, that the necessity for the practice may be avoided, as much as possible, by making a free incision into the bladder, and even enlarging the opening, if necessary, as far as can be done

with safety. In short, instead of breaking the stone, I prefer the practice of Mr. Martineau, of Norwich, perhaps the most successful lithotomist now living in this country, as out of 84 patients, whom he has cut, only two have died; a statement highly favourable to operating with a knife, and making an adequate opening. "Should the stone be large, or there be any difficulty in the extraction, rather than use much force, while the forceps have a firm hold of the stone (says Mr. Martineau,) I give the handles to an assistant, who is to draw them outwards and upwards, while the part forming the stricture is cut; which is easily done, as the broad part of the blade becomes a director to the knife; and rather than lacerate, I have often repeated this enlargement of the inner wound two or three times." (See *Med. Chir. Trans. Vol. 11, p. 411.*) The great advantage of the knife over the gorget, and even the necessity of employing it for adapting the size of the opening in the bladder to the magnitude of the stone, or its fragments, are most convincingly exemplified in several cases recently put upon record. Thus Klein, with the aid of a common scalpel, extracted a calculus, which weighed twelve ounces, thirty grains; and the patient recovered. (*Pract. Ansichten Bedeutendsten Operationen, H. 1.*) In 1818, Mr. Mayo, of Winchester, operated with a knife, and extracted a calculus, which broke in the forceps, weighing fourteen ounces, two drachms, avoirdupoise, and the patient recovered. (See *Med. Chir. Trans. Vol. 11, p. 54, &c.*) Mr. W. B. Dickenson, of Macclesfield, also succeeded with Mr. Gibson's knife, in taking out of the bladder a calculus, the fragments of which weighed eight and a half ounces, and the patient was saved. (*Vol. cit. p. 61.*) And in the same volume may be seen other instances, in which immense calculi were removed from the bladder with various results, but particularly one which weighed sixteen ounces, and which Sir A. Cooper could not succeed in breaking: he was therefore obliged to enlarge the wound, first made with the gorget "to the sacro-sciatic ligament," when with the aid of a hook applied to the forepart of the stone behind the pubes, and the simultaneous assistance of the forceps, he succeeded with considerable difficulty in removing this immense mass. The patient lived, however, only four hours after the operation. (See *Med. Chir. Trans. Vol. 11, p. 73.*)

2. The arteria pudica profunda can never be injured, because the surgeon does not let the knife, or gorget, approach nearer to the ischium, than a point which is situated a little way from the tuberosity of that bone towards the anus; and consequently the edge of the instrument cannot come into contact with the inside of the tuberosity and ramus of the ischium where the great pudic artery is situated.

3. The rectum will not be wounded, because the direction of the axis of the incision, either downwards and outwards to the above-mentioned point, or from that

point inwards and upwards, sufficiently removes the edge of the knife, or gorget, from the intestine. But, the rectum will be in still greater safety, if it be pressed downward with the fore-finger of the left hand in the wound, and the prudent custom of emptying it, by means of a clyster, a short time before the operation, be not omitted; for, no lithotomist should ever forget, that, when this bowel is considerably distended with feces, it rises up a little way on each side of the prostate gland.

4. As the seminal duct penetrates the lower part of the substance of the prostate gland, in order to reach the urethra, and the knife, or other instrument, employed, divides the upper portion of the side of that gland inward and upward, or outward and downward, it is obvious that the duct will not be in the least danger of being cut.

The judicious Callisen is well aware of the advantages of making a smooth, even, direct incision into the bladder;* but, like Professor Scarpa, he is averse to making a free cut through the neck of that viscus. Indeed, as we shall presently notice, Scarpa does not sanction cutting any portion of the bladder at all.

Every practitioner, who will take the trouble to look over the history of the lateral operation, will find, that the greater number of lithotomists, who have particularly distinguished themselves by their unparalleled success, as Frère Jacques, Cheselden, Cosme, Mr. Martineau, Dr. Souberbielle, &c. made a free incision into the bladder. This fact alone is enough to raise doubts of the goodness of the advice delivered upon this subject by Callisen and Scarpa; especially, as neither they, nor any other modern surgeon (with the exception, perhaps, of Pajola, whose individual skill is said by Langenbeck to make amends for the disadvantages of his method,) can boast of having cut patients for the stones with a degree of success at all equal to that of the above-mentioned operators. The extraordinary success which characterized Cheselden's practice we have already detailed in this volume. The accounts, which we have, of the successful operation done by Frère Jacques and Cosme, are equally remarkable.

Mr. Martineau, as I have noticed, has lost but two patients out of 84, on whom he has operated, and this without making any selection, as he never rejected any one who was brought for operation. His patients were always kept a week in the house before operating; and this precaution, with a regulated diet, and perhaps a dose or two of opening medicine, was the only preparatory treatment. (*Med. Chir. Trans. Vol. 11, p. 409.*)

During my stay at Paris, in 1815, I saw Dr. Souberbielle extract a stone of consider-

* *Vulnus sit aequale, haud angulatum, conicæ figuræ, apice vesicam respiciente, externa plaga ampullæ et quatuor pollicum longitudine, unde effluxus sanguinis, parvis lotiis, aëneis, facilitatur. See Systema Chirurgiæ Hodierne; Pars Posterior, p. 603, Infinitè, 1790.*

able size, on the plan of his well-known ancestor. The incision was ample and direct, so that the calculus was taken out with perfect ease. Now, as the operations of this professed lithotomist are very numerous, and he enjoys the reputation of scarcely ever losing a patient, are we not justified in inferring, that the advocates for a small opening are promulgating the worst advice which can be offered to the practitioner? My own observations certainly tend to such a conclusion as will be presently explained. The tract recently published by Scarpa (*Memoir on the Cutting Gorget of Hawkins, &c. trans. by Briggs*), has for its main objects the recommendation of a modification of Hawkins's gorget, and the inculcation of the propriety of making a small limited incision in the prostate gland, without cutting any part of the bladder. As sufficient room cannot thus be obtained for the extraction of even a stone of moderate size, he is an advocate for the gradual dilatation of the urethra and orifice of the bladder. He observes, that the lateral operation, though executed with the greatest precision, does not exempt the surgeon from dilating in a certain degree the orifice of the bladder, and cervix of the urethra, the dilatation of those parts, however moderate, being always necessary even where the calculus is of middling size. He states, that, in the adult, the orifice of the bladder dilates almost spontaneously to the diameter of five lines; and he adds, that the lateral incision, within proper limits, divides the body and base of the prostate gland to the depth of four, or, at most, five lines, forming with the five, to which the orifice of the bladder naturally yields, an aperture of ten lines. But, says Scarpa, in an adult, a stone of ordinary size and oval figure is sixteen lines in the small diameter, to which must be added the thickness of the blades of the forceps: consequently, even after the incision has been made with the most scrupulous exactness, the stone, though of moderate size, cannot pass out of the bladder, unless the dilatation of the base of the gland and orifice of the bladder be carried to the extent of nearly eight lines, beyond the size of the aperture made with the knife. But, says Scarpa, if, in order to avoid distending the parts to the extent of eight lines, the base of the prostate gland, together with the orifice of the bladder, and a part of its fundus, be divided to a depth equivalent to it, the event would necessarily be an effusion of urine into the cellular membrane, between the rectum and bladder, and consequently suppuration, gangrene, fistulæ, and other serious evils. (Page 4, 5.)

According to Scarpa, the apex of the prostate gland forms the greatest resistance to the introduction of the forceps and the extraction of the stone, and, therefore, ought to be completely divided; (P. 7.) but, he contends, that two, and sometimes three, lines of the substance of the base of the gland, should be left undivided; which, he asserts, is a matter of great importance, because the untouched portion, around the

orifice of the bladder, prevents the effusion of urine, and the formation of gangrene, or fistulæ, between that part and the rectum. (P. 22.)

After this statement of one of the great principles, which Scarpa wishes to be observed in the performance of the lateral operation, a question or two naturally arise. Are we then to conclude, that the plan of making a free and direct incision into the bladder ought to be abandoned? Must we forget, that it is this method, which has answered so well in the hands of Cheselden and the several renowned lithotomists already enumerated? And must we believe, that the advice delivered upon this point by Bertrandi, Desault, Mr. John Bell, and all the best modern surgeons in this country, is founded only upon a capricious partiality to the free use of cutting instruments?

Earnestly as I respect the names of a Calisen and a Scarpa, their authority cannot influence me further, than I find it coincide with the dictates of experience,—the great arbitrator of every disputed point in practice.

We have seen, that an apprehension of effusion of urine, gangrene, fistulæ, &c. is the only reason assigned by Scarpa for his aversion to making a complete division of the side of the prostate gland, and orifice of the bladder. But, I would inquire, do we find extravasation of the urine, between the rectum and bladder, and gangrene, and fistulæ, so frequent after lithotomy in England, as to render it probable, that these ill consequences can ever proceed from our usual mode of dividing completely, not only the side of the prostate gland, but also the adjoining part of the bladder? Are such bad effects so often experienced in this country, as to constitute a material source of uneasiness in the mind of a surgeon about to undertake lithotomy? Do they form a substantial reason for abandoning the maxim of always endeavouring, as far as circumstances will allow, to make an incision of sufficient size for the easy removal of the calculus? And, would not Scarpa's method of stretching and dilating the wound, in order to get the stone out of the bladder, often dangerously prolong the operation; lead to much mischief from the repeated use of the forceps; cause serious contusion and lacerations of the parts; and, for all these reasons, render inflammation of the bladder and peritonæum very likely to follow?

In the course of the twenty-four years that I have been in the profession of surgery, I have seen the lateral operation performed an immense number of times, either with various kinds of gorgets, beaked knives, the lithotomie caché, or common scalpels. In all these examples the avowed intention of the surgeon was to make a free opening into the bladder. I do not mean, however, to say, that this was always actually accomplished, since the bad construction of the instruments employed, and other causes, sometimes frustrated the wise design of the operator. But, what was the consequence? Generally speaking, those surgeons who

made only a small incision into the bladder, and kept their patients a long while upon the operating table, ere they succeeded in getting out the stone, by the repeated and forcible use of the forceps, had the mortification to see very few of their patients recover; a large proportion of them being carried off by peritonitis, on the third or fourth day after the operation.

On the contrary, when the incision was ample and direct, so that the calculus could be easily and gently removed, the patients were almost always saved.

During the first six or seven years of the long time during which I have enjoyed frequent opportunities of seeing lithotomy performed in St. Bartholomew's Hospital, gorgets were invariably used, most of which instruments made an insufficient opening. The consequence was, that many of the patients were detained a long while upon the operating table, before the stone could be extracted, and some considerable numbers were lost by peritonitis. Of late years, however, in the same institution, common scalpels and beaked knives have been often used; a freer opening has been generally made; and the proportion of deaths from peritonitis is strikingly lessened.

The following observation, made by Mr. Martineau, is also worthy of particular attention:—"In the first years of my practice," says he, "I was not very successful; and often witnessing many untoward circumstances in myself and others, which appeared to arise from the use of the cutting gorget, I determined to lay that instrument aside, and employ the knife only, and the *blunt* gorget as a conductor for the forceps." (*Med. Chir. Trans.* p. 405.)

Now, when we remember that this gentleman has lost only two out of eighty-four patients, on whom he has operated, his remarks are of great importance; and his cases, and the other facts, which I have specified, strongly impress my mind with the truth of all that I have urged, respecting the advantages of making the opening large, and in the best direction for the easy passage of the stone outward.

In Mr. Martineau's manner of operating, it is true, he does not make the external wound parallel to that in the bladder, as I venture to recommend, but directs it nearly in a line with the raphe; a circumstance which may, perhaps, account for his continuing the use of the blunt gorget as a conductor for the forceps. Neither is his internal incision carried downwards and outwards, as Bertrandi, Desault, and many other judicious surgeons consider most advantageous. But these defects (if I may presume to call them so) are rendered of less consequence by the rule, which Mr. Martineau observes, of *making his first incision long and deep*, and avoiding all stretching and laceration of the parts. Like Langenbeck (*See First Lines of Surgery*, Vol. 2,) he uses a staff, the groove of which is much wider and deeper than usual, and therefore more easily felt. This instrument his assistant holds, in the way preferred

by Scarpa, nearly in an upright straight direction. "After the first incision (says Mr. Martineau) I look if the staff is not altered in its situation, and then feeling for the groove, I introduce the point of the knife into it, *as low down as I can, and cut the membranous part of the urethra, continuing my knife through the prostate into the bladder; when, instead of enlarging the wound downwards, and endangering the rectum, I turn the edge of the blade towards the ischium, and make a lateral enlargement of the wound in withdrawing the knife*" (*See Med. Chir. Trans.* Vol. 11, p. 409.) This description is particularly interesting, as coming from a gentleman, who has had so much experience and success; and its value would have been increased, had the direction in which the edge of the knife was turned in the division of the prostate gland, been exactly specified.

With respect to the degree of importance, which ought to be attached to the fear of effusion of urine, between the bladder and rectum, gangrene, fistulæ, &c., I can only say, that they are inconveniences which are not commonly observed after lithotomy in this country. In two or three instances only I have known the urine come through the wound longer than usual, and these cases ended well. As for the extravasation of urine and sloughing, I shall merely remark, that although there cannot be a doubt of their occasional occurrence, they have not taken place after any of the numerous operations, with the results of which I have been acquainted.

All these facts and considerations, therefore, incline me to doubt whether the apprehension of the effusion of urine, fistulæ, &c. be sufficiently serious and well-founded to make it advisable for surgeons to relinquish the plan of making a complete division of the side of the prostate gland, and neck of the bladder, in the operation of lithotomy. Nor is it at all clear to my mind, that effusion of urine and sloughing are likely to be the effect of practising a free opening. Indeed, whenever they do happen, I believe they proceed from a totally different cause, viz. from the incision in the skin being too small and too high up, and from the axis of the internal part of the incision not corresponding with that of the external wound. Hence the urine does not readily find its way outward, and some of it passes into the neighbouring cellular membrane.

In confirmation of the foregoing remarks, I beg leave to cite the sentiments of one of the greatest and most experienced of modern surgeons. Speaking of the defects of Hawkins's gorget, Desault observes, "*La méthode de l'enforcer horizontalement dans la vessie sur la catheter tenu à angle droit avec le corps, a deux grands desavantages: d'un côté celui de pénétrer par l'endroit le plus rétréci du pubis, et par conséquent de ne faire que difficilement une ouverture suffisante; d'un autre côté, celui de ne pas établir de parallélisme entre l'incision extérieure des tégumens qui est oblique et celle*

du col de la vessie et de la prostate, qui se trouve alors horizontale. De-là la possibilité des infiltrations par les obstacles qui les urines trouveront à s'écouler."

No doubt also some of the worst, and most dangerous urinary extravasations after lithotomy, have proceeded from another cause, pointed out by the same excellent surgeon. "Imprudemment porté dans la vessie, le gorgeret peut aller, par le stylet beaucoup trop long qui le termine, heurter, déchirer, perforer même la membrane de la vessie, et donner lieu à des infiltrations d'autant plus dangereuses, que le lieu d'ou elles partent est plus inaccessible. Cet accident est surtout à craindre, lorsque, comme les Anglais, on se sert de catheter sans cul-de-sac." (*Sec Œuvres Chir. de Desault par Bichat*, T. 2, p. 460, 461.)

LITHOTOMY THROUGH THE RECTUM.

This method may be said to have been first suggested in a work published at Bâle, in the 16th century, by an author who assumed the name of Vegetius: "Jubet per vulnus recti intestini, et vesicæ aculeo lapidem ejicere," says Haller, in speaking of this writer. (*Bibl. Chir. Vol. 1, p. 102.*) But the proposal never received much attention until the year 1816, when M. Sanson, in France, gave an account of this manner of operating, and urged several considerations in favour of the practice. In that country, however, the operation has been performed only by Dupuytren, and, though the operation proved successful, the other French surgeons do not appear to have imitated him. Nor am I aware, that Dupuytren himself now continues the practice. Almost as soon as this method was heard of on the other side of the Alps, it was put to the test of experience by Barbantini, in a case where every other plan of operating appeared hardly practicable. "The connexion of the urethra with the rectum, prostate gland, and posterior part of the bladder, (says M. Sanson) made me easily perceive, that by dividing the sphincter ani and some of the rectum near the root of the penis, I should expose, not only the apex of the prostate gland, but a more or less considerable portion of this body, and that I should then be able to penetrate into the cavity of the bladder, either at the neck through the prostate, or at its posterior part." It was the latter method, which M. Sanson first tried upon the dead subject. The body was placed in the position usually chosen for the common ways of operating, and a staff was introduced, and held perpendicularly by an assistant. A bistoury, with its blade kept flat on the left fore-finger, was now introduced into the rectum, and the edge being turned upwards, M. Sanson, with one stroke, in the direction of the raphe, cut the sphincter ani, and the lower part of the rectum. The bottom of the prostate gland being thus exposed, the finger was next passed beyond its solid substance, where the staff was readily

perceptible through the thin parietes of the rectum and bladder. While the latter instrument was steadily maintained in its original position, M. Sanson here introduced the knife into the bladder, and, following the groove of the staff, made an incision about an inch in length. At this instant, the flow of urine from the wound indicated that the bladder had had an opening made in it. On examination, the parts divided were found to be the sphincter, the lower part of the rectum, the back part of the prostate, and the adjacent portion of the bladder. Another mode, contemplated by M. Sanson, was, after dividing the sphincter ani, to cut the termination of the membranous part of the urethra along the groove of the staff held perpendicularly, and by the same guidance to extend the incision in the median line through the prostate gland and neck of the bladder.

In Barbantini's case, the calculus was so large, that it made a considerable prominence in the rectum, where it was felt extending across from one tuberosity of the ischium to the other. On account of its size, its extraction by the lateral operation was considered impracticable, and, as it was not thought advisable or easy to break such a mass, and Barbantini regarded the high operation as more difficult and uncertain in its results than the common method, it was determined to operate through the rectum. The attempt was delayed some days, by the impossibility of introducing effectually the staff, which was stopped at its entrance into the bladder by the calculus. But, as a grooved instrument was judged to be an essential guide, Barbantini caused a long director to be constructed, which he thought might be passed more conveniently than the staff, into the first incision. He also provided himself with long forceps, the blades of which were very broad, and admitted of being put separately over the stone. A staff having been introduced, the operation was done after M. Sanson's manner, except that a wooden gorget was introduced for the protection of the rectum, and the prostate gland was left undivided at the forepart of the wound. When the bladder had been opened at the lower part of the rectum, as far as the groove of the staff served as a guide, the latter instrument was withdrawn, and the long director introduced into the incision, which, under its guidance, was then enlarged to the necessary extent. With some difficulty the stone was then extracted, and found to weigh nine ounces and a half. For about eighteen days the urine passed away by the anus, only a few drops occasionally issuing from the urethra. As this circumstance gave Barbantini some uneasiness, he introduced his finger into the bladder, the inner surface of which, near the wound, he found covered with encysted calculous matter, which was very adherent. At length, however, it was gradually removed, with a portion of new-formed membrane, by attempts repeated

with the finger several days in succession. A catheter was then introduced, through which, at first, almost the whole of the urine flowed. But the tube being afterward obstructed with mucus, it became necessary frequently to clear it by injecting tepid water. The cure now seemed to proceed with rapidity. When the feces were hard, none of them passed into the bladder; but when they were liquid, a part of them were voided with the urine through the tube, though without any inconvenience. At the end of fifty days, scarcely any urine passed out of the wound; the patient, therefore, went into the country, where, in the course of another month, the cure was complete.

About a year ago, I saw an example, in which a calculus had made its way through the prostatic portion of the urethra, and formed, with the swelling of the soft parts, a considerable prominence within the rectum. If the patient had been under my care, I should certainly have made an incision directly on the tumour just within the sphincter, by which means the calculus might have been removed with great ease, and less risk than dividing the prostate. However, the latter method was followed, and the case had a very favourable termination. In this instance, as the sound, in its passage, only occasionally touched a small point of the calculus, which approached the urethra, and this just at the instant before its entrance into the cavity of the bladder, the exact nature of the case was for some time a matter of doubt to several skilful surgeons who were consulted. Respecting the merits of lithotomy through the rectum, I think the practice well deserving the consideration of the profession, where the calculus is known beforehand to be of unusual size. It must be less painful, I apprehend, than the high operation, and, perhaps, more easy of execution. But it is difficult, with the scanty experience before us, to offer any very decided opinion whether, on the whole, it ought to be preferred either to the high or the lateral operation, by which last, stones of larger size than that extracted by Barbantini, have been successfully taken out by Mr. Mayo, of Winchester, Dr. Klein, of Stuttgart, and others. The most serious consideration is, whether a large incision, forming a communication between the bladder and rectum, will generally heal up, as well, or even more favourably, than in Barbantini's case. This is a point which can only be decided by further observation. A smaller wound in the same part, it appears, is soon cured; for in the instance reported by Sanson, the boy was quite well on the twentieth day. For further information, consult Sanson, *Des Moyens de Parvenir à la Vessie par le Rectum*, 4to. Paris, 1817; N. Barbantini *Obs. relative à l'extraction d'un calcul urinaire très volumineux, opérée au moyen de la taille vesicorectale*, 8vo. Lucques, 1819; *Journ. Complém. du Dict. des Sciences Med.* T. 6, p. 79, 8vo. Paris, 1820; *Dict des Sciences Med.* T. 28, p. 422, &c.

LITHOTOMY IN WOMEN.

Women suffer much less from the stone than men, and far less frequently stand in need of lithotomy. It is not, however, that their urine will not so readily produce the concretions which are termed urinary calculi. The reason is altogether owing to the shortness, largeness, and very dilatable nature of the female urethra; circumstances which in general render the expulsion of the stone with the urine almost a matter of certainty. The records of surgery present us with numerous instances, where calculi of vast size have been spontaneously voided through the meatus urinarius, either suddenly without pain, or after more or less time and suffering. Heister mentions several well-authenticated examples. Middleton has also related a case, where a stone, weighing four ounces, was expelled in a fit of coughing, after lodging in the passage a week. Colot speaks of another instance, where a stone, about as large as a goose's egg, after lying in the meatus urinarius seven or eight days, and causing a retention of urine, was voided in a paroxysm of pain. A remarkable case is related by Dr. Molineux in the early part of the *Philosophical Transactions*: a woman voided a stone, the circumference of which measured the longest way seven inches and six-tenths, and round about, where it was thickest, five inches and three quarters; its weight near two ounces and a half troy. And Dr. Yelloly has related an interesting example, in which a calculus, weighing three ounces, three and a half drachms troy, and lodged in the meatus urinarius, was easily taken out with the fingers. (See *Med. Chir. Trans.* Vol. 6, p. 577.) Dr. Yelloly also refers to several very remarkable instances, described in the *Phil. Trans.* Vols. 12, 15, 17, 20, 34, 42, and 55, proving what large stones will pass out of the female urethra, either spontaneously or with the aid of dilatation and manual assistance. Were any doubts now left of this fact, they would be immediately removed by other histories, especially those contained in a paper drawn up by Sir A. Cooper. (See *Med. Chir. Trans.* Vol. 8, p. 427, &c.)

Sometimes, after the passage of large calculi, the patient has been afflicted with an incontinence of urine; but, in general, this grievance lasts only a short time.

The occasional spontaneous discharge of very large calculi through the meatus urinarius led Frederic de Leauson to deliver the advice not to interfere with them, as he thought they would all present themselves sooner or later at the orifice of that passage, and admit of being taken away with the fingers. (See *Traité Nouveau pour aisément parvenir à la Vraie Curation de plusieurs belles Operations*, &c. Genève, 1674.)

When surgeons began to consider what very large calculi were sometimes spontaneously voided, and the large size, and dilatable nature of the female urethra, they suspected that it would be a good practice

to dilate this passage by mechanical contrivances, until it would allow the stone to be extracted, and thus all occasion for cutting instruments might be superseded. With this view, Tolet first proposed suddenly dilating the passage with two steel instruments, called a male and female conductor, between which the fingers, or forceps, were passed for the removal of the calculus. (*Traité de la Lithotomie, Paris, 1681.*) But as it was afterward rightly judged, that the dilatation would produce less suffering and injury, if more gradually effected, Douglas suggested the practice of dilating the meatus urinarius with sponge or dried gentian root.

Mr. Bromfield has published the case of a young girl, in whom he effected the necessary dilatation by introducing into the meatus urinarius the appendicula cœci of a small animal in a collapsed state, and then filling it with water by means of a syringe; thus furnishing a hint for the construction of instruments on the principle of Mr. Arnott's dilator. The piece of gut, thus distended, was drawn out in proportion as the cervix vesicæ opened, and, in a few hours, the dilatation was so far accomplished, that the calculus had room to pass out. (See *Chir. Obs. and Cases, Vol. 2, p. 276.*)

Mr. Thomas met with a case, in which, after dilating the meatus urinarius with a sponge tent, he succeeded in extracting an earpicker which lay across the neck of the bladder. The passage was so much enlarged, that the left fore-finger was most easily introduced, and (says this gentleman) "I believe had the case required it, both thumb and finger would have passed into the bladder without the smallest difficulty." After adverting to this, and other facts, proving the ease with which the female urethra can be dilated, Mr. Thomas remarks: "If these relations can be credited, and there is no reason why they should not, I can hardly conceive any case, in a young and healthy female subject, and where the bladder is free from disease, where a very large stone may not be extracted, without the use of any other instrument than the forceps, the urethra having first been sufficiently dilated by means of the sponge tents. For this purpose, the blades of the forceps need not be so thick and strong as those commonly employed. (See *Medico-Chir. Trans. Vol. 1, p. 123—129.*) Many facts of a similar kind are on record, and one in which a large needlecase was extracted, is referred to in a modern periodical work. (See *Quarterly Journ. of Foreign Med. Vol. 2, p. 331.*)

Some surgeons have extracted stones from the female bladder in the following manner: the patient having been placed in the position commonly adopted in the lateral operation, a straight staff, with a blunt end, is introduced into the bladder, through the meatus urinarius. The surgeon then passes along the groove of the instrument the beak of a blunt gorget, which instrument becoming wider towards the handle, effects a part of the necessary dilatation. The staff

being withdrawn, and the handle of the gorget taken hold of with the left hand, the right fore-finger with the nail turned downwards, is now introduced slowly along the concavity of the instrument. When the urethra and neck of the bladder have thus been sufficiently dilated, the finger is withdrawn, and a small pair of forceps passed into the bladder. The gorget is now removed, and the stone taken hold of, and extracted. (*Sabatier, Médecine Opératoire, T. 2, p. 103.*)

This plan, however, is liable to the objections arising from the dilatation being too suddenly effected; and the practice now generally preferred is that of gradually expanding the meatus urinarius with sponge tent. And, as the retention of the urine, during the continuance of the sponge, causes great irritation, I consider Mr. C. Hutchinson's suggestion of placing a catheter in its centre, as mentioned by Sir A. Cooper, as meriting attention. (See *Med. Chir. Trans. Vol. 8, p. 433.*)

Notwithstanding these favourable accounts of the practice of dilating the female urethra, for the purpose of removing calculi from the bladder, there are very good surgeons who deem an incision the best practice. It is certain, that some patients have found the method insufferably tedious and painful. But the strongest objection is the incontinence of urine, which occasionally follows any great distention of the urethra and neck of the bladder. Klein, one of the most experienced operative surgeons in Germany, states that he has tried both plans, and that the use of the knife is much less frequently followed by incontinence of urine. On the other hand, Mr. Thomas believes, that this unpleasant symptom is quite as often a consequence of the operation of lithotomy, as now usually performed. (*Med. Chir. Trans. Vol. 1, p. 127.*) When the stone is not very large, perhaps dilatation should be preferred; and, in other cases, an incision.

In females, lithotomy is much more easy of execution, and less dangerous, than in male subjects. It may be done in various ways; but the surgeons of the present time constantly follow the mode of making the requisite opening by dividing the urethra and neck of the bladder. Louis employed for this purpose a knife which cut on each side, and was contained in a sheath; Le Blanc, a concealed bistoury, which had only one cutting edge; Le Cat, his gorgeret-cystitome; Frère Come, his lithotome caché; and Fleurant a double-bladed lithotome caché. Of these instruments, the best, I think, is that of Frère Come. But, at present, every surgeon knows, that the operation may be done, as conveniently as possible, with a common director and a knife, that has a long, narrow, straight blade. A straight staff, or director, is introduced through the meatus urinarius; the groove is turned obliquely downwards and outwards, in a direction parallel to the ramus of the left os pubis; and the knife is thus conduct-

ed into the bladder, and makes the necessary incision through the whole extent of the passage, and neck of the bladder.

Louis and Fleurant, as I have said, were the inventors of particular bistouries for dividing both sides of the female urethra at once. The instrument of the former effected this purpose, in passing from without inwards; that of the latter, in passing from within outwards. Fleurant's bistoury bears some resemblance in principle to Frère Come's lithotome caché, or to the cutting forceps, with which Franco divided the neck of the bladder. The reason assigned in recommendation of these bistouries is, that they serve to make a freer opening for the passage of large stones, than can be safely made by cutting only in one direction. When the calculus is large, it is certainly difficult to procure a free opening, without cutting the vagina, in front of which passage, there is but little space under the pubes for the removal of the stone. Hence, Dubois invented a new method, which consists in dividing the meatus urinarius directly upwards towards the symphysis of the pubes, dilating the wound and keeping the vagina out of the way by means of a blunt gorget, and then taking out the calculus with the forceps. This method seems to me better devised for the protection of the vagina, than the acquirement of more room for the calculus, and whatever space is gained, is only gained by the distention of the parts, and the propulsion of them downwards. The plan is acknowledged to be very painful, yet generally successful, and not followed by any serious symptoms or incontinence of urine. (See *Dict. des Sciences, Méd. T. 28, p. 436.*) When the stone is known to be very large, Sabatier and some other modern surgeons prefer the apparatus altus.

A case may present itself, in which the posterior part of the bladder, drawn downwards by the weight of the stone, may displace a portion of the vagina, and make it protrude at the vulva in the form of a swelling. Here, there would be no doubt of the propriety of cutting into the tumour, and taking out the foreign body contained in it. Rousset performed such an operation, and Fabricius Hildanus in a case, where the stone had partly made its way into the vagina, enlarged the opening, and successfully extracted the foreign body.

Mery proposed to cut into the posterior part of the bladder through the vagina, after introducing a common curved staff; but the apprehension of urinary fistulæ made him abandon the project.

The existence of extraordinary circumstances may always render a deviation from the common modes of operating not only justifiable, but absolutely necessary. Thus, Tolet met with a case, where a woman had a prolapsus of the uterus, with which the bladder was also displaced. In the latter viscus, several calculi were felt: an incision was made into it, and the stones extracted, after which operation, the displaced parts were reduced, and a speedy

cure followed. (*Sabatier, Médecine Opératoire, T. 2, p. 107.*)

The incontinence of urine, consequent to lithotomy in women, is by no means an unfrequent occurrence. Mr. Hey cut two female patients for the stone, both of whom were afterward unable to retain their urine, and were not quite well when discharged from the Leeds Infirmary. These cases led Mr. Hey in a third example to endeavour to prevent the evil, by introducing into the vagina a cylindrical linen tent, two inches long and one broad, with a view of bringing the edges of the incision together, without obstructing the passage of urine through the urethra. The plan answered, if it be allowable to make such an inference from a single trial. (See *Hey's Practical Obs. in Surgery, p. 560. Ed. 1810.*)

TREATMENT AFTER THE OPERATION.

If the internal pudendal artery should be wounded, and bleed profusely, the best plan is, if possible, first to take out the stone, and then introduce into the wound a piece of firm sponge, with a large cannula passed through its centre. The expanding property of the sponge, on its becoming wet, will make the necessary degree of compression of the vessel, which lies too deeply to be tied. When there is much coagulated blood lodged in the bladder, it is customary to wash it out by injecting lukewarm water.

I cannot say that it has fallen to my lot to see any cases (out of the great number which I have seen in Bartholomew's Hospital,) in which death could be imputed to hemorrhage, notwithstanding the bleeding has often been so profuse, and from so deep a source, just after the operation, as to create suspicion that it proceeded from the internal pudendal artery. Such hemorrhage generally stopped before the patient was put to bed.

The majority of patients who die after lithotomy perish of peritoneal inflammation. Hence, on the least occurrence of tenderness over the abdomen, copious venesection should be put in practice. At the same time, eight or ten leeches should be applied to the hypogastric region. The belly should be fomented, and the bowels kept open with the oleum ricini. The feebleness of the pulse should not deter the practitioner from using the lancet; this symptom is only fallacious; and it is generally attendant on all inflammation within the abdomen. It is a curious fact, that Mr. Martineau, who has lost only 2 out of 84 patients, whom he has operated upon for the stone, should never have found it requisite to bleed; but it appears to me, that, it is a much better argument in favour of the superior safety of operating with the knife and making a free opening, than reason for discouraging venesection, when inflammation of the peritoneum has come on, which, however, may not be this gentleman's meaning, as he says, "I believe, it will be found in adults, that death follows oftener from exhaustion, after a tedious operation, or from

despondency, &c. than from acute disease; (*Med. Chir. Trans. Vol. 11, p. 412.*) a sentiment, which I am sure this gentleman would not have entertained, had he been present with me at the opening of the many unfortunate cases, which used formerly to occur in the practice with badly made gorgets in St. Bartholomew's Hospital. Together with the above measures, the warm bath, a blister on the lower part of the abdomen, and emollient glysters, are highly proper. I have seen several old subjects die of the irritation of a diseased thickened bladder, continuing after the stone was extracted. They had not the acute symptoms, the inflammatory fever, the general tenderness and tension of the abdomen, as in cases of peritonitis; but they referred their uneasiness to the lower part of the pelvis; and instead of dying in the course of two or three days, as those usually do, who perish of peritoneal inflammation, they, for the most part, lingered for two or three weeks after the operation. In these cases, opiate glysters, and blistering the hypogastric region, are the best measures. In some instances of this kind, abscesses form about the neck of the bladder.

Whoever wishes to acquire a perfect knowledge of the history of lithotomy should consult the following works: *Celsus de Re Medica, lib. 7, cap. 26. Remarques sur la Chirurgie de Chauviac, par M. Simon de Mingelonneaux, tom. 2.; Bourdoux, 1663. La legende du Gascon par Drelincourt; Paris, 1665. Van Horne's Opuscula. Marianus de Lapide Vesicae par Incisionem extrahendo; 1552. G. Fabr. LOTIOA LUMINIS.—R. Aluminis purif. ℥ss. Aquæ distillatæ ℔j. Misce.—Sometimes used as an astringent injection; sometimes as an application to inflamed parts.

LOTIO AMMONIÆ ACETATÆ.—R. Liq. ammon. acetatæ; Spirit. vin. rectif.; Aquæ distillatæ; sing. ℥iv. Misce.—Properties discutient.

LOTIO AMMONIÆ MURIATÆ.—R. Ammon. muriatæ ℥j. Spirit. rorismarini ℔j. —Has the same virtues as the preceding.

Justamond recommended it in the early stage of the milk-breast.

LOTIO AMMONIÆ MURIATÆ CUM ACETO.—R. Ammon. Mur. $\mathfrak{z}\text{ss}$. Aceti, Spirit. vinos. rectific. sing. $\mathfrak{f}\text{ij}$. Misce. This is one of the most efficacious discutient lotions. It is, perhaps, the best application for promoting the absorption of extravasated blood, in cases of ecchymosis, contusions, sprains, &c.

LOTIO AMMONIÆ OPIATA.—R. Spiritus ammon. comp. $\mathfrak{z}\text{iiiss}$. Aquæ distillatæ $\mathfrak{z}\text{iv}$. Tinct. Opii. $\mathfrak{z}\text{ss}$. Misce. Applied by Kirkland to some suspicious swellings in the breast, soda and bark being also given internally.

LOTIO CALCIS COMPOSITA.—R. Aquæ calcis $\mathfrak{f}\text{ij}$. Hydrargyri oxymuriatis $\mathfrak{z}\text{j}$ Misce.—Properties strongly astringent. Ringworms, tetters, and some other cutaneous affections yield to this application, which however, should generally be diluted. In the latter state, it may occasionally be used as an injection for various purposes.

LOTIO GALLÆ.—R. Gallarum contusarum $\mathfrak{z}\text{ij}$. Aquæ ferventis $\mathfrak{f}\text{ij}$. To be macerated one hour, and strained.—This astringent lotion is sometimes used with a view of removing the relaxed state of the parts, in cases of prolapsus ani, prolapsus uteri, &c.

LOTIO HYDRARGYRI AMYGDALINA.—R. Amygdalarum amararum $\mathfrak{z}\text{ij}$. Aquæ distil. $\mathfrak{f}\text{ij}$. Hydrarg. oxymuriatis $\mathfrak{z}\text{j}$. Rub down the almonds with the water, which is to be gradually poured on them; strain the liquor, then add the oxymuriate of mercury. This will cure several cutaneous affections.

LOTIO HYDRARGYRI OXYMURIATIS.—R. Hydrargyri oxymuriatis gr. ij .s. Arabici gummi $\mathfrak{z}\text{ss}$. Aquæ distillatæ $\mathfrak{f}\text{ij}$. Misce.—This is the injection of corrosive sublimate in use at St. Bartholomew's Hospital.

LOTIO HYDRARGYRI OXYMURIATIS COMPOSITA.—R. Hydrarg. oxymur. gr. x . Aq. distillat. bullientis $\mathfrak{z}\text{iss}$. Tinct. canthar. $\mathfrak{z}\text{ss}$. Misce.—This was ordered by Dr. H. Smith, to be applied every night to scrofulous swellings.

LOTIO HELLEBORI ALBI.—R. Decocti hellebori albi $\mathfrak{f}\text{ij}$. Potassæ sulphureti $\mathfrak{z}\text{ss}$. Misce.—This is occasionally employed as an application for curing tinea capitis, and some other cutaneous diseases.

LOTIO PLUMBI ACETATIS.—R. Liq. plumbi acet. $\mathfrak{z}\text{ij}$. Aq. distill. $\mathfrak{f}\text{ij}$. Spirit. vinos. tenuioris $\mathfrak{z}\text{ij}$. The first and last ingredients are to be mixed before the water is added.

This is the common whitewash, an application universally known.

LOTIO POTASSÆ SULPHURETI.—R. Potassæ sulph. $\mathfrak{z}\text{ij}$. Aquæ distil. $\mathfrak{f}\text{ij}$. Misce.—It is used in the same cases as the preceding application.

LOTIO OPII.—R. Opii purif. $\mathfrak{z}\text{jss}$. Aquæ distillatæ $\mathfrak{f}\text{ij}$ Misce.—A very excellent application to irritable painful ulcers of every description. It is best to dilute it, especially at first.

LOTIO PICIS.—R. Picis liquidæ $\mathfrak{z}\text{iv}$. Calcis $\mathfrak{z}\text{vj}$. Aquæ ferventis $\mathfrak{f}\text{ij}$.—To be

boiled till half the water is evaporated. The rest is then to be poured off for use. This application is sometimes employed for the cure of tinea capitis; it is also of singular service in removing an extensive scorbutic redness, frequently seen on the legs, accompanying old ulcers.

LOTIO ZINCI SULPHATIS.—R. Zinci sulphatis $\mathfrak{z}\text{j}$. Aq. ferventis $\mathfrak{f}\text{ij}$. Misce. This is sometimes used by practitioners in lieu of the lotio plumbi acet. It forms a good astringent application for a variety of cases. When diluted, by adding two pints more water, it forms the common injection, so much recommended in cases of gonorrhœa.

LUES VENEREA. See VENEREAL DISEASE.

LUMBAR ABSCESS. *Psoas Abscess.* By these terms are understood chronic collections of matter, which form in the cellular substance of the loins, behind the peritonæum, and descend in the course of the psoas muscle. Patients, in the incipient stage of the disease, cannot walk so well as usual; they feel a degree of uneasiness about the lumbar region; but in general, there has been no acute pain, even when the abscess has acquired such a size as to form a large tumour, protruding externally. In short, the psoas abscess is the best instance, which can possibly be adduced, in order to illustrate the nature of those collections of matter, which are called chronic, and which form in an insidious manner, without serious pain, or any other attendant of acute inflammation.

The abscess sometimes forms a swelling above Poupart's ligament; sometimes below it; and frequently the matter glides under the fascia of the thigh. Occasionally it makes its way through the sacro-ischiatic foramen, and assumes rather the appearance of a fistula in ano. When the matter gravitates into the thigh, beneath the fascia, Mr. Hunter would have termed it a disease *in*, not *of*, the part. The uneasiness in the loins, and the impulse communicated to the tumour by coughing, evince, that the disease arises in the lumbar region; but, it must be confessed, that we can hardly ever know the existence of the disorder, before the tumour, by presenting itself externally, leads us to such information. The lumbar abscess is sometimes connected with diseased vertebræ, which may either be a cause, or an effect, of the collection of matter.—The disease, however, is frequently unattended with this complication.

The disease of the spine, we may infer, is not of the same nature as that treated of by Pott, as there is usually no paralysis. When the bodies of patients with lumbar abscesses are opened, it is found, that the matter is completely enclosed in a cyst, which, in many cases, is of course very extensive. If the contents of such abscesses were not circumscribed by a membranous boundary in this manner, we should have them spreading among the cells of the cellular substance, just like the water in anasarca. The cysts are both secreting and absorbing surfaces, as

is proved by the great quantity of matter, which soon collects again after the abscess has been emptied, and by the occasional disappearance of large palpable collections of matter of this kind, either spontaneously, or in consequence of means which are known to operate by exciting the action of the absorbents. In short, the cyst becomes the suppurating surface, and suppuration is now well ascertained to be a process, similar to glandular secretion. While the abscess remains unopened, its contents are always undergoing a change; fresh matter is continually forming, and a portion of what was previously in the cyst is undergoing the necessary removal by the absorbents. This is not peculiar to lumbar abscesses; it is common to all, both chronic and acute, buboes and suppurations in general. It is true, that, in acute abscesses, there often has not been time for the formation of so distinct a membrane as the cyst of a large chronic abscess; but their matter is equally circumscribed by the cavities of the cellular substance being filled with a dense coagulating lymph; and though it generally soon makes its way to the surface, it also is occasionally absorbed.

The best modern surgeons make it a common maxim to open very few acute abscesses; for the matter naturally tends with great celerity to the surface of the body, where ulceration allows it to escape spontaneously; after which, the case generally goes on better, than if it had been opened by art. But, in chronic abscesses, the matter has not that strong tendency to make its way outward; its quantity is continually increasing; the cyst is, of course, incessantly growing larger and larger; in short, the matter, from one ounce, often gradually increases to the quantity of a gallon. When the disease is at length opened, or bursts by ulceration, the surface of the cyst, irritated by the change, inflames; and its great extent, in this circumstance, is enough to account for the terrible constitutional disorder, and fatal consequences, which too frequently soon follow the evacuation of the contents of such an abscess. Hence, in cases of chronic suppurations of every kind, and not merely in lumbar abscesses, it is the surgeon's duty to observe the opposite rule to that applicable to acute cases; and he is called upon to open the collection of matter, as soon as he is aware of its existence, and its situation will allow it to be done.

Certainly, it would be highly advantageous to have some means of ascertaining whether the vertebrae are also diseased; for, as in this instance, the morbid bones would keep up suppuration, until their affection had ceased, and there would be no reasonable hope of curing the abscess sooner, it might be better to avoid puncturing it under such circumstances. The propriety of this conduct seems the more obvious, as issues, which are the means most likely to stop and remove the disease of the spine, are also such as afford most chance of bringing about the absorption of the abscess itself. However, if the collection cannot be prevented from dis-

charging itself, and ulceration is at hand, it is best to meet the danger, make an opening with the lancet, in a place at some distance from where the pointing threatens, and afterward heal it, in the way which will be presently detailed.

Though we have praised the prudence of opening all chronic abscesses while small, the deep situation of the lumbar one, and the degree of doubt always involving its early state, unfortunately prevent us from taking this beneficial step in the present case. But still the principle is equally praiseworthy, and should urge us to open the tumour as soon as the fluctuation of the matter is distinct, and the nature of the case is evident. For this purpose, Mr. Abernethy employs an abscess lancet which will make an opening large enough for the discharge of those flaky substances so frequently found blended with the matter of lumbar abscesses, and by some conceived to be an emblem of the disease being scrofulous. Such flakes seem to consist of a part of the coagulating matter of the blood, and are very commonly secreted by the peculiar cysts of scrofulous abscesses. The puncture must also be of a certain size, in order to allow the clots of blood, occasionally mixed with the matter, to escape. Mr. Abernethy considers the opening of a lumbar abscess a very delicate operation. Former surgeons used to make large openings in these cases; let out the contents; leave the wound open: the usual consequences of which were, great irritation and inflammation of the cyst; immense disturbance of the constitution; putrefaction of the contents of the abscess, in consequence of the entrance of air into its cavity; and, too often, death. While such practice prevailed, very few, afflicted with lumbar abscesses, were fortunate enough to escape. The same alarming effects resulted from allowing the abscess to attain its utmost magnitude, and then burst by ulceration. If then a more happy train of events depend upon the manner, in which lumbar abscesses are punctured, the operation is certainly a matter of great delicacy.

Until the collection is opened, or bursts, the patient's health is usually little, or not at all impaired; indeed, we see in the faces of many persons with such abscesses, what is usually understood by the picture of health. Hence, how likely our professional conduct is to be arraigned, when great changes for the worse, and even death occur very soon after we have let out the matter, seemingly, and truly, in consequence of the operation. Every plan, therefore, which is most likely to prevent these alarming effects, is entitled to infinite praise; and such, I conceive, is the practice recommended by Mr. Abernethy.

This gentleman's method is to let out the matter, and heal the wound immediately afterward by the first intention. He justly condemns all introductions of probes, and other instruments, which only irritate the edges of the puncture, and render them unlikely to grow together again. The wound

is to be carefully closed with sticking plaster, and it will almost always heal.

These proceedings do not put a stop to the secretion of matter within the cavity of the abscess. Of course, a fresh accumulation takes place; but, it is obvious that the matter, as fast as it is produced, will gravitate to the lowest part of the cyst, and, consequently, the upper part will remain for a certain time undistended, and have an opportunity of contracting.

When a certain quantity of matter has again accumulated, and presents itself in the groin, or elsewhere, which may be in about a fortnight after the first puncture, the abscess is to be punctured again, in the same manner as before, and the wound healed in the same way. The quantity of matter will now be found much less, than what was at first discharged. Thus the abscess is to be repeatedly punctured at intervals, and the wounds as regularly healed by the first intention, by which method, irritation and inflammation of the cyst will not be induced, the cavity of the matter will never be allowed to become distended, and it will be rendered smaller and smaller, till the cure is complete.

In a few instances, the surgeon may, perhaps, be unable to persevere in healing the repeated punctures which it may be necessary to make; but, after succeeding once or twice, the cyst will probably have had sufficient opportunity to contract so much, that its surface will not now be of alarming extent. It is also a fact, that the cyst loses its irritability and becomes more indolent, and less apt to inflame, after the contents have been once or twice evacuated, in the above way. Its disposition to absorb becomes also stronger.

The knowledge of the fact, that the cysts of all abscesses are absorbing surfaces, should lead us never to neglect other means, which Mr. Abernethy suggests, as likely to promote the dispersion of the abscess, by quickening the action of the absorbents. Blisters kept open with savine cerate, issues, electricity, occasional vomits of the sulphate of zinc, are the means most conducive to this object. When the vertebrae are diseased, issues are doubly indicated.

In the latter complication, the case is always dangerous. If an opening be made in the abscess, the cyst is at first more likely to be irritated, than when the bones are not diseased, and the affection of the spine is rendered much less likely to undergo any improvement, in consequence of the mere formation of an outward communication. The same bad effect attends necrosis; in which case, the absorption of the dead bone is always retarded by the presence of unhealed fistulae and sores, which lead down to the disease.

Mr. Crowther succeeded in dispersing some large lumbar abscesses without opening them. Large blisters, applied to the integuments covering the swelling, and kept open with the savine cerate, effected the cure.

When this gentleman punctured such collections of matter, he used a small trocar, which he introduced at the same place as often as necessary. He observes, that the aperture so made does not ulcerate, and allows no matter to escape after being dressed. I cannot, however, discover any reason for his preferring the trocar to the abscess lancet, except that the cannula enables the surgeon to push back with a probe any flakes of lymph, &c. which may obstruct its inner orifice. But, this is scarcely a reason, when Mr. Abernethy informs us, that the opening, made with an abscess lancet, is large enough to allow such flakes to be discharged; and when they stop up the aperture, a probe might also be employed to push them back. A wound made with a cutting instrument will, *ceteris paribus*, always unite more certainly by the first intention, than one made with such an instrument as a trocar. Mr. Crowther may always have succeeded in healing the aperture; but, I do not believe, that other practitioners would experience equal success. Were the tumour not very prominent, from the quantity of matter being small, suddenly plunging in a trocar might even endanger parts, which should, on no account, be injured.

Some writers recommend opening lumbar abscesses with a seton. The matter being made to form as prominent a swelling as possible, by pressing the abdomen, and putting the patient in a position, which will make the contents of the abscess gravitate towards the part where the seton is to be introduced, a transverse cut is first to be made in the integuments down to the fascia. A flat trocar is next to be introduced within the incision, which should only be just large enough to allow the instrument to pass freely up under the skin, for at least three quarters of an inch; when the hand is to be raised, and the trocar pushed obliquely and gently upwards, till the cannula is within the lower part of the sac. The trocar must now be withdrawn, and the matter allowed to flow out gently, stopping it every now and then for some minutes. The assistant must now withdraw his hand, to take away the pressure, and the thumb of his left hand upon the opening of the cannula, holding it between his fore and middle fingers. It must then be pushed upward, nearly to the top of the tumour, where its end may be distinctly felt with the fore-finger of the right hand. As soon as it can be plainly felt, it must be held steadily in the same position, and the trocar is to be introduced into it again, and pushed through the skin, at the place where it is felt, and the cannula along with it. The trocar being next withdrawn, a probe with a skein of fine soft silk, dipped in oil, must be passed through the cannula, which being now taken away, leaves the seton in its place. A pledget of mild ointment is then to be applied over the two openings, the more completely to exclude the air. A fresh piece of the silk is to be

drawn into the abscess, and that which was in before cut off, as often as necessary. (See *Latta's System of Surgery*, Vol. 3, p. 307.)

Mr. Crowther states, that Deckers, who wrote in 1696, discharged a large abscess, in a gradual manner, with a trocar, the cannula of which was not withdrawn, but was stopped up with a cork, and the latter let out at intervals. B. Bell also advises the cannula not to be taken out.

I cannot quit this subject without mentioning a remarkable case of lumbar abscess, which I once saw in Christ's Hospital, under the care of the late Mr. Ramsden. The tumour extended from the ilium and sacrum below, as high up as the ribs. The diameter of the swelling, from behind forward, might be about six or eight inches. It was attended with so strong a pulsation, corresponding with that of the arteries, that several eminent surgeons in this city considered the case as an aneurism of the aorta. After some weeks, as the tumour increased in size, the throbbing of the whole swelling gradually became fainter and fainter, and at length, could not be felt at all. The tumour was nearly on the point of bursting. Mr. Ramsden suspected that it was an abscess, and determined to make a small puncture in it. The experiment verified the accuracy of his opinion; a large quantity of pus was evacuated at intervals; but the boy's health suffering, he went to his friends at Newbury, and I did not afterward hear the event. I

have never seen any popliteal aneurism, whose pulsations could be more plainly seen, and strongly felt, than those of the abscess we have just been describing. A singular case is related by Mr. Wilmot of a psoas abscess, the matter of which was at length absorbed, and its cavity filled with air, attended with a considerable increase in the size of the tumour, a conical elongated shape, and elastic feel, instead of a fluctuation, previously quite evident, and the subsidence of all the hectic symptoms. A complete dispersion of the swelling was effected by a bandage and compress wet with a strong decoction of oak bark and alum. M.

MAMMA, REMOVAL OF. The operation of cutting away a diseased breast, is done nearly in the same manner as the removal of tumours in general, and is indicated whenever the part is affected with an incurable disease, which admits, however, of being entirely removed with the knife. When the breast is affected with scirrhus, or ulcerated cancer, the imprudence of tampering with the disease cannot be too severely censured. Were the disorder unattended with a continual tendency to increase, some time might properly be dedicated to the trial of the internal remedies, and external applications, which have acquired any character for doing good in these unpromising cases. But, unfortunately, by endeavouring to cure the disease by medicine, we only afford time for it to increase in magnitude, and, at length, attain a condition, in which even the knife cannot be employed so as to take away the whole of the diseased parts. When the case is marked by the characteristic features of scirrhus, noticed in the article *Cancer*, the sooner the tumour is cut out, the better. There are also some malignant kinds of sarcoma, to which the female breast is subject, (as will be explained in the article *Tumour*), which cannot be removed at too early a period after their nature is suspected, or

known. Indeed, though there is not equal urgency for the operation when the tumour is only an indolent, simple, fatty, or sarcomatous disease, yet as all these tumours are continually growing larger, and little success attends the attempt to disperse them, the practitioner should never devote much time to the trial of unavailing medicines and applications, and let the swelling attain a size, which would require a formidable operation for its excision. Besides, many simple, fleshy, indolent tumours, are accompanied with a certain degree of hazard of changing into very malignant forms of disease.

It is not meant to be denied, however, there are many swellings and indurations of the breast, which it would be highly injudicious and unnecessary to extirpate, because they generally admit of being discussed. Such are many tumours, which are called *scrofulous*, from their affecting patients of this peculiar constitution; such are nearly all those indurations which remain after a sudden and general inflammatory enlargement of the mamma; such are most other tumours, which acquire their full size in a few days, attended with pain, redness, &c.; and, of this kind, also, are the hardnesses in the breast, occasioned by the mammary abscess.

In the removal of all malignant or cancerous tumours, their nature makes it necessary to observe one important caution in the operation, viz. not to rest satisfied with cutting away the tumours just at their circumference; but to take away also a considerable portion of the substance in which they lie, and with which they are surrounded. In cutting out a cancerous breast, if the operator were to be content with merely dissecting out the disease, just where his eyes and fingers might equally lead him to suppose its boundary to be situated, there would still be left behind white diseased bands, which radiate from the tumour into the surrounding fat, and which would inevitably occasion a relapse. In a vast proportion of the cases also, in which cancer of the breast unfortunately recurs after the operation, it is found that the skin is the part, in which the disease makes its reappearance. Hence the great prudence of taking away a good deal of it in every case suspected to be a truly scirrhus or cancerous disease. This may also be done so as not to prevent the important objects of uniting the wound by the first intention, and covering the whole of its surface with sound integuments. So frequently does cancer recur in the nipple, whenever it does recur any where, that many of the best modern operators always make a point of removing this part in every instance, in which it is judged expedient to take away any portion of the skin at all. The surgeon, indeed, would be inexcusable, were he to neglect to take away such portion of the integuments covering scirrhus tumours, as is evidently affected, appearing to be discoloured, puckered, and closely attached to the diseased lump beneath. Nor should any gland, in the axilla, at all diseased, nor any fibres of the pectoral muscle, in the same state, be ever left behind. There is no doubt, that nothing has stamped operations for cancers with disrepute, so much as the neglect to make a free removal of the skin, and parts surrounding every side of the tumour. Hence, the disease has frequently appeared to recur, when, in fact, it has never been thoroughly extirpated; the disease, though entirely a local affection, has been deemed a constitutional one; and the operation frequently rejected as ineffectual and useless.

But, strongly as I have urged the prudence, the necessity of making a free removal of the skin covering, and of the parts surrounding, every cancerous or malignant tumour, the same plan may certainly be regarded as unnecessary, and therefore, unscientific, in most operations for the removal of simple, fatty, fleshy, or encysted tumours, to which the breast and almost every other part are liable. However, even in the latter cases, when the swelling is very large, it is better to take away a portion of skin; for, otherwise, after the excision of the tumour, there would be a redundancy of integuments, the cavity of which would only serve for the lodgment of matter. The loose superfluous skin also would lie in

folds, and not apply itself evenly to the parts beneath, so as to unite favourably by the first intention; nor could the line of the cicatrix itself be arranged with such nice evenness as it might be, were a part of the redundant skin taken away at the time of operating.

The best method of removing a diseased breast is as follows: The patient is usually placed in a sitting posture, well supported by pillows and assistants; but the operator will find it equally convenient, if not more so, to remove the tumour with his patient in a recumbent position; and this posture is best whenever the operation is likely to be long, or much blood to be lost, which circumstances are very apt to bring on fainting. I remember that Mr. Abernethy, in his lectures, used to recommend the latter plan; which, however, without the sanction of any great name, or authority, possesses such obvious advantages, as will always entitle it to approbation.

The arms should be confined back, by placing a stick between them and the body, by which means, the fibres of the great pectoral muscle will be kept on the stretch, a state most favourable for the dissection of the tumour off its surface. The stick also prevents the patient from moving her arm about, and interrupting the progress of the operation.

When the tumour is not large, and only a simple sarcoma, free from malignancy, it will be quite unnecessary to remove any of the skin, and, of course, this need only be divided by one incision, of a length proportionate to the tumour. The cut must be made with a common dissecting knife; and as the division of the parts is chiefly accomplished with the part of the edge towards the point, the instrument will be found to do its office best when the extremity of the edge is made of a convex shape, and this part of the blade is turned a little back, in the way in which dissecting knives are now often constructed. The direction of the incision through the skin should be made according to the greatest diameter of the tumour to be removed, by which means it will be most easily dissected out.

The direction of the incision is various with different practitioners; some making it perpendicular, others transverse. In general, the shape of the tumour must determine which is the best. In France, it has been said, that when the incision follows the second direction, it heals more expeditiously, because the skin is more extensible from above downward, than laterally, particularly towards the sternum, and consequently allows the sides of the wound the more readily to be placed in contact; and that the action of the pectoral muscle tends to separate the edges of the wound when it is perpendicular. On the other hand, it is allowed that the wound, made in the latter manner, is the most favourable for the escape of the discharge, if suppuration should occur. (See *Œuvres de Desault par Bichat*, p. 312, T. 2.)

The cut through the skin should always be somewhat longer than the tumour; and as it is perhaps, the most painful part of the operation, and one attended with no danger whatever, it should be executed with the utmost celerity, pain being more or less dreaded, according to its duration, as well as its degree. The fear, however, of giving pain, has probably led many operators to err, in not making their first incision through the integuments large enough, the consequence of which has often been that there was not sufficient room for the dissection of the tumour with facility; the patient has been kept nearly an hour in the operating room, instead of five minutes, and the surgeon censured by the spectators, as awkward and tedious. It is clear also, that, besides the great deal more blood lost, from this error, than would otherwise happen, the vessels being commonly not tied till all the cutting is finished, the avoidance of pain, that fear, which led to the blunder, is not effected, and the patient suffers much more, and for a much longer time, in consequence of the embarrassment and obstacles in the way of the whole operation.

When the disease is of a scirrhus or malignant nature, the skin covering the tumour should at all events, be in part removed. As I have said before, all that portion which is discoloured, puckered, tuberculated, or otherwise altered, should be taken away. Some must also be removed, in order to prevent a redundancy, in all cases in which the tumour is large. We have said too, that in cases of scirrhus and cancer of the breast, the nipple is considered a dangerous part to be left behind. For the purpose of removing the necessary portion of skin, the surgeon must obviously pursue a different mode from that above described; and, instead of one straight incision, he is to make two semicircular cuts, one immediately after the other, and which are to meet at their extremities. The size of these wounds must be determined by that of the disease to be removed, and by the quantity of skin, which it is deemed prudent to take away; for the part, which is included in the two semicircular cuts, is that which is not to be separated from the upper surface of the swelling, but taken away with it. The shape of the two cuts together may approach that either of a circle or oval, as the figure of the tumour itself may indicate, as most convenient. The direction of the incisions is to be regulated by the same consideration.

In the above ways, the first division of the integuments is to be made in removing tumours of every description, covered with skin. The same principles and practice should prevail in all these operations; and, whether the swelling is the mamma, or any other diseased mass, whether situated on the chest, the back, the head, or extremities, the same considerations should always guide the operator's hand.

The incision, or incisions, in the skin having been made, the next object is to detach every side of the tumour from its

connexions, and the separation of its base will then be the last and only thing remaining to be done. When the tumour is a scirrhus, or other malignant disease, the operator must not dissect close to the swelling, but make his incisions on each side, at a prudent distance from it, so as to be sure to remove, with the diseased mass, every atom of morbid mischief in its vicinity. But when the tumour is only a mere fatty, or other mass, perfectly free from malignancy, the cellular bands and vessels forming its connexions, may be divided close to its circumference. It is astonishing with what ease fatty tumours are removed, after the necessary division is made in the skin; they may almost be turned out with the fingers, without any cutting at all. When they have been inflamed, however, they are then more adherent to the surrounding parts.

Thus we see, that the first stage of the operation of removing a tumour, is the division of the skin; the second, the separation of the swelling from the surrounding parts on every side; the third and last stage is the division of the parts to which its under surface, or base, is attached. The latter object should be accomplished by cutting regularly from above downward, till every part is divided.

It is a common thing to see many operators constantly embarrassed and confused, whenever they have to remove a large tumour, on account of their having no particular method in their proceedings. They first cut a few fibres on one side, then on another; and, turning the mass of disease now to this side, now to that, without any fixed design, they both prolong the operation very tediously, and present to the bystanders a complete specimen of surgical awkwardness. On the contrary, when the practitioner divides the cutting part of the operation into the three methodical stages above recommended, in each of which there is a distinct object to be fulfilled, he proceeds with a confidence of knowing what he is about, and soon effects what is to be done, with equal expedition and adroitness.

Having taken out the tumour, the operator is immediately to tie such large vessels as may be pouring out their blood; indeed, when the removal of the swelling will necessarily occupy more than three or four minutes, it is better to tie all the large arteries as soon as they are divided, and then proceed with their dissection. This was the celebrated Desault's plan, and it is highly deserving of imitation in this country, not only because many subjects cannot afford to lose much blood, but also because the profuse effusion of this fluid keeps the operator from seeing what parts he is dividing.

The largest arteries being tied, the surgeon should not be immediately solicitous about tying every bleeding point which may be observed. Instead of this, let him employ a little while in examining every part of the surface of the wound, in order to ascertain that no portion of the swelling, no hardened lump, nor diseased fibres remain behind.

Even if any part of the surface of the pectoral muscle should present a morbid feel, or appearance, it must on every account be cut away. Also, if any of the axillary glands are diseased, the operator should now proceed to remove them. After the time spent in such measures, many of the small vessels, which bled just after the excision of the swelling, will now have stopped, the necessity for several ligatures will be done away, and, of course, the patient saved a great deal of pain, and more of the wound be likely to heal by the first intention.

Some information may be derived, respecting whether any of the tumour is left behind, by examining its surfaces, when taken out, and observing whether any part of them is cut off; for, if it is, it may always be found in the corresponding part of the wound.

The axillary glands may invariably be taken out without the least risk, if the plan pursued by Desault in France, and the late Sir Charles Blicke, and other eminent surgeons in this country, be adopted. The method alluded to is, after dividing the skin covering the gland, and freeing the indurated part from its lateral connexions, to tie its root, or base, by which it is connected with the parts on the side towards the cavity of the axilla. Then the indurated gland itself may be safely cut off, just above the ligature. Were the gland cut off in the first instance, the artery which supplies it with blood would be exceedingly difficult to tie, on account of its deep situation; and by reason of its shortness and vicinity to the heart, it would bleed almost like a wound of the thoracic artery itself. In this way, there is also not the least hazard of injuring the latter vessel. It would be a great improvement in the mode of operating for the removal of these glands, if surgeons were always to make the patient lie down, with the arm placed in such a position as would let the light fall into the axilla. How much the steps of the operation would be facilitated in this way, I need not attempt to explain.

The above directions will enable a surgeon to remove tumours in general. They apply also in a great measure to *encysted tumours*; but, a few particular rules how to operate in the latter cases, will be found in the article *Tumours*. One half of each ligature is always to be cut off before dressing the wound. The edges of the incision are to be brought together with strips of adhesive plaster; and, before this can be done with ease, the stick confining the arm back must be removed, and the os brachii brought forward, so as to relax the pectoral muscle, and integuments of the breast. No sutures should ever be employed, as they are useless, painful, and irritating. The wound being closed with sticking plaster, and a pledget of simple cerate, a compress of folded linen, or flannel, may be put over the dressings; these are to be secured with a broad piece of linen, which is to encircle the chest, be fastened with pins, or stitches, and kept from slipping

down by two tapes, one of which is to go from behind forward, over each shoulder, and be stitched to the upper part of the bandage, both in front and behind. The arm on the same side as that, on which the operation has been done, should be kept perfectly motionless in a sling; for, every motion of the limb must evidently disturb the wound, by putting the great pectoral muscle into action, or rendering its fibres sometimes tense, sometimes relaxed. It is scarcely necessary to say, that, after so considerable an operation as the removal of a large breast, or any other tumour of magnitude, the patient should be given about thirty drops of the tinctura opii. A smaller dose always creates restlessness, headach, and fever, after operations, instead of having the desired effect.

Here it becomes me to state, that as I could not find in any surgical book with which I am acquainted, what I conceived to be a proper description of the mode of removing a diseased breast, and tumours in general, the foregoing remarks are given chiefly on my own authority. Whether they are just, or not, must be decided by the profession.

The removal of a diseased breast rarely proves fatal of itself, unless the parts cut away extend to a considerable depth, and occupy a very large space, or the patient is much reduced before the operation. However, about two years ago, a patient in St. Bartholomew's Hospital died, without any very apparent cause, very soon after being operated upon; and Schmucker has recorded an instance, in which the operation was followed by tetanus. (*Wahrnehmungen*, B. 2, p. 80.)

With respect to the average success, following the removal of cancerous diseases, this is a topic, which has been noticed in the article *Cancer*. The statement lately made by Baron Boyer is exceedingly unfavourable; for, in one hundred cases, in which he has removed the diseased parts, only four or five of the patients continued radically cured. (*Traité des Mal. Chir.* T. 7, p. 237, 8vo. Paris, 1821.)

The principal writers on the removal of the mamma are, Garangeot, Dionis, Le Dran, Brandi, Sharp, and Sabatier, in their respective treatises on the operations. B. Bell, Latta, &c. have also treated on the subject in their Systems of Surgery; and there is a memoir *Sur l'Operation du Cancer au Sein*, in *Les Œuvres de Desault par Bichat*, T. 2.

MAMMARY ABSCESS. *Milk Abscess.* With regard to inflammations of the mamma, as my friend, Mr. James has observed, there is "either simple phlegmon, or mammary abscess, which, as it depends upon a peculiarity of state and function, ought to stand alone. Mr. Hey also describes a deep-seated abscess, to which this gland is liable, of rather a chronic character, and is the same, perhaps, as that which Dr. Kirkland has described as the *encysted*. Dr. K. describes also two others, under the titles of *chronic* and *encysted*." Certain cases most frequently

ly occurring in unmarried females, and having very little tendency to suppuration, Mr. James suspects, are the result of inflammation of the glandular part of the breast from disorder in the digestive organs, uterine system, or both. (*On Inflammation*, p. 171.)

Women who suckle are particularly subject to inflammation and suppuration in the breast. The part enlarges, becomes tense, heavy, and painful. The integuments of the breast sometimes assume an uniform redness; sometimes they are only red in particular places. The inflammation may affect the mammary gland itself, or be confined to the skin and surrounding cellular substance. In the latter case, the inflamed part is equally tense; but, when the glandular structure of the breast is also affected, the enlargement is irregular, and seems to consist of one or more large tumours, situated in the substance of the part. The pain often extends to the axillary glands. The secretion of the milk is not always suppressed, when the inflammation is confined to the integuments, and suppuration is said to come on more quickly, than in the affections of the mammary gland itself. When the symptoms of inflammation continue to increase for four or five days, suppuration may be expected; unless the progress of the inflammation be slow, and its degree moderate, in which circumstances, resolution may often be obtained, even as late as a fortnight after the first attack. Inflammations of the breast are almost always attended with symptoms of the sympathetic inflammatory fever. (See *Fever, Surgical*.) I think authors err, who describe the febrile disorder as generally preceding the local complaint.

Women are most liable to mammary abscesses within the first three months after parturition; but they are also very much exposed to the disorder as long as they continue to suckle.

The most common causes occasioning the mammary abscess, as enumerated by writers in general, are, repressing the secretion of milk at an early period, mental disturbance, fright, &c.; exposure to cold, moving the arms too much while the breasts are very large and distended, bruises, and other external injuries. The causes are not always obvious.

The matter is sometimes contained in one cyst, or cavity; sometimes in several; but the abscess generally breaks near the nipple.

As all inflammations of the mamma are attended with considerable induration, these cases should be carefully distinguished from other swellings of a more incurable kind. It is said, that scrofulous tumours of the mamma, which have existed a long while, often disappear after the occurrence of a milk abscess. Women who have never been pregnant are sometimes affected with suppuration in the breast, supposed by Mr. James, of Exeter, to be connected with uterine, or gastric disorder. Even men are said to be liable to similar complaints.

In the early period of the affection, resolution should be attempted. The following

are the principal means for this purpose:—topical blood-letting, saline purges, low diet, keeping the inflamed breast from hanging down, gentle friction of the breast, with a soft sponge, wet with some warm emollient liquor; having the milk tenderly sucked out at proper intervals; saturnine applications, or lotions containing the muriate of ammonia.

When matter cannot be prevented from forming, an emollient poultice is the best application, and the abscess should in general be allowed to break of itself, unless of a somewhat chronic nature, in which case it should be opened in a depending part with a lancet. Sinuses sometimes form, in consequence of abscesses in the breast, and will not heal till freely opened with a director and curved bistoury. When the cavity of the abscess begins to fill up with granulations, the poultice may be left off, and superficial dressings applied.

The indurations, often remaining in the breast, in consequence of acute inflammation and abscesses, generally yield to frictions with camphorated mercurial ointment, the application of a piece of soap plaster, and the exhibition of calomel, cicuta, and other alteratives.

Mr. Hey describes a very deep-seated abscess of the breast, not of frequent occurrence, and not confined to pregnant nor suckling women. Its situation renders all superficial applications ineffectual. The inflammatory stage is tedious; and when the matter has made its way outward, the discharge continues, and there is no tendency to healing. Sometimes the matter lodges behind the mamma, as well as in the substance of the gland, and breaks out in different places, the intermediate parts of the breast feeling as if affected with a scirrhus hardness. There are numerous sinuses running in different directions, and, when opened, a soft purple fungus appears within them. The disease goes on in this state for a long while, keeping up hectic symptoms.

Mr. Hey's practice is to trace the course of all the numerous sinuses, and lay them open, and, unless this be done, with respect to every one of them, the cure cannot be accomplished. If he finds any two sinuses running in such directions, that when fully opened, they leave a small part of the mamma in a pendulous state, he removes such part entirely. As the sinuses are filled with fungus, their continuations present no visible cavity, and can only be detected by the greater softness of parts of the wound, where, on breaking down the fungus, the orifice of the collateral sinus may be found. Mr. Hey has found, that even in the most unfavourable subjects the wounds heal quickly, and the natural shape of the breast is preserved.

Consult *Pearson's Principles of Surgery*, chap. 3. *Hey's Practical Observations*, p. 504. *Kirkland* has also treated of several kinds of abscesses of the breast, in his *Inquiry into the present State of Medical Surgery*, Vol.

[***MAXILLA INFERIOR.** By a reference
to the article Osteo Sarcoma, in the Appen-
dix, will be found recorded three instances
wherein portions of the lower jaw were ex-
tirpated by Professor Mott, of New-York,
for the removal of this disease; the carotid
artery, in the several instances, having been
previously tied.—*Am. Ed.*]

MELICERIS. (from *μολι*, honey, and
κερος, wax. A tumour of the encysted kind,
filled with a substance resembling wax, or
honey, in consistence. (See *Tumours, En-*
cysted.)

MENINGOPHYLAX. (from *μηνιγξ*, a
membrane, and *φυλασσα*, to guard.) An in-
strument used by the ancients for guarding
the dura mater and brain from injury, in
their mode of trepanning. It seems to have
been something like the lenticular, only its
blade was completely round, without an
edge. It ended in a lentiform cup, like the
latter. (*Encyclopedie Methodique, Partie*
Chirurgicale.) Pott gives an engraving of
a meningophylax, which resembles a com-
mon elevator. (See Vol. 1. of his *Works.*)

MERCURY. (*Quicksilver. Mercurius.*
Hydrargyrum.) The medicinal virtues of
this mineral were almost totally unknown
to the ancients, who considered it as a poi-
son. It was first employed for purposes of
medicine by the Arabians, who made use of
it in the form of ointments for the cure of
certain diseases of the skin and the killing
of vermin. In modern times, mercury is
one of the most important articles of the
materia medica; and though perhaps recent
investigations will not strictly allow it to
be regarded as a specific for the venereal
disease, which may be cured by other
means, or sometimes even spontaneously,
while mercury, so far from being always a
certain cure, is sometimes highly detrimen-
tal, yet notwithstanding these facts, mercury
still retains the character of being generally
the most expeditious means of relief. The
possibility of curing the venereal disease
without mercury, by no means establishes
the propriety of abandoning this remedy,
any more than its unfitness for certain states
of the same disease is a reason for not avail-
ing ourselves of its superior utility in others.

Mercury, taken into the stomach in its
metallic state, has no action on the body,
except what arises from its weight or bulk.
It is not poisonous, as was vulgarly suppo-
sed, but perfectly inert. But, in its various
states of combination, it produces certain

sensible effects. It is a powerful and gen-
eral stimulant, quickening the circulation,
and increasing all the secretions and excre-
tions. According to circumstances, the
habit of the patient, the temperature in
which he is kept, the nature of the prepara-
tion, and the quantity in which it is exhibit-
ed, its effects are, indeed, various. Some-
times, it more particularly increases one
secretion; sometimes another; but its most
characteristic effect is the increased flow of
saliva, which it generally excites, if given
in sufficient quantity. (*Edinb. Dispensatory.*)

From the writings of Theodoric, it appears
that mercury was employed in the practice
of medicine and surgery as early as the 13th
century. But, its use in venereal cases was
first mentioned in a tract by Almenar, pub-
lished in 1516. (See *Thompson's Dispensatory*,
p. 205, Edit. 2.)

It has been said, that the efficacy of mer-
cury in curing the venereal disease was an
accidental discovery; but it seems more
probable, that the good effects, which it pro-
duced in cutaneous diseases, first led to the
trial of it in venereal cases, which being
frequently attended with eruptions on the
skin, ulcers, &c. seemed to present an
analogy to the affections, in which mercury
had already been found successful.

In the times, immediately following the
origin of the venereal disease, practitioners
only ventured to employ this remedy with
timorous caution, so that, of several of their
formulæ, mercury scarcely composed a
fourteenth part, and either on this account,
or some difference in the disease itself at that
period from what is now remarked, few
cures were effected. On the other hand, the
empirics, who noticed the little efficacy of
these small doses, ran into the opposite ex-
treme, and exhibited mercury in quantities
so large, and with such little care, that most
of their patients were suddenly attacked
with violent salivations, frequently attended
with very dangerous, and even fatal symp-
toms; or such as after making them lose
their teeth, left them pale, emaciated, ex-
hausted, and subject, for the rest of their
lives, to tremblings, or other more or less
dangerous affections. From these two very
opposite modes of practice, there originated
such uncertainty, respecting what could be
expected from mercury, and such fears of
the consequences, which might result from
its employment, that every plan was eagerly
adopted, which offered the least chance of
cure, without having recourse to this mineral.

A medicine, however, so powerful, and
whose salutary effects had been watched by
attentive practitioners amidst all its incon-
veniences, could not sink into oblivion.
After efforts had been made to discover an
equally efficacious substitute for it, and it
had been seen, how inferior other means
were, on which the highest praises had been
lavished, the attempts to extend its utility
were renewed. A medium was pursued,
between the too timid methods of those
physicians, who had first administered it,
and the inconsiderate boldness of the empi-

ries. Thus the causes, from which both parties failed, were avoided; the character of the medicine was revived in a more durable way, and from this period, its reputation has always been maintained.

The renowned Paracelsus first taught practitioners that mercury might be given internally with safety; for, before he set the example; it had only been externally employed, in three manners. The first was in the form of an ointment or liniment; the second as a plaster; and the third, as a fumigation.

The basis of the ointment, or liniment, was quicksilver, which was blended, by means of trituration, with hog's lard, goose's fat, &c. and composed scarcely one-sixth or one-eighth of the whole; a proportion, however, much greater, than what had been at first employed. But from a fear, that the mineral might prove hurtful to the nerves, by the cold property which they fancied it possessed, and that it might occasion numbness, tremblings, or palsies, they combined with it a multitude of ingredients of a warm, aromatic nature, or supposed to possess such; for example, oil of camomile, sesame-seeds, aniseeds, the roots of zedoary, and the florentine iris, and a thousand other substances, which were incorporated with the ointment. The members, joints, and the whole of the body, except the head, belly, and chest, were rubbed with this composition; and the frictions were repeated, at suitable intervals, until obvious signs of salivation appeared.

The ingredients of the plasters resembled those of the ointments; only they contained less fat, for which was substituted a sufficient quantity of wax, to give them a proper consistence. This composition was applied to the skin, and the whole body was covered with it, excepting the parts on which it was not usual to put ointment. The plasters were kept on, till salivation began.

The fumigations were made with quicksilver, triturated with turpentine, or saliva, or else with cinnabar. These substances were mixed with fatty, or resinous ones, such as myrrh, nutmeg, &c. and, all the ingredients being reduced to powder, were made into a paste, with a sufficient quantity of turpentine, or gum tragacanth. The patient was then placed in a box made on purpose, or under a little kind of tent, out of which the head was generally allowed to protrude. A chafing-dish, containing burning coals, was placed near his feet, and every now and then, bits of mercurial paste were thrown into the vessel. The patient was left exposed to the fumes, which arose, until he broke out into a profuse perspiration, which they took great pains to keep up and increase, by putting him into a warm bed, loading him with bedding, for about two hours, after which he was rubbed quite dry, and given some food. This plan was persisted in every day, till a salivation was produced, which was kept up as long as necessary. The method of fumigation is described by Astruc, and particular preparations, and apparatuses for the purpose, have been since

recommended by Laloette in France, and more recently, by Abernethy in England.

Of the three methods, which we have just described, only the first is at present much in use, and even this is considerably altered. It was found, not only that mercurial plasters caused heat, redness, itching, and disagreeable eruptions, but, that the method was exceedingly slow and uncertain. Hence, plasters are now only used as topical discutient applications.

Fumigations, considered as the only means of cure, fell also into discredit, because, although they formed a method of applying mercury in a very active manner, they were, as anciently managed, liable to several objections. In this way, it was next to impossible to regulate the quantity of mercury used, which varied according to the greater or lesser activity of the fire, the position of the patient, and other circumstances. The effect of the vapour on the organs of respiration also frequently proved very oppressive; and mercury, applied in the way of fumigation, more frequently occasioned tremblings, palsies, &c. than in any other manner. In Mr. Abernethy's mode, however, fumigation is, under certain circumstances, not only an eligible, but, the very best way of affecting the constitution.

Frictions with ointment have always been regarded as the most efficacious. They have undergone considerable change, and by being rendered more simple, have been greatly perfected. All the warm aromatic substances have been retrenched from the ointment, not only as useless, but as irritating and inflaming to the skin. In modern times, the proportion of mercury to the fat has also been very much increased.

GENERAL REMARKS ON THE ADMINISTRATION OF MERCURY, ITS OCCASIONAL CONSEQUENCES, &c.

With regard to the preparations of the medicine, and the modes of applying it, we are to consider two things; first, the preparation and mode attended with the least trouble or inconvenience to the patient; and secondly, the preparation, and mode of administering it, that most readily conveys the necessary quantity into the constitution. Mercury is carried into the constitution in the same way as other substances, either by being absorbed from the surface of the body, or that of the alimentary canal. It cannot, however, in all cases, be taken into the constitution in both ways; for, sometimes the absorbents of the skin will not readily receive it, at least, no effect is produced, either on the disease or constitution, from this mode of application. In this circumstance, mercury must be given by the mouth, although the plan may be very improper in other respects, and often inconvenient. On the other hand, the internal absorbents sometimes will not take up the medicine, or, at least, no effect is produced on the disease, or the constitution.

In such cases, all the different preparations of the medicine should be tried; for some-

times one succeeds, when another will not. In some cases, mercury seems to have no effect, either applied outwardly, or taken into the stomach. Many surfaces seem to absorb mercury better than others: such are probably all internal surfaces and sores. Thirty grains of calomel, rubbed in on the skin, have not more effect, than three, or four, taken by the mouth. Dressing small ulcers with red precipitate sometimes causes a salivation. (See *Hunter on the Venereal Disease*, p. 335, 336.)

Besides the practicableness of getting the medicine into the constitution in either way, it is proper to consider the easiest for the patient, each mode having its convenience and inconvenience, depending on the nature of the parts to which it is applied, or on certain situations of life at the time. Hence, it should be given in the way most suitable to such circumstances.

In many, the bowels can hardly bear mercury at all, and it should then be given in the mildest form possible, conjoined with such medicines as will lessen or correct its violent local effects, although not its specific ones on the constitution.

When mercury can be thrown into the constitution with propriety by the external method, it is preferable to the internal plan, because the skin is not nearly so essential to life as the stomach, and therefore, is capable in itself of bearing much more than the stomach. The constitution is also less injured. Many courses of mercury would kill the patient, if the medicine were only given internally, because it proves hurtful to the stomach and intestines, when given in any form, or joined with the greatest correctors. Every one, however, has not opportunities of rubbing in mercury, and is therefore obliged, if possible, to take it by the mouth. (*Hunter*, p. 338.)

Mercury has two effects; one as a stimulus on the constitution and particular parts; the other as a specific against a diseased action of the whole body, or of parts. The latter action can only be computed by the disease disappearing.

In giving mercury in the venereal disease, the first attention should be to the quantity, and its visible effects in a given time, which, when brought to a proper pitch, are only to be kept up, and the decline of the disease to be watched; for by this we judge of the invisible, or specific effects of the medicine, and know what variation in the quantity may be necessary. The visible effects of mercury affect, either the whole constitution, or some parts capable of secretion. In the first, it produces universal irritability, making it more susceptible of all impressions. It quickens the pulse, increases its hardness, and occasions a kind of temporary fever. In some constitutions, it operates like a poison; while, in others, it produces a kind of hectic fever, that is, a small quick pulse, loss of appetite, restlessness, want of sleep, and a sallow complexion, with a number of consequent symptoms; but, such effects commonly diminish, on the patient

becoming a little accustomed to the medicine. Mercury often produces pains like those of rheumatism, and nodes of a scrofulous nature. (*Hunter*, p. 339, 340.)

The quantity of mercury to be thrown into the constitution, for the cure of any venereal complaint, must be proportioned to the violence of the disease. However, we are to be guided by two circumstances, namely, the time in which any given quantity is to be thrown in, and the effects it has on some parts of the body, as the salivary glands, skin, or intestines. For, mercury may be thrown into the same constitution in very different quantities, so as to produce the same ultimate effect; but the two very different quantities must also be in different times, for instance, one ounce of mercurial ointment, used in two days, will have more effect upon the constitution, than two ounces used in ten. The effects of one ounce, used in two days, on the constitution and diseased parts, are considerable. A small quantity, used quickly, will have equal effects, to those of a large one employed slowly; but, if these effects are principally local, that is, upon the glands of the mouth, the constitution at large not being equally stimulated, the effect upon the diseased parts must be less, which may be known by the local disease not giving way in proportion to the effects of mercury on some particular part. If it is given in very small quantities, and increased gradually, so as to steal insensibly on the constitution, a vast quantity at a time may at length be used, without any visible effect at all. (*Hunter*, p. 341.)

The circumstances being known, mercury becomes a much more efficacious, manageable, and safe medicine, than it was formerly thought to be; but, unluckily, its visible effects upon the mouth and the intestines are sometimes much more violent, than its general effect upon the constitution at large. These parts must therefore not be stimulated so quickly as to hinder the necessary quantity of mercury from being used.

The constitution, or parts, are more susceptible of mercury at first, than afterward. If the mouth is made sore, and allowed to recover, a much greater quantity may be thrown in, a second time, before the same soreness is produced. However, anomalous cases occur, in which, from unknown causes, mercury cannot at one time be made to produce any visible effects; but, afterward, the mouth and intestines are all at once affected. (*Hunter*, p. 342.)

Mercury occasionally attacks the bowels, and causes violent purging, even of blood. This effect is remedied by discontinuing the use of the medicine, and exhibiting opium. At other times, it is suddenly determined to the mouth, and produces inflammation, ulceration, and an excessive flow of saliva. To obtain relief in this circumstance, purgatives, nitre, sulphur, gum-arabic, lime-water, camphor, bark, the sulphuret of potash, blisters, &c. have been advised. Mr. Pearson, however, does not seem to place much

confidence in the efficacy of such means, and the mercury being discontinued for a time, he recommends the patient to be freely exposed to a dry cold air, with the occasional use of cathartics, peruvian bark, and mineral acids, and the assiduous application of astringent gargles. "The most material objection, (says Mr. Pearson,) which I foresee against the method of treatment I have recommended, is the hazard to which the patient will be exposed, of having the saliva suddenly checked, and of suffering some other disease, in consequence of it.

"That the hasty suppression of a ptyalism may be followed by serious inconveniences, has been proved by Dr. Silvester, (*Med. Obs. and Inq. Vol. 3.*) who published the cases of three persons, who had been under his own care; two of whom were afflicted with violent pains; and the third scarcely retained any food in her stomach for the space of three months. I have seen not only pains, but even general convulsions produced from the same cause. But, this singular kind of metastasis of the mercurial irritation does not appear to me to owe its appearance to simple exposure to cold and dry air; because I have known it occur in different forms, where patients continued to breathe a warm atmosphere, but used a bath, the water of which was not sufficiently heated. Cold liquids, taken in a large quantity into the stomach, or exposure of the body to cold and moisture, will also prove extremely injurious to those, who are fully under the influence of mercury; whereas breathing a cool air, while the body is properly covered with apparel, has certainly no tendency to produce any distressing, or dangerous consequences.

"If, however, a suppression of the ptyalism should be occasioned by any act of indiscretion, the remedy is easy and certain; it consists only in the quick introduction of mercury into the body, so as to produce a soreness of the gums, with the occasional use of a hot bath." (*Pearson on the Effect of various Articles in the Cure of Lues Venerea, Edit. 2, p. 163, 164.*)

Mercury, when it falls on the mouth, produces, in many constitutions, violent inflammation, which sometimes terminates in mortification. In these habits, great caution is necessary. The ordinary operation of mercury does not permanently injure the constitution; but occasionally, the impairment is very material; mercury may even produce local disease, and retard the cure of chancres, buboes, and certain effects of the lues venerea, after the poison has been destroyed. (*Hunter, p. 342.*)

From mercury occasionally acting on the system, as a poison, quite unconnected with its agency as a remedy, and neither proportionate to the inflammation of the mouth, nor the actual quantity of the mineral absorbed, Mr. Pearson noticed that one, or two patients in general died suddenly every year in the Lock Hospital. The morbid state of the system, which tends to the fatal event, during a mercurial course is named by Mr.

Pearson *erethismus*, and is characterized by great depression of strength, a sense of anxiety about the præcordia, irregular action of the heart, frequent sighing, trembling, a small, quick, and sometimes an intermitting pulse, occasional vomiting, a pale contracted countenance, a sense of coldness; but the tongue is seldom furred, and neither the vital, nor natural functions are much disordered. They, who die suddenly of the mercurial erethismus, have frequently been making some little exertion just before. To prevent the dangerous consequences of this state of the system, the use of mercury must be discontinued, whatever may be the stage, extent, or violence of the venereal symptoms. The patient should be directed to expose himself freely to a dry and cool air, in such a manner, as shall be attended with the least fatigue, and he should have a generous diet. In this manner, patients often recover sufficiently in ten or fourteen days, to resume the use of mercury with safety. In the early stage, the mercurial erethismus may often be averted by leaving off the mercury, and giving the *mistura camphorata* with large doses of ammonia. When the stomach is unaffected, *sarsaparilla* sometimes does good. (*Pearson, p. 154, &c.*)

Occasionally, the use of mercury brings on a peculiar eruption, which has received the several names of *hydrargyria*, *mercurial rash*, *eczema mercuriale*, *eczema rubrum*, *lepra mercurialis*, *mercurial disease*, and *erythema mercuriale*.

"Eruptions of various kinds are very common symptoms of syphilis, but a very unusual effect of mercury. Therefore, until the real nature of this erythema was lately discovered, whenever it occurred in patients undergoing a mercurial course for syphilitic complaints, it was naturally enough considered, as an anomalous form of lues venerea. The mercury was consequently pushed to a greater extent, in proportion to the violence of the symptoms, and, from the cause of the disease being thus unconsciously applied for its removal, it could not fail to be aggravated, and hurried on to a fatal termination. The observation of this fact, conjoined with another, of less frequent occurrence, namely, that a similar eruption did sometimes appear in patients using mercury for other complaints, and in whom no suspicion of syphilis could be entertained, at last led some judicious practitioners in Dublin to the important discovery, that the eruption was entirely an effect of mercury, and not at all connected with the original disease. This discovery was not published till 1804." (*McMullin in Edinburgh Medical and Surgical Journal, No. 5.*) Mr. Pearson states, however, that he has been acquainted with the disease ever since 1781, and has always described its history and treatment in his lectures, since 1783.

The eruption is attended with more or less indisposition, is not confined to either sex, or any particular constitution, and seems to be equally produced by mercury applied

externally, and by any of its preparations taken inwardly. Mr. Pearson has never seen it in subjects above 50; and he says, its occurrence is more common about eight, or ten days after beginning a mercurial course. (P. 166.)

Dr. M'Mullin has described three distinct stages of the erythema mercuriale. "The first stage commences with languor, lassitude, and cold shiverings; these symptoms are succeeded by increased temperature of the body, quick pulse, nausea, headach, and thirst. The patient is troubled with a dry cough, and complains of difficult respiration, anxiety, and sense of stricture about the præcordia. The tongue is usually moist, and covered with a white glutinous slime: it sometimes appears clean, and brightly red in the centre, whilst the margins remain foul. The skin feels unusually hot and itchy, with a sense of prickling, not unlike the sensation experienced from the application of nettles. The belly is generally costive; but a diarrhœa is often produced by very slight causes.

"On the first, or second day, an eruption most commonly shows itself, the colour of which is either dark or bright red: the papulæ are at first distinct and elevated, resembling very much those in rubeola. Sometimes, but rarely, the eruption appears like urticaria, and in such instances the disease is observed to be very mild. The papulæ very speedily run together in such a manner as to form a suffused redness, which disappears on pressure: In most cases, it begins first on the scrotum, inside of the thighs, fore-arm, or where mercurial friction has been applied, and the integuments of the parts affected become much swollen. There have also been observed instances, where an eruption of a purplish colour, and unaccompanied by papulæ, has diffused itself suddenly over the entire body. This, however, may be considered as uncommon. In every instance, which came under my observation, it was confined at first to a few places, and from thence gradually extended, until the different portions of the eruption had united, and the papulæ were also rough to the feel. But in those cases, which resemble urticaria, a number of minute vesicles, which contain a serous fluid, appear from the commencement, interspersed among the papulæ. Contrary to what happens in most diseases accompanied with cutaneous affections, the febrile symptoms are much aggravated, and continue to increase after the eruption has been completed. The pulse in general beats from 120 to 130 in a minute, the thirst continues urgent, and the patient extremely restless, seldom enjoys quiet sleep. When the eruption has continued in this manner for a certain period, the cuticle begins to peel off in thin, whitish, scurfy exfoliations, not unlike those observed in rubeola. This desquamation has not been attended to by Dr. Moriarty or Mr. Alley, if they have not, by giving the same name to the decrustation which occurs in the last stage, confounded both together. It commences in those

places where the eruption first made its appearance, and in this order spreads to other parts. About this period the fauces become sore, the tongue swells, and the eyes appear somewhat inflamed.

"The duration of this stage is very various; sometimes it continues from ten to fourteen days, and, in other cases, it terminates in half that time. When the disease has appeared in its mildest form, the patient recovers immediately after the desquamation, a new cuticle having formed underneath; but, if severe, he has only experienced the smallest part of his sufferings, and the skin now assumes a new appearance, which I have considered as the second stage.

"The skin at this period appears as if studded with innumerable minute vesicles, which are filled with a pellucid fluid. These vesicles may be expected, if the patient, at the close of the first stage, complains of increased itching, and sense of burning heat; in those parts from which the cuticular exfoliations have fallen. They remain sometimes for a day or two, but are most commonly burst, immediately after their formation, by the patient rubbing them, in order to relieve the troublesome itchiness with which these parts are affected. They discharge a serous, acrimonious fluid, which possess such a very disagreeable odour as to induce nausea in the patient himself, and those who approach near his bedside. The odour is so peculiar, that it can easily be recognized by any person who has once experienced it.

"This fluid is poured out most copiously from the scrotum, groin, inside of the thighs, or wherever the skin forms folds, and sebaceous glands are most numerous. The serous discharge from these minute vesicles forms, with the cuticle, an incrustation, which may be considered as the third or last state.

"These crusts are generally very large, and, when detached, retain the figure of the parts from which they have fallen. Their colour is yellowish; but sometimes appears dark and dirty. This period of the disease might be termed, I think, with much propriety, the stage of *decrustation*, in order to distinguish it more fully from the *desquamation*, which has been already noticed. From the use of the two last terms indiscriminately, those who have described the disease have introduced into their descriptions a degree of confusion which has caused its progress not to be well understood. When this stage appears, the fauces become more affected, the eyes intolerant of light, and the tarsi tender, inflamed, and sometimes inverted. The crusts formed on the face, as in other parts of the body, before falling off, divide asunder, so as to leave cracks and fissures, which produce an hideous expression of countenance; and the eyelids are also, from the general swelling of the face, completely closed. The back and hairy scalp are last affected, and, even in very severe cases, these parts are sometimes observed to escape entirely. The patient,

whilst in this state, is compelled to desist from every kind of motion, on account of the pain which he experiences on the slightest exertion, and which he describes as if his flesh were cracking. The crusts also fall off in such abundance, that the bed appears as if strewn with the cones of hops. Whilst the eruption is only making its appearance in one place, another part may have arrived at its most advanced form; so that all the different stages of the disease may be present at one time in the same individual. It is attended with typhus through its entire course; but it is very curious to observe, that the appetite for food, in most cases, remains unimpaired, and sometimes is even voracious. This circumstance was particularly remarkable in a patient who laboured under the disease, in its worst form, for the space of three months, in the Royal Infirmary of Edinburgh; for double the usual hospital allowance of food was scarcely sufficient to satisfy his hunger. When the catarrhal symptoms have continued during the progress of the complaint, they are, at this advanced period, particularly aggravated: the anxiety and pain of the breast are also very severe, attended with cough, and bloody expectoration, and the patient always feels languid and dejected. The pulse becomes frequent, feeble, and irregular, the tongue black and parched, and at length diarrhoea, delirium, convulsions, gangrene of the surface of the body, and death, supervene. In its mild form, it only goes through the first stage, and terminates, as we have already stated, in a few days, by a slight desquamation. But, when severe, it is often protracted more than two months, every stage of the eruption continuing proportionably longer; and when, in this manner, it has run its course, it repeatedly breaks out on the new surface, and passes through the same stages." (*M'Mullin in Edinb. Med. and Surg. Journal, No. 5.*)

With respect to the remote cause, this is the employment of mercury. Dr. M'Mullin is inclined to believe with Dr. Gregory, that the application of cold to the body, while under the action of mercury, is absolutely necessary, for its production; an opinion strengthened by the constant prevalence of catarrhal symptoms. However, Mr. Pearson thinks, that cold has no concern in bringing on the complaint in patients under the influence of mercury. At the same time it merits particular attention, that the disease is not exclusively occasioned by mercury either in its general, or more partial attacks: it has been observed to follow exposure to cold, and to recur in the same individual, at irregular intervals, without any obvious or adequate cause. (*Bateman's Synopsis, p. 256, Ed. 3; Rattier in Edin. Med. and Surg. Journ. Vol. 5, p. 143; Marcet in Med. Chir. Trans. Vol. 2, art. 9.*)

In the early stage, Mr. Pearson recommends small doses of antimonial powder, with saline draughts, or the ammonia acetata. A gentle purgative should be given every three or four days, and opium to procure

sleep. The latter medicine sometimes does most good, when joined with camphor, or Hoffman's anodyne liquor. Sarsaparilla and bark may be given, when the discharge is no longer ichorous, and the tumefaction has subsided. Vitriolic acid has seemed to give relief. The diet may be light and nutritive, without fermented liquors, however, till the desquamation has somewhat advanced. Frequent use of the warm bath, and often changing the patient's linen and sheets, which soon become stiff and rough with the discharge, afford much benefit. If the warm bath cannot be had, Mr. Pearson advises washing the body very tenderly with warm water-gruel; he also covers parts, from which the cuticle is detached, with a mild cerate, and renews the application twice a day. (*P. 178.*)

Dr. M'Mullin advises the immediate discontinuance of mercury; the removal of the patient from wards, where this mineral is in use; emetics and diaphoretics; but on account of the very irritable state of the bowels, he says antimonials are hardly admissible, and that when purgatives are indicated, only the mildest ones, such as ol. ricini, sulphate of magnesia, &c. ought to be given. He advises mucilaginous draughts with opium for relieving the soreness of the fauces. In the second stage, the cold infusion of bark with aromatics and opium, or what is more praised, wine, porter, &c. To relieve the ophthalmia tarsi, the unguentum oxidii zinci, and to appease the painful sensation of the skin cracking, the linimentum calcis, which should be liberally applied as soon as crusts appear.

Consult *Essay on a Peculiar Eruptive Disease, arising from the Exhibition of Mercury, by G. Alley, 8vo. Dublin, 1804; also Observations on the Hydrargyria, or that Vesicular Disease arising from the Exhibition of Mercury, 4to. Lond. 1810. A Description of the Mercurial Lepa, by Dr. Moriarty, 12mo. Frictions with Mercurial Ointment.

No metal acts in its pure metallic state; it must first be more or less combined with oxygen. The mercury, contained in the unguentum hydrargyri, becomes in a certain degree oxydated, when triturated for the purpose of blending it with the fat. The metal, however, in mercurial ointment, is in the most simple, and least combined form, of all its preparations, and hence, it not only generally operates with more mildness on the system, but with more specific effect on the disease. Various salts of mercury, when given internally, operate more quickly than mercurial frictions: yet there are many practitioners, who do not like to confide solely in any internal preparations for curing the venereal disease, particularly, when the virus has produced effects in consequence of absorption. We shall only just mention in this part of the work, that rubbing in

mercurial ointment is the mode of affecting the system with mercury, which is generally considered to agree best with most constitutions, and to act with most certainty on the venereal disease.

Mercurial Fumigations.

We have mentioned this method, as being one of the most ancient plans of affecting the constitution with mercury, and Lalouette and Abernethy have stated circumstances in its favour, which certainly render it sometimes a very eligible mode. The latter is of opinion, that if the peculiar advantages of mercurial fumigations were generally known to practitioners, they would be much more frequently employed. The advantages of the method consist in its affecting the constitution, when other means have failed, and in producing its effects in a much shorter time than any other mode requires. How desirable this celerity of operation must often be, when venereal ulceration is making great ravages in the palate, throat, &c. it is needless to insist upon. In patients, who have not strength to rub in ointment, and whose bowels will not bear the internal exhibition of mercury, the mode of fumigation may prove of great service.

"In the year 1776, the Chevalier Lalouette, a physician at Paris, laid before the public an account of a new mode of mercurial fumigation, free from the inconveniences of former ones, and which in the space of thirty-five years, he had successfully employed in more than four hundred cases, that had resisted all the ordinary methods of cure. His method consisted in enclosing the patient, previously undressed, in a kind of box resembling a sedan chair, with an opening at the top to let out the head, and another at the bottom, to which was fitted a small grate or furnace, having in it a heated iron for converting the mercurial remedy into fume. The preparation he made use of was a kind of calomel, which by repeated sublimation from iron filings, was so far deprived of its muriatic acid, as to be in part reduced into running quicksilver; and, while it possessed considerable volatility, was perfectly unirritating. Some of this powder, being strewed upon the hot iron placed below, was immediately converted into smoke, which surrounded the patient's body, and after some time settled on his skin in the form of a white and very fine calx of quicksilver: a complete dress, having its inner surface fumigated with the same powder, was then put on.—The remedy being thus generally applied to the mouths of the cutaneous absorbents, soon got admission into the circulating fluids, and the constitution became thereby more speedily affected than by any other process known before." (*Abernethy's Surgical and Physiological Essays, Part 3.*)

As the fumigating powder used by M. Lalouette was very oporose, and consequently a very expensive preparation, and appeared to have no advantage over one made by abstracting the muriatic acid from calomel

by means of ammonia. Mr. Abernethy has always employed the latter, which is prepared at the hospital in the following manner: Two drachms of liquor ammonia are added to six ounces of distilled water, and four ounces of calomel are thrown into this liquor, and shaken up with it; the powder is afterward separated by a filter, and dried.

The powder thus obtained is of a gray colour, and contains a good deal of quicksilver in its metallic state, which of course is extremely volatile, but becomes oxydated when raised into fume, and afterward condensed into a white subtile powder.

In local disease of the joints, such, for instance, as frequently takes place in the knee, and in sarcomatous enlargements of the breast in women, the late Mr. Sharp and Sir C. Blicke were accustomed to direct fumigated stockings, or under-waistcoats, to be worn; by which these complaints were relieved, and the constitutions of the patients affected, without the trouble and unpleasantness arising from the use of the common mercurial ointment. (*See Abernethy's Surgical and Physiological Essays, Part 3.*)

Mr. Pearson procured Lalouette's machine, and made a considerable number of experiments to determine the comparative advantages of this method, and mercurial frictions. He found, that the gums became turgid and tender very quickly, and that the local appearances were sooner removed, than by the other modes of introducing mercury into the system; but that it soon brought on debility, a rapid and premature salivation, and, of course, that the medicine could not be steadily continued. This gentleman concludes, that where checking the progress of the disease suddenly is an object of great moment, where the body is covered with venereal ulcers, or where the eruptions are large and numerous, so that there scarcely remains a surface large enough to absorb the ointment, the vapour of mercury will be advantageous. But he thinks it extremely difficult thus to introduce a sufficient quantity of mercury into the system to secure the patient from a relapse, and therefore the plan by no means eligible as a general practice. The vapour of mercury, he says, is singularly efficacious, when applied to venereal ulcers, fungi, and excrescences; but this plan requires an equal quantity of mercury to be given in other ways, as if the local application itself were not a mercurial one. (*Pearson on Lues Venerea, p. 145, &c.*)

For the purpose of fumigating sores, the hydrargyri sulphuretum rubrum is commonly used. Ulcers and excrescences about the pudendum and anus in women are said to be particularly benefited in this way; and in these cases the fumes are most conveniently applied by placing a red-hot heater at the bottom of a night-stool pan, and after sprinkling on it a few grains of the red sulphuret of quicksilver, placing the patient on the stool. On other occasions, a small apparatus, sold at the shops, is used, which enables the surgeon to direct the fumes through a funnel against the ulcer in any situation.

Though mention has just been made of *venereal* excrescences, I am of opinion with Mr. Abernethy, that it is very questionable, whether any are ever really of this nature. I know, that many excrescences and verrucae about the anus, and parts of generation, diminish and are cured by a course of mercury. This is the only argument in favour of their being venereal; for, when tied, cut off, or made to fall off by stimulating them with pulv. sabinae, and the subacetate of copper, they are as effectually cured, as if mercury had been given. In the military hospital at Cambray, I remember a man, on whose scrotum there were several warty excrescences of considerable size. Mr. Booty, assistant staff surgeon, prescribed mercury, by which they were certainly cured with surprising expedition. In this particular case, I think the plan of treatment adopted was the best, because on account of the number of excrescences, and the situation of some of them at the lower and back part of the scrotum, it would have been difficult to have treated them altogether by local applications.

PREPARATIONS FOR INTERNAL EXHIBITION.

The acetite of mercury is supposed to be a mild preparation, and was the active ingredient in the celebrated Keyser's pills. In solution it has also been recommended to be applied externally for the removal of some cutaneous affections. It may be made into pills with crum of bread. The dose is from one to five grains every night.

When it is wished to excite a salivation quickly, when mercurial ointment alone will not produce this effect, or cannot be employed, and when fumigations are not convenient nor agreeable, the hydrargyri oxydum rubrum is often prescribed. The common dose is a grain, which may be increased to two, a day. It is apt, however, to disagree with the stomachs and bowels of many patients; an inconvenience sometimes obviated by conjoining the preparation with opium.

At present, the hydrargyrus cum creta is rarely or never prescribed for the cure of the venereal disease. But it is frequently prescribed as a mild alterative for children in doses of from gr. v. to gr. x. twice a day, blended with any viscid substance.

The oxymuriate of mercury (corrosive sublimate) was a medicine highly praised for its antisyphilitic virtues by the celebrated Van Swieten, and, indeed, there is no doubt, that, like other preparations of mercury, it possesses such qualities. It retains great reputation, even now, and, probably, will always do so. However, like the red oxide, it sometimes deranges the stomach and bowels, and from some surgeons does not receive the same degree of confidence, in respect to its power over syphilis, as mercurial frictions. Mr. Pearson remarks, that "when the sublimate is given to cure the primary symptoms of syphilis, it will sometimes succeed; more especially when it produces a considerable

degree of soreness of the gums, and the common specific effect of mercury in the animal system. But it will often fail of removing even a recent chancre; and where the symptom has vanished during the administrations of corrosive sublimate, I have known a three month's course of that medicine fail of securing the patient from a constitutional affection. The result of my observations is, that simple mercury, calomel or calcined mercury, are preparations more to be confided in, for the cure of primary symptoms, than corrosive sublimate. The latter will often check the progress of secondary symptoms very conveniently; and I think it is peculiarly efficacious in relieving venereal pains, in healing ulcers of the throat, and in promoting the desquamation of eruptions. Yet, even in these cases, it never confers permanent benefit; for, new symptoms will appear during the use of it; and, on many occasions, it will fail of affording the least advantage to the patient, from first to last. I do sometimes, indeed, employ this preparation in venereal cases; but it is either at the beginning of a mercurial course, to bring the constitution under the influence of mercury at an early period, or during a course of inunction, with the intention of increasing the action of simple mercury. I sometimes, also, prescribe it after the conclusion of a course of frictions, to support the mercurial influence in the habit, in order to guard against the danger of a relapse. But, on no occasion whatever do I think it safe to confide in this preparation singly and uncombined, for the cure of any truly venereal symptom." (*Pearson on Lues Venerea.*)

The dose of oxymuriate is a quarter of a grain.

The following is a common mode of ordering it: *R. Hydrargyri oxymuriatis gr. i. Aquæ Nucis Moschatæ ℥ij. Misce. ʒss. Omni nocte sumenda.*

The muriate of mercury (calomel) is not very much used by modern surgeons for the cure of the venereal disease. Sometimes, indeed, it is given in cases of gonorrhœa, both with the view of preserving the constitution from infection, and keeping the bowels regular. It is more extensively given as an alterative, and for the cure of such surgical diseases as require the system to be slightly under the influence of mercury. It generally proves actively purgative, when more than two or three grains are given.

The most simple preparations of mercury have generally been deemed the most effectual in eradicating the venereal disease. The pilulæ hydrargyri are the most simple of the internal formulæ, being merely mercury triturated with mucilaginous or saccharine substances. Next to mercurial frictions, they are, perhaps, most frequently employed for the cure of the incipient form of the venereal disease, that is, while a chancre is the only complaint. They are also very commonly given in all stages of the disease, to aid mercurial frictions in bringing the system under the influence of the specific remedy. Ten grains of the mass, kept for

these pills, is the usual dose. When they purge, opium will sometimes prevent this effect. See *Venereal Disease*.

Mercury is employed both constitutionally and locally in numerous surgical cases; for the removal of indolent thickenings and indurations of parts; for the relief of porrigio, herpetic diseases, tetanus, hydrophobia, hydrops articuli, iritis, and a multitude of other affections, which need not here be specified.

MEROCELE. (from *μερος*, the thigh, and *πλην*, a tumour.) A femoral or crural hernia. See *Hernia*.

MEZEREON was recommended by Dr. A. Russell for a particular class of venereal symptoms, in the following terms: "The disease, for which I principally recommend the decoction of the mezereon root as a cure, is the venereal node that proceeds from a thickening of the membrane of the bones. In a thickening of the periosteum, from other causes, I have seen very good effects from it: and it is frequently of service in the removal of those nocturnal pains, with which venereal patients are afflicted; though, in this last case, excepting with regard to the pain that is occasioned by the node, I own I have not found its effects so certain, as I at first thought I had reason to believe. I do not find it of service in the cure of any other symptom of the venereal disease. (*Med. Obs. and Inq. Vol. 3, p. 194, 195.*) Mr. Pearson, however, asserts, unequivocally, that mezereon has not the power of curing the venereal disease in any one stage, or under any one form, and if the decoction should ever reduce the venereal node, yet there will be a necessity for taking mercury in as large quantity, and for as long a time, as if no mezereon had been exhibited. Cullen found this medicine of use in some cutaneous affections, but, excepting an instance or two of lepra, Mr. Pearson has very seldom found it possessed of medicinal virtue, either in syphilis, or the sequelæ of that disease, scrofula, or cutaneous affections. (*Pearson on Lues Venerea, p. 55, 59.*)

As the possibility of curing most forms of the venereal disease, not only without mercury, but without any internal medicines whatever, is now well established, it is difficult to know what degree of importance to attach to observations, declaring certain articles of the materia medica efficient or inefficient in the cure of that disease; because, if it admit of a spontaneous cure, but will not get well when mezereon, or any other particular medicine is exhibited, we are necessarily obliged to suppose, that such medicine is worse than useless.

MODIOLUS. The crown or saw of a trepan.

MOLLITIES OSSIUM. A morbid softness of the bones, which become preternaturally flexible, in consequence either of the inordinate absorption of the phosphate of lime, from which their natural solidity is derived, or else of this matter not being duly secreted into their texture. The bones affected become specifically lighter. (*Sail*

lant, Hist. de la Soc. Royale de Méd. T. 8.) Dr. Bostock made some experiments, with the view of ascertaining the proportion of earthy matter in bones affected with mollities: he examined a dorsal vertebra of a woman whose bones were found soft and flexible after her decease. In one part of the diseased bone, he found, that the quantity of earthy matter only amounted to one-fifth of its weight, and in another, only to one-eighth, while the proportion in healthy bones amounted to more than one half of their whole weight. (*See Med. Chir. Trans. Vol. 4, and Wilson on the Bones and Joints, p. 253.*) In rickets, the bones yield and become distorted only by slow degrees, and retain their natural inflexibility; but, in the present disease, they may be at once bent in any direction, and frequently admit of being readily divided with a knife. The mollities ossium is an exceedingly uncommon disease, and its causes are buried in obscurity. It is supposed, however, to depend upon some peculiar state of the constitution, and the individuals, attacked with it, have been remarked to be mostly about, or rather beyond, the middle period of life, (*J. Wilson, Vol. cit. p. 252.*) and generally, if not always, women. (*Neumann in Abhandl. der K. K. Josephs Acad. 2 B. p. 173; Portal Cours d'Anatomie, T. 1, p. 15.*) One instance, however, is reported, in which the patient was a young man seventeen years of age. (*Thomassin, in Journ. de Méd. T. 43. p. 222.*) Surgical writers have usually considered mollities and fragilitas ossium as two distinct and different affections. Boyer thinks, however, that this point is by no means well established. He admits, that there have been a few rare instances of mollities, where the bones were completely flexible, without any degree of fragility. But, he contends, that in almost all the cases on record, the fragilitas and mollities have been combined. He regrets that bones, affected with fragility, have never been chymically nor anatomically examined, particularly as there have been persons who, while living, merely betrayed the symptoms of mollities ossium, yet, in whom unsuspected fractures, evidently of long standing, were discovered after death; while other fractures also happened from the slightest causes during the examination of the same bodies. (*See Boyer, Traité des Maladies Chir. T. 3, p. 607—609.*) The truth of these observations is well illustrated in the case lately reported by Mr. Wilson: (*On the Bones, &c. p. 254.*) In the present place, I shall merely describe the pure mollities ossium, or that disorder of the bones, in which they become completely flexible, and lose all their natural firmness. And in order to give an idea of the disorder, I shall quote the case of Madame Supiot. In the year 1747 she had a fall which occasioned her to keep her bed for some time, and left great pain and weakness in her loins and lower extremities. In about a year and a half afterward, she began to perceive her left leg particularly affected. Along with this weakness, she had violent

pains over her whole body, which increased after a miscarriage, and still more after a natural delivery, in the year 1751. She was now seized with startings, great inquietude, and such violent heats, that she was almost continually in a sweat, and could not bear the least covering even in the coldest weather, and while her pains continually increased, she took notice that her urine precipitated a white sediment. Her pains abated on the appearance of the sediment, but she now observed that her limbs began to bend, and from this time the softness of them gradually increased till her death. In the month of April, 1752, the trunk of the body did not exceed 23 inches in length; the thorax exceedingly ill formed, and the bones of the upper part very much distorted; those of the lower part were very much bent, and the thigh bones became so pliable that her feet might easily be laid on each side of her head. The right side did not, till after some time, become so deformed as the left; but it was surprising to observe the alterations which daily took place, and the different figures assumed by the limbs, in consequence of the increased softness of the bones; so that when the sediment in the urine was considerable, the disease of the bones seemed to be at a stand, increasing considerably when it was suppressed. Besides this, she had violent pains, startings, difficulty of breathing, spitting of blood, and lastly, a fever, with convulsions. She died in the beginning of November, 1752. and, on dissecting her body, the following appearances were observed: 1. The muscles in general were of a very soft and pale consistence, the vastus externus, fascialis, quadriceps, biceps, and external parts of the gracilis, were much shorter than in their natural state, and more firm and tense; while those on the opposite side were much elongated, thin, and very tender; in short, the whole muscular system had suffered more or less, according to the action of the muscles in her lifetime. 2. The bones were entirely dissolved, the periosteum remaining unhurt, so that they exhibited only the form of a cylinder. 3. The heart and large blood-vessels, both veins and arteries, contained large black polypi, of a viscid consistence, and very unlike those usually found in dead bodies.

A case of softness of the bones is related by Mr. Gooch, but considerably different from the above, as it was attended with a remarkable fragility of them before they became soft. It likewise began with pains through the whole body, attended with feverish symptoms; but after some weeks, these pains were confined chiefly to the legs and thighs, and they were not increased by pressure. This fragility of the bones does not appear to have been the case with Madame Supiot. In the month of June, 1749, Mr. Gooch's patient broke her leg in walking from her bed to a chair, and heard the bone snap. No callus, however, formed, though the fracture was instantly reduced, and treated by one of the best surgeons in

her part of the country; but instead of this, the bones began to grow flexible, and in a few months, were so from the knee to the ankle. The disease still continued to increase, so that, in a short time, the other leg and thigh were affected in the same manner, after which both legs became oedematous, liable to excoriations, and to discharge a thin yellow ichor. Scorbatic symptoms began to appear in the winter after the leg was broken, and her gums began to bleed. Tonic medicines were exhibited without any success, except that her menstruation became more regular, and her appetite and digestion better than before; but towards the end of her life, her breathing became difficult, the spine distorted, and a pain in the loins took place upon every motion of the vertebræ: and as her limbs were now quite useless, she was obliged to sit upright in bed. At last, the ends of the bones on which she sat, having become also very soft, spread much, and the ends of her fingers and thumbs, by frequent endeavours to raise herself, became also very broad, and the phalanges crooked. The flexibility of the bones gradually increased, and became more general, attended with a wasting of the flesh, and excessive difficulty of breathing. The menstrual flux totally ceased four months before her death; her legs, which were anasarcaous, and excoriated almost all over, became erysipelatous; but she retained her senses to the last. She expired suddenly, having talked in a composed manner concerning her miserable situation and approaching end only a few moments before.

On examining the body, she was found to have lost two feet two inches of her natural stature. The heart and lungs appeared sound, but had been much confined, principally by the liver, which was enlarged in an extraordinary degree; it was not, however, scirrhus, nor in any other way diseased. The spleen was very small, and the mesentery had one large scirrhus gland. All the bones, except the teeth, were softened, so that scarcely any of them could resist the knife; but those of the lower extremities were the most dissolved, being changed into a kind of parenchymous substance, like soft dark-coloured liver, without any offensive smell. So completely, indeed, were they decomposed, that the knife met with less resistance in cutting through them than in sound muscular flesh, though some bony lamellæ were here and there to be met with, but as thin as an egg-shell. The most compact bones, and those which contained the greatest quantity of marrow, were the most dissolved; and it was observable, that the dissolution began internally, for the bony laminæ remained here and there on the outside, and nowhere else. The periosteum was rather thicker than ordinary, and the cartilages thinner; but not in a state of dissolution. The bones were found to contain a great quantity of oily matter and little earth. No cause could be assigned for the disease; and in the case

of Madame Supiot, the one assigned, viz. that of her eating too much salt, seems totally inadequate to explain the origin of the disorder. All the cases of mollities ossium on record have proved fatal, and no means of cure are yet known.

For additional observations, connected with this subject, refer to *Fragilitas Ossium* and *Rickets*. Boyer and Richerand treat of the mollities ossium, and rickets, as one and the same disease. But, as Mr. Wilson observes, the first differs from rickets, in attacking people of middle age, or rather older, and not particularly children; and it differs also in the change produced in the bones themselves, which, when dried, do not appear as if they had been long steeped in weak acid, with their animal part nearly unchanged; but both the phosphat of lime and the animal matter appear to have been absorbed, so as to leave mere shells, which are also softer than natural bone of the same thickness. Mr. Wilson further informs us, that large cavities are met with in the substance of the bones, and sometimes communicate with the soft parts surrounding them. In some of these cavities is contained oily matter, like boiled marrow; and in others, masses of coagulated blood, and a soft inorganic substance. (*J. Wilson on the Bones, &c.* p. 253. *Acret, Diss. Descriptionem et Casus aliquot Osteomalaciæ sistens; Upsal, 1788.* *Morand in Journ. des Savans, 1792, et Mém. de l'Acad. des Sciences, 1752.* *Morand, junr. in Mém. de l'Acad. des Sciences, 1764, p. 206.* See also *T. Chir.*; the writings of *Forestus*; *Gooch's Chirurgical Works, Vol. 2. p. 393—399.* *Ed. 1792, &c.* *James Wilson, Lectures on the Structure and Physiology of the Parts composing the Skeleton; and on the Diseases of the Bones and Joints, p. 252, &c. 8vo. Lond. 1820.*

MONOCULUS. (from *μῆνς*, single, and *oculus*, the eye.) A bandage formerly applied to the fistula lachrymalis, and diseases of the eye. It consists of a single-headed roller three ells long. In order to apply it to the right eye, it is to be held in the hand, and its end in the left, *et vice versa*. This

end is to be put on the back of the neck, and one turn of the roller is to be carried round, over the forehead, so as to meet the extremity of the bandage. The roller is then to descend under the ear of the side affected, and to pass obliquely over the cheek underneath the eye, and next over the root of the nose, and opposite the parietal bone, to the nape of the neck. The third turn of the roller is to overlap the second a little: the third the fourth; making what the French call *doloires*; and the application of the bandage is completed by making turns round the head. The use of the monoculus was only to retain dressings. (*Encyclopédie Méthodique; Partie Chir.*)

MORTIFICATION is of two kinds; the one, without inflammation; the other, preceded by it. To this last species of mortification, the terms *inflammatory*, *humid*, or *acute gangrene*, are often applied; while the second, or that which is not preceded by any or much inflammation, has been distinguished by the epithets, *dry* or *chronic*, and sometimes *idiopathic*, when no cause for the origin of the disease can be assigned. According to Mr. Hunter, inflammation is an increased action of that power, which a part naturally possesses; and in healthy inflammations, at least, it is probably attended with an increase of power. In cases, however, which are to terminate in mortification, there is no increase of power; but, on the contrary, a diminution of it. This, when joined to an increased action, becomes a cause of mortification, by destroying the balance, which ought to subsist between the power and action of every part. There are, besides, cases of mortification, preceded by inflammation, which do not arise wholly from that, as a cause: of this kind, are the carbuncle and the slough formed in the small-pox pustule. (*Hunter.*)

The first general division of mortification, therefore, is into two kinds; first, into the *inflammatory*, *humid*, or *acute*; and secondly, into the *dry*, or *chronic*. But the disorder is also subdivided into many species, which are determined by the nature of their particular exciting causes, as will be presently detailed.

However, it is remarked, that acute, or rapid mortifications, are not necessarily humid, as the slough from the application *kali purum* proves, and the converse also is true in some cases of *sphacelus senilis*. (*James on Inflammation, p. 96.*) Another modern writer also asserts, that mortification from wounds and external injuries may be either humid, or dry, or of both kinds together, where the circumstances are particular. (*Guthrie on Gunshot Wounds, &c. p. 122, Ed. 2.*) The doctrine also that any case of mortification is entirely without inflammation, has sometimes been deemed questionable; and Mr. James expresses his belief that the disorder is generally preceded by inflammation, and invariably accompanied with some degree of it. And, says he, "whether mortification be a consequence of

inflammation, or not, it may, perhaps, with reason be considered, as standing in the same relation to inflammation, as adhesion, suppuration, or ulceration: they may all be preceded by a high degree, or it may be scarcely sensible." (P. 84, 85.)

When any part of the body loses all motion, sensibility, and natural heat, and becomes of a brown, livid, or black colour, it is said to be affected with *sphacelus*, that is, complete mortification. As long as any sensibility, motion, and warmth, continue, the state of the disorder is termed *gangrene*. This word is here made use of to signify only a degree of *sphacelus*, or rather the process, by which any local disorder falls into the state of complete mortification. Many authors use both terms synonymously; but it is to be observed, that *gangrene* does not invariably end in *sphacelus*; nor is the latter always preceded by the former. (Richter, *Anfangsgr. der Wundarzn.* B. 1, Kap. 3.) There are some surgical writers, who make the distinguishing circumstance of *sphacelus* to be the extension of the disorder to the bones as well as the soft parts. (Lassus, *Pathologie Chir.* T. 1, p. 30, Ed. 1809.)

At present, however, this last application of the term *sphacelus* is never made; for, as Mr. Pearson has rightly observed, the distinctions, "which are founded merely upon the parts, that suffer, or upon the profundity, to which the disease has penetrated, seem inadequate and useless." (*Principles of Surgery*, p. 115, Ed. 2.) The manner, in which Dr. J. Thomson views the subject, may be considered as coinciding with the general sentiments of the best modern surgeons. "I shall employ the term *gangrene*, (says he) to express that state of mortification, in inflamed parts, which precedes the death of the part; a stage, in which there is a diminution, but not a total destruction of the powers of life; in which the blood appears to circulate through the larger vessels; in which the nerves retain a portion of their sensibility; and in which, perhaps, the part affected may still be supposed to be capable of recovery. The word *sphacelus*, I shall use to denote the complete death, or mortification of a part; that state, in which the powers of life have become extinct; in which the blood ceases to circulate; and in which the sensibility of the nerves is lost, whether the dead, or mortified part has, or has not, become actually putrid, or shown any tendency to separate and fall away from the living and sound parts. Putrefaction, or the spontaneous process, by which animal bodies are decomposed, is an accidental, and not a necessary effect of the state of mortification. It takes place at very different periods, after the death of particular parts; and these periods, it may be remarked, are always regulated, not only by external circumstances, such as the humidity and temperature of the atmosphere, but also, by the peculiar structure and morbid conditions of the animal texture, or organ, in which the putrefaction occurs. The term *sphacelus*, has, I

know, been employed to express, that a part is not only completely dead, or mortified, but, also, that that part has become putrid, and is in a state of separation from the surrounding and living parts. But, as putrefaction is not a necessary, or immediate consequence of mortification, or partial death in animal bodies, this use of the term *sphacelus* is obviously improper." (See Thomson's *Lectures on Inflammation*, p. 504.)

The causes of mortification are either internal, or external. It is commonly taught in the medical schools on the continent, that the internal causes probably operate after the manner of a deleterious substance, which being introduced into the circulation, occasions a putrefaction of the fluids. (Lassus, *op. et loc. cit.*)—Boyer also professes a similar notion, (See *Traite des Maladies Chir.* T. 1, p. 140.) as well as Larrey in his account of *traumatic gangrene*; a statement, which has drawn forth the criticisms of Mr. Guthrie. The doctrine is supported by no sort of proof, and may be considered as entirely hypothetical, if not decidedly erroneous. There are, indeed, as Boyer has noticed, some spontaneous mortifications, the primitive cause of which is not always well understood: an inflammation, apparently slight, may become gangrenous immediately it has made its appearance. In scorbutic, venereal, and small-pox cases, we have daily instances of this fact. Other internal causes, without any very evident pre-existing disease, sometimes destroy persons, by gangrenous mischief, who are but little advanced in years. (Saviard, *Obs.* 16. Haller, *Disput. Chir.* T. 4, p. 551.) Certain poisonous, acrid, caustic substances taken inwardly, or introduced under the skin, may have the same effect, by annihilating the vital action, or destroying the texture of the parts. (Lassus, *Pathologie Chir.* T. 1, p. 31.) But, though these observations may all be entirely correct, they by no means justify the conclusion, that the internal causes of mortification ever act like a deleterious matter producing a putrefaction of the fluids. The mortification of the toes and feet so well described by Mr. Pott, is supposed to proceed chiefly from unknown internal causes, though sometimes attended with an ossified state of the arteries.

Another remarkable specimen of mortification from an internal cause, is that originating from eating bread made of bad black wheat, or rye. Besides occurring as an original idiopathic disease, and from obstruction of arteries, chronic, or dry gangrene (observes Dr. Thomson) may be induced by the action of substances taken into the stomach, which seem to produce it as a specific effect in parts remote from the source of the circulation. The most singular example, which we have of this, is in the gangrene produced by the eating of a particular kind of unsound or diseased rye. This species of mortification has been rarely observed in England; but it has been frequently seen on the continent, where it has been repeatedly known to prevail in some

districts, where rye forms a principal article of food, as an endemial disease. It occurs, however, in such districts only after wet seasons, in which that grain is affected with a particular disease, well known in France by the name of the *Ergot*, or cockspur rye. In this disease, the grains of rye grow to a large size, acquire a black colour, and have a compact horny consistence. The species of mortification, produced by eating this substance, was first particularly described by Dodard. (See *Journ. des Savans*, an. 1676.) The part affected became at first insensible and cold, and, in the progress of the disorder, dry, hard, and withered. In very malignant cases, there was delirium. Dodard's description of the complaint was very imperfect; but he has mentioned a circumstance, tending strongly to prove, that the disease actually arose from the alleged cause; viz. that fowls, fed with cockspur rye, are killed by it. Saviard informs us, that he saw this disease in the year 1694, at the Hotel Dieu of Orleans. It attacked the upper and lower extremities, which were rendered, in the course of the disorder, as dry as touch-wood, and as emaciated as Egyptian mummies. In 1710, Noel, surgeon to the Hotel Dieu at Orleans, transmitted to the Royal Academy of Sciences at Paris an account of this peculiar mortification. About fifty people, men and children, had come that season into his hospital, with the affliction. According to Noel, the disorder always began in the toes, and extended itself gradually along the foot and leg, till it sometimes rose to the upper part of the thigh. He had never seen any of the female sex affected with it, and had observed only one instance of it in the upper extremities. The Academy received the history of one case, in which the lower extremities were separated from the body in the articulations of the thigh-bones with the acetabula; the first example, (Dr. Thomson believes) of this separation upon record; and it was the occurrence of this, and of similar cases, that probably first suggested the operation of amputation at the hip-joint. (See *Thomson's Lectures on Inflammation*, p. 541.) As Noel's patients did not come under his care, till after the disease had existed some time, he could not describe from his own observation the early symptoms; but the patients had often told him, that the disease generally began in one, or both feet, with pain, redness, and a sensation of heat, as burning as the fire; and that, at the end of some days, these symptoms ceased, as quickly as they had come on, when the extreme sensation of heat, which they had formerly felt, was changed into cold. The part affected (adds Noel) was black, like a piece of charcoal, and as dry as if it had passed through the fire. After some time, a line of separation was formed between the dead and living parts, like that which appears in the separation of a slough produced by the cautery; and the complete separation of the limb was, in many cases, affected by nature

alone. In others, Noel was obliged to have recourse to amputation.

This disease appeared in Switzerland in 1709 and 1716, and its symptoms and progress in that country have been accurately described by Langius in a dissertation, entitled, "*Descriptio Morborum ex esu Clavorum Secalinorum*."

Gassaud, physician in Dauphiny, where this disease appeared also in 1709, states, that many of the patients were affected with swellings of the feet and legs, and of the hands and arms, which degenerated into a gangrene, that penetrated to the bone, and produced a separation of the affected limb. The disorder was attended with different symptoms in different individuals. Some suffered very violent pain, accompanied by an insufferable sensation of heat, although the part affected often felt cold to the touch. In other patients redness, with much swelling, supervened, attended with fever and delirium. Other patients were without any fever, or delirium, though they seemed to suffer equal pain. In some patients, the parts affected became withered, dry, and black, like charcoal. The separation of the dead parts from the living took place with the most excruciating pain, and a sensation resembling that produced by the direct application of fire. This sensation was sometimes intermittent; and, in other instances, it was succeeded by an equally harassing sensation of cold.

According to Bossau, surgeon to the hospital of St. Antoine, in Dauphiny, the cases, which he saw, were not all of the dry kind, the limb sometimes becoming putrid, and maggots being generated. He says that the disease was not infectious, and it attacked indiscriminately men, women, and children.

The degree of fatality caused by this species of mortification seems to have been extremely various. In the Memoirs of the Royal Academy of Sciences for 1748, M. Duhamel mentions, that of 120 persons afflicted, scarcely four or five recovered with their lives. According to Langius, it was equally fatal in Switzerland.

Dr. Thomson believes, that the preceding sort of gangrene has never occurred in this country, excepting, perhaps, the cases recorded by Dr. Charlton Woolaston, in the Phil. Trans. for 1762; and which proceeded from eating unsound wheat, not rye. (See *Lectures on Inflammation*, p. 548.) For further particulars relating to this curious kind of mortification, I must refer the reader to this valuable work.

The external causes of mortification, which are manifest, and act mechanically or chymically, are burns; excessive cold; the application of caustics; the presence of any ichorous, urinary, or fecal matter effused in the cellular substance; violent contusions, such as are produced by gunshot wounds, or bad fractures; the strangulation of a part, as in cases of hernia, or when polypi, or other tumours are tied; a high degree of in-

flammation; and, lastly, every thing, that has the power of stopping the circulation and nervous energy in parts. (*Lassus, Pathologie Chir. T. I, p. 34, 35.*)

Inflammation is one of the most frequent occasional causes of mortification. But, as we have already remarked, the death of a part may take place without any well-marked appearance of previous inflammatory disorder; and the latter even when present has frequently less share in the mischief, than other incidental circumstances, and is in reality, only an effect of the very same cause, which produces the sphacelus itself. It is oftentimes a matter of doubt, whether actual inflammation precedes the occurrence or not; for a part, before it mortifies, is in certain instances only affected with pain, and with no degree of preternatural redness. Lastly, when mortification is, unquestionably, preceded by inflammation, there are so many varieties of the disorder depending on incidental causes, that these latter demand more attention than the inflammation. (*Richter, Anfangsgr. B. I. Kap. 3.*)

Mr. James enumerates the following circumstances, as capable of influencing, in a very great degree, the disposition of inflammation to terminate in mortification. 1. The powers of the part, in which the inflammation occurs, being naturally weak, as in fibrous membranes, the scrotum, &c. 2. The remote supply of blood, or nervous energy, as in the lower extremities. 3. Obstruction to the return of blood. 4. To the supply of blood. 5. Disease in the heart or vessels. 6. Debility from age, habits of life, disorder of the digestive organs, or fever. 7. Poor living, foul air, improper food, scurvy, &c. 8. Impairment of organization from external injury. 9. Of the nervous power by poisons. 10. Undue excitement of weakened parts. 11. Depressing remedies. 12. Pressure and tension. 13. Excessive violence of inflammatory action. 14. Peculiar disposition in the constitution. (*James on Inflammation, p. 102.*)

Healthy phlegmonous inflammation seldom ends in mortification, except when it is unusually violent and extensive.

Of all the inflammatory complaints, to which the system is liable, erysipelas is observed most frequently to terminate in gangrene; and whenever phlegmon is, in any degree, conjoined with an erysipelatous affection, which it not unfrequently is, it seems thereby to acquire the same tendency, being more difficult to bring to resolution or suppuration than the true phlegmon, and more apt to run into a mortified state.

The symptoms of mortification from inflammation take place variously, yet generally as follows:—The pain and sympathetic fever suddenly diminish, the part affected becomes soft, and of a livid colour, losing, at the same time, more or less of its natural warmth and sensibility. In some places, the cuticle is detached; while, in other situations, vesicles arise, filled with a clear, or turbid fluid. Such is the state, to which we apply the term *gangrene*, and which stage of

the disorder too often rapidly advances to *sphacelus*, when the part becomes a cold, black, fibrous, senseless substance, called in technical language, a *slough*.

It merits notice, however, that, "in cases, in which gangrene immediately succeeds to inflammation, these two morbid states may, in some measure, be regarded as stages, or periods, of the same disease. They pass insensibly into one another; nor is it possible to say precisely where the one state ends, and the other commences. The symptoms of inflammation, in these cases, do not disappear before those of gangrene come on; but seem rather to undergo a gradual and almost imperceptible change, or conversion, into one another. The redness acquires a deeper tinge, and spreads further, than formerly; the swelling increases and becomes more doughy; and, in this incipient stage, the gangrene, particularly when it attacks the cutaneous texture, often bears a considerable resemblance to erysipelas." (*See Thomson's Lectures on Inflammation, p. 506.*)

It is to be observed, also, that "the part of the body which becomes affected with gangrene, does not immediately lose its sensibility; for the pain, on the contrary, is often very much aggravated by the approach of this state. The blood also still continues to circulate, at least in the larger vessels of the part, but, perhaps, with less force; and from the resistance which it meets with in passing through the capillaries, in less quantity, than formerly. The serous effusion into the cellular membrane continuing to increase, and the action of the absorbent and sanguiferous vessels to diminish, the part becomes at length incapable of being restored to its former office in the animal economy. It is, therefore, in its earlier stages only, that gangrene is to be considered as an affection admitting of cure; for there are limits, beyond which, if it pass, recovery becomes impossible. These limits it may not, in every instance, be easy to define; but they form the boundaries between incipient gangrene and the ultimate termination of that state in sphacelus." (*Thomson, op. cit. p. 507.*)

The causes which produce mortification by impeding the return of blood from the part affected, for the most part operate by making pressure on the trunk or principal branches of a vein. In these instances, there is always an accumulation of blood in the part which first swells, becomes of a livid colour, tense, and very painful. Soon afterward, blisters arise, and the part becomes soft, œdematous, cold, insensible, emphysematous, black, and fetid. Such are the circumstances which happen in strangulated hernia, in tied polypi, and in a limb in which the veins have been so compressed by any hard swelling, such as the head of a dislocated bone, as to excite mortification.

Other causes operate by preventing the entrance of arterial blood. The application of a ligature to an artery, as practised in several surgical cases, and all external pressure, that closes the artery, or arteries,

on which a part entirely depends for its supply of blood, have this effect. Mortification does not, however, always take place when the trunk of an artery is rendered impervious, because nature furnishes the necessary supply of blood through collateral ramifications. But when the disorder does happen, the part commonly first becomes pale, flaccid, and cold, and soon afterward shrinks, loses its sensibility, grows black, and perishes.

It is usually represented by writers, that mortification may proceed from a mere lessening of the communication of blood and nervous energy to a part. However, it is to be observed, that parts, deprived of all connexion with the sensorium, by the division or paralytic state of their nerves, do not frequently perish on this account. But as their functions are carried on with less vigour, and their vitality is weakened, the same causes which sometimes produce mortification in parts differently circumstanced, must much more readily occasion it in them. Among the causes of the present species of mortification, may be mentioned great universal debility; extreme old age; a thickening and ossification of the coats of the arteries, and a consequent diminution of their capacity, and of their muscular and elastic power.

Cowper, the anatomist, was one of the earliest writers who took notice of this ossification of the arteries of the leg, in persons who had died of mortification of the feet and toes. (See *Phil. Trans.* Vol. 23, p. 1195, and Vol. 24, p. 1970.) A similar case was remarked by Mr. Becket, of which he has given an account in his *Chirurgical Observations*. The occurrence was also mentioned by Naish. (See *Philosoph. Trans.* Vol. 31, p. 226.) Dr. J. Thomson has seen one example of a very complete ossification of the arteries of the leg, accompanying a mortification of the feet and toes. (*On Inflammation*, p. 537.) Speaking of the same subject, Mr. Hodgson remarks: "Experience has proved this condition of the arteries to be at least a constant attendant upon one species of gangrene, to which the extremities of old subjects are liable; and I have found the three principal arteries of the leg nearly obliterated by calcareous matter in two fatal cases of this disease. But our knowledge of the power of collateral circulation, in every part of the body, will not allow us to admit the obliteration of the trunks as a sufficient cause of mortification, from a deficient supply of blood. It is therefore necessary for us to remember, that the same disease may probably exist in the collateral branches, upon which it has produced similar effects. But if an extent of vessel be converted into a calcareous cylinder, it loses its elasticity and organic powers, so as to be unable to afford any assistance to the propulsion of the blood; and the existence of parts, supplied by vessels in this state, constitutes a strong argument against the agency of the arteries in the circulation of the blood. The above observa-

tions, on the cause of this species of gangrene, at once expose its incurable nature; and this state of the blood-vessels renders the danger of amputation very considerable, unless fortunately the disease in the arteries does not extend to the part at which the ligature is applied." (See *Hodgson's Treatise on the Diseases of the Arteries and Veins*, p. 41.) However, although the ossified state of an artery must certainly be unfavourable to its healing, it does not constantly prevent this desirable event. (See *Case in Medico-Chir. Trans.* Vol. 6, p. 193.)

The preceding facts are particularly entitled to attention, because, as we shall presently find, the opinion that the mortification of the toes and feet arose from an ossification of the arteries, was considered by Mr. Pott as destitute of foundation.

It is probable, however, that sometimes other causes are concerned. Fabricius Hildanus mentions a fatal case of mortification of the feet and legs, where the patient was in the vigour of life, and apparently of good constitution. After death, a scirrhus tumour was found surrounding and compressing the inferior vena cava, and aorta, near their bifurcation, so as to prevent the free circulation of the blood in the lower extremities. Mortification of the extremities also sometimes occurs from deficient circulation, in the progress of diseases of the heart.

The mortification, arising from long continuance in the same posture, is chiefly attributable to the unremitted pressure which parts sustain, and which obstructs the circulation. Surgeons have frequent occasion to see melancholy examples of this kind of mortification, particularly in cases of fractures, paralysis from disease of the vertebræ, &c. The mischief most readily occurs where the bones have the least flesh upon them, and, consequently, where all external pressure has the greatest effect; as, for instance, about the os sacrum, os ilium, spines of the scapula, &c. The disordered part always first becomes soft, livid, red at the circumference, and œdematous, afterward losing its sensibility, and acquiring a black appearance: at length it is converted into a foul sloughing ulcer.

Though long continuance in the same posture is the grand cause of this kind of mortification, yet incidental circumstances are frequently combined with it, and have great influence over the disorder. These are, great debility, the same state of the system as exists in typhus fever, impure air, unclean bedding, &c.

There are some causes which produce death in a part at once, by the violence of their operation. A very powerful blow on any portion of the body may destroy the vitality of the fibres and vessels in this sudden manner. Lightning, strong concentrated acids, and gunshot violence, sometimes act in a similar way. When a ball enters the substance of parts with great force and rapidity, many of the fibres, which are in its track, are frequently killed at once, and must be thrown off in the form of sloughs,

before the wound can granulate and heal. (See *Hunter on Gunshot Wounds*.)

Cold is often another cause of mortification, and when parts which have been frozen, or frostbitten, are suddenly warmed, they are particularly apt to slough.

I find in Baron Larrey's valuable publication, some interesting observations on the gangrene from cold. He acquaints us, that after the battle of Eylau, one of the most grievous events to which the French soldiers were exposed, was the freezing of their feet, toes, noses, and ears: few of the vanguard escaped the affliction. In some, the mortification was confined to the surface of the integuments of the toes or heels; in some, the skin mortified more deeply, and to a greater or lesser extent; while, in others, the whole of the toes, or foot, was destroyed. (See *Programma quo frigoris acrioris in corpore humano effectus expendit. Haller, Disp. ad Morb. Lips. 1755.*)

"All the writers, on this species of mortification (says Larrey) have considered cold as the determining cause; but, if we attend to the period when the complaint begins its progress, and the phenomena which accompany it, we shall be convinced, that cold is merely the predisposing cause. In fact, during the three or four exceedingly cold days which preceded the battle of Eylau, (the mercury having then fallen to 10, 11, 12, 13, 14, and 15 degrees below zero of Reaumur's thermometer) and until the second day after the battle, not a soldier complained of any symptom depending upon the freezing of parts. Nevertheless, they had passed these days, and a great portion of the nights of the 5th, 6th, 7th, 8th, and 9th of Feb. in the snow, and the most severe frost. The imperial guard especially had remained upon watch in the snow, hardly moving at all for more than four and twenty hours, yet no soldier presented himself at the ambulance,* nor did any one complain of his feet being frozen. In the night of the 9th, and 10th of February, the temperature suddenly rose, the mercury ascending to 3, 4, and 5 degrees above zero. A great quantity of sleet, that fell on the morning of the 10th, was the forerunner of the thaw which took place in the course of that day, and continued in the same degree for several days. From this moment, many soldiers of the guards and the line applied for succour, complaining of acute pain in the feet, and of numbness, heaviness, and prickings in the extremities. The parts were scarcely swollen, and of an obscure red colour. In some cases, a slight redness was perceptible about the base of the toes, and on the back of the foot. In others, the toes were destitute of motion, sensibility, and warmth, being already black, and, as it were, dried. All the

patients assured me, that they had not experienced any painful sensation during the severe cold to which they had been exposed on the night-watches of the 5th, 6th, 7th, 8th, and 9th of February, and that it was not till the night of the 10th, when the temperature had risen from 18 to 20 degrees, that they felt the first effects of the cold."

It is further noticed by Larrey, that such patients as had opportunities of warming themselves in the town, or at the fires of the night-watches, suffered in the greatest degree. (See *Larrey's Memoires de Chirurgie Militaire, T. 3, p. 60—62.*)

Sometimes mortification seems to depend either upon the operation of some infectious principle, or, at all events, upon causes which simultaneously affect numerous individuals; for instances have been known, in which almost all the ulcers and wounds in large hospitals became nearly at the same time affected with gangrenous mischief. (See *Hospital Gangrene.*)

Mortification is very frequently occasioned by the injury which parts sustain from the application of fire and heated substances to them. When the heat is very great, the substance of the body is even decomposed, and of course killed at once. On other occasions, when the heat has not been so violent, nor sufficiently long applied, inflammatory symptoms precede the sloughing.

Cutaneous texture is that in which we have the best opportunity of observing the phenomena and progress of gangrene. When it occurs as a consequence of inflammation, the colour of the skin changes from the florid red to a darker shade; and in the progress of the disease it acquires a livid hue. The cuticle often separates at certain points from the skin, and the vesications, termed *phlyctenæ*, are formed, which usually contain a bloody-coloured serum. As sphacelus comes on, the livid hue disappears, and a slough is formed, which is sometimes ash-coloured; sometimes black. It is not always easy to judge of the extent of mortification from the appearance of the skin; for, when the subjacent cellular membrane is affected, the disorder may occupy a greater extent internally, than upon the surface.

In a spreading gangrene, the red colour of the affected skin is insensibly lost in the surrounding integuments; but, when gangrene, followed by sphacelus stops, a red line, of a colour more lively than that of gangrene, is generally perceptible between the dead and living parts. It is at the inner edge of this inflamed line, where we usually see the ulcerating process begin, by which the separation of the dead from the living parts is affected. (See *Thomson's Lectures on Inflammation, p. 511, 512.*)

Mortification occurs frequently in cellular texture. The skin which covers dead cellular substance, generally has a gangrenous appearance, and afterward either ulcerates, or sloughs. In some cases, the portion of sphacelated cellular texture is small, as in the malignant boil; in others, extensive, as in cases

* The ambulances of the French army are caravans, furnished with an adequate number of surgeons, and every requisite for the dressing of wounds, and the immediate performance of operations, upon which last circumstance, in particular, the life of the wounded soldier often depends. These caravans follow the most rapid movements of the army, and are always capable of keeping up with the vanguard.

of carbuncle. In erysipelas phlegmonoides, the cellular membrane, connecting together the muscles, tendons, nerves, blood-vessels, &c. often perishes to a great extent. Here large portions of skin are frequently also destroyed by sloughing, or ulceration, so that muscle, blood-vessel, tendon, nerve, &c. are exposed to view, quite denuded of their proper coverings, and in different states of disease.

Artery is the texture, endowed with the greatest power of resisting its own destruction by mortification. "I have (says Dr. Thomson) in various instances of erysipelas phlegmonoides, seen several inches of the femoral artery laid completely bare by the gangrene, ulceration, and sphacelus of the parts covering it, without its giving way before death. The arteries in these, and other similar instances, in which I have seen them laid bare in the neck and arm, by abscess terminating in mortification, had the appearance of raw flesh, and were obviously thicker and more vascular than natural. The blood circulated through them, and assisted in supplying with nourishment the parts upon which they were distributed." (P. 513.) I have often seen the truth of the foregoing statement sadly illustrated in cases of sloughing buboes, by which several inches of the femoral artery were exposed. I have seen the throbbing brachial artery denuded for more than a month, nearly its whole extent along the inside of the arm, by the ravages of malignant and pseudo-syphilitic ulceration, attended with repeated sloughing; and yet hemorrhage had no share in carrying off the unfortunate patient.

It is a curious fact, that the blood coagulates in the large arteries, which lead to a mortified part. This occurrence takes place for some distance from the slough, and is the reason why the separation of a mortified limb is seldom followed by hemorrhage.

The same occurrence also affords an explanation, why, in the amputation of a mortified limb, there is sometimes no hemorrhage from the vessels, although the incisions are made in the living part. This fact was first particularly pointed out by Petit, the surgeon. (See *Mém. de l'Acad. des Sciences*, 1732.) "When a gangrened limb (says this celebrated surgeon) is cut off in the dead part, no hemorrhage occurs, because the blood is coagulated a great way in the vessels." He adds, "We have several examples of limbs amputated, on account of gangrene, in which no hemorrhage occurred, although the amputation was made a considerable way in the living parts; because the clot was not confined in these cases to the dead part, but was continued forwards into the living as far as the inflammatory disposition extended."

According to Dr. Thomson, cases, in confirmation of the foregoing statement, are recorded by other practical writers, especially Quesnay, and Mr. O'Halloran. In one of the cases, mentioned by the latter gentleman, and in which no hemorrhage followed the removal of the limb, the inci-

sions were made four inches above the division of the dead from the living parts. Dr. Thomson has seen a still longer portion of femoral artery closed up with coagulated blood, after a mortification of the foot and leg; and, in one example, where the mortification began in the thigh, he saw the coagulation of the blood in the external iliac, extending up to the origin of this vessel from the aorta. "So common, indeed, is this coagulation of the blood in the limbs affected with mortification (observes Dr. Thomson,) that it has been supposed to be a necessary and constant effect of this disease. This opinion, however, does not appear to be well founded; for I have now seen several instances in which a limb has mortified and dropped off, without hemorrhage having occurred from the vessels divided by nature: and yet, in examining the vessels of the stumps of these patients after death, I have not been able to find any clots, either of coagulated blood, or of coagulable lymph. In the cases to which I allude, the adhesive inflammation, occurring in the line of separation between the dead and living parts, had extended to the blood-vessels, and their inner surfaces being inflamed and pressed together by the swelling which occurs, had adhered so as to close up their extremities. It is in this way we shall find, that the common ligature acts, which is applied to the divided extremities of arteries and veins; and it is this obliteration, by the process of adhesion of the extremities of the arteries and veins in the neighbourhood of the sphacelated parts, that in reality prevents the occurrence of hemorrhage, when the mortified limbs fall off, or are removed by the knife. The coagulation of the blood in the canal of the vessel is not alone sufficient. It may tend, in the cases in which it occurs, for a time to restrain hemorrhage; but it is by the obliteration by adhesion, of the canal in the extremities of the arteries and veins, that the occurrence of hemorrhage can be securely and permanently provided against. Indeed, to me it seems doubtful, whether that coagulation of blood, which takes place in mortified limbs, ever takes place in the canal of the vessel, till its extremity and lateral communications have been plugged up by the coagulating lymph, which is extending during the state of the adhesive inflammation." (See Thomson's *Lectures on Inflammation*, p. 554.)

When gangrene and sphacelus happen to any extent, the patient is usually troubled with an oppressive hicough; a symptom well known to the surgeon of experience, and often an indication of the mischief, when external signs are less instructive. The truth of this remark is frequently seen in strangulated herniæ.

The constitution also suffers immediately a considerable dejection. The patient's countenance suddenly assumes a wild, cadaverous look; the pulse becomes small, rapid, and sometimes irregular; cold perspirations come on, and the patient is often affected with diarrhœa and delirium.

As Dr. Thomson observes, the constitutional symptoms "form fevers, which partake in individual cases, more or less, of an inflammatory, typhoid, or bilious character. But, the degree of these fevers varies, in every particular case, from their almost total absence to the highest degree of intensity. The skin is usually hot, and dry at the commencement of the attack; the tongue is without moisture, brown and hard; the pulse is quicker, and less full and strong, than in inflammation; and this state of the pulse is often attended by fluttering intermissions, and a considerable degree of subsultus tendinum. The fever has, in general, more of the asthenic, than of the sthenic character; or it is more of the typhoid, than of the inflammatory type; a circumstance of great importance in the constitutional treatment of mortification. The fever in gangrenous affections is often accompanied with great uneasiness and restlessness, dejection of spirits, wildness of the looks; and, in severe cases, with almost always more or less delirium. In the progress of the disease, cold sweats, palpitations, and convulsions, sometimes occur; a hiccough, accompanied with nausea, often comes on, and proves a most distressing symptom to the patient. Frequently, this hiccough is the forerunner of death. Some patients die comatose; others, after suffering severe pain, spasms, and delirium. But, in some, a slow, in others, a sudden abatement of the constitutional symptoms takes place, accompanied also with the amelioration of the local affection. The gangrenous inflammation stops, and a red line is formed by the adhesive inflammation in the extreme verge of the living parts; the dead part separates, and granulations form; and when the constitution has strength to sustain the injury it has received, recovery takes place." (See *Lectures on Inflammation*, p. 509.)

In cases of sphacelus, the prognosis chiefly depends on the nature of the cause of the disorder. The more easy the cause is of removal, the less room is there for alarm. It is an erroneous supposition, that mortification arising from an external local cause is more easy to be stopped and cured, than that originating from an internal cause. The local cause is sometimes exceedingly difficult, or even incapable, of removal; and a sphacelus, which is at first entirely local, may afterward become a general disorder, by the universal debility and derangement of the system, resulting from the complaint. Hence, it is obvious, that a sphacelus may easily extend beyond the bounds of its outward local cause. On the other hand, a mortification may be reduced to one of a nature entirely local; though it arose at first from constitutional causes. Sphacelus from extreme debility, or from such a state of the system, as attends the scurvy, typhoid fevers, &c. is constantly perilous, because these causes are very difficult to remove. It is also a fact, that, when numerous causes are combined, it is an unfavourable occurrence, not merely because the surgeon is apt to overlook some

of them, but because there are in reality more obstacles to the cure.

Humid gangrenes, which are frequently accompanied with emphysema of the cellular membrane, usually spread with great rapidity. "Some authors, (says a modern writer,) have attributed this to the influence of the air extricated, and Dr. Kirkland has described emphysematous gangrene, as distinct from the others, and some have imputed this disposition, in a considerable degree, to the putrefaction of the juices, which are effused." With regard to the former, the author has mistaken an effect for a cause; yet, "it is important to recognize the fact, that gangrene, when accompanied with emphysema, has a remarkable disposition to spread." (*James on Inflammation*, p. 96.)

Sometimes a mortification spreads so slowly, that it does not occupy much extent at the end of several months, or even a whole year. The case, however, is often not the less fatal on this account. The danger is never altogether over, until the dead part has completely separated. The entrance of putrid matter into the circulation (says Richter) is so injurious, that patients sometimes perish from this cause, long after the mortification has ceased to spread. (*Anfangsg. der Wundarzn. B. 1, Kap. 3, p. 78, 79.*)

This last circumstance is very much insisted upon, by all the modern continental surgeons; but the doctrine has never gained ground among English surgeons, who entertain little apprehension of the bad effects of the absorption of putrid matter in cases of mortification; and the opinion of Mr. Guthrie may be more correct, that nature receives the shock through the nervous system, and not through the absorbents. (*On Gunshot Wounds*, p. 123, Ed. 2.)

The idea of a deleterious principle being absorbed was long ago well refuted by Mr. J. Burns, who pointed out, that the impression upon the constitution was in no degree commensurate with the size of the slough, and consequently with the quantity of putrid matter, as the effects produced by a small slough of intestine, or cornea, will exemplify. But when the sloughs are of equal size, and in the same parts, the differences of constitutional sympathy, as Mr. James observes, may depend upon the nature of the surrounding inflammation, which, however, he conceives, may itself be affected by the quantity of putrid irritating fluids. (*On Inflammation*, p. 98.)

The danger of sphacelus is also proportioned to the size and importance of the part affected. The event of the distemper likewise depends very much on the patient's age and constitution.

Parts, affected with gangrene, do not immediately lose the whole of their sensibility; the circulation is still continued in a certain degree; and when the progress of the distemper does not surpass certain bounds, the functions of such parts may be completely re-established. Gangrene, strictly speaking, is not a decided mortification; but only the

forerunner of this latter mischief, and may be regarded as the intermediate link, between the most violent stage of inflammation and sphacelus. The presence of this last implies the total loss of life in the part affected, the destruction of its organization, the abolition of all its functions, and an absolute inability to resume them again. However, even when we see the surface of a part manifestly sphacelated, we must not always conclude, that the entire destruction of its whole substance or thickness is certain; for, in many cases, the disorder only affects the skin and cellular substance. In this state, the integuments frequently slough away, leaving the tendons, muscles, and other organs, perfectly sound.

It is only in external affections of the body that the progress of inflammation to gangrene and sphacelus can be marked with any degree of precision. The approaches of the latter are also not invariably announced by the distinct and manifest symptoms of gangrene, even when the disorder is quite superficial. There are cases, which justify the conclusion, that a small part of the body may be affected with sudden death, just in the same manner as the whole machine. Sphacelus is often seen making its appearance in a part, which is apparently quite healthy, without being preceded by any other symptoms, than a sudden acute pain in the seat of the mischief. Sometimes, in the earliest period of the complaint, a black spot, which rapidly spreads on every side, is the only change that can be observed.

In order to form a just prognosis, all the above circumstances must be taken into consideration, and, in particular, we must never deliver an opinion, without having closely examined the progress of the disorder; for, should we make a favourable prognosis from such appearances as might justify us as much as possible in so doing, there would be great risk of finding ourselves most miserably mistaken by the event of the case. In all cases of considerable mortification, even when arising from an external cause, the patient cannot be deemed exempt from danger, not only while no separation of the mortified parts has begun, but also, not before such parts have been completely detached.

TREATMENT OF MORTIFICATION.

I shall arrange under two heads what is to be said of the treatment of mortification. Under the first will be comprehended every thing, which relates to internal remedies, and such other means, as are indicated by the general state of the system; under the second, topical remedies, and the local treatment of the parts affected.

In the treatment the surgeon will always have one thing for immediate consideration; viz. whether the case before him is one of acute mortification, attended with inflammation and inflammatory fever; or whether it is a chronic mortification, beginning without fever, or attended with a fever of a ty-

phoid nature and great prostration of strength? By making up his mind upon this point, the practitioner will establish an useful general principle for his guidance, especially in the commencement of the treatment.

1. When mortification is acute, and seems to depend on the violence of inflammation, the first indication is to moderate the inordinate action of the sanguiferous system, by the prudent employment of such means as are proper for counteracting inflammation. In short, relief is to be sought in the antiphlogistic regimen, which consists in the employment of blood-letting, purgatives, diaphoretics, and diluents, and in abstinence from all vegetable or animal substances, which have a tendency to excite, or to augment the febrile action. It is a regimen which must be pursued, so long as inflammatory fever continues. It is only in cases in which the fever from the first assumes a typhoid character, or where the mortification takes place without the previous occurrence of fever, that any deviation from the antiphlogistic regimen can be allowed.

Dr. Thomson, from whom I have borrowed the foregoing passage, also notices the present common aversion to bleeding in compound fractures, erysipelas, carbuncle, hospital gangrene, burns, and frostbite; cases in which the patient, it is said, can seldom bear with impunity any considerable loss of blood. "In many instances of these injuries and affections (says he) blood-letting, I know, is not required; but I am doubtful, even if it were generally employed, whether it would produce all the mischiefs, which have of late years been ascribed to it. I believe it to be the most efficacious of any of the remedies that can be employed, in all cases of inflammatory fever threatening to terminate in gangrene, and that its use in such cases ought never to be omitted in the young, strong, and plethoric." (See *Lectures on Inflammation*, p. 559.) When bleeding has not been sufficiently practised, during the state of the inflammation antecedent to the mortification; when the general symptoms, which point out the existence of this state, continue violent; and, especially, when the pulse is still quick, hard, or full; it is absolutely necessary to empty the vessels a little more, even though mortification may have begun, particularly if the patient be young and plethoric. Bleeding, by diminishing the fever, and abating the general heat, is frequently the best means of all. It may then be considered better, than all antiseptics, for stopping the progress of the disorder. But this evacuation is to be employed with a great deal of circumspection; for, should it be injudiciously resorted to, from the true state of the system not being understood, the error may be followed by the most fatal consequences. It should also be well remembered, that however strongly bleeding may be indicated, the moment is not far off, when this evacuation is totally inadmissible, especially if the mortification make much progress.

In cases of acute mortification, after as much has been taken away as may be deemed safe or proper, the other parts of the antiphlogistic regimen must be continued, as long as any increased action of the heart and arteries continues. "The use of purgatives seems to be particularly required in those cases, in which the local inflammatory affection is accompanied with derangement of the digestive and biliary organs. Antimonial diaphoretics are those from which I should be inclined to expect most advantage in the commencement of the attack; but, after the inflammatory action has been subdued, opiates, either alone, or combined with antimony, or what is still better, with ipecacuanha, as in Dover's powder, are frequently of singular service, not only by diminishing pain, but also, by inducing a soft and moist state of the skin." (Thomson, p. 560.) A strict regimen, which may have been useful, and even necessary, during the inflammatory stage, may have a very bad effect, if continued too long, by diminishing the patient's strength, which, on the contrary, should be supported by the most nourishing food.

A vegetable diet, as Dr. Thomson observes, is to be preferred in the commencement both of acute gangrene with inflammatory fever, and of chronic gangrene with a fever from the first of a typhoid nature. Wine and animal food given too early in diseases, which have a tendency to gangrene, increase the febrile heat and frequency of the pulse, oppress the stomach, render the tongue foul, the patient restless and delirious, and his situation dangerous, if not hopeless. In the transition from gangrene to sphacelus, an abatement of the symptomatic fever usually takes place in almost all cases, which have ultimately a favourable termination. Dr. Thomson believes, that *this is the first period, at which it is safe to allow vinous liquors, or diet, chiefly animal.* (P. 561.)

I next come to a second very essential and important indication, to be fulfilled, as soon as the symptoms, announcing the existence of the inflammatory state, appear to abate, and the patient begins to be debilitated. This indication is *to prevent excessive weakness by the suitable employment of cordials, and, particularly, of tonics.* These same means also contribute to place the system in a proper state for freeing itself from the mortified parts, or, in other words, for detaching them. For, inflammation is the preparatory step, which nature takes to accomplish the separation of mortified parts from the living ones, and such salutary inflammation cannot take place, if the energies of life be too much depressed.

In order to fulfil the above indication, it is necessary to prescribe a nourishing diet, with a certain quantity of good wine, proportioned to the patient's strength, and the symptoms of the complaint. This diet is generally productive of more real benefit than the whole class of cordial and stimulating medicines. However, when the patient is much weakened; when the mortifi-

cation of the part affected is complete, and the disorder is spreading to others, some of the following remedies may be ordered: ammonia, aromatic confection, æther, &c. In general, however, wine is best, because more agreeable than cordials; and for this purpose, one ought to prefer the most perfect wines, such as those of Spain and Madeira.

Of all the medicines, hitherto recommended for the cure of mortification, there is certainly not one, that has acquired such a character for efficacy, as the Peruvian bark. It is said, that this remedy often stops, in a very evident and expeditious manner, the course of the disorder. Being a very powerful tonic, it is thought to operate by strengthening the system, and thus maintaining in every part the necessary tone for resisting the progress of mortification. But, whatever may be its mode of acting, the advocates for this medicine contend, that it is now a well-known fact, that it ought to be employed in almost all cases of mortification, as soon as the violence of the inflammatory symptoms has been appeased.

It was Mr. Rushworth, a surgeon at Northampton, who made this discovery in the year 1715. Amyand and Douglas, two surgeons in London, soon afterward confirmed the virtue of this remedy. Mr. Shipton, another English surgeon, has also spoken, in the Philosophical Transactions, of the good effects which he has seen produced by this medicine. In the Medical Essays of Edinburgh, Drs. Monro and Paisley published several cases, illustrative of the efficacy of bark in cases of mortification. We are there informed, that when its exhibition was interrupted, the separation of the eschars was retarded, and that, on the medicine being resorted to again, such a separation went on again more quickly. Since this period, all practitioners, both in England and elsewhere, have had recourse to this remedy, which has every where obtained the highest praises. Unfortunately, these praises have induced surgeons to employ it indiscriminately, and with equal confidence, in all cases.

We cannot indeed doubt, that bark has frequently had the most salutary effect, in cases of mortification, though sometimes it may probably have had imputed to it effects, which were entirely produced by nature. The following observation, made by Dr. Thomson, is highly worthy of recollection: "In attending to the effects, supposed to result from the operations of the external and internal remedies, which are daily employed for the cure of mortification, there are two facts, well ascertained, which appear to me to be peculiarly deserving of your regard. The first of these is, that mortification often stops spontaneously, without any assistance whatever from medicine; the second, that it often begins, and continues to spread, or even after it has stopped for a while, recommences and proceeds to a fatal termination, in spite of the best directed efforts of the healing art." (See *Lectures on Inflammation*,

p. 557.) In many cases, bark is evidently hurtful, when exhibited prematurely. There are other instances, in which it is impossible to employ it in a sufficient quantity, the stomach not being able to bear it in any form. In general, it should never be administered, when the pulse is high, and other inflammatory symptoms exist; but, when the tension of the part diminishes, the pulse sinks, and symptoms of weakness commence, and particularly, when with these circumstances, we perceive a separation beginning to take place between the dead and the living part, bark hardly ever fails to support the strength of the constitution, and powerfully to accelerate the separation of the mortified parts. (*Encyclop. Method. Art. Gangrene.*)

However, as I have already remarked, it is quite wrong to prescribe bark, in every instance, as the sole remedy; for there are many cases, in which it is unnecessary; some, in which it does harm; and others, in which it is totally inefficacious. It is a medicine obviously of no service, when the mortification arises from an external cause, and is the only complaint, in a healthy, strong constitution. It is equally unnecessary, when the sphacelus is of the dry sort, and has ceased to spread, at the same time, that the living margin appears to be in a state of inflammation, without any universal debility. But it deserves particular notice, that the circumstances of each individual case are liable to such considerable variation, that though bark may be at first unnecessary, it may afterwards be indicated.

In some cases of sphacelus, bark is hurtful. The disorder is generally attended with fever, which may be of three kinds; inflammatory; typhoid, or attended with extreme debility; or one connected with a disordered state of the abdominal viscera.

In the latter case, which is far more common than is supposed, bark is manifestly pernicious. Here, the indication is to empty the stomach and bowels as quickly as possible. When this has been done, if bark should now be indicated by any of the circumstances already pointed out, it may be safely administered. But there is a great necessity for procuring evacuations as speedily as possible, before much debility has occurred.

Sometimes, mortification is accompanied with a low typhoid kind of fever, which, whether the cause, or the consequence of the local mischief, demands the exhibition of bark.

However, mortification may be attended with common inflammatory fever, and then the living margin is generally inflamed and painful. This is particularly the case, when mortification is the consequence of genuine acute inflammation, or of an external injury in a healthy subject. Here, bark must obviously be injurious. Still, it is wrong to regard this medicine as invariably hurtful, whenever sphacelus is the effect of inflammation. It has already been observed, that the inflammation frequently has less share in the origin of the disorder than some incidental cause, which oftentimes requires the

exhibition of bark. Even when mortification is the pure effect of inflammation, great prostration of strength may subsequently arise, and indeed does mostly take place at a certain period of the disorder. In this circumstance, the voice of experience loudly demands the employment of bark, though its exhibition would have been at first useless or hurtful. While genuine inflammatory fever, and local inflammation, are co-existent with mortification, antiphlogistic means are undoubtedly useful; but, great caution is requisite, since, in cases of humid gangrene, as it is termed, the inflammatory state very soon changes into one, in which the great feature is prostration of strength.

When there is mere prostration of strength, without any symptom of gastric disorder, or of inflammation, or typhoid fever, bark is evidently proper, though seldom effectual alone; diaphoretic, and nervous medicines being also proper, opium, wine, camphor, ammonia, brandy, &c. The constitutional disorder may be either inflammatory, typhoid, or one connected with gastric disorder. Consequently, there are three plans of constitutional treatment, and it is easy to determine the particular cases, in which bark is unnecessary, hurtful, or inefficacious.

We meet with one species of mortification, in which the patient experiences severe pain in the part, without the smallest appearance of inflammation. Here bark is never of any use, and opium is regarded as the only medicine of much efficacy. This subject will be more fully considered presently, when Mr. Pott's remarks on a peculiar mortification of the toes and feet will be introduced.

Bark sometimes occasions purging, and then it also proves inefficacious and hurtful.

This effect, however, may frequently be prevented by adding a few drops of laudanum to each dose.

Bark often disagrees with the stomach; but it less frequently does so, when given in an exceedingly fine powder, which also generally proves most inefficacious. Also the administration of bark with wine, some aromatic water, or in the form of the cold infusion, is less likely to disorder the stomach. (*Richter, Anfangsgr. der Wundarzn. Kap. 3.*)

Several years ago I published a critique on the indiscriminate employment of bark in cases of mortification, and my remarks were inserted in the article *Gangrene* in *Dr. Rees's Cyclopædia*. Many of them were introduced into the 2d edition of this Surgical Dictionary, printed in 1813. (*See Cinchona.*) Since this period, I am happy to find, that the blind enthusiasm with which bark was prescribed is beginning to subside, and that on this subject some eminent surgeons have of late publicly avowed sentiments, which entirely coincide with my former statements. "I think (says Dr. Thomson) I have frequently seen it prove hurtful, when administered in cases of mortification, by loading the stomach of the patient, creating a

dislike to food, and sometimes by exciting an obstinate diarrhoea. *I believe it to be, in mortification, a medicine completely inert and inefficacious.*" (See *Lectures on Inflammation*, p. 563.) By this expression, Professor Thomson does not mean to say that bark can never be useful in cases of mortification, but only that it has no specific power in checking the disorder, as many have erroneously inculcated.

"Bark (says Professor Boyer) has been considered by several distinguished English practitioners, as a true specific against gangrene in general, and especially against that which depends upon an internal cause; but, subsequent observations to those published in England have proved, that it has no power over the immediate cause of gangrene, and that it only acts as a powerful tonic in stopping the progress of the disorder, and promoting the separation of the mortified parts." (See *Traité des Maladies Chir. T. I. p. 151, Paris, 1814.*) Boyer also particularly objects to bark being given while inflammatory fever prevails; but, whenever he prescribes bark in cases of mortification, he seems to entertain the old prejudice of expecting benefit in proportion to the quantity which can be got into the stomach. On the contrary, Mr. Guthrie declares, that he has not found bark useful, "further than as a tonic, and given in such quantities as not to overload the stomach." (*On Gunshot Wounds*, p. 148, Ed. 2.) a plan which I have always recommended. For further observations on bark, the reader is referred to the article *Cinchona*.

The sulphuric acid may frequently be advantageously given at the same time with the bark, and the best method of exhibiting it is to acidulate with it every thing which the patient drinks. Other acids are also sometimes used for the same purpose.

Carbonic acid gas is another remedy of the highest efficacy in cases of chronic mortification. It has even been known to have the most beneficial effects when bark has failed in doing good. Water impregnated with this gas should be recommended, as a most beneficial kind of drink.

"The hospital gangrene is a case for which bark has been much recommended. The best mode of treating this particular case, however, has been detailed in a separate article. (See *Hospital Gangrene*.)

A third indication, which should be observed together with the second, or which should even precede it in many instances, is to lessen the irritability and sufferings of the patient, by the use of opium. Attention to this desideratum frequently contributes more than any thing else to stop the progress of the disorder, and is often indispensable in order to promote the operation of other remedies. In all cases of mortification, every thing which heats, irritates, or adds to the patient's sufferings, appears, in general, to augment the disorder, and increase the rapidity of its progress. On the other hand, every thing which tends to calm, assuage, and relax, frequently retards the

progress of mortification, if it produce no greater good. The pain also, which is a constant mark of too much irritation, contributes of itself to increase such irritation, and, in this double point of view, we cannot do better, in the majority of cases, than endeavour to appease it by the judicious and liberal use of opium. When the inflammatory stage evidently prevails, this medicine may be conjoined with antiphlogistic remedies, such as the nitrate of potassa, antimony, &c. In other instances, attended with debility, it may be given with bark and cordials.

Mr. Pott has described a species of mortification, for which bark is most frequently ineffectual, and opium the remedy which is to be depended upon. It is that particular kind, which, beginning at the extremity of one or more of the small toes, does, in more or less time, pass on to the foot and ankle, and sometimes to a part of the leg, and, in spite of all the aid of physic and surgery, most commonly destroys the patient.

It is very unlike the mortification from inflammation, that from external cold, from ligature, or bandage, or from any known and visible cause, and this as well in its attack as in its progress. In some few instances, it makes its appearance with little or no pain; but, in by much the majority of these cases, the patients feel great uneasiness through the whole foot and joint of the ankle, particularly in the night, even before these parts show any mark of distemper, or before there is any other, than a small discoloured spot on the end of one of the little toes.

It generally makes its first appearance on the inside, or at the extremity of one of the smaller toes, by a small black or blueish spot: from this spot the cuticle is always found to be detached, and the skin under it to be of a dark red colour.

If the patient has lately cut his nails, or corn, it is most frequently, though very unjustly, set to the account of such operation.

In some patients, it is slow and long in passing from toe to toe, and from thence to the foot and ankle; in others, its progress is rapid and horridly painful: it generally begins on the inside of each small toe, before it is visible either on its under or upper part; and when it makes its attack on the foot, the upper part of it first shows its distempered state, by tumefaction, change of colour, and sometimes by vesication; but wherever it is, one of the first marks of it is a separation or detachment of the cuticle.

Each sex is liable to it; but, (says Mr. Pott) "for one female in whom I have met with it, I think I may say, that I have seen it in at least twenty males. I think also that I have much more often found it in the rich and voluptuous, than in the labouring poor; more often in great eaters, than free drinkers. It frequently happens to persons advanced in life, but is by no means peculiar to old age. It is not, in general, preceded or accompanied by apparent distemperature either of the part, or of the habit. I do not

know any particular kind of constitution which is more liable to it than another; but as far as my observation goes, I think that I have most frequently observed it to attack those who have been subject to flying uncertain pains in their feet, which they have called gouty, and but seldom in those who have been accustomed to have the gout regularly and fairly. It has, by some, been supposed to arise from an ossification of vessels: but for this opinion I never could find any foundation but mere conjecture."

In this article I have already stated the observations of Cowper, Dr. Thomson, and Mr. Hodgson upon the ossified state of the arteries in this species of mortification. The facts, recorded by the two latter writers, at least prove, that the opinion is founded, not upon mere conjecture, as Mr. Pott alleges, but upon actual observation and experience.

With respect to the insufficiency of peruvian bark, Mr. Pott observes: "I believe I may venture to say, that I have tried it as fairly, as fully, and as variously as any man has or can; I have given it in the largest quantity, at the shortest intervals, and for the longest possible space; that is, as long as the patient's life would permit: I have given it by itself in decoction, extract, and substance; I have combined all these together; I have joined it with nitre, sal. absynth. with snakeroot, with confect. cardiac. with volatile salts, and with musk, as different circumstances seemed to require, or admit; I have used it as fomentation, as poultice, as dressing; I have assisted it with every thing which has been usually thought capable of procuring or assisting digestion; still the distemper has continued its course, perhaps a little more slowly, but still it has ended in death."

Mr. Pott afterward relates the first cases in which he gave opium. His plan was generally to give one grain every three or four hours; but never less than three or four grains in the course of four and twenty hours. Mr. Pott, however, did not propose opium as an universal infallible specific; but only as a medicine which would cure many cases not to be saved by bark.

The observations of Mr. Pott on the local treatment of these cases are of great practical importance: no part of his writings has a stronger claim to attention.

"I have found (says he) more advantage from frequently soaking the foot and ankle in warm milk, than from any spirituous or aromatic fomentations whatever; that is, I have found the one more capable of alleviating the pain which such patients almost always feel, than the other; which circumstance I regard as a very material one. Pain is always an evil, but, in this particular case, I look upon it as being singularly so. Whatever heats, irritates, stimulates, or gives uneasiness, appears to me always to increase the disorder, and to add to the rapidity of its progress; and, on the contrary, I have always found, that whatever tended merely to calm, to appease, and to relax, at least retarded the mischief, if it did no more.

"The whole plan of the chirurgic treatment of this disease is founded on a general idea of warming, invigorating, stimulating, and resisting putrefaction; and the means generally made use of are very proper for such purpose: but I must own that I think the purpose, or intention, to be improper."

Mr. Pott afterward observes: "Cases exactly similar, in all circumstances, are not to be met with every day, but I am from experience convinced, that of two, as nearly similar as may be, in point of pain, if the one be treated in the usual manner, with a warm, stimulating cataplasm, and the other only with a poultice made of the fine farina seminis lini, in boiling milk or water, mixed with ung. sambuc. or fresh butter, that the pain, and the progress of the distemper, will be much greater and quicker in the former than in the latter.

"When the black or mortified spot has fairly made its appearance on one or more of the toes, it is the general practice to scarify or cut into such altered part with the point of a knife or lancet. If this incision be made merely to learn whether the part be mortified or not, it is altogether unnecessary, the detachment of the cuticle, and the colour of the skin, render that a decided point: if it be not made quite through the eschar, it can serve no purpose at all: if it be made quite through, as there is no confined fluid to give discharge to, it can only serve to convey such medicines as may be applied for the purpose of procuring digestion to parts capable of feeling their influence, and on this account they are supposed to be beneficial, and therefore right.

"When the upper part of the foot begins to part with its cuticle, and to change colour, it is a practice with many to scarify immediately; here, as in the preceding instance, if the scarifications be too superficial, they must be useless; if they be so deep as to cause a slight hemorrhage, and to reach the parts which have not yet lost their sensibility, they must do what indeed they are generally intended to do, that is, give the medicines, which shall be applied, an opportunity of acting on such parts.

"The medicines most frequently made use of for this purpose are, like the theriaca, chosen for this supposed activity; and consist of the warm, pungent oils and balsams, whose action must necessarily be to stimulate and irritate: from these qualities they most frequently excite pain, which, according to my idea of the disease, is diametrically opposite to the proper curative intention; and this I am convinced of from repeated experience.

"The dressings cannot consist of materials which are too soft and lenient; nor are any scarifications necessary for their application. But I would go farther and say, that scarifications are not only useless, but, in my opinion, prejudicial, by exciting pain, the great and chiefly to be dreaded evil in this complaint. The poultice should be also soft, smooth, and unirritating; its intention should be merely to soften and relax;

it should comprehend the whole foot, ankle, and part of the leg; and should always be so moist or greasy as not to be likely to become at all dry or hard, between one dressing and another."

When the toes are, to all appearance, perfectly mortified, and seem so loose as to be capable of being easily taken away, it is, in general, thought right to remove them. But, however loose they may seem, if they be violently twisted off, or the parts, by which they hang, be divided, a very considerable degree of pain will most commonly attend such operation, which therefore had much better be avoided; for Mr. Pott has seen this very pain, thus produced, bring on fresh mischief, and that of the gangrenous kind.

If the patient does well these parts will certainly drop off; if he does not, no good can arise from removing them. (*Pott's Works*.)

In cases, in which the disorder is attended with a great deal of irritation, many subsequent practitioners have attested the efficacy of opium; though it has not always had the same success in their hands, when the mortification depended chiefly on constitutional debility. Dr. Kirkland observes, that we must be careful not to force the doses, especially at first; and that the medicine does more harm than good, when its soporific effects go so far as to occasion delirium, take away the appetite, or cause affections of the heart.

Some authors have also recommended the use of camphor, which, by reason of its narcotic virtue, has sometimes produced good effects. Pouteau attributes considerable efficacy to it, especially in the erysipelatous gangrene arising from wounds. In such cases, he recommends it to be given in the dose of five grains, with a double quantity of nitre, every four hours.

Few surgeons of the present day believe, that opium possesses as much power in the preceding cases, as Mr. Pott represented. While Dr. Thomson allows, that opium is much more entitled to the attention of practitioners than bark, as an useful medicine in the treatment of mortification, yet, "in saying so much in favour of opium, (he observes,) I would not by any means have you to place the same reliance on its powers for stopping, even the mortification of the toes and feet in old people, which appears to have been done by Mr. Pott. From the trials which I have made, and which I have seen made by others, I cannot allow myself to believe, that its powers in stopping this particular sort of mortification are greater, than in stopping any other form, or variety of the disease. It is obvious, however, from Mr. Pott's account, that his mind was strongly impressed with a very different opinion. His opinion seems to me to have been formed from the results of a very small number of cases, and in complete forgetfulness of the invaluable observations of his preceptor Mr. Sharp, with regard to the frequent spontaneous stoppage of mortification in cases

in which no medicines whatever are used." (See *Thomson's Lectures on Inflammation*, p. 568.)

2. With respect to the external, or local treatment of mortification, the first indication consists in removing, if possible, such external causes, as may have occasioned, or kept up the disorder; as the compression of bandages, ligatures, tumours; all irritating substances, &c.

When mortification arises from inflammation, which still prevails in a considerable degree, it is evident, that the dead part itself only claims secondary consideration, and that the principal desideratum is to prevent the mortification from spreading to the living circumference, by lessening the inflammation present. Hence, under such circumstances, the application of linen, wet with the saturnine lotion, and the maintenance of a continued evaporation, from the inflamed parts surrounding the mortified flesh, must be just as proper as if the mortification itself did not exist, and were quite out of all consideration.

It has been justly remarked by an eminent man, (*Hunter*) that the local treatment of mortification, (meaning that in consequence of inflammation) has been as absurd as the constitutional; scarifications have been made down to the living parts, in order that stimulating and antiseptic medicines might be applied to them; such as turpentine, the warmer balsams, and sometimes the essential oils. Warm fomentations have been also applied, as being congenial to life; but, warmth always increases action, and should, therefore, be well adjusted to the case; for, on the other hand, cold debilitates or lessens powers, when carried too far, though it first lessens action. Stimulants are likewise improper, as the actions are already too violent. It is proper to keep the parts cool, and all the applications should be cold. In cases of mortification from inflammation, good effects have also been seen to arise from the topical, as well as internal employment of opium.

But it must be acknowledged, that however proper the employment of cold applications may be in principle, in cases of mortification, attended with inflammation, fomentations and emollient poultices are most commonly preferred in practice.

Besides common poultices, there are several others, which have acquired great celebrity, as topical applications in cases of mortification. Of this kind are the cataplasma carbonis,* cataplasma cerevisiæ,† and the cataplasma effervescens.‡

These local remedies are, perhaps, in nine cases out of ten, superior to all others.

With respect to stimulating and spirituous applications, such as brandy, spirit of wine,

* Prepared by mixing about oz. ij. of finely powdered wood-charcoal with half a pound of the common linseed poultice.

† Prepared by stirring into the grounds of strong beer as much oatmeal, as will make the mass of a suitable consistence.

‡ Prepared by stirring into an infusion of malt as much oatmeal, as will render the substance of a proper thickness, and then adding about a spoonful of yeast.

balsams, resins, and aromatic substances, which have been recommended by a vast number of authors, they are almost entirely laid aside by modern practitioners. Though such things are indeed really very useful in preserving dead animal substances from becoming putrid, a very little knowledge of the animal economy is requisite to make us understand, that they cannot act in this manner on parts still endued with vitality; but, on the contrary, that they must have highly prejudicial effects, in the cases under consideration, by reason of the violent irritation which they always excite, when applied to the living fibres. It may now and then, however, be justifiable to apply spirituous applications to the dead parts themselves with a view of diminishing the fetid effluvia, which, by contaminating the air, have some share in injuring the patient's health; but the greatest care is requisite to keep these stimulants from coming into contact with the living surfaces around and beneath the sloughs.

There are a few surgeons, however, who still place confidence in certain stimulating applications. "In the less acute and more chronic cases of gangrenous inflammation, as in malignant erysipelas and carbuncle, in the gangrene of the toes and feet of old people, in the sphacelating state of hospital gangrene, and in severely contused wounds, in which gangrene and sphacelus have supervened, the emollient poultice, which is applied to promote the separation of the dead parts, may have an addition made to it of a greater or less quantity of the unguentum resinosum, or even of oil of turpentine itself. In the more severe of these cases, where we have reason to dread the extension of the sphacelus, warm dressings, as they have been termed, which are formed by dipping pledgets of charpie in a mixture of equal parts of the unguentum resinosum and oil of turpentine, may be applied, of a temperature as hot as the patient can bear without pain; and over these we may lay an emollient poultice, of a large size and soft consistence.

"After the sphacelus stops, and the process of ulceration begins in the inflamed line of contact, between the dead and living parts, it will often be found, that the turpentine dressings are too stimulating, and occasion a considerable degree of pain. When this happens, we must either diminish the quantity of the turpentine in the dressings, or remove it altogether, according to circumstances. Besides the pain, a considerable extension of the ulceration would be, in general, the effect of continuing these applications after they begin to produce uneasiness. The ulcerating surface is, in the progress of separation, liable to pass under every mode of treatment, into the state of a painful and irritable ulcer; and in this state, it may require to be treated with decoctions of poppy-heads, or with the application of the turnip, carrot, fresh hemlock leaf, stale beer, fermenting, poultices, &c." (See *Thomson's Lectures*, p. 577, 578.)

The hospital gangrene is undoubtedly a

case, which requires powerful applications, like Fowler's solution of arsenic, or the undiluted mineral acids; and, in Guy's Hospital, phagedenic sloughing ulcers are usually treated by Sir A. Cooper with the nitric acid lotion, 50 drops to a quart of water, and the internal exhibition of the subcarbonate of ammonia. The cases also termed sloughing phagedæna by Mr. Welbank, and considered by him as analogous to hospital gangrene, may be cured by dressing them with the undiluted nitric acid. (See *Med. Chir. Trans.* Vol. 11.) I conceive, that it has only been in hospital gangrene, and other cases of sloughing phagedenic ulcers, that various acids, diluted, or undiluted, other caustic substances, and the actual cautery, have sometimes proved really serviceable. The muriatic acid, diluted with six times its quantity of water, was particularly recommended by Van Swieten, who applied it after making scarifications. In this manner, he stopped a sloughing disease extending all over the scrotum and penis. This author strongly recommends the same topical application to the sloughy state of the gums in cases of scurvy. In this kind of case, he mixed the muriatic acid with honey, in various proportions; sometimes, he even employed the pure acid itself for touching the parts, which were likely to slough. It is also by supposing, that the diseases referred to, were of a phagedenic character, that I account for the good effects, imputed by Dr. Kirkland and others, in cases of mortification, to another still more active caustic, namely, a solution of mercury in nitrous acid, with which the edges of the living flesh were touched. At all events, if the diseases were common cases of sloughing, I infer, that such remedies were not really necessary, and that nature triumphed both over the disease and the supposed remedy. The following is a case related by Dr. Kirkland:

A man met with a fracture of the forearm, and the ends of the bones projected through the integuments. The fracture was very expeditiously reduced; but, at the end of five or six days, the whole arm seemed to be completely mortified up to the shoulder. Amputation was performed as near the joint as possible, and the stump, which had mortified as far as the acromion, was cauterized. The following day the mortification had reached the inferior extremity of the scapula. A little of the solution of mercury in nitrous acid was now applied, by means of a probe, along the edges of the parts affected, and from this moment the disorder made no further progress. This cauterizing was repeated every day, for seven teen or eighteen days. The sloughs, and even the scapula itself, were detached, and the patient got well.

On the continent, liquid caustics are sometimes used as topical applications to gangrenous diseases, more especially, however, in cases of hospital gangrene, and malignant carbuncle. Of this last disorder, Larrey has recorded a very dangerous example, in which he effected a cure by first cutting

away as much of the sloughs as possible, and then applying to the disorganized surface underneath liquid caustics. Under the use of emollients, two persons had already fallen victims to the disease in the same family. (See *Mémoires de Chirurgie Militaire*, Tom. 1, p. 53.)

With respect to the actual cautery, Celsus recommended it to be applied to the line, which separates the dead parts from those which are still living, whenever medicines, and, particularly, topical emollient applications, failed in stopping the progress of the disorder. Pouteau ventured to revive this practice, which had been entirely exploded from modern surgery, and he was of opinion, that the method would have the most beneficial effects, in cases of erysipelatous gangrene, which is so often seen in hospitals, in consequence of wounds. For this purpose, he recommends cauterizing chiefly the edges of such parts, as are of a dark red colour, and are on the point of perishing; and he advises this to be done with a heated iron, or boiling oil, and to repeat the cauterizing of the dead parts, at every time of dressing them, until the sensation of heat is even felt with a certain degree of force in the sound parts. The whole of the affected part is afterward to be covered with a large emollient poultice.

Pouteau relates a case of anthrax, which took place on a woman's cheek, and which he cured in the above manner. The tumour, which, on the third day, was quite black, and as large as a walnut, was accompanied by an erysipelatous œdema, which extended over the whole cheek, eyelids, and front of the neck. Pouteau, after having opened the tumour in different directions with a lancet, introduced the red hot cautery, and repeated the application several times, until the heat was felt by the sound flesh. The patient felt herself very much relieved immediately after this had been done; an oppressive headach, and a very afflicting sense of strangulation, which she had before experienced, were got rid of, and, in ten days more, the slough was detached on the occurrence of suppuration. (*Encyclopédie Méthodique, Partie Chirurgicale, Art. Gangrene.*)

But perhaps, of all the species of mortification, the hospital gangrene is that, for which the use of caustics and the actual cautery itself, has had the most numerous and respectable advocates. The heated iron is even now employed by the first surgeons of Paris for this particular case. (See *Sketches of the Medical Schools of Paris*, by J. Cross, p. 84, and *Hospital Gangrene*.)

The foregoing observations are introduced into this work, that the reader may not be left entirely ignorant of what violent measures have been adopted in cases of mortification, and the account is not given, in order that such practice may be again imitated, with the exception perhaps of certain cases of phagedœna and hospital gangrene, cases, in which the most powerful local applications seem indispensable. See *Hos-*

pital Gangrene, and *Nitric Acid*.) The common employment of these terrible applications, viz. the actual cautery, the undiluted mineral acids, and boiling oils, is as unscientific, and unnecessarily painful, as it is unproductive of any essential good. The grand object in almost every case of mortification, is to diminish the irritation of the parts in immediate contact with those already dead. This is indicated, lest the parts still alive, and so situated, should experience the same fate as the contiguous ones. In most of the other cases specified by Dr. Thomson, my experience leads me to prefer emollient soothing applications, none of which are stronger than the cataplasma carbonis, or the stale beer, fermenting, hemlock, or carrot poultices. When the process, by which a slough is detached, is somewhat advanced, I have seen a weak solution of the extract of opium in water put under the emollient poultice, along the line of separation, give considerable ease, at the same time that it seemed to promote the changes, by which the dead parts were loosened.

In the gangrene produced by pressure and weakness in persons, who are compelled by diseases and injuries to lie for weeks and months in one posture, the mode of treatment is a matter of extreme importance, and frequently makes the difference of life or death to the poor sufferer. This affection usually has its seat in parts which are but thinly covered with muscular flesh. It occurs towards the latter stages of long-continued febrile diseases, as after typhus, or hectic fever, attended with tedious suppurations; or even without these fevers, as in paralysis, and in very bad compound fractures. However, as Dr. Thomson observes, there are two forms of disease, arising from pressure, which have not always been accurately discriminated. One of these is the preceding sort of sloughing; the other is a chafed, excoriated, and ulcerated state of the parts.

Sometimes uncleanness tends to cause this sort of mortification, that is, when the urine wets the patient's clothes. When this is the case, such irritation must be prevented by every possible means. If the skin be excoriated and broken, the powder of tuffy, or lapis calaminaris, should be sprinkled over the part; or if an ointment be required, says Dr. Thomson, those which contain zinc or lead are the best. But, when the ulceration threatens to extend, these remedies are to be laid aside, and an emollient, hemlock, carrot, or fermenting poultice used. (P. 580.) I have seen in the irritable state of such ulceration, the solution of opium under a common linseed poultice do more good than any other application.

But no topical remedies will in any of these cases avail, unless the chief cause of the disorder be removed. This is to be effected by change of position, and laying pillows and cushions of the softest materials in convenient places under the patient; not directly under the disease itself, but in situations where they will tend to raise the

parts affected from the contact of the bedding. A circular hollow pillow will often accomplish this important object; but, when possible, an entire change of posture is to be preferred.

When sphacelus succeeds to gangrene from pressure, I have often seen camphorated spirit applied; but never with decided advantage. A common emollient poultice, and in very bad cases, the topical use of the solution of opium along the living margin, are the means upon which I place most reliance, care being taken to improve the general health, without which grand indication, neither the removal of the pressure, nor the virtues of any dressings, will answer. Dr. Thomson speaks most highly of the fermenting poultice, which I believe to be in these cases an excellent application. He confesses, however, that he has sometimes found it too stimulating, and been obliged to substitute the simple emollient, carrot, or turnip poultice. (P. 580.)

When mortification arises from cold, every sort of warm emollient application must be avoided, and cold water, or even snow, or ice, employed. See *Chilblains*.

The local treatment of the mortification of the toes and feet, as described by Mr. Pott, has been already considered, and is that to which my observations incline me to give the preference.

The gangrenous affection of the pudenda, to which female children are liable, was successfully treated by Mr. K. Wood by applying the liquor plumbi acet. dilutus in a tepid state, and bread poultices made with the same lotion. As soon as the ulcers became clean, they were dressed with the unguentum zinci. (See *Med. Chir. Trans. Vol. 7*.) Other cases, which also ended well, have been dressed with lint, dipped in camphorated spirit, and covered with a poultice; or, at first, poultices made with the opium lotion, and after the separation of the sloughs, the ulcer was dressed with port wine and decoction of bark in equal proportions. In some cases, however, mild stimuli proved injurious. (*James on Inflammation*, p. 289.)

The old practitioners used to give vent to putrid matter, by making deep scarifications in the integuments. The majority of authors who have treated of mortification have very much insisted upon this plan, which they recommend in all cases. They even advise the incisions to be made down to the sound parts, in order to facilitate the application of topical stimulants, and to favour the operation of the supposed antiseptic qualities of these dressings. But, with the exception of cases, in which the gangrenous parts lie under an aponeurosis, or others in which the integuments, which have escaped destruction, cover a mixture of matter and sloughy cellular substance, either in consequence of foregoing inflammation, or any other cause, such as the extravasation of urine in the scrotum, all scarifications which penetrate as far as the living parts, are often productive of the most serious mischief, instead of

advantage. Such incisions cannot be practised, without occasioning a great deal of pain, and producing inflammation, which often makes the mortification spread still further. But, as parts, which are in a complete state of sphacelus, are absolutely extraneous substances, in regard to those which still retain their vitality, all such portion of them as is already loose should be removed. By lessening the size of the putrid mass, the fetor is diminished, an outlet may sometimes be made for the escape of a great deal of putrid discharge, which, being confined, might have a bad effect on the neighbouring living parts; and the latter are enabled to free themselves more easily from the rest of the sloughs.

The too common practice of accelerating, with a cutting instrument, the separation of the mortified parts, previously to the completion of the process, by which nature breaks the connexion between them and the living flesh, in general ought to be strongly reprobated, as causing unnecessary pain, and irritation, and creating the risk of a renewal of the sloughing. As far as my experience goes, gangrenous phagedæna is the only instance, in which it seems useful to remove the sloughs, before they are loose, so as to let the topical applications extend their action without delay to the subjacent living surface. (See *Hospital Gangrene*.) Pott's sentiments, with respect to the danger and inutility of cutting the tendons and ligaments, in the mortification of the toes and feet, have been already stated.

If the surgeon prudently await the event of things, the separation of the mortified from the living parts will soon follow the establishment of inflammation and suppuration at the edges of the slough.

But when the whole thickness of a limb is affected with mortification, ought the surgeon to leave things to nature? or ought he to have recourse to amputation?

In general, the performance of amputation is indispensable; not that nature would not in many instances detach the sphacelated part; but, because a great length of time would be required for the completion of the process, and a serviceable stump would rarely be left.

Another important question then arises, Should the surgeon amputate, while the mortification is in a spreading state? Or ought he to defer the operation, until a line of separation begins to form between the dead and living parts?

“Amputation (says a distinguished professor) was long regarded as one of the most effectual means which could be employed to prevent the extension of gangrene. This practice, however, has not received the sanction of experience; on the contrary, it has been generally found, wherever it has been practised, in either acute or chronic gangrene, to accelerate much the progress of the disease; and, in this way, to hasten the death of the patient. The parts, which were divided in amputation, though at a distance from a spreading gangrene and from sphace-

lus, were found speedily to assume the appearance of the affection, for which the operation had been performed. *Till, therefore, the adhesive inflammation comes on, and a distinctly marked separation of the dead from the sound parts takes place, amputation is, in few, if any cases of mortification, admissible.* We never know, previously to this, where a gangrene, or sphacelus, is to stop, nor whether the powers of the constitution be sufficient to sustain the injury that the mortification has inflicted. Even when the adhesive inflammation comes on, it is in most cases best to allow some time to elapse before we operate, partly with a view to give time for the constitutional symptoms to abate, in other instances, to allow the patient's strength to be recruited by nourishment and cordials; and partly also with a view to learn whether the constitution of the patient be indeed capable of so great a fresh shock, as that which amputation must necessarily occasion." (See Thomson's Lectures, p. 582.)

According to Richter, there is never any certainty, that we are amputating in living parts. Mortification rapidly ascends along the cellular substance, surrounding the large blood-vessels, and is frequently much more extensive internally, than external appearances would lead one to suppose. The adjacent surface, still apparently alive, is often so affected, that it must inevitably slough, though, at present, it may not actually have sphacelated. The surgeon imagines, that amputation is performed on living parts; but, soon afterward discovers, that he has been dividing those which are dead. The operation, he observes, can do no good, while the mortification is in a spreading state, and it may do considerable mischief. The disorder enlarges its limits, because its cause still operates, and this is not removable by amputation. If the operation be now injudiciously undertaken, the sphacelus invades the wound, and is the more certainly mortal, as the patient has been further weakened by amputation, and its consequences.

Many mortifications, especially those which arise from external causes, very often spontaneously stop and separate. But the place where this will happen, can never be foreseen. By amputating in this circumstance, we run a risk of disturbing nature in her salutary work, and rendering the disorder fatal.

The following are the only cases, in which Richter allows that the use of the knife is justifiable and proper. There exists a species of sphacelus, which rapidly occasions death, before it is yet of great extent. Here indeed, amputation might be really advisable; but, the nature of the case is unfortunately never disclosed, before the fatal catastrophe. Some external injuries would be, without the operation, inevitably followed by mortification. In such cases, early amputation is evidently proper; for, the simple incision is attended with less danger than sphacelus. Sometimes, says Richter, a sphacelus spontaneously ceases to spread. This happens most frequently in cases which originate from an external cause, such as a

violent contusion, burn, &c. But, the occurrence is not restricted to this kind of case, nor is it invariably attendant on it. When there are no other occasional causes present, the mortification does not readily go beyond the limits of the contusion, or violent burn; but the interference of surgery can hardly ever put a stop to its progress, before it has spread as far as the extent of the local injury. (*Anfangsgrunde der Wundarzneykunst, Band. 1, Kap. 3.*)

How different are the doctrines of Baron Larrey upon this subject from those entertained by Richter, and, indeed, the generality of eminent modern surgeons. "Writers on gangrene, or sphacelus of the extremities, (says Larrey) indiscriminately recommend the amputation of a sphacelated limb never to be undertaken before the mortification is bounded or limited by a reddish circle, forming a true line of separation between the dead and living parts. This circumstance can only occur in a case of spontaneous gangrene from an internal cause; or if it happens, as is very unusual, in a case arising from a wound, its progress is different, and it would be exceedingly imprudent to wait for it. *The gangrene from external injuries almost always continues to spread; the infection becomes general; and the patient dies.*" (*Mém de Chirurgie Militaire, T. 3, p. 142.*) Respecting the want of foundation for this hypothesis of infection, I need here offer no remarks, having already expressed my opinion upon it in a foregoing page. On the other hand, Larrey asserts, that, in the dry, or spontaneous gangrene, absorption takes place with more difficulty, and it is not uncommon to see the sphacelated parts separate from the living ones by the powers of nature alone, without the general functions being impaired. He argues that there is a manifest difference between what he terms the *traumatic* and the *spontaneous* gangrene, or, in other words, between the *humid* gangrene from an external cause, and the *dry* gangrene, which ordinarily proceeds from an internal cause. (P. 148.)

In cases of mortification, arising from external injuries, Larrey maintains, that, "notwithstanding any thing that writers and practitioners may allege to the contrary, we should not hesitate about promptly performing amputation, as soon as the necessity for the operation is decidedly established. There is no reason to apprehend, that the stump will be seized with gangrene, as in the spontaneous mortification, which has not ceased to spread, *because the traumatic gangrene, after having arisen from a local cause, is only propagated by absorption, and a successive affection of the texture of parts by continuity of the vessels.* Amputation, performed in a proper situation, stops the progress and fatal consequences of the disorder.

"Supposing then the lower half of the leg should be affected with sphacelus, in consequence of a gunshot injury, attended with a violent contusion of the part, and a forcible concussion of the vessels, nerves, and ligaments, if the skin is elsewhere unin-

jured, the operation may be done in the place of election, without any fear of the stump becoming gangrenous, notwithstanding the cellular membrane of the upper part of the member may be already affected. But, when the skin of the whole leg is struck with mortification, the operation must be done on the thigh, and no time should be lost. The same practice is applicable to the upper extremities. We must be careful not to mistake a limb affected with stupor for one that is actually sphacelated. In the first case, warmth, motion, and sensibility are still retained, although the skin may be blackish and the parts may be swollen. Besides, if there were any doubt, it would be proper to try at first tonic repellent applications, and cordial medicines, &c." (See *Mém de Chirurgie Militaire*, T. 3, p. 152, 153.)

When amputation has been practised, this author recommends the exhibition of bark, good wine, tonics, &c. in order to promote the good effects of the operation. (P. 154.)

"The facts (says Larrey) which I shall relate in the course of this dissertation, will prove, I think, in an incontestable manner, the truth of the principle which I lay down, that *when gangrene is the result of a mechanical cause, and puts the patient's life in danger, amputation ought to be performed, without waiting until the disorder has ceased to spread.*

"I have been a witness of the death of several individuals, from too rigorous an adherence to the contrary precept; and, at length, grievously impressed with this loss, I had long ago determined to depart from an axiom, which was always considered by me as false. Besides, following the maxim of Celsus, I preferred employing an uncertain remedy, rather than abandon the patient to an inevitable death. *Satius est enim anceps auxilium experiri quàm nullum.*

"I made the first attempt at Toulon, in the year 1796, upon a soldier, who, in consequence of a violent contusion of the foot, was afflicted with a gangrenous ulcer, which soon threw the whole part into a sphacelated state. While the mortification was yet spreading, I resolved to amputate the leg. The success of the operation surpassed my expectations; the stump healed; and, in less than forty-five days, the patient got quite well. This case served to encourage me.

"During the siege of Alexandria, in Egypt, in 1801, a second case, very analogous to the preceding, occurred in my practice; it happened in a dragoon of the 18th regiment, whose fore-arm and afterward arm sphacelated, in consequence of a gunshot wound in the articulation of the left arm. The mortification had extended nearly as high as the shoulder, and the patient's life was in great danger, when I determined to amputate the limb at the shoulder-joint. The disorder was manifestly spreading, and the patient's brain already affected, for he had symptoms of ataxia; the operation, however, arrested the progress of the sloughing, and saved the

patient's life, who, at the conclusion of the siege of Alexandria, was quite cured.

"After the taking of Ulm, M. Ivan, surgeon to his majesty the Emperor, performed in my presence, and at my ambulance established at Elchingen, the amputation of the thigh of a soldier belonging to the 76th regiment of the line, the leg having sphacelated in consequence of a gunshot injury. The gangrene was not limited, and evidently extending itself; yet, the effects of the disorder were destroyed, and the patient was quite cured on our return to Austerlitz.

"A fourth patient, an officer in the same regiment, shot in the ankle, at the capture of the same town, was conveyed to my ambulance, in order to be dressed: it was the third day after the accident; the foot was gangrenous, and the leg was swelled, and threatened likewise with mortification. Febrile symptoms had also come on. I hastened to amputate the leg a little above the place of election. The cellular membrane of the stump, of a yellow blackish colour, was already infected with the gangrenous principle (as Larrey terms it.) The operation, however, stopped the progress of the mischief; suppuration took place in the stump; some sloughs were detached; and wound assumed a cleaner appearance; and cicatrization was completed on the fifty-second day. The patient could already walk with a wooden leg, when he caught the hospital fever, which was epidemic at Ulm, where he awaited his regiment, and, to my great regret, he was carried off by this disease, after having escaped the former danger.

"After the battles of Austerlitz and Jena, (continues Larrey,) several of my colleagues, surgeons of the first class, undertook, in consequence of my advice, and the examples of success which I had recited to them, the amputation of limbs equally sphacelated, although the mortification was not limited, rather than abandon the patient to a death, which appeared inevitable. In general, these practitioners experienced the same success as I did myself." (Larrey, in *Mém. de Chirurgie Militaire*, T. 3, p. 154—157.)

In Larrey's memoir upon this subject, there are some additional facts and arguments in favour of what he endeavours to prove, viz. that, in cases of mortification from external injuries, if the patient's life is in danger, amputation ought to be performed, although the sloughing may yet be in a spreading state. I must be content, however, with having stated the particulars already explained; and the reader, desirous of more, must refer to Larrey's own publication. Certainly, the facts, which this gentleman has adduced, are highly important: they tend to subvert a doctrine, and to prove the error of a practice, which have been urged in most forcible terms by most of the distinguished surgeons of modern times. The sentiments of Mr. Sharp are rendered questionable; and the truth of the positive assertion of Mr. Pott is yet a matter to be examined. The latter, it is well known, tells us, that he

has often seen the experiment made of amputating, while a mortification was spreading, but never knew it answer. Are we to conclude, that all these cases, which Pott alludes to, were mortifications from an internal cause? Or, are we to suppose that the operation failed from having been delayed too long? Or, must we imagine, that the nature of the human constitution has been changed between the era of Pott, and that of Larrey?

It should be remarked, that the practice of amputation, in cases of spreading mortification, has generally had some partisans for many years past; but the weight of authorities has unquestionably been against it, and few surgeons in this country have ventured to deviate from the advice of Sharp and Pott. It is curious, however, that Mehee, a writer who wrote for the express purpose of declaring his disapprobation of the early performance of amputation in gunshot wounds, should have admitted of only one case, in which the operation is proper, namely, *gangrene succeeding the wound made by a cannonshot*. Here he thinks, that amputation ought to be performed on the first appearance of the gangrene, in order to prevent it from spreading up the limb. (See *Traité des Plaies d'Armes à feu*, Paris, 1799.) It appears, that about the year 1809 Mr. A. C. Hutchison performed with success two amputations in cases of spreading gangrene from gunshot wounds. (See *Practical Observations on Surgery*, p. 72.)

My friend Mr. Lawrence has also successfully amputated at the shoulder joint in a spreading mortification of the arm, the consequence of external violence. "The skin of the amputated limb was greenish and livid; but the cuticle not yet detached. The cellular substance distended with air, and with a discoloured offensive sanies; its appearance was not quite natural, where the incision took place; it was yellowish and anasarcaous. Small effusions of blood were observed here and there in the course of the nerves; even as high as the amputated part. No coagulation of blood in any of the arteries, even down to the ulnar and digital branches. All the soft parts were discoloured, dark red, and livid, and a frothy reddish fluid issued on incision." This case had the most favourable termination, and it clearly proves, that the *humid* kind of gangrene, which occurs in a healthy subject from severe local injury, which so rapidly affects a whole limb, and reaches the trunk in a few hours, must constitute an exception to the general maxim, that amputation should never be done, before a line of separation is established between the dead and living parts. Mr. Lawrence, however, would not be understood as meaning to recommend the practice in all instances of mortification from local injury. He conceives, that a gangrene may arise, in an unsound constitution, from a comparatively slight accident; so that it may be regarded as the result of constitutional disposition, rather than of the local cause. Amputation would be hopeless

under such circumstances. It is particularly in mortification, following very severe injury, in a subject otherwise healthy, that Mr. Lawrence believes the operation to be proper. (See *Medico-Chir. Trans.* Vol. 6, p. 184.)

Mr. Lawrence also reports another instance, in which he saw the operation succeed, though the mortification was in a spreading state. About three years ago, I was asked my opinion about the propriety of amputating at the shoulder in a spreading mortification of the arm from external violence. The operation was done, and the patient lived a fortnight afterward, which is favourable to the practice, inasmuch as he would certainly have perished in a few hours, if the operation had not been done.

Among the experienced approvers of Larrey's advice, I must not omit to mention Dr. Hennen, who has repeatedly amputated, under the circumstances above pointed out, without waiting for the line of separation; "and (says he) although I certainly was not uniformly successful, I have no reason to imagine, that death was occasioned by a departure from the rule so generally laid down by authors." (*On Military Surgery*, p. 243, Ed. 2.)

With regard to the early performance of amputation, where the substance of a limb perishes after exposure to cold, I find some difference of sentiment between two very high authorities. Thus Schmucker observes: "The mortification, which comes on after a part has been frozen, increases so rapidly, if the limb be exposed to warmth, that, in the space of twenty-four hours, its vitality and organization are quite destroyed, and nothing will now avail in restoring its sensibility. Here the speedy performance of amputation is the only means of preservation to be depended upon. In mortification from an internal cause, the case is different." (See *Vermischte Chirurgische Schriften*, B. 1, p. 15, 8vo. Berlin, 1785.) According to Larrey, however, this species of gangrene at length stops, and a line of separation forms between the dead and healthy parts. If the disorder be superficial, the sloughs are usually thrown off between the ninth and thirteenth days, leaving an ulcer of proportionate extent, that soon heals up. If the whole of the limb be sphacelated, nature cannot of herself effect a cure, or but very rarely, the patient mostly falling a victim to the effects of absorption, when the sloughs are detached, and the mouths of the lymphatics are opened on the occurrence of suppuration. Larrey assures us that he has seen numerous patients carried off by this cause, while the examples of a spontaneous cure were exceedingly few, and, in these, the stump was left irregular, and unfit for bearing the pressure of a wooden leg. He agrees, therefore, with the generality of surgeons, that it is in these instances advantageous to amputate the mortified portion of the limb, but not before the extension of the gangrene has ceased, and the mischief is

dounded by an inflammatory line. (See *Mem. de Chir. Mil. T. 3, p. 65—72.*)

In the article *amputation*, notice has been taken of a sloughing, which commences in the foot, and extends up the leg, and sometimes follows gunshot injuries of the thigh, which involve the femoral artery: this is a case particularly instanced by Mr. Guthrie, as requiring the very early performance of amputation. Sir Astley Cooper also refers to cases, in which the rule was successfully deviated from, of not amputating, before limits are set to the spreading of mortification; the instances in question arose from injury of blood-vessels, and other local violence, in patients of a healthy constitution. In such cases, it is admitted by this very experienced surgeon, that the practice should be different from what is usually pursued in mortification from constitutional causes. MOXA. A soft lanuginous substance prepared from the young leaves of a species of mugwort. It is used in the following way: A little cone of the moxa is laid upon the part, previously moistened, and set on fire at the top. It burns down with a temperate glowing heat, and produces a dark-coloured spot, the separation of which is promoted by applying a little garlic. The ulcer is left to discharge, or is healed up according to the object in view. The moxa is famous in the East for curing several diseases; and the French are much in the habit of using it; but, when English surgeons wish to produce a slough, they generally have recourse to caustics, in preference to actual fire.

M. Roux, when he visited the London hospitals, had two opportunities afforded him of applying the moxa, in order to convince the rising generation of surgeons in this country of its superior efficacy. The first was in a case of spontaneous paralysis of the deltoid muscle at St. Bartholomew's. The moxa was applied a little below the acromion, and a few days afterward the motion of the arm began to be restored. This, however, was a case, which, according to the account of Roux himself, had relapsed, after having been cured by other means. I think one of the surgeons of St. Bartholomew's informed me, that notwithstanding the moxa, the relief proved again only temporary. If, however, the moxa had succeeded, a caustic issue, a blister, or volatile liniments, would probably have answered equally well. The second instance, in which M. Roux applied the moxa, was a case of white swelling at Guy's Hospital; but the disease had advanced too far to allow any hope of a favourable issue. (See *Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Française*, p. 19, 20.) M. Roux flatters himself that, "*les chirurgiens Anglois répugneront sans doute moins à l'avenir à faire usage du moxa.*" The truth is, English surgeons, as well as English farriers, knew very well before the arrival of M. Roux what might be done with moxa and the actual cautery. But, though the application of fire still pre-

vails in the veterinary art, as a mode of curing diseases, it has long been abandoned as a means of relief in the English practice of surgery: not on the ground of its being always ineffectual; but, because equal good has been found to result from measures, which are milder, always less terrific, and frequently less painful. In order to convince an English surgeon that moxa and the actual cautery ought to be introduced into practice, M. Roux should prove, that there is at least some particular disease, which may in this manner be cured, but which cannot be cured by other means, ordinarily employed in our practice. He should also make us forget, that the application of actual fire was once as common in English surgery as in French; but that it had not attractions enough to maintain its ground.

MURIATIC ACID. *Acidum Muriaticum.* Gargles, containing this acid, are often made use of with advantage in various cases of sore throat, and the disease known by the name of cancrum oris. The following formula is employed at St. Bartholomew's Hospital. *R. Rosæ rubræ exsiccatae ʒij. Aquæ ferventis ℥j. Infunde per horam dimidiam, dein cola et adde Accidi muriatici ʒj. Mellis Rosæ ʒij. Sacchari purificati ʒvj. Misce.*

Muriatic acid appears to have been tried in syphilis earlier than the nitric, Dr. Zeller, of Vienna, having employed it as a successful remedy for this disease ever since the year 1789. (*Vid. Sim. Zeller's Prakt. Bemerk. über den vorzögl. Nutzen d. allerem. bekannt. Badeschwamms, &c. Nebst. einem Anhange v. d. Salzsäure, &c. Wien. 1797.*)

As a medicine capable of improving the appearance of venereal ulcers, and of restraining for a time the progress of the disease, it has been known to Mr. Pearson many years. He says, that he was first induced to give this acid in venereal ulcers of the tongue, and of the throat, in consequence of the great benefit which he had seen result from its use in examples of cancrum oris: and without viewing it as an antidote for lues venerea, he has frequently availed himself of its useful qualities, when it was desirable to gain a little time previously to the commencement of a mercurial course. (*Obs. on the Effects of Various Articles in the Cure of Lues Venerea, p. 193, Ed. 2.*) From what he saw, however, he never inferred that the sulphuric and muriatic acids could radically cure the venereal disease; and he ascribed the benefit derived from them partly to their salutary effects on the stomach and constitution, and partly to their agency on ulcers of the throat and tongue, as local applications. (*P. 117.*) When Mr. Pearson made these observations, the fact, which has now been so unequivocally demonstrated in the army hospitals, that nearly, if not all, the forms of disease, going under the name of syphilis, may be cured without mercury, had not undergone the strict and impartial investigations which have of late years been devoted to the subject. (See particularly *Obs. on the Treatment of Syphilis, with an account of several cases of that*

disease, in which a cure was effected without the use of Mercury, by T. Rose, in *Medico-Chir. Trans. Vol. 8, p. 349.*) If this point be admitted as fully established, the question about the antisyphilitic virtues of various articles of the materia medica requires to be taken up in a very different light, not clouded with a notion that the disease will certainly get worse and worse, if no remedy whatever be exhibited, or that it cannot finally get well of itself. While these doctrines prevailed, the amendment of any syphilitic affection during the use of muriatic, or any other acid, was entirely referred to some specific effect, supposed to appertain to such medicine. But now the question involves several considerations; first, the actual virtue of the medicine in expediting the cure of the disease; secondly, the changes which might happen if the complaint were left to itself; and thirdly, the benefit sometimes ascribable to the improvement produced in the constitution, under particular circumstances, by the discontinuance of mercury. The latter mineral no longer claims the name of a specific for the venereal disease, either in the sense of the only, or a completely certain, antidote; because nature herself would in time bring most cases to a favourable conclusion; because the cure can be completed by a variety of other medicines, noticed in this publication; and, lastly, because mercury, though it may be generally the quickest means of cure, is, in particular cases, complicated with much debility and constitutional irritability, the surest medicine for aggravating the complaint, and preventing any progress towards a favourable termination. Here it is enough to know, (and Mr. Pearson himself acknowledges the fact) that in the circumstances above specified, muriatic acid is a safer medicine than mercury. The dose is from ten to twenty drops, which are to be mixed with a proper quantity of water.

Muriatic acid has sometimes been employed as the active ingredient in injections for the cure of gonorrhœa, in the proportion of eight or ten drops to four ounces of distilled water.

In cases of poison from muriatic acid, the experiments made by Orfila lead him to consider calcined magnesia and prepared soap the most fit substances for neutralizing such portion of the acid as may not yet be combined with the texture of the œsophagus, stomach, &c. They should be given as soon as possible after the corrosive poison has been swallowed, care being taken to let the patient drink copiously of warm water, milk, broth, or some mucilaginous diluting liquid. When, from the symptoms, there is reason to believe that inflammation exists in the viscera, or when spasms and convulsions come on, antiphlogistic remedies, and antispasmodics, are indicated. (*Traité des Poisons, p. 476, Vol. 1, Ed. 2, Paris, 1818.*) In order to detect the presence of muriatic acid, when mixed with wine or other fluids, we are recommended to distil a portion of it from a small retort, over a candle, into a

phial containing a solution of nitrate of silver. The precipitation of muriate of silver, which is soluble in ammonia, but not in nitric acid, will take place if the poison contain muriatic acid. (*Thomson's Dispensatory*, p. 434, Ed. 2.)

By Morveau, who employed himself in investigating the merits of Dr. Carmichael Smith's mode of destroying infection, the muriatic acid, in the new form of gas, was alleged to have the very important quality of neutralizing putrid miasmata. The gas

is extricated from common salt by means of sulphuric acid. In this way it is often employed in hospitals as a mode of preventing and obviating infection.

The use of muriatic acid, as an application to certain cases of sloughing, and phagedæna, has been explained in the articles *Hospital Gangrene* and *Mortification*.

MYDRIASIS. (from *μῑδαν*, to abound in moisture.) A preternatural dilatation of the pupil.

N.

NÆVUS. (*Congenitæ Notæ*; *Envies*; *Mutter-mahl*; *Mother-spots*, &c.) A mole, or congenital mark, or excrescence of the skin. Nævi materni signify the little spots, excrescences, or swellings, with which many children are born. Some of them (says Dr. Bateman) are merely superficial, or stain-like spots, and appear to consist of a partial thickening of the rete mucosum, sometimes of a yellow, or yellowish brown, sometimes of a bluish, livid, or nearly black colour. To these the term *spilus* has been more particularly appropriated. Others again exhibit various degrees of thickening, elevation, and altered structure of the skin itself, and consist of clusters of enlarged and contorted veins, freely anastomosing, and forming little sacs of blood. These are sometimes spread more or less extensively over the surface, occasionally covering even the whole of an extremity, or one half of the trunk of the body; and sometimes they are elevated into prominences of various form and magnitude. Occasionally, these marks are nearly of the usual colour of the skin; but most commonly they are of a purplish red colour, of varying degrees of intensity; such as the presence of a considerable collection of blood-vessels, situated near the surface, and covered with a thin cuticle, naturally occasions. (See *Bateman's Practical Synopsis of Cutaneous Diseases*, p. 324, Edit. 4.) When a nævus is of a dark red colour, its intensity is generally augmented by every thing which tends to accelerate the circulation of the blood. Fits of anger, hot weather, fevers, and the period of menstruation, in particular, are observed to be attended with an increased turgescence and discolouration of the part affected. Indeed the excrescence sometimes bursts, and pours out a dangerous quantity of blood, and in females it has been known to become the seat of a regular menstrual discharge. (*Boyer, Traité des Maladies Chir.* T. 2, p. 277; and *John Bell's Principles*, Discourse 9.) Some nævi, especially those usually called *moles*, frequently have long irregular hairs growing upon them; while the surface of others is streaked, and even granulated. Such as appear in the form of a mere red, purplish stain, have been absurdly supposed to arise from a desire for claret, or some other wine

of that colour, entertained by the mother of the patient during her pregnancy. The granulated nævi have been compared with raspberries, strawberries, mulberries, &c. for which the mother's longing is ascribed by the vulgar as a cause. The truth is, however, that this doctrine, imputing the origin of nævi to fancies of the mother, is neither consistent with experience nor sound physiology. The causes (as Callisen observes) "*potius autem in evolutione primorum flaminum, a naturæ solita via aberrante, uti in aliis rebus monstrosis quærendæ erunt.*" (*Syst. Chir. Hodiernæ*, Vol. 2. p. 201.)

From what has been said, then, it appears that certain nævi are merely cutaneous spots, of a red, violet, or purplish colour, of greater or lesser extent, and with scarcely any perceptible elevation. They are an organic malformation of the skin, the natural texture of which does not exist, but has substituted for it a plexus of vessels, not endued with the natural sensibility of the cutis itself. These nævi generally continue stationary during life, and may be regarded rather as a deformity than a disease. (*Lassus, Pathologie Chir.* Tom. 1, p. 477.) Other nævi are either of the same nature as the disease, well known by the name of the aneurism by anastomosis, or bear a considerable resemblance to it. They are sometimes of great size, and their shape is subject to much variety. They are soft and indolent, and of a violet or dark red colour. The skin which covers them is very thin, and, when they are opened, their structure is like that of a spleen, whose blood-vessels are varicose. Some are covered with a delicate white skin, and do not increase with age. Others are more disposed to grow large. These tumours frequently occur in the skin of the face, and in other parts of the integuments, on the inside of the labia pudendi, and cheeks, and in the substance of the upper and lower lip, where they sometimes form a kind of elongation, attended with great disfigurement. Nævi of this kind, so situated in new-born infants, may produce a serious obstacle to the action of sucking. M. A. Severinus has particularly described them under the appellation of "*tuberculum atro-cruentum labii inferioris.*" (*De Abscessuum natura*, Cap. 29, p. 803.)

The *nævi*, which form in the subcutaneous cellular substance, and were named by Petit "loupes variqueuses," (*Œuvres Posthumes*, Tom. 1, p. 276.) are also of the same nature as the aneurism by anastomosis. In time, they attain a very large size. Mr. Latta says, he once saw in a child, two years old, a tumour of this kind weighing fourteen ounces, which, at the time of birth was only equal in size to a large bean. During the first year, it did not enlarge much; but it afterward grew rapidly to the size already specified. (*System of Surgery*, Vol. 2, Chap. 22.) Lassus has even seen a tumour of this description as large as a man's head. (*Pathologie Chir.* Tom. 1, p. 479.) Having treated particularly of the "aneurism by anastomosis," in another place, (see *Aneurism*;) I shall merely repeat the necessity there is for cutting every particle of the disease away, every portion of the congeries of vessels and cells of which it consists, whenever it is meddled with at all. Puncturing the swelling, or the partial removal of it, has cost many persons their lives by hemorrhage, as the records of surgery fully prove. (Petit, *Traité des Maladies Chir.* T. 1; Lassus, *Pathologie Chir.* T. 1, p. 484, &c.)

Although the original causes of *nævi* are buried in obscurity, experience proves, that whatever produces irritation in the part affected, or an increased determination of blood to it, has generally the effect of accelerating the growth and enlargement of the swelling. Thus, a trifling bruise, or a tight hat, will sometimes excite a mere stain-like speck, or a minute livid tubercle, into that diseased action, which occasions its growth. (Bateman's *Pract. Synopsis*, &c. p. 327, Edit. 3.)

With regard to the treatment of *nævi*, the subject may be explained in a few words. When these marks, or swellings, are superficial, without any disposition to enlarge, or spread, and their trivial elevation does not expose them to accidental rupture, there appears to be no good reason for interfering with them. Indeed, they could only be destroyed with caustic, or the knife, and these severe means would leave scars, accompanied with nearly the same degree of disfigurement.

But, as a valuable writer observes, when *nævi* evince a tendency to enlarge, or are very prominent excrescences, and either troublesome from their situation, or liable to be ruptured, either their growth must be repressed by sedative applications, or the whole congeries of vessels extirpated with the knife. Mr. Abernethy has proposed the application of cold washes, and the pressure of a bandage. This practice was found by him in several instances to have the desired effect of checking the growth of the tumours, which afterward shrunk, and became no longer objects of any consequence. (See *Abernethy's Surgical Works*, Vol. 2, p. 224.) Boyer also knew of a case, in which a *nævus* of the upper lip was cured by the mother pressing the part with her finger

unremittingly for seven hours at a time, and the use of alum wash. (*Traité des Maladies Chir.* T. 2, p. 269.) Boyer, however, is not generally an advocate for this mode of treatment; and Dr. Bateman expressly states, that, in the majority of cases, pressure is the source of great irritation to these maculæ, and cannot be employed. (P. 329.)

For all those examples, which partake of the nature of aneurism by anastomosis, and are disposed to grow, the best general mode of cure is extirpation with the knife. The prudence of this practice, and the necessity of taking away every particle of the disease, has been already explained: this is what was advised by F. Hildanus, (*Cent. 5. Obs. 46.*) what was strongly urged by the celebrated Petit, (*Œuvres Posthumes*, T. 1.) what was recommended in still more animated terms by Mr. John Bell, (*Principles of Surgery*, Discourse 9.) and it is what is particularly insisted upon in another part of this Dictionary. See *Aneurism*.

In general, stimulating applications cannot be made to *nævi*, without risk of exasperating, instead of lessening them. Mere thickenings, and discolourations of the rete mucosum, however, have sometimes been removed by a mixture of spirit and the liquor potassæ. (Bateman, p. 330.)

Formerly caustic was much in vogue for the removal of *nævi*; but, unless its action extend deeply enough to destroy every part of the disease, it may cause a dangerous degree of irritation, copious hemorrhages, and a sudden and fatal enlargement of the tumour. Therefore, as it is a more painful measure than the knife, and less certain in its effects, it should be on every account discarded from practice. It cannot be denied, however, that the old surgeons had success with their caustics, where the *nævi* were altogether superficial. Thus, in speaking of caustic remedies, Callisen observes: "inter quæ eximio cum successu adhibetur sapo cum æquali parte calcis vivæ subtilissimæ commixtus, nævo per emplastrum perforatum admovendus, et alio emplastro imposito firmandus; hoc remedio eschara inuritur, qua soluta, cicatrix alba remanere solet." (*Syst. Chirurgiæ Hodiernæ*, Vol. 2, p. 202.)

Trans.* Vol. 9, p. 199, &c.

NECROSIS. (from *νεκρῶς*, to destroy.) This word, the strict meaning of which is only mortification, is, by the general consent of

surgeons, confined to this affection of the bones. It was first used, in this particular sense, by the celebrated M. Louis, who restricted its application, however, to examples, in which the whole thickness of a bone was destroyed. (*See Mém. de l'Acad. Royale de Chirurgie, T. 5. 4to.*) By the ancients the death of parts of bones was not distinguished from caries. However, necrosis and caries are essentially different; for, in the first, the affected part of the bone is deprived of the vital principle: but this is not the case when it is simply carious. Caries is very analogous to ulceration, while necrosis closely resembles mortification of the soft parts.

Between caries and necrosis, says Weidmann, there is all that difference, which exists between ulcers and gangrene, or sphacelus of the soft parts. In caries, the nutrition of the bone is only impaired, and an irregular action disunites the elements of the bony structure, which consequently sustains a loss of substance; but every remaining part of it is yet alive. In necrosis, on the contrary, the vitality and nutritive functions cease altogether in a certain portion of the bone, the separation of which then becomes indispensable. (*De Necrosi Ossium, p. 7.*)

I have mentioned that M. Louis confined the term necrosis to cases, in which the whole thickness of a bone perished; but Weidmann judiciously criticises this limitation of the word, and maintains, that the nature of the disorder is the same whether it affect a single scale, the whole, or a mere point, of the bone. He also objects to the definition of necrosis proposed by Chopart, (*Dissert. de Necrosi Ossium, Paris, 1765,*) and adopted by David. (*Obs. sur une Maladie connue sous le nom de Nécrose, Paris, 1782.*) These two authors have defined necrosis to be a disorder, in which a portion of bone perishes, and turns dry, in order to be soon separated from the living parts, and replaced by a new bony substance, which is to perform its functions. But as Weidmann observes, it may happen, that a piece of bone, which dies and separates, may not be replaced by any new formation of bone, though the disease is of the same character, and merely varies in some modifications. He therefore argues, and every rational surgeon will agree with him, that a true necrosis must always be said to exist, whenever a dead portion of bone has either separated, or is about to separate. "*Vera demum necrosis semper est, si aliquod ossis roamentum, in quo vis vitæ extincta est, abscessit, vel proxime abscessurum, est.*" (*P. 7.*)

The tibia, femur, lower jaw, clavicle, humerus, fibula, radius, and ulna, are the bones most frequently affected with necrosis. Excepting the lower jaw and scapula, the process of regeneration has only been noticed, in the cylindrical bones. From 12 to 18 years of age, is the time of life, most subject to necrosis. The necrosis of the lower jaw, however, seldom occurs before the age of 30. In some persons, the bones

are affected at once, owing to constitutional causes.

No climate, age, sex, mode of life, nor condition, (says Weidmann) is exempt from this disorder. Childhood and puberty, however, are the periods most liable to it. The same thing may be said of persons, who labour hard, and are much exposed to external injuries. Every bone of the human body is subject to necrosis; but those which are superficial, and enter into the formation of the extremities, are more frequently affected than others whose situation is deeper. Necrosis less commonly attacks the spongy substance of the bones, because this being endued with a higher degree of vascularity and life, suppuration is most apt to occur. Necrosis, on the contrary, is oftener seen in the compact substance, where the vital principle is less energetic, and more readily extinguished. Lastly, the disorder may affect the long bones, or the broad; the large or small; and even those of the very least size; since it is well known, that the ossicula of the ear may be destroyed by necrosis, and separate. I have seen this happen in two instances, and the fact is recorded by several writers. (*See Astruc de Morbis Venereis, lib. 4. cap. 1. Henri, Journal de Médecine, T. 15, p. 363.*)

Though necrosis mostly attacks the cylindrical bones, the flat ones are not exempt from the disease. Pott makes mention of a parietal bone, the whole of which was detached, and of an os frontis, the greatest part of which came away. In a thesis on necrosis, in 1776, *aux écoles de chirurgie*, may be found the case of a young man, a very large part of whose scapula perished and separated. Chopart, who relates the case, mentions, that he saw the patient quite recovered, and felt a new triangular moveable bone, firmly supporting the clavicle, but smaller and flatter than natural, and without any spinous process. The same has happened to the lower jaw, as may be seen by referring to the *Ephemerides Nat. Cur.* and *Mém. de l'Acad. de Chirurgie*. In the fifth volume of the latter work, is an account of a woman, who applied to be relieved of some venereal complaints. From the beginning of the treatment, the bone was discovered to be loose just under the gums, and seemed shortly afterward, to move backwards and forwards with a tooth. M. Guernery took hold of the tooth with a key-instrument, and found it firmly inserted in the moveable jaw; he made with caution the necessary manœuvres for extracting the portion of bone; but was greatly surprised on finding what an extensive part yielded to his very moderate efforts. It was the whole of the lower jaw, above its right angle from its division into the coronoid and condyloid processes to the space between the first and second of the front grinders of the left side. On the right, there only remained the condyle in the articular cavity of the temporal bone. This destruction left a considerable empty space, from which great deformity was apprehended, in consequence of the unsupported

soft parts falling down. The woman, however, got well in two months, and had the most perfect use of a new jaw. A similar fact is recorded in the *Journal de Médecine*, 1791.

When the body of a cylindrical bone, or the middle portion of a flat bone, is destroyed by necrosis, their extremities, which are of a cellular texture, continue unaffected, so that, for example, in the cylindrical bones, the articular ends are always formed of portions of the original bone, which are engrafted, as it were, on the new production. There are, however, a few bad cases, in which the necrosis does not altogether spare the heads of the bones, and the disease communicates with the joint. These examples are very uncommon, and are attended with considerable danger to the limb: indeed, they generally require amputation. (See *Boyer, Traité des Mal. Chir. T. 3, p. 442.*) Mr. Brodie has known an instance, in which, without any obvious cause, a large portion of the head of the tibia died, and exfoliated, and the destruction of the knee-joint was the consequence. (*Pathol. and Surg. Obs. on the Joints, p. 269.*)

Besides the differences arising from the particular bones affected, necrosis also varies, according as the portion of bone attacked happens to be thin, and of little extent, or large and of considerable thickness. The disease is *simple*, when it is confined to one bone, and the patient is in other respects healthy; *compound*, when several different parts of the same bone, or several distinct bones, are affected at the same time; when the health is bad; and other parts of the body are also diseased. It should also be known, because the information is of practical importance in the treatment, that necrosis has three different stages, or periods. In the first, the bone affected perishes; in the second, the process of exfoliation or separation of the dead bone from the living, is going on; and, in the third, the separation is completed. (See *Weidmann, p. 8.*)

The causes of necrosis are not essentially different from those which produce ulcers and gangrene of the soft parts. As, however, the vitality of the bones are weaker, we may infer, that necrosis may be occasioned in them by causes which are less numerous and intense, and such as would only give rise to suppuration in the soft parts. Every thing, whether in the periosteum or the substance of the bone itself, that tends to interrupt the nutrition of the bone, must be regarded as conducive to the origin of necrosis. It is observed, however, that when the mischief in the periosteum, medulla, or substance of the bone, is of trivial extent, the consequence is merely an abscess. Some of the causes of necrosis are *external*, while others are *internal*, or constitutional. Sometimes the life of the bone is instantaneously destroyed by them; but in other instances, the bone is first stimulated and enlarged, so that its death is preceded by true inflammation.

The external causes, which injure the periosteum and medullary structure, and thus produce necrosis, are wounds, contusions, pressure, fractures, comminutions, acrid substances, caustics, and extreme degrees of heat or cold.

When the periosteum, in consequence of an external cause, inflames and sloughs, or is at once deprived of its vitality, as it may be by the action of caustic, fire, or intense cold, the vessels which conveyed nourishment to the bone are destroyed, and the death and exfoliation of the denuded portion of the bone are inevitable. But, if the detachment of the periosteum is of little extent, the patient young and healthy, and the treatment calculated to prevent inflammation, and preserve uninjured the vessels distributed to the bone, hopes may be entertained that no part of the bone will die, but that granulations will very soon arise from its surface, being adherent to it as the periosteum was, and that they will grow to and cicatrize with the surrounding parts. Weidmann has explained, that this fact of bones not always exfoliating when deprived of the periosteum, which is of great practical importance in the treatment of wounds, was inculcated by Felix Wurtz, Cesar Magatus, and Belloste, at a time when the contrary opinion prevailed. Weidmann also adverts to his own experience and to the experiments of Tenon, in further proof of the preceding fact. (*Mem de l'Acad. des Sciences, 1758, p. 372.*)

On the other hand, when the detached piece of the periosteum is extensive; when the bone itself is contused; or when it has been long exposed to the air, the effect of which is to dry up the few vessels which belong to it; when the inflammation is violent and extensive; when the patient is old, decrepit, or of bad constitution; and more especially when improper applications are used, as was almost always the case in former times; necrosis cannot be avoided.

An internal necrosis, affecting the spongy texture of bones, generally arises from constitutional causes, though sometimes an external cause, which seems to affect only the surface of a bone, extends its action to the interior, so as to destroy the medullary membrane, and produce an internal necrosis.

In external injuries of the head, where the pericranium is lacerated, contused, or otherwise hurt, or where the outer table, or the diploe, of the skull, is injured, the inflammation frequently extends to the inner table, and the dura mater becomes detached. Hence, a collection of matter forms, which may occasion many bad symptoms, and even death itself; or if the patient survive, exfoliation of part of both tables of the skull is the consequence. (See *Pott's Chir. Works, London, 1779, Vol. 1, p. 32.*)

The same thing may occur in other bones, as well as those of the cranium. Bromfield had an opportunity of seeing a necrosis of the spongy substance of the upper and internal part of the tibia, brought on by the

improper mode in which an issue was dressed. In order to keep the peas from slipping out of their places, a compress with a shilling in it, and a tight bandage were applied; but the part was attacked with excruciating pain, and the spongy texture of the tibia in the vicinity became affected with necrosis. (*Chir. Observations and Cases, Vol. 2, p. 9.*)

This circumstance, as Weidmann observes, ought not to surprise us: as numerous vessels quit the periosteum to descend into the substance of the bone, to ramify on the medullary cells themselves, and freely anastomose there, it cannot be difficult to conceive, how inflammation, which is at first confined to the outside of the bone, may (through the medium of the vessels which serve as conductors to it) penetrate more deeply, and extend its ravages in every direction.

But necrosis may proceed from another description of causes, which are of a constitutional nature. In fevers of bad type, in the small-pox, and in the measles, experience has fully proved, that the bones are sometimes attacked with necrosis. Scrofula, lues venerea, and the scurvy, are also diseases, which, according to the testimony of all surgical writers, frequently produce such mischief in the bones as terminates in necrosis. It is likewise well ascertained, that mercury, the judicious employment of which in venereal cases will prevent necrosis, or cure them when formed, may itself give rise to the disorder, especially in the lower jaw-bone. (See *Mém. de l'Acad. de Chir. T. 5, p. 356, 4to.*)

This happens either in consequence of mercury having been introduced too quickly into the system, or because the patient exposes himself to cold, or deviates in some other respect from a proper regimen. Certain necroses of the lower jaw, however, appear also to have been caused by blows, and the application of acrid substances to carious teeth. But, says Weidmann, "I feel it incumbent upon me particularly to declare, that the irrational treatment pursued by the ancient practitioners, who neither understood the nature of the bones, nor the differences of their diseases, and which treatment is too confidently adopted in our own days, had frequently the effect of killing these parts, by attacking with spirituous, acrid, or caustic remedies, or even with the knife, diseases which required the mildest applications, and to be left in a great measure to nature. The old surgeons were afraid of laying on the exposed injured surface of a bone unctuous emollient dressings, and yet, for what reason I know not, they subjected the part to the action of spirituous, acrid, drying applications. As for myself, I deem it proved by infallible and frequently repeated trials, not only that an exposed injured bone may be dressed with a mild ointment without any ill consequences, but even with the greatest advantage. Why should that which is beneficial to the soft parts, be so prejudicial to the bones? In ulcers of the soft parts, indeed, the employ-

ment of the remedy which I recommend, is less important, because these parts are naturally humid, and there is no risk of their becoming dry. But with regard to the bones, whose dry texture is only penetrated by few vessels, which may easily be destroyed if they be suffered to become quite dry, it is absolutely necessary to use an emollient ointment, as a dressing, well calculated to defend these vessels, which are the support of life, and preserve them from the bad effects of exposure to the air. Therefore, observes Weidmann, if a surgeon would avoid producing a necrosis himself, and not neglect any means that tend to prevent such disorder, *he should make it a rule never to apply any thing acrid to exposed bones, but, on the contrary, to defend them with a dressing of some unirritating ointment.*" (*De Necrosi Ossium, p. 11.*)

It was formerly supposed, that purulent matter, collected near a bone, might in time become acrimonious, corrode the bone, and produce necrosis. Hence, it was a rule to open such an abscess as soon as its existence was known. But Weidmann questions whether there was any real necessity for this practice. No doubt, says he, the preceding erroneous opinion arose from the circumstance of the bones being often found bare, carious, or even affected with necrosis, when abscesses were near them; but things happened thus, because the inflammation which caused the suppuration, had also extended its effects to the periosteum and bone. He affirms, that he has witnessed ulcers, in which the surface of bones, bare and uncovered by the periosteum, lay bathed in pus for a very considerable time; yet, being dressed with a mild ointment, they continued entire, granulations grew from them, and cicatrization followed. He had also in his possession portions of bones affected with necrosis, which had lain for years in pus; still their surface was smooth, and presented no marks of erosion. If then these pieces of bone underwent no alteration, how much less likely to do so are bones, which are endued with life!

But though Weidmann wisely rejects the doctrine of pus being capable of destroying the periosteum and bones by any corrosive qualities, he acknowledges his belief, that the matter of an abscess may by its quantity compress and inflame the adjacent parts, and occasion their removal by the absorbents. While the periosteum intervenes between an abscess and the bone, he does not see how the latter can be hurt by the pus; but when the abscess is copious and lodged between that membrane and the bone, the vessels passing from the former will be destroyed, and either caries or necrosis ensue.

The inflammation arising from the causes which excite necrosis, may be either *acute* or *chronic*. It is chronic, when it begins and passes through its different stages slowly, and when the mildness of the symptoms may lead us to mistake the nature of the case. This sort of inflammation chiefly happens in debilitated constitutions, in which

the necrosis only affects the external part of a bone, and originates from some chronic cause, such as scrofula, lues venerea, and the scurvy. But when necrosis attacks the interior, and the disease occurs in a strong, irritable, plethoric subject, inflammation is immediately kindled, attended with the most acute symptoms, severe pain, considerable fever, restlessness, delirium, &c. Chronic inflammation is more supportable; but its duration is longer: acute inflammation is more afflicting, but sooner comes to a crisis.

The part in which a necrosis is situated, is affected with swelling. What has been observed, respecting the inflammation, is also applicable to this tumour, which most frequently forms gradually, but sometimes with great rapidity. In the first case, the accompanying pain is dull and inconsiderable; in the second, it is violent. The swelling has not, like that of abscesses, an elevated apex. On the contrary, it is so widely diffused, that the limits which circumscribe it, can hardly be distinguished.

This diffusion of the swelling is the greater, in proportion as the diseased bone is more deeply buried in soft parts: it may extend over the whole morbid bone, or even over the whole limb.

The swelling comes on at the very beginning of the disorder, and continues to increase, until the matter which it contains finds its way out, when the evacuation is followed by a partial subsidence of the tumour. The swelling is sometimes also combined with œdema, especially in persons whose constitutions have been impaired by the severity of the disease, the violence of the sufferings, and the long and profuse discharge.

When the inflammation is acute, purulent matter of good quality soon collects in the vicinity of the necrosis. In the contrary case, the pus forms slowly, and is thinner and less healthy.

The abscess which accompanies a necrosis, naturally soon bursts when it arises from intense inflammation, and is situated near the skin, which is itself inflamed. But when the bone is surrounded by a great thickness of soft parts, and the inflammation is chronic, the quantity of matter daily increases, the cavity which it occupies becomes larger and larger, and considerable pressure is made in the abscess on every side. The bones and tendons resist for a long while the progress of the matter; but the cellular substance yields, and different sinuses form, which sometimes run to a vast distance from the main collection of matter, especially when the abscess lies under an aponeurosis.

It was supposed a few years ago, that in cases of necrosis, the matter was invariably sanious, acrid, and fetid. But the celebrated Weidmann exposed the error of this opinion. He had often seen abscesses and ulcers, arising from necrosis, discharge a whitish, inodorous, thick pus, absolutely devoid of any bad quality whatsoever. He had particularly seen this happen in patients

whose necroses proceeded from an external cause, or an internal one of a slight nature, and whose health was generally good. (*De Necrosi Ossium*, p. 16.) If, says the same excellent writer, we sometimes find in practice the suppuration dark and fetid, we must not ascribe it to the affection of the bone, but to the weakness and bad state of the patient's health. Under the same circumstances, common sores of the soft parts would also emit a discharge of bad quality.

After the ulcerated openings have emitted for some time a profuse discharge, the sinuses, if considerable, receive the appellation of fistulæ, on account of their edges putting on a callous appearance, throwing out fungous granulations, and there being impediments to cicatrization. These impediments are caused by the dead portions of bone, which, whether loose or adherent, act as extraneous bodies in hindering the sores from healing. In some instances also, the ulcers will not heal though the dead bone has come away, because they run to a great depth, and such a quantity of pus is secreted from every point of their surface, as prevents all contact, and the adhesions which would result from it.

The fistulæ vary in number; but they are fewer in proportion as the disease is slighter. In an extensive necrosis, several of these openings are seen, either near together, or separated by considerable spaces; and, when the necrosis affects every side of the bone, the fistulæ in the integuments occur on every side of the limb.

Besides the inflammatory fever, which attends the beginning of every severe case of necrosis, which is sometimes accompanied with exceedingly violent symptoms, and which usually abates when matter is formed, the patient is subject to another fever of a slow hectic type. This takes place in the decline of the disease, is the effect of the long-continued profuse suppuration, gradually reduces the patient, and at length brings him to the grave, unless the timely removal of the sequestrum be effected either by nature or art.

Let us next endeavour to trace the signs, by which we may not only ascertain the presence of the disease, but its modifications.

In the first place, we should make ourselves acquainted with every thing, which may have predisposed to the disorder; as, for instance, what accidental circumstances have occurred, and what symptoms followed them. We should also inquire into any previous treatment which may have been adopted; for, as Weidmann truly remarks, injudicious remedies have caused many a necrosis that would not have occurred at all, if the case had been properly treated, or confided to nature.

The kind of inflammation with which the disease commences, may afford grounds for suspecting that necrosis will happen: it is generally slow and deeply seated, passing through its stages tardily, and the attendant symptoms are severer. The skin retains its natural colour a long while; but, at length,

exhibits a reddish, or livid discolouration. The matter does not reach the skin till a considerable time has elapsed, and when the abscess bursts, the inflammatory symptoms are still slow in subsiding. When the inflammation is acute, the patient suffers intolerable pain a long time.

There are also other symptoms of a necrosis; viz. the swelling which accompanies the inflammation, is situated upon a bone, or rather the bone is included in the tumour; the swelling is at the same time very diffused; and the suppuration lies deeply, and can only be felt in an obscure way.

The ulcers, beneath which a necrosis is situated, discharge a large quantity of matter, and their edges are bent inward. The granulations are either yellowish and pale, or else of an intense red colour; they are also irregular, and generally not very tender, though sometimes extremely painful, and on being slightly touched, they bleed.

It has been already noticed, that, some years ago, the discharge from the sores, which attend necrosis, was described as being always thin, fetid, and sanious; and such qualities of the matter were regarded as a symptom of the disease of the bone. But that excellent practical writer, Weidmann, has well explained, that it is a symptom undeserving of confidence. In cases of necrosis the pus is often thick, white, and inodorous; while other ulcers, unattended with diseased bone, sometimes discharge thin fetid matter. Weidmann, at the same time, does not mean to assert, that in cases of necrosis the sores never emit unhealthy pus; but he firmly believes, that such discharge is not always the result of a disease of the bone. As far as he could judge, the suppuration from ulcers, situated over diseased bones, continues white and laudable as long as the patient's general health is good; but, that it deviates from these properties, in proportion as the health becomes impaired.

Neither is the black colour, imparted to the dressings of ulcers, a circumstance which necessarily indicates the existence of necrosis; for it may occur when the bone is sound, and may not happen when the bone is affected.

None of the preceding symptoms convey such information, as leaves no doubt of the positive existence of necrosis. The touch is the only thing which can give us this knowledge, when the bone is not too deeply situated, and the sinuses not tortuous, nor obstructed with fungous growths.

When the openings of the ulcers are considerable, the finger may be introduced. If in this way the bone can be felt to be extensively uncovered by the periosteum, the surgeon may conclude that all such portion of the bone has perished. He may be still more certain of the fact, when he finds the edges of the denuded bone unequal and rough.

The examinations, made directly with the finger, give the most correct and exact information of the state of the bone; but the

orifices of the sores are sometimes so small, that the finger cannot be introduced without causing great pain. A probe must then be used for the purpose of ascertaining the extent of the denudation of the bone; whether its edges are rough; whether the dead portion is loose, and likely to separate soon.

Sometimes the dead fragment of bone protrudes from the ulcer, or is visible on separating its edges. When it is black, there cannot be a doubt of its being actually dead; but, on the other hand, when its whiteness is increased, the diagnosis is difficult, because bones being naturally white, much experience is necessary to be able to judge whether they are so in excess.

It merits attention, also, that the black colour of the bone is not owing to the necrosis itself, but seems rather to depend upon the fragment having been exposed to the air. In fact, dead pieces of bone with which the air comes into contact, turn black, while those which are covered with matter, retain their whiteness. The cylindrical portion of a humerus, which was almost totally affected with necrosis, was universally black at the part, which protruded through the flesh; but the rest, which lay under the integuments, remained white. (*Weidmann de Necrosi Ossium*, p. 19, et Tab. 9, fig. 1.)

When the early symptoms of the disease are mild, the surgeon may infer that it is only a superficial portion of the bone which is about to be separated. But this judgment will be more certain if confirmed by examination with the finger or probe; or, if the swelling which occurred in the beginning, has not spread beyond the affected point, and if the pain affects only the outer part of the bone. In this sort of case, there is also great probability that the dead bone will be separated within a moderate time.

It is also of importance to ascertain the existence of an internal necrosis, and to learn whether it is situated in the spongy substance, or in the internal parietes of the canal of the bone; whether it affects only a part, or extends to the whole body of the bone. When there is an internal necrosis, says Weidmann, the disease is generally more aggravated, and of longer duration; and in the first stage, the patient is affected with severe symptoms, intolerable pain, loss of rest, ardent fever, profuse perspirations, and such disorder of the system, as may prove fatal, unless the patient be young and strong. The hard swelling which was observable at the commencement of the disease, increases but slowly, and extends very gradually over the circumference of the limb, while the skin yet remains free from redness and tension. *If the part be somewhat roughly handled, the pain, which is fixed in the bone, is not rendered more acute, as would happen, were the case an external inflammation.* In this suffering condition the patient continues a good while, before the formation of matter brings a degree of relief. When the matter is formed, it spreads through the adjacent

cellular substance, among the muscles and other parts, and the abscess generally bursts after a considerable time, by several openings, very distant from the main collection of matter, as also remote from each other, sometimes in diametrically opposite situations. The evacuation of the matter, however, does not produce any material subsidence of the swelling. The pus is of good quality, and issues in large quantities from the ulcerated apertures, *the quantity, however, not being increased when pressure is made.* If some of the openings heal, others are formed; but, in general, the edges become callous, and they lose all disposition to cicatrize. When the case presents the foregoing circumstances, and the weakened limb can neither bear the action of the muscles, nor the weight of the body, and by either of these causes, its shape becomes altered, the surgeon may conclude that the disease is an internal necrosis. But, in order to avoid mistake, he should introduce into the sinuses a probe, which, passing through the openings in the subjacent bone, will touch the dead-piece, which it contains, and which will sometimes be even distinguished to be loose and moveable. *The extent of the sequestrum must be judged of by the extent of the swelling, and the distances between the apertures in the bony shell, which includes the sequestrum.*

The surgeon should also endeavour to ascertain with the probe, whether there is only a single sequestrum, or several. When there are several, they may be felt with the probe in different places, down to which this instrument is passed, and the removal of one or two of the fragments is not followed by a cure. It ought to be remembered, however, that the same fragment may be touched by the probe in several different places, when it is very extensive. If there are several dead pieces of bone, situated at a distance from each other, each of them is generally accompanied with a distinct swelling, and sinuses. Frequently, these fragments are so concealed, that they cannot be felt with a probe; but, their existence may then be suspected from the ulcers not healing, which can be ascribed to nothing else.

It is also necessary to distinguish with the greatest attention the different stages of the disease. The *first stage* may be considered as existing, when the attack is yet recent, and the inflammation and its concomitant symptoms, the pain, swelling, and symptomatic fever, prevail in a high degree, and when no suppuration has taken place, or at least no discharge of matter. The *second period*, in which the dead bone is undergoing the process of separation, is indicated by a diminution of the inflammation, a partial subsidence of the swelling, and the discharge of purulent matter. When a probe is passed into the ulcers, the bone is felt bare, and dry, and, towards the limits of the swelling, it is rough, where, as will be afterward noticed, an excavation is formed. Every part of the bone, however, which is to be detached, still continues adherent to the rest of the

living bone. At length, the surgeon knows, that the disease has reached its *last stage*, or that in which the dead portion of bone is entirely separated, when sufficient time for the completion of this separation has expired, and when the dead bone can be distinguished with the finger, probe, or even the eye, to be loose and free from all connexions.

Although a necrosis must generally be classed with diseases which are serious and of long duration; yet, the character of the disorder is not essentially bad, since it is often cured by nature, or with the assistance of surgery. Confident hopes of a cure may be entertained when the necrosis is confined to the external part of a bone; when it is simple and of moderate extent; when it is not situated in a bone, destined for important uses, or near any viscus, or organ, that may be injured by it; and when it proceeds from an external cause, and the general health is good. On the contrary, the cure is difficult, and the prognosis doubtful, when the disease is extensive, and complicated with other affections, either of the same, or different bones: when it attacks bones, which are of high importance on account of their functions, or situation; when it is situated in the interior of the bone, and affects several parts of it; when it arises from an internal cause, for which there is no certain and quick-acting specific; when the patient is weakened by age, or disease; and especially, when the sinuses extend into the neighbouring articulations. (*Weidmann de Necrosi Ossium, p. 22.*)

The process of cure is said to take place with more celerity in the lower jaw, than any other bone, and may be completed in three months. Mr. Russell has never known a necrosis of the tibia get well in less than a year; but, in general, nearly two years elapse first; sometimes, the cure is protracted to a much greater length of time.

Necrosis of the lower jaw and clavicle never proves fatal: that of the lower extremities, which is the worst case, does so very seldom, and only from the violence of the first inflammatory symptoms, which rapidly bring on a hectic fever, which proves incurable, unless its local cause be removed by a timely amputation. When the violence of the first stage, however, has abated, the irritation ceases, and the hectic symptoms, if there are any, are generally moderate. Nor is this state of tranquillity disturbed, till the sequestrum, in making its way outward, again produces irritation. At this second period of urgency, extensive inflammation may originate, ulcerations spread all over the surface of the limb, assume an unhealthy appearance, violent fever succeed, and the patient either perish, or sink into a state, in which he must consent to amputation, as the only means of saving his life. This is the last crisis of imminent danger; but, in general, it is less perilous, than when the inflammation comes on in the incipient stage of necrosis. (*Russell.*)

In the treatment of necrosis, the first grand object of the surgeon should be to aid nature

in her endeavours to effect a cure, and not to disturb her operations by any superfluous, or unseasonable interference. The second should be to assist her sometimes by the boldest proceedings, when she loses her way, and cannot by herself accomplish the end.

But, in order not to attempt any thing wrong, the surgeon must understand correctly what nature does in this disease, what it is in her power to perform; what she either cannot accomplish at all, or not with any degree of certainty; and lastly, the circumstances in which she may err, and endanger the patient's life.

When a portion of bone dies, nature uses all her endeavours to bring about its separation from the part of the bone which still remains alive. Surgeons have denominated this process, *exfoliation*, (see *this word*) which resembles the separation, that occurs between parts affected with gangrene and sphacelus, and the living flesh. An exfoliation of bone, however, happens much more slowly, than the separation of a slough of the soft parts. Neither are all exfoliations completed at a regular period; for they proceed most quickly during youth, when the constitution is usually more full of energy, the bones more vascular, and less replete with solid inorganic earthy matter. On the other hand, the process is slower, in old, debilitated subjects, whose vitality is less active. A thin small scale of bone separates sooner, than a large thick portion; and the most tedious exfoliation is that of a thick bone, from which a portion, including its entire diameter, is coming away. The separation of a necrosis takes place more expeditiously in bones of a light texture, than in those of a solid structure; and sooner, in the less compact parts of bones, such as the epiphyses and spongy substance, than in those of greater density.

When a necrosis has originated from the scurvy, syphilis, &c. and appropriate remedies are not administered, nature cannot effectually accomplish the process, by which the dead bone is separated; the case becomes worse; and life endangered.

The separation happens precisely at the different points where the living and dead parts of the bone come into contact; and it is obvious, that the particles of the dead bone, which are at a distance from the part that retains its vitality, cannot be acted upon by it.

A variety of opinions have been entertained, concerning the means employed by nature in effecting this separation. Hippocrates believed, that the dead part was pushed away by a fleshy substance, which grew underneath it. (*De Cap. vuln. Cap. xxiv.*) Ludwig, Aitken, Bonn, and many others, adopted the same idea. (See *Adversaria Med. Pract. Vol. 3, p. 63; Systematic Elements of the Theory and Practice in Surgery, p. 287. Thesaur. Oss. Morb. p. 1.*)

Van Swieten conceived, that the dead part was forced away by the incessant beating of the arteries. (*Comment. in Aphor. Boerrhavi,*

§ 252.) M. Fabre ascribed the separation to the extension and expansion of the vessels. (*Mém. de l'Acad. de Chir. Tom. 4, p. 91.*) Others supposed that the exfoliating piece of bone became loosened partly by the supuration, and partly by the rising of the new granulations. (See *B. Bell on Ulcers.*)

As Weidmann observes, there is unquestionably a reddish fleshy substance formed between the dead and living bone, and which Celsus has noticed under the appellation of *caruncula*. (*De Medecina, lib. 8, cap. 3.*) But, it would be erroneous to refer the expulsion of the dead portion of bone to it, since it can never be produced, before a change has taken place in the structure of bone, there being in fact no space for it to grow in; and hence, it is never seen before the disunion of the parts has considerably advanced. There must consequently be some other power, which destroys the cohesion between the dead and living bone, and produces the groove, or interspace, in which the soft granulations arise. Besides, among other facts proving the falsity of the idea, that the granulations push off the dead bone, Weidmann particularly adverts to the occasional exfoliations of the whole circumference of a cylindrical bone. Here, if the granulations had the power of causing a disunion on one side, they could not have the same effect on the opposite one; but would tend to make the contact more intimate.

The separation also cannot be made by the pulsation of the small arteries, nor by the weak expansive motion of the vessels of the bone. Weidmann knows not what motives have induced certain writers to impute the effect to suppuration, and observes, that as the doctrine is not founded upon reasoning, it is superfluous to offer any arguments against it. If the least attention be paid to what nature really tries and accomplishes in this operation, nothing will be more manifest, than that it is completed in a very different manner. Swelling first affects the periosteum and bone, which by degrees softens. (*Vid. Troja passim. Bonn. Thesaur. Oss. Morbos, p. 122, and Weidmann de Necrosi Ossium, Tab. 4, Fig. 1, and 3.*) At the margins of the necrosis, the bony surfaces, which were smooth, become rough, and irregular. A fissure is there produced, which extends in every direction under the piece of bone, that is about to be detached. The bony texture is also daily rendered less solid, so that the number of adhesions between the dead and living parts diminish, and in the end are totally destroyed. Weidmann then explains, that the true mode by which the separation is effected consists in the absorption of the particles, situated betwixt the living and dead parts of the bone, in such a way, however, that the first loses a great deal of its substance; the last, scarcely any thing. (*P. 25.*) After the dead bone has come away, the swelling of the periosteum subsides, and the living bone recovers its original hardness and solidity. (*Troja, p. 67.*)

For a further account of the process, by

which dead portions of bone are separated from the living, see *Exfoliation*.

When dead portions of bone are separated and loose, they still lodge in the cavities of the ulcers, and, like all other extraneous bodies, occasion irritation of the soft parts, and keep up a discharge of matter. Sometimes, however, nature of herself succeeds in expelling them. This happens in cases, where the size and shape of the ulcer are calculated to facilitate the issue of the dead bone, which does not lie too deeply, and is propelled outward by its own weight. In necroses of trivial size, indeed, it is asserted, that the small fragments of bone may be dissolved in the pus, and come away with it; (*David; Boussetin, Hist. de la Société Royale de Médecine, Tom. 4, p. 308; Weidmann de Necrosi Ossium, p. 26;*) but, such an event can never be expected when the dead portion of bone is at all extensive.

The last thing which nature does, is to restore the loss of substance which the bone has suffered. Although this operation is so extraordinary and wonderful, that one might be disposed to doubt its reality, numerous examples, recorded in the annals of surgery, prove not only its possibility, but, also, its frequency.

In works referred to at the conclusion of this article, the following authors speak of the regeneration of a part, or the whole of the lower jaw-bone: viz. Bonetus, Bayer, Guernery, Belmain, Acrel, Van Wy, Trioen, Bonn, Reiplein, Desault, Henkel, and Dusaussoir. A student showed Weidmann a lower jaw-bone, which had been thus regenerated, and taken from the body of a man, whom the latter distinguished writer had been well acquainted with. The bone could not be freely depressed; but, yet it performed its functions tolerably well.

Moreau saw a case, in which the clavicle was regenerated, and the new bone was presented by Dangerville, after the patient's decease, to the Academy of Surgery at Paris. (*De Necrosi Ossium Theses, Pras. F. Chopart, resp. P. G. Robert, Parisiis, 1776.*)

Chopart had an opportunity of witnessing the death and reproduction of a scapula.

Weidmann saw an instance, in which nearly the whole cylindrical shaft of the humerus perished, and was afterward regenerated; a phenomenon, that had been observed at earlier periods by Job of Mekren, Cajetano Tacconi, E. Blancard, Duhamel, David, Acrel, Bœhmer, Cheselden, and Vigaroux, whose respective works are cited at the end of this article.

Morand, Cheselden, and Bromfield published engravings, respecting a reproduction of the upper part of the humerus, where the old dead bone was included in a sort of bony tube.

Regenerations of the ulna have been observed by Ruysch, Duverney, and Fowles. (See *Thesaur, X. No. 176. Traité des Mal. des Os. Paris, 1751; and Phil. Trans. No. 312.*)

A similar reproduction of the lower ends of the radius and ulna was witnessed by Acrel.

(*Chirurgische Vorfälle von Murray, Vol. 1, p. 194.*)

Similar reproductions of the thigh-bone are recorded by Wedel, Battus, Koschius, Hofmann, Scultetus, Diemerbroeck, Wright, Fabricius Hildanus, Raw, Dobyns, M'Kenzie, Ludwig, David, Rousselin, Larrey, Hutchison, &c. in publications specified at the conclusion of this subject.

The following case of necrosis of the thigh-bone is related by Dr. M'Kenzie. William Baxter, a boy thirteen years old, received a blow on his thigh at school, of which he at first hardly complained; but, in a few months, he began to have pain in the thigh, which inflamed, swelled, and appeared to have matter in it. The parents being poor, no surgeon was called, and the boy was allowed to linger for a great while. At length the matter made its way through the skin, by a small opening, on the interior part of the thigh, about three inches above the knee, and a thin sanies continued to be discharged for eighteen or twenty months. At length, the hole in the skin enlarged, and the point of a bone began to protrude, and give a good deal of pain, when the clothes rubbed against it. After suffering in this manner for two years and a half, the boy, as he lay in bed one morning, felt the bone looser, and projecting more than ordinary. He gave it a strong pull, and brought the piece away entirely, which proved to be seven inches and a half of the thigh-bone. A good deal of bleeding followed; but, the wound soon healed, and he has never since found the least inconvenience. Dr. M'Kenzie, hearing of this singular case, sent for the boy, carefully examined his thigh, and found it as firm as the other. The only difference was, that it was somewhat thicker, and a little more curved. The muscles retained their natural softness, and looseness on the bone. The detached piece of bone was a portion of its whole circumference. (See *Med. Obs. and Inquiries, Vol. 2.*)

We may infer, that the occurrence is more frequent in the tibia than any other bone, from the accumulated facts, mentioned by Albucasis, La Marche, Muralto, De La Motte, Ellinchuys, Ruysch, Tacconi, Laing, Johnson, Hunter, David, Boehmer, Sigwart, Th. Bartholine, Hofmann, Saviard, Le Oran, Duverney, Trioen, Gunther, Ludwig, Michael, Boussetin, Weidmann, Russell, Whately, Desault, &c. See the works referred to at the end.

Dr. Hunter mentions a tibia which was sent to him by a Mr. Inett, after amputation. On examination, the case at first sight seemed to be a swelling of the whole bone, with a loose internal exfoliation. However, it proved to be a remarkable instance of the separation of the greatest part of the original bone, whose place was supplied by a callus. The external surface of the enclosed loose piece of bone was smooth. A small part of the surrounding bony substance being removed, the contained piece was taken out, and found to be the whole body of the tibia. It had separated from the epi-

physis at each extremity. The middle part of the bone had perished, consequently, had lost its connexion with the periosteum, and was gradually thrown off from the living parts of the bone at each end. A callus extended from end to end, united the two extremities of the original tibia, preserved the length, and gave firmness and inflexibility to the part. The exfoliation was so encompassed by the new bony case, that though quite loose, it could not be thrown out. (*Med. Obs. and Inq. Vol. 2.*)

Weidmann saw a shoemaker, who, after much suffering, extracted himself the greatest part of the diaphysis of the tibia; yet, the loss was so well repaired, that the man could walk afterward nearly as ably as ever. (*De Necrosi Ossium, p. 29.*)

"We are not to imagine, (says Weidmann) that these regenerations happen by chance: experiments made upon living animals by Troja, Blumenbach, Koehler, Desault, and myself, prove that they invariably follow certain laws."

In fact, whenever the medullary structure of the long bones of pigeons, or dogs, is destroyed, these bones become affected with necrosis, and are afterward reproduced to the full extent of their destruction.

The observations and experiments, cited by Weidmann, also prove, that it is the long bones which are usually reproduced; though the flat ones are not entirely destitute of the power of regeneration, since experience fully evinces, that, when a portion of the skull is removed, either by a wound, by disease, or by the trepan, nature always endeavours to cover the deficiency, the edges of the aperture extending themselves by means of a bony substance, furnished by the periosteum, the dura mater, and cranium itself. (*Tenon Mém. de l'Acad. des Sciences, 1758, p. 412, 413, 415, 416, 418.*) But still the reproduction is imperfect, as a space unfilled up is always left, even when the bone has lost only a small piece, like what is taken out by the trephine; and when the destruction of the cranium is very extensive, no reproduction at all happens. This fact is proved by examples mentioned by Savard, Pott, Sabatier, &c.

When in a case of necrosis, says Weidmann, a scale or table, of either a long or flat bone, is separated, no regeneration follows, because the granulations, which rise up under the sequestrum, then serve as a periosteum, and as soon as the dead bone is removed, they become united to the adjacent parts.

It is likewise ascertained, that the power of reproduction in the bones is particularly active in the early periods of life, and in healthy subjects; and that it is languid and even annihilated in old persons, pregnant women, (*Bonn's Thesaur. p. 174.*) and in venereal, cancerous, and rickety patients. (*Callisen, Syst. Chir. Hodiernæ, Pars 1, p. 636.*)

In order that a new bone may form, the periosteum and other membranes, concerned in the nutrition of the original bone, must

have been spared from destruction. In fact, continues Weidmann, we observe that in cases where the tube of a long bone has suffered necrosis, the bone is never reproduced, when the periosteum has been destroyed by inflammation or other causes. Surgeons ought also to understand that it is not always a reproduction which has happened, when a part of a bone perishes; not even when a tubular portion of a long bone dies, and is contained in the medullary canal. For, says Weidmann if the innermost layers of a long bone perish, while those which compose, as it were, the bark, are preserved, the latter swell and soften, as if they were actually a new bone. Several round apertures are observable upon their surface, which serve for the transmission of vessels, and are larger than those which perform this office in the natural state. There are likewise formed large openings, or fistulæ, which, as in a new bone, lead to the medullary canal. Here it would be erroneous to conclude that a new bone has been produced, and a very little attention will discover that all is limited to some changes in the external part of the bone, which the necrosis has not affected.

When, therefore, the interior of the canal of a long bone is destroyed by a necrosis, which does not extend to the external layers, the case is not a reproduction of the bone.

When, however, we find the tube of any long bone included in a sort of osseous shell, and the surface of this tube smooth, like that of a bone in the natural state, we may be certain that it has been detached directly from the periosteum, and that the bony shell which contains it, is a new production. On the contrary, if the surface of the dead tube is rough, we may infer that the separation has taken place between the innermost layers of the bone and those which are superficial, the latter composing now the osseous shell, in which the sequestrum is included. (*Weidmann De Necrosi Ossium, p. 31.*)

This last theory, concerning the production of the osseous shell in necroses of the long cylindrical bones, is adopted by Richerand as the true one, not only in the instances specified by Weidmann, but in every other example where the old bone seems to be included in another which has the appearance of being a new production, and which was supposed by Troja, David, &c. to be formed by the vessels of the periosteum. (*See Nosographie Chir. T. 3, p. 158, 161, Edit. 4.*) Boyer does not espouse this theory exclusively; but represents the thing as sometimes happening. (*See Traité des Mal. Chir. T. 3, p. 426.*)

As far as the observations of Weidmann informed him, the short or cuboid bones do not appear to be capable of reproduction. (*P. 31.*) Duverney mentions an astragalus, which was destroyed by necrosis, but does not state that any substitute for it was after-

ward formed. (*Traité des Maladies des Chir. Os. p. 458.*)

Weidmann also never witnessed a reproduction of the spongy substance, such as it was before its destruction, round the medulla. He always found the substituted matter dense and compact, at least for some time after its formation.

It is now admitted, however, that in process of time, the inner surface of the new bone becomes cellular, and is lined with a membrane containing medulla. The regeneration of the medulla was first observed by Koehler, and afterward in an extensive series of experiments, which Professor Thomson made with Dr. Alexander McDonald, and which were published in the latter gentleman's inaugural dissertation, in 1799. (See Thomson's *Lectures on Inflammation*, p. 393.) Mr. Russel does not appear to adopt this opinion concerning the regeneration of the medulla; for, he states that, after the absorption or removal of the sequestrum, the cavity of the new bone becomes filled up with granulations, which are at length converted into bony matter. Thus, he says, the new bone differs from the original one, in being solid instead of hollow. Authorities, however, are decidedly against Mr. Russel on this point: in the 5th vol. of the *Mém. de l'Acad. de Chir.* is the history of a man, the whole of whose clavicle came away without his being deprived of any of the motions of the arm. The death of this patient, which happened shortly afterward, afforded an opportunity of examining how nature had repaired the loss. Another clavicle was found regenerated, which neither differed from the original one in length nor solidity; but only in shape, being flatter, and not so round. It was connected with the acromion and sternum, just like the primitive bone.

The power, which thus reproduces bones, is only a modification of that which unites fractures. Indeed, what consolidates broken bones, and is known by the name of *callus*, presents all the characters of new bone, begins and grows in the same way, and may be impeded and retarded in its formation by the same causes. (See *Callus and Fractures*.) It is further highly probable, as Weidmann remarks, that the power which effects the reproduction of bones, is the same as that, which, in the sound state, nourishes and supports these parts. But to what organ appertains the function of reproducing bones?

Many able men have ascribed the whole work to the periosteum. (*C. Havers; Duhamel, Mém. de l'Acad. des Sciences, 1739, 1741, 1742, 1747. Fougereux, Mém. sur les Os; Paris, 1760. Swencke, Harlemer Abhandlungen 1, th. p. 39. Bertin, Osteologie. Marignies, Abhandlung von der Natur und Erzeugung des Callus, p. 199.*)

Haller, (*Elem. Physiol. T. 8, p. 352.*) Callisen, (*Collect. Hafn. T. 2, p. 187.*) Tennon, (*Mém. de l'Acad. des Sciences, 1758, p. 415.*) Bordenave, (*Mém. sur les Os, p. 227*) and many others, have seen a part of the

new production spring up from the substance of the old bone; a thing, says Weidmann, which one is also led to believe by the fact, that, when the whole tube of a long bone is affected with necrosis, the epiphyses which remain sound and untouched, unite and grow to the new tube, though no periosteum exists in the situation of the union.

Nor does Weidmann think that the specimen of a fractured thigh, of which Blumenbach has published an engraving, proves the contrary. (*Geschichte und Beschreibung der Knochen; Göttingen, 1786, Tab. 1, fig. 1.*) This preparation exhibits an union which had taken place by means of a very broad osseous ring, encompassing the ends of the fracture which lie far asunder. The event appears to Weidmann to have been the result of rachitis, or lues venerea, with which the young patient, according to Blumenbach himself, had been affected, and by which the nutrition of this bone had been disordered. For, says Weidmann, in other examples of united fractures, the ends of the bone are so connected together by the callus, that there does not exist a single point between them, where this substance is not effused, and the medullary canal itself is obstructed and filled with it. In the *Journ. Complém. du Dict. des Sciences Med. T. 8*, may be found some considerations, offered by Larrey, against the doctrine that the periosteum is the organ of ossification.

That, however, the periosteum is frequently the organ of the reproduction of the bones, seems proved by the experiments of Troja, Blumenbach, Desault, and Koehler, since in these the bones were invariably regenerated, though there was nothing left of the old bone that could furnish the new reproduction, except the periosteum.

If we examine the new bone, at different periods of its developement, it appears in the earliest state in the form of a reddish fluid, as has been observed by Duhamel, Fougereux, Bordenave, Haller, Callisen, and others. If we also attend to the progressive changes which this fluid undergoes, we cannot but believe that, as in the embryo, an organic and fixed arrangement of parts takes place. Indeed, it would be erroneous to consider such fluid as destitute of organization and extravasated at random. Thin and little in quantity on its first appearance, its consistence and quantity afterward gradually increase (*Troja, p. 42, 44.*) so that what at first appeared like a liquid, soon becomes a gelatinous substance, in which are developed, especially at its inner surface and towards its lower part, bony fibres, which incessantly become more and more numerous. These fibres in a short time form little layers and cells, and extend themselves every where, so that at length all which was fluid disappears, and the new bone is produced. While young, however, it is still spongy and reddish, (*Troja, p. 44.*) but soon becomes denser, harder, and more solid, than that was for which it is a substitute, and it acquires the ordinary colour of the rest of the bones.

The external surface of the new bone, which, during the period of its formation, was irregular, and studded with several excrescences of various sizes, and pierced with apertures of different dimensions, becomes in the course of time smooth and regular, especially after the expulsion of the sequestrum.

The sides, or walls of the new bone, which at first were of considerable thickness, in time also grow thinner. (*Troja*, p. 21.) When the entire dead bony cylinder continues in its cavity, the new bone is neither shorter, nor longer, than the original. But, should one of the ends of the dead tube protrude from the cavity, while by the side of the affected bone, there is not another one capable of resisting the action of the muscles, the new bone will be shortened, and undergo some change in its shape and direction. Indeed, says Weidmann, the new bone in its early state, from want of consistence, must yield to the efforts of the muscles.

Its shape is not exactly like that of the original bone: the sides are flatter; the usual angles, depressions, and eminences are not observable, and sometimes others are formed.

How admirable is the process, by which the muscles, detached from a bone affected with necrosis, have other insertions given to them, and are thus rendered capable of performing their functions! (*Troja*, p. 27.)

The periosteum, which swells as soon as the exfoliation of the old bone commences, shrinks, and is not at all thickened, when the exfoliation is finished. *Troja*, having destroyed the medullary structure of a long bone, found the periosteum swelled at the end of 36 hours; but he observed, that the whole of such swelling disappeared before the 25th day. (P. 43, 67.)

The periosteum, which thus survives, adheres to the new bone, as it did to the old one: its vessels, which are now increased in diameter, and convey a larger quantity of blood, dive into large apertures in the regenerated bone, ramify every where in its substance, and nourish it.

Dr. Macartney's observations nearly agree with those of *Troja* and Weidmann, respecting the formation of the new bone by the periosteum, with this difference, however, that he does not describe the original periosteum as becoming afterward attached to the new bone, but as disappearing. Dr. Macartney remarks, "that the first and most important circumstance is the change, which takes place in the organization of the periosteum; this membrane acquires the highest degree of vascularity, becomes considerably thickened, soft, spongy, and loosely adherent to the bone. The cellular substance, also, which is immediately connected with the periosteum, suffers a similar alteration: it puts on the appearance of being inflamed, its vessels enlarge, lymph is shed into its interstices, and it becomes consolidated with the periosteum. These changes are preparatory to the absorption of the old bone, and

the secretion of the new osseous matter, and even previous to the death of the bone, which is to be removed. In one instance, I found the periosteum vascular and pulpy, when the only affection was a small abscess of the medulla, the bone still retaining its connexion with the neighbouring parts, as it readily received injection. The newly organized periosteum, &c. separates entirely from the bone, after which it begins to remove the latter by absorption;" and, while this is going on, its inner surface becomes covered with little eminences, resembling granulations. "In proportion as the old bone is removed, new osseous matter is dispersed in the substance of the granulations, whilst they continue to grow upon the old bone, until the whole, or a part of it, is completely absorbed, according to the circumstances of the case. What remains of the investment, after the absorption of the old bone, and the formation of the osseous tube, which is to replace it, degenerates, loses its vascularity, and appears like a lacerated membrane. I have never had an opportunity of examining a limb, a sufficient time after the termination of the disease, to ascertain, whether the investment be at last totally absorbed, but in some instances, I have seen very little remaining. During the progress of the disease, the thickened cellular substance, which surrounded the original periosteum, becomes gradually thinner; its vessels diminish, and it adheres strictly to the new-formed bone, to which it ultimately serves as a periosteum." Dr. Macartney states, that the anatomical preparations, which authenticate the above observations, are preserved at St. Bartholomew's Hospital. (See *Crowther on White Swelling*, p. 183. Ed. 2.)

Mr. Stanley, however, lately showed me in the same museum, a preparation, which tends to confirm the accuracy of *Troja's* account of the old periosteum becoming adherent to the new bone. In this example, the periosteum is perfectly continuous with that covering the epiphyses. If this were not the fact, we should have to explain in what way the periosteum of the new bone is formed. We know that the vessels of the original periosteum enter the new bone, in order to complete its formation, and it seems more consonant with the uniform simplicity of nature's operations, to suppose that this connexion is kept up, than that the old periosteum should be totally removed, after the production of the new bone, and another membrane of the same kind be then generated.

An interesting example of necrosis of the thigh-bone, published some time ago by Mr. C. Hutchison, tends also to prove, that the new osseous shell is commonly formed by the periosteum, as, in this case, the medullary bags, or cells, were found completely ossified, (*Practical Obs. in Surgery*, p. 135) and could not therefore be supposed to be capable of the work. Among the moderns, also, Dr. McDonald deserves to be mentioned as one of the most distinguished advocates for the truth of *Troja's* explanation of

this subject. (See *McDonald's Thesis de Necrosi ac Callo*; Edinb. 1799.) Another late writer has adduced many arguments to prove that the pulpy mass, which extends from one epiphysis to the other, and is itself at last converted into bone, is formed quite independently of the original bone, or the periosteum. (See *Russell's Practical Essay on Necrosis*, p. 27, Edinb. 1795.) This account, however, is contrary to the observations of Troja, David, Weidmann, McDonald, Macartney, and numerous other observers. Indeed, a modern author seems to think the periosteum so essential to ossification, or the production of a new bone, that he attempts to explain the cause of fractures of the patella not becoming united by a bony substance, by adverting to the deficiency of periosteum upon it; a circumstance which he deems also a strong argument against Mr. Russell's doctrine. (See *Hutchison's Practical Observ. in Surgery*, p. 141, 142.)

These very same cases, however, fractures of the patella, do sometimes unite by bone, and, therefore, while Mr. Hutchison is urging them as facts against Mr. Russell's opinion, Baron Larrey is actually adducing them in its support. (See *Journ. Complém. du Dict. des Sciences Méd.* T. 8.) The experiments of Breschet and Villermé are decidedly against the periosteum being exclusively the organ of ossification.

Professor Boyer does not refer all the work of reproducing bones exclusively to the periosteum in every instance; but joins Weidmann in believing, that what seems a new bone is sometimes only a separation and thickening of the external layers of the original bone, which have escaped destruction. He notices the modifications, to which the phenomena of necrosis are subject when the disorder affects the whole thickness, and the whole, or the greater part, of the circumference of a long cylindrical bone. When the periosteum is destroyed together with the bone, and the medullary membrane, which does the office of an internal periosteum, is preserved, Boyer represents the latter membrane as undergoing similar changes to those which we have mentioned as taking place, under other circumstances, in the external periosteum, and he describes it as becoming the organ by which the new bone is formed. (See *Traité des Maladies Chir.* T. 3, p. 432.) But when the whole thickness and circumference of a long bone are destroyed, together with the medullary membrane, while the periosteum survives, Boyer agrees with Troja, &c. in believing the latter membrane to be the means by which the new bone is generated.

The internal surface of the new bone is lined by a new membrane, which serves as a periosteum, and is at first hardly distinguishable. (Troja, p. 56.) In the early state, it is soft and pulpy; (*ibid.* p. 22.) but, by degrees, it grows thicker and firmer, and is at length converted into a true membrane, which sends a great number of vessels into the substance of the bone. When this mem-

brane is torn off, the surface, which it covered, is found somewhat smooth, the edges of the bony layers, and projections of the fibres being blunt and rounded.

The cavity of the new bone includes, and almost entirely conceals the dead fragments. Sometimes, however, the new bone forms a sort of bridge over the sequestrum, in such a manner that the cavity is open above and below, in both which situations the sequestrum can be felt. (Hunter, in *Med. Obs. and Inquiries* Vol. 2, p. 418.)

Sometimes, it is only a narrow cross-piece, which forms the bridge retaining the sequestrum. (Weidmann, *vid.* Tab. 5, Fig. 1, a.)

The new bone may also have an opening in it, out of which the dead portion protrudes. (*ib.* p. 35.)

Sometimes the cavity of the new bone is single; while in other instances, there are several successive cavities in the direction of the length of the bone, with transverse interspaces between them; or else the cavities are situated laterally with respect to each other, and divided by partitions. (Weidmann, Tab. 7, Fig. 2.)

These cavities are proportioned in size and shape to the fragments of dead bone, which lodge in them. It occasionally happens, that they open into some neighbouring joint, and bring on suppuration there: a very unfavourable complication. (*Ibid.* p. 34, and Tab. 6, Fig. 3; also, Boyer, *Traité des Mal. Chir.* Tom 3, p. 435.)

Let us next follow Weidmann, and take notice of the holes, by which the cavities, including the dead pieces of bone, open externally, which Troja denominated the large foramina, and which the preceding excellent writer preferred calling the *cloacæ*, because they serve to convey outward the matter and any separated pieces of bone. In the beginning of the disorder, they are not observable, a certain space of time appearing to be requisite for their formation. They are noticed in long cylindrical bones, whether original, or of new production, whose cavities contain dead fragments.

These openings vary in number: when the sequestrum is small, only one is found; but, when the piece of dead bone is extensive, there may be two, three, or four. Weidmann never saw more than five. But Troja met with eight. (P. 58.) Weidmann possessed a small portion of the diploe of the os innominatum, which was affected with necrosis, and contained in a bony cavity, that had no external opening whatever.

When there are several distinct cavities in the same bone, containing dead fragments, each cavity has at least one external opening.

These *cloacæ*, or apertures, are commonly situated at the lower and lateral parts of the cavities; pass obliquely outwards; and communicate with fistulous ulcers, which open on the surface of the skin. (David, p. 186.) Some of the *cloacæ*, however, form at the middle, or (what is exceedingly rare) at the upper part of the cavities, and proceeding

outward, without any oblique track, go to the front, back, or lateral parts of the limb.

They are of a round, or oval shape, or nearly so. Their usual size is such, that it will just admit a quill, and they vary very little from this dimension.

They terminate internally by converging approaching edges, in the manner of a funnel; while, on the contrary, the margins of their outer extremity expand. The canal between these two orifices is sometimes long, sometimes short, and in certain cases, of no extent at all.

Different opinions have been broached, respecting the causes which produce the apertures in the new bone, termed by Weidmann the *cloacæ*.

M. David says, that the pus collecting in an early stage of the disease between the bone and periosteum, distends and corrodes this membrane, and that the openings which form in it become afterward a cause of fistulae in the new bone. (P. 186.) But it is observed by Weidmann, that this explanation is inadmissible, since the existence of the collection of pus, mentioned by M. David, is not proved by observation: in fact, it was never met with by Troja, Blumenbach, Desault, Koehler, and many others, in repeated experiments made on the subject. (Troja, p. 56 and 66; Weidmann, p. 36.)

Koehler thought he had seen the new bone itself destroyed by the pus, and *cloacæ* thus produced. (P. 68—72.)

Weidmann, however, deems this opinion quite as improbable as the preceding, for the fact of the surface of these bony apertures being always smooth, always formed in one manner, and constantly lined by the periosteum, decidedly proves that they cannot arise from erosion.

Troja, in his third experiment upon the regeneration of bones, remarked, that forty-two hours after the destruction of the medulla, there took place, between the bone and the periosteum, an effusion of lymph, which was at first thin and little in quantity, but afterward became thicker. He noticed, in the midst of this gelatinous substance, some small spaces, where it was deficient, and which had, instead of it, a subtile, whitish, dry incrustation, which, though tolerably adherent, could be rubbed off. These small spaces, according to Troja, produce the apertures called the *cloacæ*. (Troja, p. 45.)

In another experiment, he had an opportunity of examining the above little spaces at the end of forty-eight hours; he affirms, that they were replaced by the large apertures, or *cloacæ*, of the new bone (P. 47;) and that such openings were invariably formed in the place of the small incrustated spaces already described. (P. 58.) As Troja took notice that no lymph was effused at these particular points, he was inclined to impute the circumstance to a defect in the ossification, and, perhaps, to the death of some parts of the periosteum. Weidmann acknowledges, that the mode, in which the formation of the *cloacæ* happens, is exceedingly obscure; and expresses his belief, that

Troja's account of it approaches the nearest to the truth. But, says he, one thing is certain, namely, that these openings have no other use, but that of conveying outward the pus which collects in the cavity, and the small bony fragments, since, as soon as every atom of dead bone has passed out, they diminish, and, at length, are totally obliterated. (Weidmann *De Necrosi Ossium*, p. 36.)

It is a remarkable circumstance, in the history of necrosis, that, in favourable instances of the disease, the inflexibility and firmness of the limb are preserved during the whole of the process, by which the new bone is formed. Consequently, the new bone must have begun to grow, and have acquired firmness before the old bone separates, or is absorbed. Were this not the case the limb must become flexible and useless, the moment the dead bone is removed. Another consequence of the new bone being formed, before the removal of the old one, is that the former must surround and include the latter. For, since the lifeless portion of bone completely occupies the space between the two living ends, these cannot be immediately connected by the new bony matter. The connexion can alone be completed by the new bone being deposited on the outside of the old one, from one end to the other, and attaching itself to the portions which still remain alive. The new bone must also be necessarily larger than the old one, because externally situated, and hence the affected limb, after the cure is complete, will always continue larger, clumsier, and less shapely than the other. The length of it, however, remains unaltered, because the old bone retains its attachment, while the rudiments of the new bone are lying on its outside, and connect the living ends of the old one, by an inflexible mass, equal in length to the portion which is destroyed.

Thus we see, that, in the process which nature follows in the formation of the new osseous shell, the old bone serves as a mould for the new one, and the first step of the process is to surround the old bone with an effusion of coagulating lymph. (See Russell on Necrosis, p. 2—7.)

When the sequestrum is thrown off slowly, the inflammation is moderate; but when it separates quickly, while the new bone is in a soft state, the detachment is always preceded by severe inflammatory symptoms, and followed by a temporary loss of the natural firmness of the limb. This premature separation of the sequestrum often occurs in necrosis of the lower jaw, and the chin consequently falls down on the neck. In certain cases, the sequestrum separates at each end from the living portions of the old bone, before the new osseous shell has acquired firmness, so that the limb feels as if it were broken in two places. (Russell.)

Let us next consider the states and circumstances of necrosis, in which the art of surgery may be advantageously exerted in the assistance of nature, and the means which may be employed for this purpose.

A common error of medical and surgical practitioners is always to impute the cure of every disease to whatever remedies happen to be employed, and successes are too often boasted of, the merit of which belongs entirely to nature. It is, indeed, not very unfrequent to hear remedies panegyrically spoken of, which counteract the salutary efforts of nature, who, in this case, is obliged to overcome both the disease, and the irrational treatment, which is applied to it. As Weidmann observes, this erroneous mode of considering things has happened particularly often among surgeons who have had cases of necrosis under their care, all of whom boast of the cures which they have accomplished, although some employed absorbent earths, others, aromatics; some, spirituous applications; others, balmy remedies; some, acids; others, caustics; and some, armed with a wimble, made numerous perforations in the dead bone; while many others rasped the part, or attacked it with the trepan, cutting forceps, the gouge and mallet, or even the actual cautery; and a certain number did nothing more, than apply dry lint. Nature, who was favourable to all, did her own work in silence, whatever were the remedies employed for her assistance, whether mild and inert; acrid and corrosive; or hurtful and improper.

We have already noticed, that a dead portion of bone separates from the living exactly in the same way, as gangrenous soft parts spontaneously drop off, without the interference of art. The separation happens precisely at the points to which death has extended; limits, which are well understood only by nature, and of course can be measured only by her. Art would incur great risk of either going beyond them, or else of not reaching them at all. Perhaps, it may be deemed unsafe to confide the process of separation, or exfoliation, to nature. But, in what other manner could it be more safely accomplished, without hemorrhage, or pain to the patient—without any risk of a recurrence of inflammation, or of a fresh necrosis?

Is there reason to fear, that, when every thing is left to nature, the separation cannot be finished till after a very long period of time? It is true, say Weidmann, that the process frequently requires a considerable time; but, as the vitality of the bones is not possessed of much energy, and their component parts strongly cohere, slowness is inevitable in an operation, which depends entirely upon the vital power. What is it then which surgery can do to accelerate the process?

Will any of the above-mentioned topical applications have this effect? They are put upon the inert surface of a dead piece of bone, in which no vital power, or action, can be again excited. When acrid, they prove irritating, inflaming, and destructive of the neighbouring flesh, without any utility—and cause pain to the patient, which is compensated by no good. Would the perforations, recommended by Celsus, Belloste, and many others, have the desired effect? If,

says Weidmann, they are confined to the dead bone, they cannot have more effect, than the scarifications, which were formerly practised by ignorant surgeons in cases of gangrene; and, if they extend to the living bone, this will be injured or at least run the risk of being so. Lastly; Weidmann demands, if the separation can be accelerated by the actual cautery, which cannot act upon every point of the necrosis, and which, unless applied with the greatest precautions, will burn the subjacent parts, and bring on a new attack of inflammation, without forwarding the exfoliation in the smallest degree?

Of what use can rasping and scraping instruments be, which act merely upon the dead part? Or will the gouge, and other cutting instruments, do more good? They cannot take away the whole of the dead portion, without injuring the adjacent living bone, and causing a risk of another necrosis. And, if they leave any pieces of the old dead bone behind, nature will be as long in effecting the separation of these, as she would have been in detaching the entire necrosis.

Weidmann mentions a case, which occurred in the hospital of St. Roch at Mentz. A man's legs were seized with mortification, in consequence of exposure to cold; the whole of the dead parts separated; and the bones were sawn through on a level with the living flesh. A portion of the end of each bone, however, was afterward thrown off altogether by nature, and Weidmann thence concludes, that the previous use of the saw had been fruitless. Weidmann then cites another case of mortification of the leg and half of the thigh, which was the consequence of a putrid fever. The leg sloughed away, leaving the lower portion of the thigh-bone uncovered and projecting. Under a tonic plan of treatment, this part of the bone spontaneously separated. As, however, a considerable quantity of integuments had been destroyed, the ulcer was slow in healing; but, it cicatrized at last, and the young woman continued well long afterward.

Weidmann has quoted the memorable case, in which Mr. Charles White first sawed off the upper part of a diseased humerus. (See *Amputation*.) As, in this instance, nature accomplished of herself the separation of another dead portion of the same bone, two months after the operation, Weidmann seems disposed to think the cure would have happened equally well without it.

In cases of slight superficial necrosis, surgeons have frequent opportunities of trying every kind of topical application; and when the cure takes place, during the use of any of them, the benefit is ascribed to whatever happens to be in use. But, says Weidmann, in numerous more serious examples of necrosis, it is impossible to make these applications reach the whole surface of the dead bone; but, notwithstanding this circumstance, the separation is not impeded. Some exfoliations happen, without our knowing of their occurrence, and without a thought

having been entertained of promoting them by any vaunted applications. We even see necrosis separate, whose situation rendered them inaccessible to our remedies; such are the necrosis, which occur within the long bones, and comprehend the whole of their cylindrical shaft or body. What surgeon shall presume to boast of his having effected by topical applications, the separation of the whole lower jaw-bone, a thing, which nature has very frequently accomplished? And, when, as often happens, the entire diaphysis of the thigh-bone, tibia, or other long bone, comes away; or, split longitudinally, such bone loses a half of its cylinder; how is it possible for any topical applications to reach every point, at which the separation occurs?

The internal remedies, such as assafoetida, madder, sarsaparilla, hemlock, belladonna, onopordum, lime-water, &c. recommended by numerous practitioners, have in reality no direct efficacy in promoting the separation of necrosis: if, says Weidmann, they do any good, it can only be by their tonic and alterative qualities, or rather by keeping the patient amused, so as to gain the requisite time for the completion of the process of exfoliation. The employment of all these ineffectual means, Weidmann conceives, must have originated from ignorance of the process, followed by nature in separating dead portions of bone, and from ascribing to the arterial pulsations or the power of the granulations, what certainly depends upon the action of the absorbent vessels.

A question here naturally presents itself.—Would there be any utility in exciting by stimulants the action of the lymphatic vessels, in order to accelerate the separation, of which it is the efficient cause?

Weidmann thinks, that very beneficial effects might result from the plan. But, he asks, what means should be used for this object? Cold? Purgative medicines? Repeated vomits? Squills? Camphor? Neutral Salts? Issues? (*Vid. Wrisberg, Comment, Soc. Reg. Gott. Vol. 9, p. 136, 1789.*) He adds, that, perhaps, many valuable discoveries will hereafter be made on this subject.

The reasons already detailed, and a variety of experiments successfully made by Weidmann, lead him to set it down as an established principle, that the separation of a necrosis is almost entirely the work of nature, and that surgery can do very little in the business.

Ignorance of this important fact paved the way to the wrong practice of making incisions, for the purpose of exposing the whole surface of a necrosis, immediately the existence of the disorder was known. As such incisions very soon closed up again, so as to leave only a small outlet for the matter, they were in many cases repeatedly practised before the dead bone became loose.

The avowed design of the incisions was to make room for the topical remedies, which were to render the exfoliation quicker; but, as these remedies possess no real efficacy, it follows, that making incisions, before the

dead bone is loose, only torments the patient, without producing the least benefit.

The orifices of the ulcers, then, which allow the discharge to escape freely, are, says Weidmann, sufficient as long as the fragments of bone are not entirely detached, and the surgeon should all this period abstain from the use of the knife.

Although Weidmann condemn every mode of treatment, which is inefficacious, painful, and sometimes even hurtful, he would not have it supposed that he altogether rejects all assistance from medicine. On the contrary, he approves of all those means, which are consistent with the views of nature, which really assist her, and do not tease the patient to no purpose. In short, says he, *the indications are limited to removing the original cause of the disease; to alleviating the symptoms; to supporting the patient's strength, and improving the state of the constitution, in whatever respect it may be bad; and, lastly, removing the dead portions of bone, when they become loose.*

Above all things (continues this sensible practitioner) the surgeon must not regard every piece of exposed bone, as necessarily affected with necrosis, and, in consequence of such idea, have recourse to acrid, drying caustic applications. Such means are not only useless, but absolutely pernicious; because they may actually cause a necrosis, which did not exist, before they were used, and which would not have taken place at all, if only mild simple dressings had been employed.

When the disease presents itself with violent symptoms, the inflammation and fever being intense, the severity of the case is to be assuaged by low diet, antiphlogistic remedies, emollient applications, and venesection in moderation, the disease being one which is of long duration, and apt to wear out the patient's strength. Here, perhaps, topical bleeding ought always to be preferred to venesection. When the necrosis has arisen from syphilis, scrophula, or scurvy, &c. the medicines, calculated for the cure of these affections, must be exhibited, ere any favourable changes can be expected in the state of the diseased bone.

Lastly, it is the duty of the practitioner to extract the fragments of dead bone, in order that the deficiencies produced by them may be filled up, and the ulcers of the soft parts heal.

Nature, who succeeds by herself in detaching the dead pieces of bone, can do very little in promoting their passage outward. Frequently, indeed, she has no power at all in this process, and it is only from surgery that assistance can be derived. When a dead piece of bone is still adherent at some points, its extraction should be postponed, until it has become completely loose. If it were forcibly pulled away, there would be danger of leaving a part of it behind, which must have time to separate, ere the cure can be accomplished.

But, when a fragment is entirely detached, and the orifices of the sores are sufficiently

large, it is to be taken hold of with a pair of forceps, and extracted.

When the ulcer has only a very narrow opening, suitable incisions must be practised, in order to facilitate the removal of the loose dead bone.

Sometimes, the dead fragment protrudes from the ulcer, and projects externally, so that, if loose, it admits of being taken hold of with the fingers, and removed. In this way, Weidmann took away a large dead piece of the humerus, which protruded nearly two inches out of an ulcer in the middle of the arm. The patient was a young lad, 14 years of age; and the limb concave within, convex externally, thicker, and one inch shorter than its fellow. He got quite well three weeks after the removal of the dead bone.

We have already adverted to the example, recorded by Weidmann, in which a shoemaker removed by himself nearly the whole body of the tibia. Doubtless, the projection of the bone, and its looseness, enabled the man to do this easily with his fingers. But, there are cases, which present more difficulty; such are those, in which the sequestrum is included in a cavity, either of the original, or new bone.

The old surgeons were in the habit of amputating limbs which were in this state; although instances were not wanting in their days to prove the possibility of relieving the disease, without amputation. This blamable custom of removing every limb, thus affected, is justly exploded from modern surgery. Albucasis was the first who attempted to cure such a case of necrosis, by the judicious employment of the knife and saw. (*Lib. 2, cap. 88.*) The same kind of practice was successfully adopted in two instances by the celebrated Scultetus. (*See Armament Chirurg. Tab. 46, and Obs. 81.*) This commendable method, however, afterward fell into disuse, until M. David, by twenty examples of success, refuted all the objections which had been urged against it. (*P. 197.*) Since the period of this distinguished author, the practice has been imitated by all enlightened surgeons, so that the case is no longer regarded as a disease necessarily requiring amputation. M. Boussetin has cut out the sequestrum eight times from the tibia, and four times from the thigh-bone, with perfect success. (*Vid Mém. de la Société Royale de Médecine, Tom. 4.*)

The method consists in exposing the bone, and making in it an opening of sufficient size for the removal of the loose dead fragments.

Experience has proved, not only that, patients affected with necroses, easily bear this operation, but also that after its performance, the ulcers commonly heal very favourably, the health becomes re-established, and the functions of the part affected are hardly at all impaired.

Surgeons, however, are not indiscriminately to choose any period for doing the operation. If they are too hasty, they will run a risk of finding the dead portion of bone still

adherent to the adjacent parts; and, if they delay too long, the patient may be irrecoverably reduced, while the new bone, on account of the hardness which it has now acquired, cannot be so easily perforated.

Patients are met with, who have been afflicted with necrosis several years. In such cases, great circumspection is necessary, and the practitioner should carefully endeavour to ascertain, that the dead pieces of bone have not been absorbed, or come away piecemeal in the discharge, lest an useless operation should be done, as once happened in the practice of M. Boussetin. (*Mém. de la Société Royale de Médecine. T. 4, p. 304.*) Therefore, when the disease is of long continuance; when the discharge is much less than it was at the commencement; when small pieces of bone have at times been voided; and the sequestrum cannot be felt with a probe; it is doubtless, says Weidmann, most prudent to abandon all idea of operating, and allow nature to finish what she has so well begun. In short, when the sequestra are undergoing a gradual absorption, without ever making their appearance externally, or giving any considerable disturbance to the constitution, or, when the dead bone is making its way outward, without occasioning urgent inconveniences; the surgeon should interfere very little with the natural progress of the case. When the dead bone does not tend to make its way through the skin, but lies quietly concealed in the new osseous shell, the occurrence of extensive suppurations may be prevented, by occasionally applying leeches, and keeping open a blister with the savine cerate, as recommended by Mr. Abernethy in his lectures, and Mr. Crowther, in his work on the White-Swelling. The blister will, at the same time, have great effect in promoting the absorption of the sequestrum, and, of course, in accelerating the process of cure.

If the surgeon operate as soon as the sequestrum becomes loose, he will find the new bone so soft, that it can be divided with a knife; a circumstance, which materially facilitates and shortens the operation.

Keeping in mind the foregoing precepts, the surgeon is to begin with exposing the bone in which the sequestrum is contained. When the bone lies immediately under the skin, Weidmann recommends making such incisions as will lay bare the whole of its surface, and when its situation is deeper beneath the muscles, he even sanctions cutting away as much of the flesh as may be necessary to allow the instruments to be freely worked upon the bone. I cannot, however, see the propriety of this advice; exposing the whole surface of the bone in the first instance, before it is known whether the saw need be so extensively used as to require such a denudation, certainly appears irrational. And, as for cutting away any portions of muscle, this can be no more necessary here, than it is in the operation of trephining. But it is unquestionably proper

to make with the bistoury sufficient space for the use of whatever instrument is employed for the division of the bone. Yet it is only necessary to make this exposure in the first instance in one place. The surgeon can afterward enlarge the incision or practise others, as circumstances may indicate. The surface of the bone being brought into view, if the cavities, in which the dead fragments lodge, present apertures which are too narrow, these apertures must be rendered larger by means of small trephines, or saws constructed on the principles of those described by Mr. Hey of Leeds. The perpendicularly acting wheel-like saw, turned by machinery, and invented by Mr. Machell, here promises also to be of important assistance. It has been used by Sir Astley Cooper, who has given an engraving of it in his *Surgical Essays*, Part I. Pl. 8. Fig. 7. And another saw, constructed on somewhat similar principles, has been employed by Graefe of Berlin with great advantage for several years. A tract, giving an account of it, was sent to me by the late Dr. Albers, a little before his death; but, as I have now lent the publication to Mr. Stanley for the purpose of assisting Mr. Evans in the construction of the instrument, I shall merely add, that Graefe's saw is turned by a handle which projects horizontally from the cutting part of the instrument, and that it has a frame or fulcrum, on which it works. With such instruments the pieces of bone extending across the above openings, and impeding the extraction of the sequestra, may also be removed.

But when the preceding cavities are closed on every side, and it is impossible to reach into them in any other way, than through the cloacæ, a trephine is to be applied, which must comprise within its circle a half of the fistulous opening. The crown of the trephine, however, must not be broader than the cavity of the bone, nor yet narrower than the sequestrum.

If, after making a perforation in this manner, the sequestrum should be found too large to pass through the opening, a small saw must be employed for enlarging the aperture.

When the bone is so hard and thick that it cannot be well cut with a saw, the surgeon has the sanction of authority and experience, for using a gouge and mallet.

When the sequestrum is found to be very large, it will be necessary to expose more of the surface of the bone by incisions. In this sort of case, Weidmann recommends applying the trephine to the upper and lower parts of the cavity, and then cutting away the intervening portion of bone with the saw or gouge. But there can be no doubt that a more prudent way would be to go on with the enlargement of the aperture in the bone, at the place where the first perforation took place, if the sequestrum presented itself equally well there, because, by proceeding in this manner, the surgeon might discover that the dead fragment could be taken out without so great a destruction of

bone as is caused in the other mode; and, if this were not to be the case, no harm is done, as the necessary removal of bone can be continued.

When the bone, which includes the sequestrum, is a new production, and the operation is not too long deferred, the soft state of the bone will enable the operator to perform the needful excisions with the bistoury alone.

When the sides of the cavity, in the original bone, are thin, fragile, and pierced with numerous holes, the surgeon can break away a sufficient portion with a pair of forceps.

When several sinuses exist in the bone, each may be dilated, in the manner which seems most advantageous.

Sufficient openings having been made into the cavities including the sequestra, the next object is to extract these dead portions of bone. In accomplishing this part of the operation, Weidmann particularly advises two things; first, that no piece of the sequestrum be left behind; secondly, that no injury be done to the membrane, which lines the cavity in which the dead bone is lodged.

This author observes, that there are examples, in which the vicinity of certain parts impedes the surgeon from making an opening in the bone, large enough for the extraction of a voluminous sequestrum in an entire state. In this circumstance, he recommends the sequestrum to be broken into pieces by any convenient means, and the fragments to be separately removed.

Weidmann has recorded an extremely interesting case to prove how much may sometimes be effected by taking away the sequestrum. A man, 34 years of age, who had an internal necrosis of the tibia, with abscesses and œdema of the whole limb, and who was reduced to the lowest ebb of weakness, was put under this excellent surgeon's care. A perforation was made with a trephine in the upper head of the tibia; but, this opening not proving ample enough, it was enlarged with a small saw, and a gouge and mallet. The sequestrum was then extracted. The patient's state afterward gradually improved, and in nine months he was completely well.

It is not to be dissembled, however, that cases do exist, in which amputation affords the only chance of saving the patient's life. In fact, it sometimes happens, that the cavities, in which the sequestra are contained, communicate with those of the neighbouring joints, which then become filled with matter, and carries attacks part of the bones, to which the necrosis does not extend. On some occasions, the dead pieces of bone are very numerous, and each has a separate cavity; while, in other instances, the sequestra lie so deeply, that a passage for their extraction cannot be prudently attempted. Sometimes, also, a necrosis is complicated with another disease in its vicinity. Lastly, such may be the reduced state of the patient's health, and the parti-

cular condition of the necrosis itself, that the constitution cannot hold out during the whole time which would be requisite for the detachment of the sequestrum. Under circumstances like these, amputation is necessary, and ought not to be delayed.

removed the mental portion of the lower jaw, may be found in the *London Medical Repository*, Vol. 3, p. 432. The wound healed by the first intention, and the patient recovered.

*NEEDLE. See APPENDIX.

NEPHROTOMY. (from *nephe*, a kidney; and *τομή*, to cut.) The operation of cutting a stone out of the kidney; a proceeding which, perhaps, has never been actually put in practice. In the *Abrégé Chronologique de l'Histoire de France par Mézerai*, and in the *Phil. Trans.* for 1696, two cases of what is called nephrotomy are mentioned; but several circumstances in the accounts led Haller and others to conclude, that the operation alluded to in the first work was nothing more than the high operation for the stone. With respect to the example in the latter work, the particulars are not detailed enough to prove that an incision was really made into the kidney. There is no doubt that stones have often been extracted from abscesses about the region of the kidney, after being touched with a probe. But, with regard to cutting into the kidney, the deep situation of this viscous, and the want of symptoms by which the lodgment of a stone in it can be certainly discovered, will always be strong objections to the practice. When a stone, from its size, cannot pass from the kidney, and excites inflammation and suppuration, no doubt the surgeon may make an incision into the tumour, and extract the calculus. In this sense, nephrotomy is certainly a practicable operation. Warner contends that it can only be practised in such circumstances, notwithstanding whatever may have been said by Marchetti or others, upon the subject. In such a case, the operation would not be attended with any greater difficulty than the opening an abscess in any other part of the body. (See *Warner's Cases in Surgery*, p. 241, Edit. 4.)

NITRIC and NITROUS ACIDS. As these are medicines of considerable importance in surgery, they claim particular notice. Nitrous acid is a yellow, or orange-coloured fluid, emitting when exposed to the air, deep orange-coloured extremely suffocating fumes. It consists of nitrous gas, loosely combined with nitric acid and water; and the colour varies according to the proportion of nitrous gas which is present.

Nitric acid is a colourless, or very pale yellow, limpid fluid, emitting when exposed to the air, white suffocating vapours. It is highly corrosive, and tinges the skin yellow, the tint remaining till the epidermis peels off. The constituents of nitric acid, independent of the water, which gives it the fluid form, are 25.97 azote, and 74.03 oxygen, in 100 parts. (See *Thomson's Dispensatory*, p. 438, 439, Ed. 2.)

Both these acids, in a diluted state, have been extensively tried, as a substitute for quicksilver in the cure of lues venerea; and really upon looking over the mass of evidence brought forward in proof of the power which they seem to possess over this disease, it is at first difficult to entertain the

slightest doubt of their efficacy. The cases adduced are numerous, some of them minutely detailed, the gentlemen who have published them, men of reputation and abilities, and (what especially claims attention) these examples of successful treatment are generally allowed to have been syphilitic, or, at all events, complaints, the differences of which from the venereal disease have not been, and could not be, specified. Whoever impartially considers the immense body of facts published by Dr. Kollo, Mr. Cruickshank, Dr. Beddoes Dr. P. G. Prioleau, of Charleston, South Carolina, and others, exemplifying the success with which the venereal disease may be treated by the nitrous or nitric acid, must be surprised to find, that the accounts delivered by these gentlemen by no means correspond to those of some other eminent practitioners. How to reconcile these seemingly discordant statements, whether by supposing some undefined differences in the nature of the cases adduced, or some variation in the goodness of the medicine itself, is indeed perplexing. Nor is a solution of the question at all facilitated, by the results of later investigations, tending to prove the general curability of syphilis without mercury, or any medicine whatever; because, if we admit this as a fact the circumstance of a considerable proportion of cases not yielding, or being radically cured, when the nitric and nitrous acids are exhibited, as asserted by Mr. Pearson and others, would argue, that giving such acids is worse than leaving the disease entirely to itself. The more I reflect upon all that we know about the venereal disease, however, the more I am inclined to adopt the sentiment, that it is not one disorder, but probably many, which go under this name, their exact shades of difference not having yet been detected nor described. If this supposition be admissible, the contradictory statements, given by various authors about what their experience has taught them of this or that mode of treating the disease, may all be immediately reconciled.

The practice of exhibiting nitric acid, in lieu of quicksilver, began with Mr. Wm. Scott, a surgeon at Bombay, who is said to have been led to the experiment by a suggestion thrown out by Girtanner, that the efficacy of the various preparations of quicksilver probably depended upon the quantity of oxygen combined with them. (*Grens. Journ. d. Physick. B. 3, p. 31, 1790.*) In August, 1793, Mr. Scott being himself afflicted with chronic hepatitis, resolved to take a quantity of oxygen, united to some substance, for which it has no great attraction, and after some reflection, nothing appeared to him better than nitric acid. September 11th, he took at different times about a dram of the strong nitric acid diluted water. Soon after drinking it, he felt a sense of warmth in his stomach and chest; but no disagreeable sensation, nor any other material effect. The two following days the medicine was continued, the gums beginning to be somewhat red, and enlarged. He slept ill; but

could lie for a length of time on his left side, which the disease of the liver had prevented him from doing during many months previous to this period. He also felt a pain in the back of his head, resembling what he had commonly experienced, when taking mercury. On the fourth day, his gums were a little tender; the headach and pain about his jaws still troubled him; but the symptoms of his liver complaint had already left him. The acid was continued on the 4th, 5th, and 6th days; the soreness of the mouth increasing, and a salivation taking place. On the 7th day, he felt his mouth so troublesome, that he took no more acid. His mouth got gradually well, and he found his health considerably improved.

Mr. Scott likewise administered the nitric acid in several cases of tedious intermittents, in two cases of diabetes, and in many syphilitic cases, with the happiest effect.

This gentleman's account of the nitrous acid was first published in the *Bombay Courier* of April 30th, 1796, and soon afterward republished in this country. (See "*An Account of the Effects of the Nitrous Acid on the Human Body*," by W. Scott, in *Duncan's Annals of Medicine* for 1796, Vol. 1, p. 375—383.) The hypothesis suggested by Girtanner, in 1790, that the efficacy of mercury in the treatment of the venereal disease depended upon the oxygen combined with this mineral, required but little extension to lead to the discovery of the antisyphilitic virtues of the acids. Yet Girtanner had all his attention so fixed on mercury, that it never struck him, that the principle on which he explained the efficacy of this medicine, might apply to other substances, which abound with oxygen, and are readily separable from it. This was the idea, which made Mr. Wm. Scott begin to suspect, that the nitric acid might be as efficacious as mercury in venereal cases; and as he had already observed a great analogy between the effects of this acid and mercury in the experiments which he made with the first of these medicines in his own case of chronic hepatitis, and other diseases, he ventured to recommend the trial of it in syphilis. The result was, that the acid was found not only to equal the preparations of mercury, but sometimes to surpass them; for it had the best effect in some cases where mercury had been tried in vain, and it was observed to remove the disease in less time than the common remedy. Nor were any of the inconveniences, usually known under the names of *mercurial symptoms*, *mercurial fever*, found to be the consequence of its employment, however long continued. With it alone many syphilitic cases are stated to have been cured, the disease not having returned at the end of two years. (See *Duncan's Annals of Medicine*, &c. Vol. 1, 1796, p. 383, &c.)

The letter from Mr. Scott to Sir Joseph Banks, describing these effects of the nitric acid in India, soon excited the attention of medical practitioners both in Europe and America, the inquiry being taken up with

all the zeal which the preceding accounts were calculated to inspire. In 1797, Mr. G. Kellie, a surgeon of the navy, gave the nitric acid to five sailors affected with gonorrhœa, venereal sores, and buboes. Three of them were perfectly cured. A fourth, who had sores on the glans, and who had been much debilitated by the long use of mercury, recovered nearly his original strength, while taking the acid; but the sores were not healed, before mercury had been repeatedly exhibited. In the fifth patient, who was also scrofulous, the nitric acid contributed very essentially to heal the sores. On the whole, Mr. Kellie seems to regard this medicine as possessing very efficient power of stopping and eradicating the venereal disease. (See *Letters from G. Kellie, respecting the Effects of Nitrous Acid in the Cure of Syphilis*. *Duncan's Annals of Medicine* for 1797, p. 254, 277.)

In the same year appeared a letter, in a German periodical work (*Hufeland's Journal der Prakt. Heilk.* 4 Bd. p. 356—359,) written by Albers, giving the history of a venereal ulcer on the breast, successfully treated by the nitric acid.

The reports of Dr. Prioleau, who tried the nitric acid in the autumn of 1797, are particularly favourable to the practice. "We have seen (says he) every stage and form of syphilis cured by this medicine, and even in habits broken down by the antecedent use of mercury, under which the disorder had gained ground. The patients recovered their health and strength in a short time, without the use of diet-drinks, bark, or any other tonic medicine whatever." (See *Caldwell's Medical Theses*, p. 103, 8vo Philadelphia, 1805.)

The praise of the nitric acid from numerous quarters induced Dr. Rollo to try it in the military hospital at Woolwich, and in conjunction with Mr. Cruikshank to examine further into the antisyphilitic virtues of oxygenated substances. The results of Mr. Cruikshank's investigations constitute the second part of Rollo's work on diabetes, published in 1797. The medicines which were selected for the experiments, were the nitric, citric, and muriatic acids, and oxygenated muriate of potash. Of these, the nitric acid and the oxygenated muriate of potash were found to possess the greatest efficacy; the first acting in many cases with remarkable mildness; the second, with greater expedition and certainty. The new plan was tried upon young persons, affected with primary venereal complaints, who had never used mercury, and no other internal medicine was given, except opium, when required for diarrhœa, or colic. The liquor plumbi acetatis dilutus was used as a wash for chancres. In debilitated subjects, sure and speedy good effects were observed uniformly to follow, and hence, previously to giving the acid to strong, plethoric patients, the method of preparing them for this treatment by purging and bleeding was adopted, as is alleged, with great success. In some cases, after the nitric acid had been continued, a

good while without producing a salivation, the exhibition of mercury for a short time completed the cure. Mr. Cruikshank's opinion in favour of the new remedies was on the whole extremely sanguine, as he ventures to express his conviction, that they would render the employment of mercury in the cure of the venereal disease unnecessary. (See *An Account of two Cases of Diabetes Mellitus, with Remarks, &c.*, by John Rollo, M. D. Vol. 2, 8vo. Lond. 1797.)

In the same year, Dr. Beddoes published a valuable work, comprising all the information, which had then transpired respecting the antisyphilitic virtues of the nitric acid, with additional communications from his medical friends. (See *Reports principally concerning the Effects of Nitrous Acid in the Venereal Disease*, by Thom. Beddoes, Bristol, 1797.) And two years afterward, the same author finished a still more comprehensive volume on the subject. (*A Collection of Testimonies, respecting the Treatment of the Venereal Disease by Nitrous Acid*. Lond. 1799.)

From the preceding work we learn, that, in the Plymouth hospital, Mr. Hammick, gave the nitric acid to between sixty and seventy venereal patients, and that the cures were generally more speedily accomplished, than with mercury, no ill effects being produced on the system, similar to those usually remaining after the use of the latter mineral. He assures us, that, after the removal of the symptoms, the disease never returned, and that for debilitated, scorbutic, or scrofulous patients, affected with venereal complaints, the acid was found a most valuable means of relief.

Dr. Geach of the same hospital is also stated to have employed the nitric acid with such effect that he rarely had occasion for mercury, the livid colour of the countenance, sordid fetid excoriations of the scrotum, and other symptoms, which had long resisted the latter mineral, all quickly giving way to the new medicine. Another practitioner of the name of Giedlestone, however, had not equal success in his experiments, for, in several cases, the acid did not bring about a cure, and, after being continued eight or ten days, and inducing a salivation, it even rendered the condition of some patients worse. On the other hand, Mr. Sandford, a surgeon at Worcester, found the acid a very useful and effectual medicine in venereal cases, where mercurials had been long exhibited in vain. The trials of the nitric acid, made by Professor Rutherford at Edinburgh, had various results: the medicine sometimes proving completely ineffectual; and, in other instances, appearing to be a perfect antidote for the worst syphilitic complaints.

Dr. Beddoes concludes with some observations in answer to Mr. Blair, who had become averse to the new practice.

In 1798, Dr. Ferriar published some remarks on the nitrous acid. (See *Medical Histories and Reflections*, Vol. 3, p. 290—310.) He tried this medicine, in various ways, either alone, or after, or in conjunction with,

the exhibition of mercury. His inferences are, that, in the treatment of the venereal disease, the nitrous acid is useful only in protracted cases. He corroborates, however, the generally received opinion, that where the patient has been considerably reduced by the long, or injudicious employment of mercury, the nitrous acid is a most beneficial medicine.

In the same year, Mr. Blair wrote some observations on the venereal disease, and the new method of treating it. (*Essays on the Venereal Disease, and its concomitant Affections*, Lond. 1798.) In this work, the new remedies are generally condemned, as ineffectual, and hence originated a paper-war between this writer and Dr. Beddoes, "literarium certamen, non sine ble gestum," as Dr. Holst has expressed it. (*De Acidi Nitrici Usu Medico*. p. 73, 8vo. Christianæ, 1816.) In this controversy, numerous other practitioners readily joined, as for instance, Macartney, Rowley, Philips, Hooper, Lidderdale, &c., all of whom adduced cases, in proof of the frequent inefficacy of nitrous acid, and these were collected and published by Mr. Blair, who suspecting the cases of failure with this medicine to be more numerous, than those of success, considers himself unjustified in regarding it as an antisyphilitic to be depended upon. At the same time, he bears testimony to the virtues of the acids, exhibited in venereal cases either singly, or alternately with mercury, where the patient's strength had been much reduced; and he confesses, that venereal buboes, indurated glands, nocturnal pains in the bones, and gonorrhœa, yielded to these remedies.

Seven years after the appearance of Mr. Blair's work, Mr. Pearson delivered his sentiments in a book of considerable merit. (*Observations on the Effects of various Articles of the Materia Medica in the Cure of Lues Venerea*, 2d Ed. Lond. 1807, p. 198, &c.) He relates a very few examples, in which the nitrous acid appeared effectual in curing chancres, and one of its virtues in gonorrhœa; the only one, which this gentleman had ever seen. The rest of his observations are unfavourable to the character of the medicine, as an antisyphilitic meriting confidence. The first trials, which Mr. Pearson made, were of the nitric acid; but, as he did not remark any of its effects to be different from those produced by the nitrous acid, he commonly employed the latter in the following form. Nitrous acid, two drachms, pure water a pint and a half, syrup four ounces. This mixture was usually taken in the space of twenty-four hours. As local applications, he employed a saturnine lotion to the sores; and emollient poultices to tumours and inflamed parts. All mercurial applications were absolutely prohibited. (P. 200.) In making his inferences, in a subsequent page, he says, "The nitric and nitrous acids have removed both primary and secondary symptoms of syphilis; and, in some instances, it seems that the former have not recurred, nor have secondary symptoms appeared at the period they commonly show

themselves, when the cure has been imperfect. But, as far as my own experience extends, and that of many respectable friends, who are connected with large hospitals, a permanent cure has never been accomplished by these acids, where secondary symptoms have been present. The same acids, when exhibited with the utmost care and attention to many patients, labouring under the primary symptoms of the venereal disease, and where they have agreed perfectly well with the stomach, have been nevertheless found inadequate to the cure of those symptoms. Indeed, the failures which have occurred, both in my own practice, and that of many of my surgical friends, have been so numerous, that I do not think it eligible to rely on the nitrous acid, in the treatment of any one form of the lues venerea." However, Mr. Pearson joins several other writers in bearing witness to the good effects of this medicine, where impairment of the constitution renders the employment of mercury inconvenient, or improper. Here, he says, it will restrain the progress of the disease, and improve the health and strength. On some occasions, he thinks, that it may be given, in conjunction with a course of mercurial inunction, and he agrees with other practitioners about its supporting the tone of the stomach, acting as a diuretic, and counteracting the effects of mercury on the mouth and fauces. (P. 236—238.)

While these inquiries were going on in England, numerous experiments on the same subject were undertaken in France. In a work, published in 1797, Alyon positively declares, that mercury ought to be entirely relinquished in the cure of the venereal disease. (*Essai sur les Propriétés Médicinales de l'Oxygène, et sur l'application de ce principe dans les maladies vénériennes, psoriques, et dartreuses*; Paris, an. 5, 8vo.) Here we find a relation of many cases, successfully treated in the hospitals of Val-de-Grace and St. Dennis, by the oxygenated muriate of potash, the nitric, oxymuriatic, and citric acids, an ointment of the author's own invention, called the unguentum oxygenatum, being applied to the sores. (See *Unguentum*.) In a second edition of the above book, which came out in 1799, the same doctrine and practice are corroborated by further observations.

In 1798, Dr. Swediaur brought out the third edition of his treatise on the venereal disease, (*Traité Complet sur les Symptômes, les Effets, la Nature, et le Traitement des Maladies Syphilitiques*), in which he highly commended the virtues of the nitrous acid, and oxygenated acid, as expediting the cure, with very few exceptions. But, in the fourth edition, he retracts, and details the results of the new practice, as tried upon twenty-six venereal patients in the *Hospice d'Humanité*: of these only seven cases remained permanently cured; the issue of seven others was doubtful; and, in twelve, no amendment was observed.

Nor were the statements of Lagneau much more favourable to the reputation of the ni-

trous acid as an antisyphilitic; for, from the trials which he had seen made of it, he concluded, that it was not unfrequently ineffectual, while it was apt to excite an obstinate cough and hæmoptysis. (*Exposé des Symptômes de la Maladie Vénérienne, des diverses Méthodes de traitement, &c.* 3me Ed. Paris, 1812.)

The reports of Dr. Odier, of Geneva, however, were rather more propitious, as he says, the nitrous acid increases the efficacy of mercury, and lessens or removes the inconveniences arising from its unskilful administration. But he candidly acknowledged, that his experience had not been great enough to enable him to pronounce, what degree of confidence ought to be put in the acid as a remedy for syphilis. (*Man. de Méd. Pratique*; Genève, p. 249.)

The practice of exhibiting the nitric acid for the cure of syphilitic affections was not tried in Germany so soon as in England and France. Albers, however, in 1797, gave an account of Scott's successful experiments, and of the efficacy which they evinced in some cases seen by that gentleman in the Infirmary at Edinburgh. (*Hufeland Journ. d. Prakt. Heilk.* Vol. 20, p. 68;) while Behn, who had visited Paris in the winters of 1797 and 1798, briefly noticed the various results of the trials, which he had seen made of this acid, in the "Clinique de Perfectionnement," for the cure of obstinate syphilitic cases. (*Erinnerungen an Paris, zunächst für Aerzte geschrieben von G. H. Behn* Erst. Heft. Berl. 1799, p. 110.) At length, in 1799, Struve, who translated Mr. Blair's first publication into German, communicated to the profession the particulars of some experiments made by himself with the acid; he declares, that he had very often found it an excellent remedy for inveterate pains in the bones, and derangement of the constitution, produced either by the syphilitic virus or the injudicious employment of mercury. However, in common cases, mercury is represented as the best antisyphilitic medicine.

Afterward Professor Würzer was induced to try the nitrous acid in a case, that had resisted mercury for six months, the patient having got rid of some chancres and a sore throat, but being left with violent nocturnal pains, blotches, and sores all over his body, and in a very reduced condition, without the least appetite. Here, in 27 days the acid, together with sarsaparilla and the warm bath, not only removed all the complaints, but actually restored the patient's original strength, and healthy appearance. In a short note annexed to this case, Hufeland gives it as his opinion, derived from experience, that the nitrous acid is effectual in obviating the sequelæ and anomalous diseases induced by lues venerea, but that it does not permanently cure the latter affection itself. (*Etwas über die Keilkraft der Salpetersäure in venerischen Krankheiten*, Hufel. Journ. d. Prakt. Heilk. 8 Bd. 4 St. p. 139—143.)

These vague and endless contradictions induced Schmidt, an eminent professor at Vienna, to make a series of experiments with

the nitric acid, for the purpose of ascertaining its power in cases of syphilis. (See *Beobacht. der Kaiserl. Königl. Med. Chir. Josephs Akademie zu Wien*, 1, Bd. Wien 1807, p. 147—189.) Under his directions, the acid was given in the winter of 1799 to five soldiers, affected with the venereal disease in various degrees and forms. In every one of these cases, the medicine was found efficacious; but the degree of efficacy was remarked to vary considerably according to the nature of the constitution, and the kind of local complaints. Thus, in robust patients, moderate doses of the acid soon produced benefit; while, in weak persons, disposed to scurvy or scrofula, a larger quantity of the medicine, and more time were requisite. This assertion we see is exactly the reverse of what appeared to happen in the cases treated by Mr. Cruikshank. However, Professor Schmidt entertains strong doubts, whether the nitric acid is adequate to the cure of all the forms of syphilis, and he thinks, that neither this nor any similar medicines will ever supersede the necessity for mercury.

Ontyd, a Dutch practitioner, approves of the use of the nitric acid, with some limitation: while he admits its efficacy in removing local symptoms, he is strongly against its employment in cases of confirmed lues, as they used formerly to be termed. The latter assertion, I conceive, is exactly contrary to the results of modern experience, most of these protracted bad cases being those, which are particularly benefited by this acid. (*Nieuwe scheidekundige Bibl. te Amsterdam*; by Doll. 6de St. 1799, p. 166.) The tracts of Boetticher, (*Bemerk. über Medicinal-verfass. Hospit. u. Curarten. 2tes Heft. Königsb. 1800*, 8,) of Ritter (*Erfahr. über die innerl. u. äusserl. Anwendung d. Salpeters. Hufel. Journ.* 10 B. 3 St. p. 191—197,) and of Frankenfeld (*Hufeland's Journ. der Prakt. Heilk.* 22 Bd. 4 St. p. 96—98) need only be specified here, as decidedly unfavourable to the character of the nitrous acid, as a remedy for syphilis.

The following German practitioners are to be classed with the moderate approvers of the medicine, though as Holst observes, (*De Acidi Nitric Usu Medico*, p. 88; *Christianæ*, 1816,) they do not appear to have made any new experiments of their own with it, viz. Munchmeyer (*Comm. de Viribus Oxygenii in procreandis et savandis Morbis*; *Goett.* 1801, p. 54); Burdach (*Hdb. d. neuest. Entdeck. in d. Heilmittellehre*; *Leipz.* 1806, p. 11, 12); Aronsson (*Vollst. Abhdl. aller venerischen Krankh. Berl.* 1808, p. 211); Horn (*Hdb. der Prakt. Arzneymittellehre, 2te. Aufl. Berl.* 1805, p. 95); Consbruch (*Taschb. d. Arzneymittellehre, 2te. Aufl. Leipz.* 1810, p. 283); Toepelmann (*Neuere Erfahr. über zweckem. Behdl. venerisch. Schleim ausflüsse, &c. Leipz.* 1809, p. 151); and Wollkopfs (*Pharmac. extemp. Leipz.* 1811, p. 92.)

Another German author, who has entered into the present inquiry, is F. A. Walch, whose statements are very unfavourable to the use of the nitrous acid, as he absolutely denies, that it ever accomplishes a lasting

cure. (*Ausführl. Darstell. d. Urspr. &c. d. Venerisch. Krankh. Jena*, 1811, p. 197, 198.)

In a periodical work, mention is made of one case, which, after resisting a long course of mercury, and also the nitric acid, was ultimately cured by restricting the patient for a few weeks to a very reduced diet. (*Hufel. Journ. d. Prakt. Heilk.* 34, Bd. 2 St. p. 56.)

For much of the foregoing historical account, I am indebted to *Holst's Diss. de Acidi Nitrici Usu Medico*, 8vo. *Christ.* 1816; in which an explanation of the results of further trials of the medicine in Denmark and Sweden may be perused. From these countries, the reports are mostly less favourable to the reputation of the medicine, than the accounts already delivered.

According to Holst the following are the chief circumstances, under which the employment of nitrous, or nitric acid is generally sanctioned.

1. Where the disease is complicated with scurvy.

2. Where it is attended with scrofulous enlargement of the glands, and other strumous symptoms. I may remark, however, that these complaints are often as undefinable, as some of the forms of syphilis, and therefore the rule is frequently difficult of application.

3. Where the disease is accompanied with considerable debility, either brought on by mercury, or febrile indisposition.

4. Where from idiosyncrasy, mercury cannot be safely exhibited. Experience fully proves, that there are some patients, more especially females, in whom a few grains of mercury taken inwardly, or mercurial frictions on the most limited scale, bring on vomiting, rheumatic pains, nervous febrile symptoms, colic, spasms, severe headach, and a rapid immoderate salivation.

5. Where pregnant women are the subjects of the disease, several practitioners forbid the use of mercury, during the latter months of pregnancy. (*Bangii, Prax. Med. Hafn.* 1789, p. 570; *Swediaur*; *Aronsonn Vollst. Abhdl. aller Ven. Krkht. Berlin*, 1811, p. 211.) Holst observes, that the reason of this advice is not stated, though no doubt it must proceed from an apprehension of mercury exciting a miscarriage.

Mr. Pearson's mode of exhibiting the nitrous acid has been already mentioned. Some practitioners give it as follows: *R.* Gum. Arab. \mathfrak{z} iv. aquæ menth. \mathfrak{z} viiij. acid. nitrosi, vel nitrici \mathfrak{z} ij. \mathfrak{z} ij. F. M. Of this mixture, a table spoonful is to be taken every hour mixed with some sweetened water. Should the acid occasion colic, or diarrhœa, its quantity must be lessened, and opium added to the mixture.

As the nitrous and nitric acids decompose and destroy the teeth, some care must be taken to prevent so serious an effect. Their being properly diluted, and blended with sugar, syrup, or mucilage, will materially tend to hinder the evil. But the safest way is always to drink the mixture through a glass tube, and wash the mouth well immediately after every dose.

Strong nitrous acid, extricated in the

form of vapour, is often employed as a means of purifying the air of large crowded hospitals and sick-rooms; a subject on which the observations of Dr. J. C. Smyth and G. de Morveau are particularly interesting. The nitrous acid is sometimes taken by accident, or design, as a poison. Here, according to the observations of Tartra, Orfila, &c. the best antidote is calcined magnesia, or soap. If the first of these articles be at hand, a dram of it, suspended in a glass of water, is to be instantly given, followed by copious draughts of some mucilaginous drink, the design of which is to fill the stomach, and excite it to reject the diluted poison. While the vomiting is going on, the doses of magnesia are to be repeated, and followed as in the first instance by draughts of linseed tea, solution of gum arabic, milk, or broth.

The nitrous acid has also been extensively tried as a means of curing syphilitic complaints, in the form of what is termed the *nitro muriatic bath*, of which a description will be given in speaking of the *Venereal Disease*.

When reiterated courses of mercury induce dropsy, as not unfrequently happens in very impaired constitutions, Mr. Carmichael prescribes the nitrous acid, in as large doses as the stomach will bear, conjoined with digitalis. (*Essays on Venereal Diseases*, &c.) Taken in doses of eight, ten, or fifteen drops, two or three times a day, it is alleged to be efficacious in the cure of some eruptive complaints, especially of the lower extremities, connected with disorder of the liver. (*Wilson's Pharm. Chir.* p. 6.) Another well-informed writer also bears testimony to its good effects when used together with mercury, for old obstinate ulcerations of the legs, though no venereal taint can be suspected; and, he says, it may be applied with benefit as a local stimulant to fetid ulcers, attended with a thin ichorous discharge, and in some examples of caries. In such cases ℥ij. of the diluted acid is to be mixed with ℥j of water. (See *A. T. Thomson's Dispensatory*, p. 441, Ed. 2.) With respect to caries, in the sense of *necrosis*, however, the reader will understand from what is stated in the article on that subject, that it can rarely be advisable to apply this or any other acid either to the exfoliating portion of bone or to that which is yet alive. The nitrous acid has sometimes been used for destroying warts, condylomata, and other excrescences. By Sir E. Home it is praised as a local application for certain ulcers when properly diluted. (See *Ulcers*.) It is likewise commended by some writers as a very useful local application in cases of hospital gangrene. And an interesting paper has been just published by Mr. R. Welbank, detailing the excellent effects of the undiluted nitric acid as an application to diseases which he has described under the name of sloughing phagedæna, and which he considers as identical with hospital gangrene. "If the disease be not far advanced, (says this gentleman) I at once apply the undiluted acid, after cleansing the surface with tepid

water, and absorbing the moisture with lint. Where, however, there is a thick and pulpy slough, it is better to remove as much of it as possible, with forceps and scissors, before the application is made. The surrounding parts being then protected by a thick coating of lard, or cerate, I proceed to press steadily, and, for some minutes, a thick pledget of lint, previously immersed in the undiluted acid on every point of the diseased surface, till it appears converted into a firm and dry mass. The parts may be then covered with simple dressings, and evaporation kept up externally by cooling lotions." An opiate is afterward given, and the eschar removed at the end of 16 or 20 hours. When there is no pain, and the subjacent parts present a florid healthy appearance, the sore may now be treated as a common wound, though stimulant dressings are generally best. Mr. Welbank uses the *ceratum lapidis calaminaris*, or a solution of the *argentum nitratum*, in the proportion of two or three gr. to an ounce of distilled water. But, if there is any recurrence of pain, whether the affection be slight or severe, and the remaining slough deep or superficial, Mr. Welbank advises the reapplication of the undiluted acid. (See *Med. Chir. Trans.* Vol. 11, p. 369.) The cases reported by this gentleman are highly favourable to the practice which, as may be seen by reference to the article *Hospital Gangrene*, is not entirely new with respect to this disease, and in speaking of *Mortification*, I have mentioned, that it was Dr. Kirkland's practice sometimes even to dress certain sloughing diseases with a solution of mercury in nitrous acid. But, notwithstanding these facts, and the well-known custom of Sir Astley Cooper to apply to sloughing phagedenic ulcers the nitric acid lotion, composed of 50 drops of the acid, and a quart of distilled water, I feel that Mr. Welbank has rendered a service to the profession by drawing their attention still more particularly to the use of undiluted nitric acid in the forms of phagedæna, which he has so well described.

NODE. A swelling of a bone; a thickening of the periosteum, or a fascia; or a tumour on a tendon, from a venereal cause. See *Exostosis* and *Venereal Disease*.

NOLI ME TANGERE. A species of *lupus*, under which term Dr. Willan intended to comprise, together with the *noli me tangere* affecting the nose and lips, other slow tubercular affections, especially about the face, commonly ending in ragged ulcerations of the cheeks, forehead, eyelids, and lips, and sometimes occurring in other parts of the body, where they gradually destroy the skin and muscular parts to a considerable depth. (*Bateman's Synopsis of Cutaneous Diseases*, p. 296, Ed. 3.)

Sir E. Home says, that the ulcers, for which he has been led to employ arsenic, are named, from the virulence of their disposition, *noli me tangere*, and are very nearly allied to cancer; differing from it in not contaminating the neighbouring parts by

absorption, but only spreading by immediate contact. Ulcers of this kind differ exceedingly from one another in their degree of virulence; but they are all so far of the same nature that arsenic in general agrees with them, and puts a stop to their progress, while they are aggravated by milder dressings. (*Home on Ulcers, Edit. 2, p. 267.*)

The disease generally commences with small tubercles which change after a time into superficial, spreading ulcerations on the ala of the nose, more or less concealed beneath furfuraceous scabs. The whole nose is frequently destroyed by the progressive ravages of this peculiar disorder, which sometimes cannot be stopped or retarded by any treatment, external or internal.

The specific ulcerations do not generally extend to the parts far within the nostrils; but, at the time that I am writing this article, there is, under Sir L. Harvey, in St. Bartholomew's Hospital, a curious example, in which the greatest part of the nose is destroyed, and the ulceration proceeds even through the front part of the palate into the mouth. The morbid process sometimes stops for a considerable time, and then is renewed with increased violence. The following case illustrates the nature of *noli me tangere*, and one mode of treatment, to which it yielded. Jane Chatillon, 45 years of age, was attacked, in the course of September, 1788, with an inflammation on the left ala of the nose. Some time afterward the part ulcerated, which occasioned a troublesome and sometimes a painful itching; different means were unsuccessfully employed, and the case remained nearly in the same situation till the month of September in the following year. At this period the ulcer spread very fast; the septum nasi, the muscles and cartilages of both sides were, in a short space of time, destroyed. The ulceration extended on the left side, along the loose edge of the upper lip. This was the state of her case on her admission into the Hospital of St. Louis, in the month of October, 1789.

A poultice moistened with aq. veg. was applied twice a day to the ulcer; a sudorific ptisan prescribed, and a pill, composed of one grain of calomel and one grain of sulph. aurat. antimonii, ordered to be taken every day. From the fifth day, the inflammation lessened. No other sensible alteration took place till the 21st. The suppuration, which till this time had been black and putrid, now became white and inodorous.

On the 37th the discharge was trifling, and the part was dressed with pledgets dipped in a solution of verdigris and corrosive sublimate, in the proportion of six grains of each to a pint of water. On the 40th day, cicatrization began to take place, and was finished by the 60th.

Some time before the disease was completely cicatrized, an issue was made in the arm, which was healed up without any inconvenience to the patient, six months after the cure. (*Parisian Chirurgical Journal, Vol. 1.*)

One of the best external applications to *noli me tangere* is the following lotion: \mathcal{R} . Kali arsenicati, gr. iv. Aq. menthæ sativæ, \mathfrak{z} iv. Spiritus vini tenuioris, \mathfrak{z} j. Misce et cola. I have seen several cases in St. Bartholomew's Hospital, which were either cured or seemed disposed to get well with this useful application. The solution of arsenic, which Sir E. Home has always used, is made by boiling white arsenic in water for several hours, in a sand heat. When given internally, the dose is from three to ten drops; when for external application, a dram is to be diluted with \mathfrak{h} ij. of water; and this solution is gradually made stronger, as the parts become accustomed to it, till it is of double strength. However, this mode of using arsenic is by no means a well-regulated one; and Plunket's caustic (see *Arsenic*) for outward employment, is not nearly so neat an application as the above-mentioned lotion. At St. Bartholomew's Hospital, arsenic is administered internally in the following formula: \mathcal{R} . Kali arsenicati, gr. ij. Aquæ menthæ sativæ, \mathfrak{z} iv. Spiritus vin. ten. \mathfrak{z} j. Misce et cola. Dosis \mathfrak{z} ij. ter quotidie. In this way, the quantity of arsenic is nicely determined. We shall only just add, with regard to this medicine, that, both as an external application and an inward remedy, in cases of *noli me tangere*, it perhaps deserves the highest rank. One scruple of the argentum nitratum, dissolved in half an ounce of distilled water, makes a very good application, which, although generally inferior, in point of efficacy, to arsenical ones, in the present disease, occasionally does good, when nothing else seems to produce any benefit. The above case makes us acquainted with another lotion, which deserves further trial. All fluid remedies must be applied to the part, by dipping little bits of lint in them, placing these on the ulcerations, and covering the whole with a pledget.

The ointments which seem most likely to prove useful applications to *noli me tangere*, are the unguentum hydrargyri nitrati, the unguentum picis, and unguentum sulphuris. As far as my experience extends, they are generally less efficacious than lotions in the present cases; but, in particular instances, they prove superiorly useful, and it deserves especial notice, that surgeons can often make no progress against this inveterate disease, unless they apply a different sort of dressing every day; sometimes a lotion; at other times an ointment. The little ulcers may occasionally be touched with the argentum nitratum. The small furfuraceous scabs, which are continually forming on the part affected, should be softened with a little of the unguentum spermatæ ceti, and removed with as much tenderness as possible.

We have already remarked, that arsenic is a good medicine to be given internally, and the best mode of exhibiting it has been already explained. Another medicine, which is often useful in these cases, is what is known by the name of Plummer's pill, or the compound calomel pill. \mathcal{R} . Hydrargyri

submuriatis, sulphuris antimonii præcipitati, singulorum gr. xii. Guaiaci gummi resinæ, gr. xxiv. Saponis quod satis sit. Misce; fiant pilulæ duodecim. Dosis una bis quotidie.— In other instances, we may try the decoctum ulmi, or sarsaparillæ, with one of the following pills thrice a day: R. Hydrargyri submuriatis gr. vj. Succo spissati cicutæ ʒj. Misce; fiant pilulæ duodecim. The hydrargyrus sulphuratus has occasionally been given as an alterative medicine, for the relief of *noli me tangere*; with what good effect I cannot pretend to say.

In three or four less severe cases of lupus tubercles on the face, which had made no progress towards ulceration, Dr. Bateman saw the solution of muriate of barytes, taken internally, materially amend the complaint. Sometimes, also, a separation of the diseased parts from the sound has been effected with the knife, or caustic, and the progress of the complaint been stopped. (*Synopsis of Cutaneous Diseases*, p. 296., Edit. 3.)

NYCTALOPIA. (from *νύξ*, night; and *ὄψα*, the eye; or *ὄρα*, to see.) An affection of the sight, in which the patient is blind in the daylight, but sees very well at night.

Nyctalopia, *visus nocturnus*, or day-blindness, vulgarly called owl-sight, (says M. Lassus) is an affection in which the patient either cannot see at all, or sees but very feebly, objects, which are in the open daylight, or situations where there is a strong light; but discerns them very well, when they are in a darkish place, or at sunset, or in the nighttime, if not immoderately dark. (See *Pathologie Chirurgicale*, T. 2, p. 539, 540.)

The Greek physicians are divided in their opinions concerning the now uncommon disease nyctalopia. Hippocrates expressly says, "we call those nyctalopes who see by night." The author of *Defin. Medic.* "that they see nothing in the daytime, but have their sight by night." On the contrary, Paulus Ægineta and Actuarius are as explicit in asserting, that they have their sight perfect in the daytime, but are blind by night. Ætius is of the same mind, though he is thought to favour the contrary opinion, when he says, "they see better by night than in the day, and if the moon shines they are blind." The author of *Isagoge* embraces both opinions, when he says, "they call those nyctalopes who, in the daytime, see more obscurely, at the setting of the sun more clearly, but, when it is night, much better; or, on the contrary, by day they see a little, but, in the evening, or at night, they are blind." Galen explains the word by a night blindness. Pliny, Varro, Nonius, Festus, Celsus, and other writers, give equally opposite definitions of the disorder. Dr. Pye questions, whether these two descriptions of nyctalopia, so diametrically opposite to each other, may not be reconciled by considering the disorder as an intermittent one. The difference then will only consist in the different times of the approach of the disease; that of Hippocrates came on in the morning; that of Ægineta, in the evening;

both were expressly periodical, and the distance of time between the paroxysms, in both, was respectively the same; a whole day, or a whole night. The various shapes, in which intermittents appear, very much favour, says Dr. Pye, such an opinion; and the apparent success of bark in the case, which he has related, notwithstanding the unfavourable circumstances of the evacuations his patient laboured under, and the consequent necessity of its disuse, seem to confirm it in this gentleman's mind. (*Med. Obs. and Inq.* Vol. 1.)

In this work I shall follow Callisen, Richter, and the best modern surgical writers, in calling day-blindness, *nyctalopia*, and night-blindness, *hemeralopia*. (See Callisen, *Syst. Chir. Hodiernæ*, Vol. 2, p. 392. and Richter, *Anfangsgr. der Wundarzn.* B. 3, p. 479.)

Nyctalopia, in the sense of day-blindness, is a very rare disease, in comparison with hemeralopia, which is a very common disorder in warm climates. According to Dr. Hillary, there are a people in Siam, in the East Indies, and also in Africa, who are all of this cat-eyed species, or subject to the disease of being blind in the daytime, and seeing well by night. (*Mod. Univ. Hist.* Vol. 7.) The same author notices the general rarity of the disorder, and mentions his having met with but two examples of it.

With respect to the causes of the complaint, Dr. Hillary observes, that it proceeds from too great a tenderness and sensibility of the iris and retina. M. Lassus thinks the causes may be of different kinds. "If, for instance, (says he) there were a very small opacity, like a point, exactly opposite the pupil, or centre of the crystalline lens, the pupil, contracting in the open daylight, would stop the entrance of the rays of light into the eye, and a day-blindness arise, which would be diminished by the expansion of the pupil in the shade. Here, the cure would depend upon the removal of the opacity.

"Persons, whose pupils do not move freely, but remain much dilated, and do not sufficiently contract in light situations, are also affected with nyctalopia; for, so large a quantity of the rays of light pass into their eyes, that it serves rather to destroy, than assist vision. Such persons see tolerably well, and better than the preceding class of patients, in a darkish place, and they ought to wear green spectacles in the daytime, in order to weaken the impression of the rays of light. When a person is shut up a long while in a dark place, the pupils become habitually dilated, and if he exposes himself suddenly and incautiously to a strong light, the eyesight may be destroyed. There are other individuals, who, from excessive sensibility of the iris, cannot bear much light; their pupils instantly contract, and close. This case (continues M. Lassus) may be brought on by too great indulgence in venereal pleasures, and in persons, who have debilitated their constitutions during their youth." The same author mentions other cases, which seem to depend upon a species of irritability of the iris. In one instance, an

issue in the arm effected a cure, and he mentions the utility of blisters. He admits likewise with Dr. Pye cases of intermittent or periodical nyctalopia, which begin regularly in the morning, and go off in the evening, the patient continuing blind, whether he keep himself in a dark or a light place. The cause of these instances, which, he observes, are very uncommon, is generally seated in the primæ viæ, and requires emetics, resolvents, purgatives, and bark. (See *Pathologie Chir.* T. 2, p. 540—542. Also *Richter, Anfangsgr. der Wundarzn.* B. 2, p. 481.) In 1787, Baron Larrey met with a case of day-blindness in an old man, one of the galley-slaves at Brest, who had been shut up incessantly for thirty-three years in a subterraneous dungeon. His long residence in darkness had had such an effect on the organs of vision, that he could only see in

the dark, and was completely blind in the daytime. (See *Mém. de Chir. Militaire*, T. 1, p. 6.)

Nyctalopia may sometimes depend on a peculiarity in the structure and organization of the eye; by reason of which, the quantity of light, which only suffices for vision in an eye of natural formation, proves too abundant for a nyctalops, and absolutely prevents him from seeing at all. We know, that in the eye there is a black substance, named the *pigmentum nigrum*; one supposed use of which is to absorb the redundant rays of light, which enter the pupil. A deficiency of it might perhaps account for a nyctalops being blinded with daylight, and seeing best at night.

For an account of nyctalopia, in the sense of night-blindness, refer to *Hemeralopia*.

O.

ŒDEMA. (from *œdēō*, to swell.) The ancients understood, by this term, all kinds of tumours; but it is now restricted to a swelling, arising from the effusion of a serous fluid in the cellular substance of a part; the affection, when more extensive, and accompanied with a general dropsical tendency, becoming a medical case, and receiving the name of *anasarca*. An œdematous part is usually cold, and of a pale colour; and, as it is little, or not at all elastic, it *pits*, as surgeons express themselves, or, in other words it retains, for some time, the mark of the finger, after being handled, or pressed. Œdematous swellings are often connected with constitutional causes. In many cases, however, they seem to be entirely local affections, arising from such causes as only act upon the parts, in which the swelling is situated. Thus we observe, that after violent sprains of the wrist, or ankle-joint, the hands and feet often become œdematous; and limbs are frequently affected with œdema, in consequence of the return of blood through the veins being obstructed by the pressure of tumours on them, or that of splints, bandages, &c. Pregnant women are known to be particularly subject to œdema of the legs, owing to the pressure of the gravid uterus on the iliac veins. Persons who have been confined in bed, with fractured thighs, or legs, generally have more or less œdema in their feet and ankles, on first getting up again; and the affection in these cases is probably quite dependent on loss of tone in the vessels of the limb.

In the treatment of œdema, great attention must always be paid to the nature of the cause, in order to determine whether the disease originates from a mere local, or a general constitutional affection. When it depends on the pressure of a tumour on the veins, as we often see happen in cases of aneurisms, the effect cannot be got rid of

till the cause is removed; and the aneurismal swelling must be lessened, before the œdematous one can admit of the same beneficial change. When œdema is the effect of vascular weakness in a limb, in consequence of sprains, contusions, &c. the best means of relief is to support the parts affected, with a laced stocking or a flannel roller, while they are also to be rubbed with liniments, and bathed with cold spring water, till they have perfectly recovered their tone.

With regard to the œdema, attendant on the advanced stage of pregnancy, a complete cure cannot be expected till after delivery. The affection is generally more considerable in the afternoon than the morning, owing to the different effects of an erect and a recumbent position. Some relief may be obtained by the patient's keeping as much as possible in a horizontal posture; and, when much inconvenience and pain are felt, the parts may be fomented with any aromatic or spirituous application.

Frequently, œdema is one of the symptoms of suppuration, and, when the collection of matter is very deeply situated, sometimes leads to its discovery, as is exemplified in cases of empyema.

There is a species of œdema, accompanied with a degree of heat, pain, &c. in the part, and which, in short, seems combined with phlegmon. In this case, cold evaporating lotions, the application of leeches, and the exhibition of saline purgatives, are proper. An erysipelatous œdema is also met with, in which the treatment should very much resemble what is explained in the article *Erysipelas*.

ŒSOPHAGOTOMY. (from *œsophagus* and *τομή*, to cut.) The operation of cutting into the œsophagus, in order to take out of this tube any foreign body which lodges in it, and can neither be extracted through the

mouth, nor pushed down into the stomach, though its removal is absolutely necessary for the preservation of the patient's life. A substance, above a certain size, lodged in the upper part of the œsophagus, not only obstructs deglutition, but by its pressure against the trachea, produces the most urgent symptoms of suffocation. In this circumstance, if relief cannot be expeditiously afforded in any other manner, and the situation of the foreign body is denoted by a prominence distinguishable in the neck, œsophagotomy should be practised without delay. However, when the symptoms are pressing, yet unattended with any possibility of feeling the foreign body, either externally or with a probang, desperate as the situation of the patient may be, modern surgeons do not sanction the practice. And this difference from the opinion of the first proposers of œsophagotomy, does not arise so much from any reflections upon the greater difficulty of the operation in this circumstance, as from the consideration of its being unlikely to answer the only purpose, which makes its performance at any time proper, viz. enabling the practitioner to extract with reasonable certainty the substance, whose continuance and pressure in the œsophagus are the immediate cause of the patient's danger. Hence, when the symptoms of suffocation are extremely urgent, but the foreign body produces no external prominence in the neck, the surgeon should in the first instance perform tracheotomy, so as to obviate the imminent peril arising from the impeded state of respiration, and afterward try such measures for the removal of the substance lodged in the œsophagus as experience points out as most likely to prove successful. Though œsophagotomy was cursorily mentioned by Verdué in his "Pathologie Chirurgicale," Guattani, formerly a distinguished surgeon at Rome, is entitled to the honour of having published the first valuable observations on the subject. (*Mém. de l'Acad. de Chir. T. 3, 4to.*) Guattani proved by experiments, that the operation might be safely performed upon dogs, which recovered after it very well, and he demonstrated on the dead body, that it was equally practicable on the human subject. Nay, what is still more to the point, he brought forward two instances, in which the practice had been successfully adopted on living patients. "In May, 1738, Goursauld, a surgeon at Coussat-Bonneval, in Limousin, was called to a man, in whose œsophagus a bone was lodged, an inch long and half an inch broad. Various ineffectual endeavours were made to force it down into the stomach, and, as it was perceptible on the left side of the neck, Goursauld ventured to make an incision for its extraction. The bone was thus easily taken out, no bad symptoms followed and the wound healed up favourably with the aid of an uniting bandage. For six days the patient was not allowed to swallow any kind of food, but was nourished entirely with clysters. According to Morand, a similar operation was performed, with equal success, by Roland, surgeon-major of the regi-

ment of Mailly." (*Mém. de l'Acad. de Chir. T. 3.*)

Although the deep situation of the œsophagus, among the most important parts in the neck, makes œsophagotomy an operation of considerable delicacy in the hands even of a skilful surgeon, and one of great danger in those of a man, deficient in anatomical knowledge, and ignorant of the right way of proceeding, yet the propriety of performing it, under the circumstances, which have been specified, is universally admitted. When, however, I refer to the delicacy and difficulty of the operation, I am meaning a case, in which a deliberate dissection is made down to the œsophagus, without any guidance from the projection of the foreign body within it; a case, in which my views of the subject lead me to think, contrarily to Guattani, that the experiment would generally be attended with no practical benefit; which is also the sentiment of Baron Boyer. For, with respect to opening the œsophagus, with the view of tracing a substance in it, not externally perceptible, and either of taking hold of the same substance with forceps, or pushing it down into the stomach with other instruments, introduced through the incision, as suggested by Guattani, the chances of success must be too small to justify a practice, in which it is above all things of consequence to have the guidance afforded by the prominence in the throat, as a test of the foreign body being actually lodged in the œsophagus, and capable of being removed from it by the proposed operation. Indeed, the uncertainty of being able to reach and extract the foreign body, when its precise situation is not indicated by any external swelling, appears to me an objection of greater validity, than any consideration either of the increased difficulty of cutting into the œsophagus under these circumstances, or of the usual consequences of such an incision, after it has been accomplished; because the practicable nature of the operation, and the tendency of wounds of the œsophagus to heal favourably, when not complicated with other mischief of too serious a description, are facts proved beyond the possibility of dispute. In attempts at suicide and murder, and in cases of gunshot injury, the œsophagus is sometimes wounded, together with other parts in the neck, and yet the patients frequently recover; and, when they die, their fate seems to depend rather upon other unfavourable circumstances in their cases, than upon the accidental injury of the gullet. The cures of wounds of the neck, involving the latter tube, as well as the trachea, are reported by numerous writers, B. Bell, Desault, Bohnius, &c. and some have fallen under my own observation. If it were necessary to substantiate this point further, I might cite the instance, recorded on the authority of Dr. James Johnson, where a man recovered after the larynx had been completely severed between the thyroid and cricoid cartilages, and one half of the calibre of the œsophagus divided. (*See Hennen's Military Surgery, p. 364, Ed. 2.*) But, supposing a wound of the

œsophagus, abstractedly considered, were more dangerous, than it really is, the question of the propriety of œsophagotomy would not be materially affected by it, because the operation is never recommended, except as a matter of necessity, and without which the patient would have no chance of preservation.

As the œsophagus does not descend exactly in a straight line, between the trachea and vertebræ, but inclines rather to the left side of the spine, Guattani directs the left side of the neck to be preferred for the performance of œsophagotomy. But, Boyer has justly remarked, that as the operation should never be attempted, unless there be projection of the foreign body, the place for the incision is always to be determined by the situation of the projection, the left side being chosen only when the prominence is either most distinguishable there, or at all events not less, than on the opposite side of the neck. (*Traité des Mal. Chir. T. 7. p. 192.*)

The parts, which cover the œsophagus, from the middle and external part of the neck to the upper part of the sternum, are the skin, fat, cellular substance, muscles proceeding from the sternum to the larynx, the thyroid gland, the thyroid arteries and veins, the trachea, the recurrent nerve, &c. Guattani, who preferred the left side of the neck, recommended the following mode of operating. The patient is to sit on a chair, with his head inclined backward, and steadily supported by an assistant. The skin having been pinched up into a transverse fold, an incision is to be made in the integuments from the upper part of the sternum. The cellular substance, between the sterno-hyoideus and sterno-thyroideus muscles and trachea, is next to be divided. With two blunt hooks, the lips of the wound are to be kept open; and, on separating the cellular substance at the side of the trachea with the aid of the finger and a few strokes of the knife, the œsophagus will be seen. The lower part of this tube is then to be opened, and the wound in it enlarged with a pair of curved blunt-pointed scissors, a director being employed, if any difficulty arise. With a small pair of curved forceps, similar to those used for the extraction of polypi, the foreign body may then be removed. According to Guattani, the wound will serve for the extraction of the foreign body, whether this be situated above, or below it, and he asserts, that the opening will even be useful, when the extraneous substance has passed so far down, that it cannot be taken out, as it can now be easily pushed into the stomach. Guattani lays great stress on the usefulness of endeavouring to unite the wound, and adverts to his experiments, proving that, in animals, wounds of the œsophagus heal very favourably. If, says he, the vein, which brings back the blood from the inferior parts of the thyroid gland, and runs into the subclavian, happen to be cut, the hemorrhage may be stopped with a dossil of lint held upon the aperture in the vein during the operation, and afterward if the bleeding continue,

compression, or a ligature, is to be employed. The recurrent nerve, if at all likely to be touched with the knife, is to be cautiously drawn a little out of the way with the blunt tenaculum. Guattani also particularly insists upon opening the œsophagus as near as possible to the trachea, especially at its upper part, where the artery, which goes from the subclavian to the thyroid gland, sometimes runs. When the foreign body requires an ample opening, and particularly when the thyroid gland is enlarged, Guattani approves of separating this part a little from the side of the trachea. (See *Mém. de l'Acad. Chir. T. 3, 4to.*)

There can be no doubt, that Guattani's directions for finding the œsophagus are very good; but his chief defect is representing the place for the incision as being always the same, whereas it ought to be partly regulated by the situation of the foreign body itself. However, his advice to make the incisions close to the trachea appears to me more judicious, than that recently delivered by Boyer, who directs them to be made through the cellular substance between the sterno-hyoideus and sterno-thyroideus muscles, and the omo-hyoideus. (see *Traité des Mal. Chir. T. 7, p. 193, 8vo. Paris, 1821.*) in which method, he quits the trachea, which is the best guide to the œsophagus, and approaches unnecessarily the large blood-vessels of the neck. Yet, I agree with Boyer, respecting the general impropriety of attempting œsophagotomy, when the situation of the foreign body is not indicated by any prominence in the neck, and the prudence of determining the place of the incision in a great measure by such projection. Boyer also cautions the operator to let his incisions always be made in such manner, as to leave unhurt the trachea and recurrent nerve at the inner edge of the wound; the carotid and internal jugular vein at its outer edge; the superior thyroideal vessels, above; and the inferior ones, below. With this view, the cellular substance is to be slowly divided layer by layer, and the blood repeatedly absorbed with a sponge; but, if any vessel bleed freely, it is to be immediately tied.

After the operation, an elastic gum catheter should be passed from one of the nostrils down the pharynx and œsophagus, by which means, the requisite food and medicines may be injected into the stomach, without any risk of their passing through the incision, and retarding the cure. But, a still stronger motive for this practice is the avoidance of the convulsive action of the muscles in deglutition; a source of very hurtful disturbance to the parts. Before the advantages of this contrivance were duly appreciated, the patient, for the first week, was allowed to swallow scarcely any thing, and was kept alive with broths injected up the rectum.

ŒSOPHAGUS, Foreign bodies in the. There are few situations, in which foreign bodies lodge more frequently, than in the œsophagus; a fact, explicable by the con-

sideration of the function of this tube, the nearness of part of which to the windpipe at the same time accounts for the frequent danger of suffocation, when a substance, above a certain size, is lodged in it. The lodgment often takes place at the lower part of the pharynx, or beginning of the œsophagus, and sometimes just above the diaphragm; but very rarely in the intervening portion of that canal.

Foreign bodies, liable to lodge in the œsophagus, are not only articles of food, such as pieces of crust, or meat imperfectly chewed, the yolk of an egg, boiled very hard, and not masticated, a chesnut, or small apple, &c.; but also various substances, which are accidentally swallowed either alone, or together with the food, such as pieces of bone, stones, pins, needles, buttons, pieces of money, knives, forks, scissors, spoons, keys, &c. These latter articles, by lodging in the pharynx, or œsophagus, may occasion very bad and fatal symptoms, and, if forced down into the stomach, may produce effects of a not less serious description. Hence, an immediate attempt should always be made to extract them. For this purpose, the fingers may be employed, and, if they will not reach far enough, a pair of long curved forceps should be used. But, no instrument seems better calculated for cases, in which the body lodged in the œsophagus is not too wide, than the urethra-forceps, invented by Mr. Weiss, of the Strand, and used by Sir Astley Cooper for the removal of calculi under a certain size, from the bladder. (See *Med. Chir. Trans.* Vol. 11.) Nooses of wire, and bunches of thread with a multitude of nooses, fastened upon the end of a probang, and a piece of sponge fixed on the extremity of the same instrument, or on that of the strong wire stilet of a long elastic gum-catheter, and various other contrivances have been made with the view of extracting different articles from the œsophagus. The bunch of thread seems well calculated for catching hold of small substances, like fish-bones, needles, &c.; and the sponge, when expanded with moisture and withdrawn, will sometimes bring up articles, which on its introduction, it had passed in its dry and diminished state. When the stomach is full, the excitement of vomiting has sometimes answered; but, if the foreign body be sharp and pointed, the method is not free from danger, and, instead of relieving the patient, may put him to great pain, and bring on violent inflammation of the passage, and the most distressing symptoms.

When the substances are not of a very hurtful kind, and cannot be extracted, they must be pushed down into the stomach with a large bougie, or a whalebone probang, fifteen or sixteen inches long, and on the end of which a piece of fine sponge is securely fastened. But such practice is not advisable, when the foreign bodies have a sharp, pointed form, so as to be likely to prove a source of at least equal danger and suffering, if placed in contact with the inner surface of

the stomach. Experience proves, that hard, angular substances, and pointed bodies, like nails, pins, needles, &c. which surgeons have not ventured, or not been able, to force down into the stomach, have often made their way after a time to the surface of the body, where an abscess has formed, out of which they have been discharged.

When very hard, irritating bodies have either passed of themselves, or been pushed with a probang into the stomach, their ill effects should be counteracted, and their passage through the bowels promoted, with mucilaginous draughts, containing the oleum amygdalarum or oleum ricine. When the substances, lodged in the œsophagus, can neither be extracted, nor pushed down into the stomach, if respiration be not dangerously obstructed, and liquids can yet be swallowed, the wisest plan is to avoid irritating the passage with the further use of instruments, and leave the case to nature, that is to say, as far as manual interference is concerned; for, bleeding, and macilaginous oily draughts, may be in some cases useful. But, when the lodgment of a foreign body in the œsophagus dangerously obstructs respiration, and the substance itself can be felt externally, the patient would perish, if some means of facilitating the breathing were not immediately adopted; and, under these circumstances, perhaps, the most prudent plan would be to make an opening in the trachea. (See *Branchotomy*.) The subsequent treatment, with reference to the foreign body itself might be determined by the circumstances of the case.

In this part of surgery, one fact deserves to be particularly remembered, which is, that after a sharp, hard substance has been either ejected, or propelled into the stomach by nature, or art, the same painful sensations in the throat frequently continue a certain time afterward, which were experienced while the foreign body was actually lodged in the passage. These sensations, however, are only owing to the manner, in which the œsophagus has been irritated, and, consequently, would be seriously aggravated by the further unnecessary introduction of probangs, and other instruments.

There may be cases, in which the patient would lose his life by suffocation, if a foreign body of considerable size were not taken out of the œsophagus, so as to remove the compression of the trachea. Here, if it could neither be extracted, nor pushed into the stomach by common means, and its situation were indicated by any hardness, or prominence in the neck, an operation would be necessary for its removal. (See *Œsophagotomy*.)

A foreign body, not large enough to cause danger of suffocation by pressure on the trachea, may yet bring on fatal symptoms, as is exemplified in a case, which fell under the notice of Guattani. As a man was throwing up a boiled chesnut in the air, and catching it in his mouth, it passed down his throat, and he was immediately seized with a difficulty of swallowing, and sent to the hospital.

However, as he breathed and spoke with facility, and had vomited since the accident, which happened when he was tipsy, the story of his having swallowed the chesnut was disbelieved. His symptoms grew worse, and he died on the 19th day. Guatani made an incision in the left side of the neck, below the larynx and thyroid gland, which was considerably swelled, and soon came to a large abscess, formed around the portion of the œsophagus enclosing the chesnut.

When the extraneous body is sharp and pointed, so as to stick in the mucous membrane of the passage, and it cannot be removed, nature will sometimes expel it herself, without any dangerous symptoms being the consequence. The foreign body is gradually loosened by ulceration, and is then either ejected by vomiting, or descends into the stomach, whence it is voided either through the bowels with the fæces or, as is more common, by making its way through some part of the alimentary canal, and approaching the surface of the body, where an abscess forms, out of which it is discharged. In other instances, foreign bodies, like pins and needles, which cannot be removed, pierce the œsophagus itself, gradually pass completely out of this canal, and afterward travel to remote parts of the body, without exciting much inconvenience until perhaps, at the end of some years, they come near the surface of the body, in a very remote situation from the throat; and an abscess is produced, in which they are unexpectedly found. However, this transport of sharp-pointed substances from one part of the body to another, which is effected by a process, in which the absorbents have a principal share in the work, is not conducted in every instance with so little disturbance, and, when foreign bodies of this description come into contact with particular organs, symptoms of a dangerous and fatal kind may be excited.

The great art of passing any instrument down the œsophagus, for surgical purposes, consists in putting its extremity at once directly against the posterior part of the pharynx, and keeping it closely against the vertebræ so as to avoid touching the epiglottis. The knowledge of this circumstance will be found extremely useful in passing probangs and bougies. When elastic gum-catheters are intended to be left in the passage, they are introduced down the pharynx from one of the nostrils, and, being secured, they serve for the conveyance of liquid food and medicines into the stomach with great advantage, in many cases, either where the patient cannot swallow at all, or where the disturbance of swallowing would be attended with considerable harm. When, however, the plan is not to leave the instruments introduced, as Boyer observes, they may be passed through the mouth.

ŒSOPHAGUS, Strictures, and other Diseases of the. Properly speaking, a difficulty, or impossibility, of swallowing should not be regarded as a disease itself; but only as a symptom of different affections, to which the

organs of deglutition are liable, or of other diseases, which affect parts in the vicinity of the pharynx and œsophagus. The object of the present article is not the consideration of all the diseases, which may produce dysphagia, as a symptom, but chiefly to notice this effect, as depending upon spasm, paralysis, or some morbid change of structure affecting the pharynx or œsophagus.

Spasmodic dysphagia, as Baron Boyer has remarked, principally occurs in nervous individuals, hysterical females, and hypochondriacal men. It is sometimes an attendant on fevers; it is declared to be constant in hydrophobia, and epilepsy, and occasionally present in particular forms of mania. (*Traité des Mal. Chir. T. 7, p. 151.*) However, with respect to hydrophobia, the foregoing assertion should be received with some qualification, for reasons so fully detailed in another part of this work (see *Hydrophobia*), that it is unnecessary here to dwell upon the subject. Spasmodic dysphagia is said also to be sometimes a consequence of taking cold drink, after a violent fit of anger; of strong impressions on the imagination; of worms in the stomach, &c.

When the spasm is situated in the pharynx and upper part of the œsophagus, and is considerable, neither solids nor liquids can be swallowed, and the patient has great pain and a sense of constriction in his throat. When he tries to swallow any thing soft, or even fluid, he is seized with acute pain, insufferable nausea, and violent agitation of the whole frame. In this case, the spasm is never restricted to the pharynx and upper portion of the œsophagus, but extends to other organs, the inability of swallowing coming on in the midst of numerous other spasmodic symptoms, exceedingly complicated, and sometimes of a very alarming nature. When it is the middle, or lower, part of the œsophagus, which is concerned, as is frequently the case in hysterical women, the food passes through the pharynx and unaffected portion of the œsophagus with tolerable facility; but, as soon as it reaches the seat of the spasm, it is either stopped, or descends further with great difficulty and effort. Liquids, especially when warm, and swallowed slowly in small quantities at a time, usually pass down with more ease, than solid substances. When the matter to be conveyed into the stomach reaches the point of obstruction, the generality of patients are attacked with pain extending along the spine between the shoulders, and sometimes shooting to the stomach, which is considerably disturbed, and often discharges its contents. In some cases, however, no such pain is experienced, and whatever the patients try to convey into their stomachs regurgitates quietly into their mouths. Although spasmodic dysphagia is mostly complicated with other marks of disorder of the nervous system, it is sometimes unattended with any particular impairment of the health. (*Boyer, T. 7, p. 152.*)

As the treatment of spasmodic affections of the pharynx and œsophagus belongs rather

to the physician than the surgeon, I shall be very brief on the subject. This removal of the cause of the infirmity, that is to say, of the particular state of the mind, or constitution, giving rise to the spasm, is the principal thing, at which the practitioner should first aim. Thus, Boyer cured an hysterical woman of a difficulty and dread of swallowing solid food by attending her, at her meals twice every day for a month, and gradually convincing her of the absurdity of her apprehension of being suffocated by attempting to swallow solid aliment. (*Vol. cit. p. 154.*) Sauvages makes mention of an hysterical female, whose difficulty of swallowing was cured by a regimen consisting of regular exercise, cold bathing, and milk-diet. The most successful remedies, however, are said to have been camphor in large doses, and opium taken in draughts, or pills, or administered in clysters; blisters and cupping-glasses applied to the nape of the neck, or to the epigastrium. Anodyne embrocations are also stated to have been useful. At the present day, the common idea, that many anomalous affections depend upon disorder of the liver and digestive organs, leads to the frequent employment of the compound calomel pill, and decoct. sarsaparilla, with draughts of senna, rhubarb, and gentian *pro re nata*.

Dysphagia may originate from a weakened, or paralytic state of the muscular fibres, which enter into the structure of the pharynx and œsophagus. The affection may be either symptomatic, or idiopathic. The first case frequently occurs in febrile diseases, and is generally set down by writers, as a very unfavourable omen. The idiopathic form of the complaint may be complete, or incomplete, and is chiefly seen in persons of advanced age, though occasionally the patients are young and in the prime of life. The causes may be said to be little, or not at all understood, and the only remark, which can be safely made respecting them, is, that they are usually connected with constitutional derangement.

With regard to the symptoms of paralysis of the œsophagus, when the disorder is complete, deglutition is absolutely prevented, and, if the patient tries to swallow, the food lodges in the pharynx, and sometimes produces violent fits of coughing. Some patients eat solid substances with moderate facility; but, find more or less difficulty in taking liquids. Others can swallow hastily a large quantity of fluid at a time, yet, cannot drink slowly and a little at once. Morgagni relates an instance of still greater singularity, which was an ability to swallow all kinds of food very well, except the last mouthful, which always remained in the œsophagus until the next repast. (*De Sed. et Caus. Morb. Epist. 28, art. 14.*) In cases of dysphagia from paralysis the patient suffers no pain, nor sense of choking; if the neck be examined, no hardness nor swelling can be felt; and a probang descends down the gullet without the slightest impediment (*Boyer, T. 7, p. 158.*)

In its duration and termination, dysphagia

from paralysis presents considerable variety: the complete paralysis sometimes proves rapidly fatal, not however, as I conceive, on account of the affection of the œsophagus alone, but other complications, and the exhaustion arising from inadequate nutrition. Thus, Tulpus relates an instance, in which a woman died on the seventh day from the commencement of the inability to swallow, notwithstanding every endeavour was made to support her with nourishment thrown up the rectum, which was the only thing that could be done, as she would not allow a tube to be passed down the œsophagus. In other cases the patients live a considerable time, and afterward perfectly recover, and this sometimes under the disadvantage of having been entirely supported for several weeks with broth-clysters, as we find exemplified in a case recorded by Ramazzini. Certain examples are also reported, in which the patients had their food forced into the stomach by means of probangs, for years, and either ultimately recovered their power of swallowing, or in this manner prolonged their days, without any cure taking place. (*Stalpart van der Wiel, Vol. 2, Obs. 28; Willis, Pharm. Rat. Sect. 2, cap. 1, p. 45.*)

Paralysis of the œsophagus is to be treated on the same principles, as other paralytic affections; a subject, which I shall not be expected to discuss; but, it is of importance that practitioners recollect, in these cases, the very essential service derived from the use of elastic gum-catheters, with which the requisite food and medicines may be injected into the stomach.

Dysphagia from organic disease, or morbid change of structure, is the most frequent case, and generally the most difficult of cure. In dissections, the parietes of the œsophagus are often found considerably thickened, indurated, and scirrhus, or sometimes almost cartilaginous, and even ossified. The parts, where the pharynx terminates in the œsophagus, and where the latter tube joins the stomach, are occasionally converted into thick scirrhus rings with or without ulceration, exactly in the same manner as the pylorus. But, such diseases are not restricted to those parts of the œsophagus, but sometimes occupy other points of the passage. However, the organic disease, producing a difficulty, or impossibility of deglutition, is not always situated in the coats of the œsophagus itself; for the parts, surrounding this canal, are subject to various diseases, which may have the same effect. Thus, dysphagia may depend upon enlargement of the thyroid gland; tumours formed between the trachea and œsophagus, or at some other point near the latter tube; swelling and induration of the thymus gland; aneurism of the aorta; enormous enlargement of the liver; and diseased lymphatic glands in the vicinity of that portion of the œsophagus, which is covered by the peritoneum, and the largest of which glands are situated near the fifth dorsal vertebrae, just at the point where the œsophagus inclines a

little to the right side to make way for the aorta. (Boyer, T. 7, p. 162.)

This last author sets down every case of dysphagia, depending upon organic disease of the œsophagus, as incurable; and with respect to the cure of other examples, in which that tube is compressed by swellings in its vicinity, as these are almost always beyond the power of medicine and surgery, the prognosis is nearly as unfavourable, as where there is a change of structure in the œsophagus itself. There are no unequivocal symptoms, by which a case of dysphagia from enlargement of glands in the vicinity of the œsophagus can be known from several other forms of the complaint. Hence, it is difficult to estimate the correctness of certain cases, recorded by Ruysch (*Advers. Anat. Med. Chir. Dec. 1, art. 10, p. 24.*) and Haller (*Opuscul. Pathol. Obs. 78.*) where dysphagia, stated to have been produced by enlarged lymphatic glands, was cured by mercurial frictions, or pills composed of calomel, aloes, and camphor. As Boyer justly remarks, these accounts of the nature of the diseases, thus cured, are the more doubtful, inasmuch as the resolution of chronic swellings of lymphatic glands, even when externally situated, is very difficult, and frequently impracticable, notwithstanding the use of topical applications may here be combined with the exhibition of internal medicines. (T. 7, p. 169.) However, dismissing the question, whether the cases really arose from the pressure of enlarged lymphatic glands, or not, the facts of the cures having taken place, under the use of mercurial medicines, are of themselves interesting. Several writers consider, that there is a great analogy between certain forms of constriction of the œsophagus, and strictures of the urethra, and Mauchart recommended the two diseases to be treated, on the same principles, with bougies, and elastic gum-catheters. Baron Boyer, however, represents this doctrine as completely erroneous, declaring that the affection of the œsophagus is of the nature of scirrhus, and absolutely incurable. He relates one case, in which a woman's life was prolonged by the use of an elastic gum-catheter, though it proved of no service as a means of permanently dilating the diseased part; and, notwithstanding nourishing liquids were plentifully injected into the stomach, the patient suffered a good deal from hunger, and died exhausted about three years after the beginning of the disorder. This case, however, cannot be received, as a proof of the inefficacy of bougies for what is commonly implied by a stricture of the œsophagus, because the nature of the disease was not ascertained by an inspection of the œsophagus after death, and the case might have depended upon some organic disease either of this tube, or the parts in its vicinity not classed by the generality of modern writers with strictures of the passage.

The following are some of Sir Everard Home's sentiments, respecting these last cases.

As the œsophagus is required to be wider

at one time, and narrower at another, in order to be fitted for conveying the different kinds of food into the stomach, it is nearly under the same circumstances, with respect to the formation of stricture, as the urethra. For obvious reasons, strictures of the œsophagus are much less frequent than those of the urethra. However, they are by no means uncommon, and produce symptoms even much more distressing and dangerous, than those, which ordinarily arise from analogous obstructions in the passage for the urine.

Of course, the most remarkable symptom of a stricture in the œsophagus is the difficulty of swallowing, which must be greater or less, according as the obstruction is more or less complete. Sometimes no solid food whatever can pass down into the stomach, and fluids can only descend with great difficulty, and in very small quantities. This is, in some instances, attended with considerable pain, which extends along the fauces to the basis of the skull, and through the eustachian tube to the ear. The pain sometimes returns at intervals, and lasts a considerable time, even when no effort is made to swallow. If a bougie of proper size be introduced down the pharynx, it will often be stopped by the stricture just behind the thyroid, or cricoid cartilage; for from Sir Everard Home's remarks, it appears that the obstruction is generally as high up as this situation. However, there are other cases, in which the obstruction is only of a spasmodic nature, and in these a bougie may be passed quite down. It is curious, that strictures high up in the œsophagus, often occasion ulceration in this tube very low down towards the stomach, just as strictures in the urethra occasion ulceration in that passage towards the bladder. This is most apt to occur, when strictures of the œsophagus have been of long continuance, and may arise from the efforts in retching, which frequently come on, and must strain the parts already deprived of their natural actions, and of the benefit of the secretions, with which they are lubricated in a healthy state. When such ulceration takes place, the characters of the original disease are lost; and when the ulceration extends upwards, the stricture itself may be destroyed. A bougie, introduced under such circumstances, will, in general, have its point entangled in the ulcer; and when so skilfully directed as to go down into the œsophagus, it will meet with a difficulty while it is passing the commencement of the ulcerated part of the œsophagus, and another impediment where it leaves the ulcer, and enters the sound portion of the œsophagus below. These two resistances may lead to the supposition, that there are two strictures, while in fact there is not one, only ulceration as above described.

Strictures in the œsophagus are sometimes so complete, that swallowing even fluids is utterly prevented; the patient is obliged to have all nourishment injected *intra anum*,

and in general, soon perishes in a most emaciated condition.

Though any part of the œsophagus is liable to the kind of contractions forming strictures, the part immediately behind the cricoid cartilage, where the pharynx ends, and the œsophagus begins, is the most frequent seat of the obstruction. Those which are situated further down do not so easily admit of being examined, and relieved by any surgical operation. Strictures of the œsophagus occupy very little extent of the passage, consist of a transverse fold of the internal membrane, and are attended with little thickening of the adjacent parts. These latter circumstances are such as render the disease capable of receiving relief either from simple or armed bougies.

There are two other diseases of the œsophagus, which have symptoms similar to those of strictures. One is a thickening of the coats of the œsophagus, which extends to the surrounding parts, and generally ends in a cancer, or an incurable disease. The other affection is an ulcer of the lining of the passage, commonly situated a little below the seat of the stricture, on the back part of the tube. In the early state, these diseases can only be distinguished from a stricture, by an examination with a bougie; afterward their nature becomes clear enough from other symptoms which arise. Strictures also take place more commonly in young subjects; the other two diseases in the more advanced periods of life.

Sir E. Home has found, that a bougie can be more easily introduced into the œsophagus, when the tongue is brought forwards out of the mouth. This gentleman remarks, that when a bougie is passed, with a view of learning the nature of the case, if it passes down to the distance of eight inches, measuring from the cutting edge of the front teeth in the upper jaw, its extremity has gone beyond the usual seat of stricture. If it be withdrawn without any resistance, the aperture in the œsophagus must then be larger than the bougie employed. But if the bougie stops at the distance of six inches and a half, or even lower, it must be retained there with a uniform pressure for half a minute, so as to receive on its point an impression of the surface by which it was opposed. If the end of the bougie retains its natural form, or nearly so, and there is an indentation on one side of it, or all round it, the surgeon may conclude there is a stricture. On the other hand, should the bougie descend without impediment, as far as seven inches and a half, and, when withdrawn, the surface of its point appear irregular, and jagged, the disease is an ulcer on the posterior part of the œsophagus.

The mode of treatment adopted by Sir E. Home, consists either in passing a common bougie occasionally through the stricture, and employing one of a larger size, in proportion as the dilatation of the obstruction is effected; or else in introducing an armed bougie at convenient intervals. The views, which I take of the disease, would

lead me to prefer giving a full and fair trial to the employment of elastic gum-catheters. Consult *Practical Observations on the Treatment of Strictures in the Urethra and Œsophagus*, 3 Vols. Edit. 3, 1805. Vol. 2, 1803, and Vol. 3, 1821, by Sir E. Home, Ph. H. Beuttele de Struma Œsophagi; hujusque coalitu difficili ac abolitæ deglutitionis Causis: (in Haller's Disp. chir. 2, 395,) Tubing. 1742. Mauchart de Struma Œsophagi, Tubing. 1742. J. Warner. Eccardus. de his qui diu vivunt sine alimento, 4to. Kilæ Holsat. 1711. Boyer Traité de Mal. Chir. T 7, 8vo. Paris, 1821.

OLEUM CAMPHORATUM. R. Olei olivæ. ℞j. Camphoræ ℥iv. Misce et solvatur camphora. Sometimes employed for promoting the suppuration of indolent, particularly scrofulous swellings, which are to be rubbed with it once, twice, or thrice a day according to circumstances.

OLEUM LINI. In surgery, linseed oil is sometimes used as an application to burns, either alone, or mixed with an equal quantity of the liquor calcis. It has also been applied to cancerous ulcers.

OLEUM ORIGANI. The oil of marjoram is often used for dispersing ganglions: the tumours are to be rubbed with it two or three times a day.

OLEUM PALMÆ CAMPHORATUM. R. Camphoræ ℥ij. Olei palmæ ℞j. The camphor is to be reduced to powder, and the palm oil, being melted, and suffered to become almost cold, is to be mixed with it in a mortar. This application is a mild topical stimulant; and has been used for promoting indolent suppurations, especially those of a scrofulous nature, which take place under the jaw, and are attended with a good deal of chronic induration.

OLEUM RICINI. In surgical cases, requiring the bowels to be opened with the slightest degree of irritation possible, the oleum ricini is the best and safest medicine. The usual dose is one large table-spoonful, which must be repeated every two or three hours, till the desired effect is produced.

OLEUM TEREBINTHINÆ. Oil of turpentine is employed externally as a stimulating liniment and a styptic. In the article *Liniment* may be seen some formulæ, in which turpentine is the most active ingredient. It is sometimes exhibited internally, for the cure of gleet.

OLEUM TEREBINTHINATUM. R. Olei amygdalæ ℥ss. Olei terebinthinæ gutt. xl. Misce.

In deafness, occasioned by defective, or diseased action of the glandulæ ceruminæ, Mr. Maule directs a little of this oil to be dropped into the patient's ear, or applied at the end of a small dossil of cotton.

When a thin secretion takes place, the

cure is also promoted by a small blister, which is placed as near the ear as convenient, and kept open with the savine cerate. The meatus auditorius externus must also be cleansed every day with a lengthened bit of soft cotton, affixed to a probe. (See *Pharmacop. Chirurgica*.)

OMPHALOCELE. (from *ομφαλος*, the navel, and *κελη*, a rupture.) A rupture, or hernia at the navel. (See *Hernia*.)

ONYCHIA. (*ονυξ*, the nail.) An abscess near the nail of the finger. (See *Whitlow*.)

ONYX. (from *ονυξ*, the nail.) A small collection of matter, situated in the anterior chamber of the aqueous humour, and so named from its being shaped like a nail. It is of the same nature as *Hypopium*, to which word I must refer the reader. Maitre-Jean, Mauchart, and several other oculists, imply by the term *onyx*, a small abscess between the layers of the cornea.

OPHTHALMY. (from *οφθαλμος*, the eye.)

Ophthalmia. *Ophthalmilis.* Inflammation of the eye. This is not only a consequence of several affections of the eye, and adjacent parts, on the existence of which other disorders its continuance entirely depends, but is frequently the primary complaint, and too often the forerunner of such irreparable mischief as for ever bereaves the patient of vision. The determination of a preternatural quantity of blood into the organ, and fulness of its vessels, or a congestion, as several writers express themselves, is, according to Beer, the earliest change which occurs in ophthalmia in general. The next symptom is said to be redness, which becomes more intense, as the disorder makes progress, and if the complaint be protracted, the red assumes a dark hue, then a brownish, and lastly a bluish tinge. However, when the arteries and veins affected soon return to their natural state, the redness of the textures of the eye may not attain the greatest intensity. Professor Beer seems to adopt similar views of the nature of the process of inflammation to those which are taken by Dr. W. Philip, and some other writers already mentioned, (see *Inflammation*;) for, in consequence of the small arteries and veins being deprived of their propelling power, he considers that the blood in the texture, which is the immediate seat of inflammation, is in a state of actual stagnation. (*Lehre von den Augenkrankheiten*, B. 1, p. 30.) The third general symptom of ophthalmia, described by Beer, as closely following the redness, is a tense, hard, painful swelling of the texture, directly affected. Lastly, in proportion as the pain, redness, and swelling are considerable, the more obvious is another common effect of inflammation viz. an increase of temperature or heat. But although the disturbed intercourse between the arterial and venous systems is more obvious than the effects of inflammation in other parts of the organization of the eye, yet, that the secreting and excreting vessels, and the absorbents, are also affected, is evinced by the augmented secretion and excretion in the early stage of the disorder.

followed, when the inflammation has become more intense, by a suppression of these functions, and a dryness and want of pliancy in the inflamed textures of the eye. The disturbance of the connexion between the nerves and muscles also produces first various involuntary movements, which, as the inflammation makes progress, become more and more limited, and, at length, there is a complete loss of action in the textures of the eye, which are the seat of inflammation.

But inasmuch as every disease of the eye presents some differences, depending upon the nature of the disorder itself, and others arising from the peculiar organization of the texture, which happens to be principally affected, the characteristic appearances of ophthalmia must be subject to a vast number of modifications, according as this or that structure of the eye is inflamed; and hence, sometimes one symptom of inflammation, sometimes another, chiefly predominates, while others are less conspicuous, and often scarcely distinguishable. Yet, says Beer, none of the characteristic marks of inflammation are ever entirely absent. This author represents the degree of pain as being proportioned in a great measure to the tough unyielding nature of the parts immediately around the inflamed texture of the eye, to the firm nature of the inflamed texture itself, and to the quantity of nerves with which such texture, and the parts in its immediate vicinity, are supplied. In proof of the truth of this doctrine, he instances whitlows and internal ophthalmia, where the pain is very severe; while inflammations of the conjunctiva, not extending to the deeper textures of the eye, are described as cases in which the pain is slight, because the structure affected is loose and yielding. But, without scrutinizing every reason assigned by Beer, for the varieties observable in the symptoms according to the texture which happens to be most affected, I shall briefly state a few other examples quoted by the same author. That the degree of redness, as well as of pain, varies considerably in different states of ophthalmia, is a fact universally known. In the beginning of the complaint, such redness is generally less perceptible than when the inflammation has attained its highest pitch; but it is not equally great in every individual, nor in every species of ophthalmia, being sometimes more intense and diffused, sometimes less both in degree and extent. This diversity is referred by Beer, and probably with reason, to the texture affected in the eye, being furnished with many considerable blood-vessels, obvious to the sight, or only containing vessels, more concealed and rather filled with a colourless fluid than with red blood. The looseness or unyielding nature of the texture is also represented as making a difference in the degree of redness. In inflammation, principally affecting the conjunctiva and sclerotica, says Beer, the redness is so intense, as to give the eye a frightful appearance, as is

seen in chemosis; while in inflammations of the innermost textures of the organ, the redness is scarcely perceptible, and, in the erysipelatous inflammation of the eyelids, the redness is very faint. (*Beer, Lehre von den Augenkrankheiten, B. 1, p. 34—36.*)

Dr. Vetch remarks, that the conjunctiva is capable of being stretched to a great extent, owing to the loose structure of the cellular membrane on which it lies, and consequently little resistance is made to the enlargement of its vessels. From slight irritation, they soon become distended with red blood, "but their tone or power of reaction is speedily exhausted, and, if the exciting cause is not kept up in an increasing ratio, they quickly fall into a chronic or varicose enlargement, or again contract to the diameter of the serous vessels." On the other hand, (as the same experienced writer has pointed out,) inflammation of the sclerotic coat is slow in its commencement, and often insidious in its progress, even when its ultimate violence is great. *In the early stage of conjunctival ophthalmia, the inflammation is most observable at a distance from the cornea, round which the membrane often preserves for a length of time its natural appearance. Precisely the reverse takes place in the case of sclerotic inflammation, which invariably appears at the circumference of the cornea, forming a zone, more or less complete around it, and most conspicuous above it, the form and colour of the vessels being at the same time wholly different from those which appear in the course of conjunctival inflammation. Intolerance of light (says Dr. Vetch,) invariably accompanies sclerotic inflammation, and is entirely unconnected with that of the conjunctiva. (A Practical Treatise on the Diseases of the Eye, p. 10.)* If the latter observation be strictly correct, it is to be inferred that, in all common cases of acute ophthalmia, involving the conjunctiva on the front of the eyeball, the sclerotica is more or less affected, as in the beginning of the disorder, light may be said to be seriously annoying to every patient.

According to Mr. Travers, when the sclerotica partakes of the inflammation of the conjunctiva, the vessels, which pursue a straight course to the margin of the cornea, are strongly distinguished, and have a somewhat darker hue, than the areolar vessels upon the loose portion of the conjunctiva. (*Synopsis of the Diseases of the Eye, p. 128.*)

Diversified as the pain, redness, swelling, and heat, the four characteristic symptoms of inflammation, may be in cases of ophthalmia, the incidental appearances in the eye are not less subject to numerous modifications. Thus, sometimes an extraordinary involuntary action of the muscles of the eyeball and eyelids, or of the secreting and excreting lachrymal organs, and of the Meibomian glands may be noticed; and sometimes the action of all these parts is either diminished, or completely stopped. These differences Beer refers to the latter parts being either themselves inflamed, or sympathizing with the inflamed texture of the eye.

In the first case, the action of the muscles, and the functions of the lachrymal organs, and Meibomian glands, are more and more interrupted in proportion as the inflammation increases, and must thus remain, while the inflammation lasts in its genuine form; but, in the second case, they go on, and this even with greater activity, while the inflammation continues, and until it has ceased to become more violent. (*B. 1, p. 39.*)

Acute ophthalmia in general, when at all severe, and particularly when the inner textures of the eye are affected, produces a febrile disturbance of the whole constitution. This change from a local to a general indisposition takes place with greater certainty and quickness, in proportion as the focus of inflammation is extensive, the constitution irritable, the disorder of the eye neglected, and the mischief considerable, which is actually produced in the organ, whether accidentally, or in consequence of unskilful treatment. (*Beer, Vol. cit. p. 42.*)

Many of the appearances and effects of ophthalmia are different, as the inflammation happens to be of an acute, or chronic nature. And, as Scarpa has taken particular pains to impress upon the minds of surgical practitioners, every acute ophthalmia, though treated in the best possible manner, is never so completely resolved as not to be followed by a certain period, at which all active disturbance ceases, in the place of which a degree of chronic ophthalmia remains in the conjunctiva, or lining of the eyelids: the effect either of local weakness in the vessels, or of the continuance of a morbid irritability in the eye, after the removal of the acute stage of the inflammation. As it occasions a diseased secretion in the organ, and a slow accumulation of blood and coagulating lymph, the inexperienced are apt to suppose, that the acute stage is not yet entirely subdued, while it is completely so. Now, if the inculcations of Richter and Scarpa be correct, immediately the critical moment arrives, when the acute stage changes into the chronic, attended with local weakness, it is of the highest importance to alter the treatment without delay, and to substitute for emollient relaxing applications, such as partake of an astringent corroborant quality, as the former only protract the turgescence of the vessels, and the redness of the conjunctiva. "*Quo major autem fuit inflammationis vehementia (says Richter,) eo major plerumque sequitur partium affectarum atonia, eoque major opus est adstringentium et roborantium longo usu, ut auferantur penitus reliquiae morbi, &c.*" (*Fosical. Obs. Chir. 1, p. 109.*)

It is on the accession of the second stage of ophthalmia, that one may remark the sudden increase of redness in the inflamed texture, with a brown and afterward a blue tinge; actual extravasations of blood in the chambers of the aqueous humour; ecchymosis of the conjunctiva; a considerable increase of swelling; the decline and irregularity of the pain; the decrease of the inflammatory heat and throbbing; a sensation

of cold and heaviness in the organ; and more or less œdematous swelling of the surrounding parts. It is also in the second stage, that suppuration is liable to happen. (Beer, *Lehre, &c.* B. 1, p. 46.) And in another page the same author observes, that the characteristic signs of the second stage of ophthalmia consist in the following appearances: while the redness and swelling undergo a sudden and striking increase, the hardness manifestly diminishes, and the pain becomes very unequal, and not continual; the secretions and excretions also, which, during the first stage, were completely stopped, commence again, but more copiously, and are of a very different quality from what they were in the state of health. The disorder is now quite in its second stage, and this is the time when purulent matter may begin to be formed. (B. 1, p. 50.) According to Beer, the duration of idiopathic ophthalmia depends upon the circumstances of each individual case; first, the nature of the causes giving rise to the affection; secondly, the irritability of the patient in relation to constitution, sex, and age; thirdly, what may be termed the constitution of the affected eye itself, and the texture in it immediately inflamed. Thus ophthalmia is likely to be attended with great severity, when it attacks plethoric individuals, in whom there has been for some time previously a great determination of blood to the head and eyes, or whose sight has been strained by looking at shining objects, or constitutions hurt by good living and hard drinking. Every severe ophthalmia runs through its first stage much more rapidly in weak, irritable subjects and children, than in robust individuals. It is also another remark made by Beer, that every inflammation of the eye, at all considerable, is generally of shorter continuance in gray or blue-eyed, than in dark, or black-eyed persons; and in the same manner, inflammation of the internal, sensible, and tender textures of the eyeball always passes through its first stage more quickly, than inflammation of the eyelids.

With respect to the *causes of ophthalmia in general*, as the disorder frequently affects the innermost parts of the eye, and when severe, is attended with some risk of the loss of the organ, the annihilation of its functions, or the spoiling of some of its textures; and also, as inflammation is the most frequent complaint to which the eye is subject, it is important to learn, as far as possible, the causes, which either directly or indirectly give rise to it.

The atmospheric air and light have a direct and powerful operation upon the eyes; and in order that the former may have no hurtful effect upon these organs, it should be pure, that is to say, its regular component parts should not be altered, nor blended with extraneous substances. The temperature of the air is likewise described by Beer, as making a good deal of difference in the susceptibility of the eyes for inflammation, either a very warm, or cold air, being, in

this respect, hurtful. The observation, however, is qualified with the admission, that the terms *warm* and *cold* have only a relative signification to individual circumstances. The effect of a blast of cold air on the eye, in exciting inflammation, is universally known, and needs no comment. It is an opinion of Beer, that the eye is much affected by the quantity of electricity in the atmosphere, and he says, that on this account, no experienced practitioner would undertake the extraction of a cataract during, or on the approach of a storm. (B. 1, p. 65.)

Passing over many interesting observations made by Beer, on the contamination of the atmospheric air by the admixture of other gases, and the injurious effect of this change upon the eyes, I come to his remarks on the operation of light upon these organs. Though light, he observes, is indispensable to the functions of the eye, it becomes pernicious, when suddenly increased beyond what the organ can bear, so as to be a source of irritation. As a proof of this fact, he cites an instance, in which a young, plethoric, strong man, whose eyes had been for some time unavoidably strained by immoderate exercise of them, was suddenly attacked with a violent ophthalmia, while looking at an optical representation of the rising sun, and carried home in great agony. But with respect to the influence of light, Beer observes, that every statement is to be received only in a relative sense; for the degree of light which would answer very well for the eye of an African, would destroy many European eyes; and the same light, which is borne without inconvenience by the eye of an adult, would excite in the eye of a new-born infant the *ophthalmia neonatorum*, by which so many children are deprived of the most valuable of the senses in the first days of their existence. Beer further explains, that the same degree of light produces a stronger, or weaker effect, according to the greater or lesser irritability of the eye of the same person at different times, as we see exemplified in every individual in the tenderness of his eye to light when he first awakes in the morning. Light is also not hurtful to the eyes, merely according to its quantity; for the direction of the rays makes a great deal of difference, the eye being less capable of bearing them with impunity the more they recede from a perpendicular line, and strike the organ slopingly, or horizontally. Much likewise depends upon the kind of light; that which is reflected from a scarlet surface, being even more prejudicial than the sunshine which is reflected from a country covered with snow; another convincing proof, that the bad effects are not always in proportion to the quantity of rays. The light of burning-glasses, concave mirrors, white screens, the full moon, &c. and the shining of diamonds, are well known to render the eyes weak, and prone to inflammation. Among other occasional causes of ophthalmia, Beer enumerates the custom of washing the eyes immoderately with cold water, a remark in

which I do not place much confidence myself; the application of various stimulating medicated substances to them; compresses and bandages; the badness of instruments employed in operations upon the eyes; the employment of spectacles unnecessarily, or of such as are not adapted to the eyes of the individual; and every immoderate exertion of the eyesight.

But, among the most important and frequent exciting causes of ophthalmy, are extraneous bodies, which insinuate themselves between the eyeball and eyelids, and every kind of wound or injury of the eye.

Foreign bodies, liable to enter under the eyelids, are of three kinds; first, they may either be such as are in themselves completely innoxious to the eye; or such as are likely to hurt the eye only when strongly pressed upon by the spasmodic closure of the eyelids, or by the patient's imprudently rubbing the eye; or they may be of a quality which injures the eye the moment they come into contact with it. Foreign bodies of the first description lie loose under one of the eyelids, and, for the most part, either immediately behind its edge in the groove destined for the conveyance of the tears, or else in the fold, seen when the eyelid is everted, exactly at the line where the palpebra and sclerotic conjunctiva join together. They never actually lodge in the coats of the eye; but they irritate it either mechanically or chymically, or in both ways together, according to their size, shape, and chymical properties.

In the list of such extraneous substances are inverted eyelashes; particles of dust; snuff; pepper; minute insects; and other small things generally carried under the eyelids by the wind.

As these foreign bodies are all of them more or less irritating to the eye, they must be considered as a principal exciting cause of ophthalmy, which frequently follows their entrance under the eyelids with extraordinary rapidity. However, the redness and effusion of tears, sometimes instantly following the insinuation of extraneous substances under the palpebræ, and as suddenly ceasing on their removal, Beer considers rather as preliminaries to inflammation, than as this disorder itself. (*B. 1, p. 92.*)

Wounds and other injuries of the eye, regarded as causes of ophthalmy, Beer divides into three kinds; viz. *mechanical*, *chymical*, and *mixed*. A prick of the eye with a fine needle is an example of a simple mechanical injury; the action of quicklime upon the organ is an instance of one purely chymical; and the violent propulsion of a red-hot bit of iron against the eye is a lesion, which may be said to be both mechanical and chymical. The same author makes a variety of original reflections upon the differences connected with the extent and intensity of such injuries. Their intensity, he views only as something relative; thus, either the force, with which the eye is injured, is of itself too great ever to be resisted, as is seen in a gunshot wound; or the organic

powers of the patient are, from age, sex, or constitution, much too feeble for the eye to bear favourably any considerable injury, as is the case with children and weak unhealthy females; or the organization of the eye itself may be weak, and the effects of the violence therefore greater, as exemplified in the fact of a brown or black eye generally bearing a wound better than a gray or blue one; or, lastly, the organic powers of the texture of the eye, immediately injured, may be too feeble to bear even a slight lesion, as is the case with the retina. (*B. 1, p. 95.*)

Mechanical injuries of the eye may be made either with sharp or obtuse bodies. Sharp-pointed and cutting instruments are capable of readily penetrating the eye, without occasioning at the moment of their entrance, any violent compression, or laceration of the neighbouring textures; and consequently the injury inflicted is a simple puncture, or an incision. Sabre-cuts of the eye, however, are to be excepted; for, though the weapon may be sharp, the blow is always attended with more or less concussion, and injury of the textures, adjoining the wound, which are very delicate and readily spoiled. Blunt weapons, or bodies, can only enter the texture of the eye by dint of great force, and, in this case, always cause a serious degree of compression, stretching, and laceration; but sometimes when they do not penetrate the organ, the contusion is such as is productive of not less mischief.

In the case of a simple puncture or incision of the eye, Beer seems to think that the subsequent ophthalmy is generally more owing to the incapacity of the wounded organ to bear the effects of the light, air, &c. than to the injury itself abstractedly considered. He observes, that a proof of the truth of this opinion is seen in the extraction of the cataract; for, if the operator is careless in the operation itself, opening the flap of the cornea very wide, so as to let the atmospheric air have free access to the inner textures of the eye; or if after the operation is finished, he do not apply the dressings with caution, and properly darken the patient's chamber, he is letting the eye be subjected to some of the most active causes of inflammation. But though Beer is unquestionably correct, in regard to the injurious effects of light on the wounded eye, it may be doubted, whether his theories do not make him attribute too much to the irritation of the air, and too little to that of the mechanical division of the parts.

Passing over many of Beer's observations on injuries of the eye produced by blunt bodies, and substances acting chymically upon it, I leave the topic of the direct exciting causes of ophthalmy, and come to the consideration of those which he regards as *indirect*. And the first to which he adverts, is every thing that has a tendency to keep up a determination of a large quantity of blood into the small vessels of the head and eyes. Immoderate bodily exercise; violent

emotions of the mind; injudicious clothing; and high living, are afterward enumerated as having an indirect effect in the production of ophthalmia; but it does not appear to me, that Beer's sentiments upon these points are entitled to much attention. With respect to *infection* and *contagion*, as causes of inflammation of the eye, Beer understands by *infection*, what at first takes effect only upon a small point of the body, but never the whole animal economy directly, that is to say, before absorption has taken place. Hence, says he, infectious diseases are very seldom the cause of ophthalmia, unless some of their matter be applied immediately to the eye itself; but he admits that they often dispose this organ to inflame from slight causes, by the impairment which they produce of the general health. On the other hand, he considers all *contagions* as very quickly affecting the whole of the constitution directly through the medium of the skin, or the trachea, lungs, œsophagus, &c. Hence, contagion is set down as being much more frequently, than infection, the indirect cause of ophthalmia. Beer conceives, however, that as the contagious principle is blended with the atmosphere, it may also have an immediate operation upon the eyes, and thus he attempts to account for the organs not unfrequently exhibiting a tendency to inflammation at the very moment of the contagion taking effect. (B. 1, p. 121.) But this is a difficult and obscure subject, which can be viewed to more advantage when particular kinds of ophthalmia are considered.

In Beer's general observations on the treatment of inflammations of the eyes, the first indication specified, is to *remove immediately every thing, which is obviously producing an irritating effect upon the eye, and to take care that no fresh source of irritation to the organ incidentally take place.* And, as it frequently happens, even in healthy, strong individuals, that ophthalmia is occasioned by foreign bodies, either lodged under the eyelids, or inserted in some part of the eyeball, and not suspected to be there, the earliest attention should always be paid to their gentle and skilful removal. Easy as this object is of accomplishment, when not delayed, when the eye has not been seriously irritated by friction and pressure, and the patient is not of a weak, irritable constitution, it is often attended with great difficulty under one, or the other of these circumstances, especially the last. In this case, strong convulsive rotations of the eyeball, followed by a violent and obstinate spasmodic closure of the eyelids, render it impossible to separate them; and the spasm is the stronger and more lasting, the more the extraneous substances are calculated by their shape and chymical quality, to irritate the eye; and the greater the irritability of the patient is. In this state of things, every attempt forcibly to open the eye, or to examine it in the light, is not only useless, but increases and keeps up the spasm, which nothing will lessen and shorten, except darkness and perfect repose. But, as timid irritable persons are exceeding-

ly apprehensive of the consequences of the lodgment of extraneous substances in the eye, the surgeon should endeavour to lessen their inquietude, by assuring them that every thing will be right again, which is strictly true when the foreign bodies are of the first class. Then the spasmodic closure of the eyelids will cease, and the extraneous substance admit of being properly taken away.

Success, however, does not always attend this simple method; for, in very weak subjects, the spasm of the orbicularis palpebrarum is so violent and obstinate, especially when a foreign body lodges in the eye, and at the same time mechanically and chymically irritates it, (as is the case with particles of snuff,) that it becomes indispensable to have recourse to medicinal applications. For this purpose, Beer's experience has convinced him, that the best thing is a bread poultice, made either with milk or water, and containing some of the vinous tincture of opium. Care is to be taken, however, never to let it become quite cold, during its application; for then the spasm would only be aggravated by it; and, if such spasm has been of long continuance, when the surgeon is first sent for, the poultice, according to Beer, may be rendered more efficacious by the addition of hyosciamus to it. In very irritable hysterical and hypochondriacal persons, such local treatment alone is frequently insufficient, and recourse must be had to the internal exhibition of antispasmodic anodyne medicines. At length, when the spasm of the orbicular muscle is so far diminished, that the eyelids can be effectually opened without any force for the extraction of the foreign body, great caution and gentleness will yet be necessary, and, in particular, the eye should be kept in a very moderate light, as the spasm would be immediately excited again, either by sudden exposure of the eye to too much light, or rough handling of the eyelids.

Sometimes, a person rubs his eye at first awaking in the morning, and if the eyelashes are very numerous and rigid, one of them will lodge between the eyeball and lower eyelid: it may readily be taken away with the end of a fine moist sponge, or camel-hair pencil, the eyelid being depressed as much as possible and the eye itself turned upward, so that the hair may not be concealed in the fold of the conjunctiva. When the hair is situated under the upper eyelid (which Beer says rarely happens) it always lodges in the fold of the preceding membrane, whence it may be extracted in the manner above directed, with the difference that the eyelid must be raised or everted, and the eye rotated downwards. (*Lehre von den Krankh.* B. 1, p. 128, 130.)

For directions respecting the treatment of redundant and inverted ciliae, see *Distichiasis* and *Trichiasis*.

Small globular smooth extraneous bodies, lodged under the eyelids, are very easily extracted, when the eyelid is gently taken hold of both by its edge and the eyelashes, and lifted up from the eye, while the patient inclines

his head forwards, and the eye is turned completely downwards: the effusion of tears, excited by these manœuvres, will now generally wash these extraneous substances out of the eye, as they are not at all fixed. When the fissure between the eyelids is wide and open, but the eyeball at the same time very prominent, the object may also be easily accomplished, when the upper eyelid is gently and repeatedly stroked with the finger from the outer towards the inner canthus; in which case, the round smooth foreign body soon makes its appearance above the *caruncula lachrymalis*, whence it falls out of itself, or may be taken with the corner of a pocket handkerchief. The worst cases are those, in which the eyes are very prominent, and the fissure of the eyelids small, as all the above methods are then useless, and only productive of irritation. In this circumstance, therefore, Beer recommends the surgeon to take hold of the eyelid by the ciliæ, and its edge with the thumb and forefinger, and separate it from the eyeball, which is to be turned downwards, while, with Daviel's small scoop, or the head of any large curved needle, introduced straight under the eyelid, at the outer canthus, as high as possible, the extraneous substance is to be extracted with a semicircular movement, directed towards the nose. Though this method will almost always succeed, Beer confesses, that it is not without the production of a great deal of mechanical irritation.

In consequence of the detention of such substances under the eyelids, the conjunctiva sometimes becomes thickened; this change, when slight, soon disappears of itself after the removal of the foreign bodies; but, in other cases, Beer recommends the diseased part of the membrane to be removed with a pair of scissors; and, after the bleeding has ceased, the frequent application of the *lotio plumbi acetatis* to the eye.

Particles of common dust, and of the sand and powders, frequently thrown over letters, and very apt to get into the eyes of persons who open their letters carelessly, or from short-sightedness, are obliged to bring them close to the nose, are generally more difficult of extraction. In the attempt, however, the eye must never be subjected to too much irritation. According to Beer, these extraneous particles of dust, or sand, may sometimes be removed by washing the eye well, or by dropping into it milk, or some other viscid fluid, while the patient lies upon his back, and the eyelid is lifted up from the eye. But, the most expeditious and certain plan is to employ a syringe, the pipe of which is to be introduced under the upper eyelid near the outer canthus, and the fluid thrown briskly in the direction towards the nose. If all the extraneous matter cannot be thus removed, the rest may sometimes be taken out with a camel-hair pencil, dipped in some viscid fluid, or fresh butter, and the eye is then to be washed again.

When particles of sugar, or other soluble, not very irritating substances, happen to in-

sinuate themselves into the eye, professional aid is seldom required, as they generally dissolve in the tears, and are voided before a surgeon can arrive. Snuff, pepper, and other minute irritating bodies, as well as small winged insects, are to be removed in the same manner, as particles of dust and letter-sand; but, particular care is to be taken afterward to wash the eye well with some lukewarm mucilaginous collyrium, until the irritation, caused by the chymical effect of such foreign bodies, has been completely obviated.

The removal of foreign bodies of the second class is usually attended with more difficulty, because they, as well as those of the third class, more frequently produce a violent and obstinate spasmodic closure of the eyelids, and are seldom loose, being generally fixed in the cornea. However, when they happen to be detached, they may be extracted in the same way, as small round smooth extraneous bodies, except that the stroking of the eyelid with the finger should be omitted, not only as useless, but likely to press any of these substances, which are of a pointed shape, into the loose conjunctiva, so as to injure the eye itself, which would otherwise not be hurt. The nibs of pens, the parings of the nails, and small hard-winged insects, when lodged in a depression of the cornea, or white of the eye, Beer says, may be easily dislodged by means of a small silver spatula. Other foreign bodies of the second class are not only fixed in a depression, but even penetrate more deeply than the conjunctiva; and, in old subjects, in particular, they often insinuate themselves into the loose cellular membrane under the conjunctiva in the white of the eye, partly in consequence of the convulsive motions of the eyeball and eyelids, and partly by reason of the attempts made to loosen them. Hence, they frequently become situated a great way from the place of their entrance, and are completely covered by the conjunctiva. But, even when they lie immediately in the wound, they are so intimately connected with the subjacent loose cellular membrane of the conjunctiva, that every attempt to remove them with forceps is not only unavailing, but hurtful to the eye, inasmuch as the injury is thereby rendered deeper. They may be taken away with facility, however, when lifted up with a pair of small forceps, and are cut away with a pair of scissors, together with the piece of cellular membrane, with which they are directly connected. If such extraneous substance should be actually underneath the sclerotic conjunctiva, Beer recommends the eyelids to be well opened, and the eye to be brought into a position, in which the part of the conjunctiva covering the foreign body, is rendered tense when an incision is to be made with a lancet down to the extraneous substance, which is to be taken hold of, and removed with a pair of scissors, the assistant being careful to keep hold of the eyelids during the operation. On the other hand, when the

foreign body is actually lodged between the layers of the cornea, Beer considers that its extraction may be best accomplished with a lancet-pointed couching needle. But whatever instrument is used, its point must be passed with great caution closely and obliquely under the foreign body; and care must be taken not to introduce it too deeply, lest the anterior chamber be opened, which may readily happen in young subjects; and when it does, the aqueous humour flows out, and the cornea becomes so flaccid, that the removal of the extraneous substance is quite impracticable, before the puncture has healed, and the anterior chamber is again distended.

The removal of foreign bodies of the third class mostly demands very great caution, first, because, as Beer observes, no particles of them should be allowed to remain in the eye, which, without the utmost vigilance, is apt to be the case; and secondly, because the wound of the eye, already considerable, should not be made larger than can be avoided. The extraction of small bits of glass is particularly difficult, as they cannot be seen, but must be found out entirely by the feelings of the patient, or the *tactus eruditus* of the surgeon, assisted with a probe. When in this way, a particle of glass is detected, Beer directs us to take hold of it with a pair of forceps, and cut it away with scissors. The place from which it has been removed, must then be carefully probed, in order that no other fragment may be left in it. (*Beer.*)

According to the same author, pieces of iron and steel, which strike the eye so forcibly as to enter it, as well as all other fragments of metals, which are readily oxydized, should be as carefully removed as bits of glass; for the more easily they combine with oxygen, and the longer they remain, the more brittle they become, and the more apt are minute particles to be left in the eye, especially in the cornea. A speck on the part of this membrane, where the splinter has lodged, is the least serious consequence of such an event. When fragments of steel, which have quite a black appearance, remain fixed in the cornea several hours, it is found, after their removal, that the whole circumference of the depression, from which they have been extracted, is of a reddish-brown colour, produced by the rust left behind, and firmly adhering to the cornea. Every particle of rust must be carefully removed with a couching needle, or else a permanent speck will ensue; but, caution must be used not to puncture the anterior chamber. The extraction of particles of lead and gunpowder is generally difficult, as they have mostly been projected with great force against the eyelids, so as to produce not only a great deal of spasm, but instantaneous swelling of those parts. Hence, Beer says, that they should commonly be taken hold of with forceps, and cut away. Particles of cantharides are easily removed with a small silver spatula, or the end of an eye-probe; but, their violent

chymical effect must be obviated, by frequently applying to the part a little fresh butter, touching it with a camel-hair pencil, dipped in diluted liquor ammoniac, or dropping into the eye lukewarm mucilaginous collyria.

The attempt to wash out of the eye particles of quicklime, mortar, &c. Beer says, only has the effect of rendering the violent chymical operation of these substances more diffused, and he recommends them to be taken out of the eye, by means of a fine hair pencil, dipped in fresh butter, or oil. This is the only way of immediately counteracting their chymical effect, and, after their extraction, the application of unctuous substances to the part should still be continued.

The stings of small insects, when lodged in the sclerotic conjunctiva, are often very difficult of detection; but they are more readily seen on the skin of the eyelids. Beer directs us to remove them with a pair of forceps, or a couching needle, and then to have recourse to means calculated to diminish the ophthalmia, which, in these cases, always begins on the first occurrence of the accident. Small shots, lodged in the loose cellular texture of the conjunctiva, must be cut out. In general, says Beer, it is necessary to divide the conjunctiva, as they are mostly situated some distance from the place of their entrance, and of course are quite covered by that membrane.

As soon as a foreign body has been extracted from the eye, all precursors of ophthalmia diminish, as for instance, the redness, intolerance of light, and the increased secretion and effusion of tears. Even the inflammation itself, when already developed, subsides; but, this affection is slight, if the eye has not itself been injured by the extraneous body. On the other hand, when the eye has suffered more or less irritation from the nature of the substance itself, and the treatment requisite for its complete extraction, the inflammation may become more severe, unless the surgeon pay immediate attention to the injury left on the eye. (*Beer.*)

According to the principles laid down in the foregoing columns, the first indication in the treatment of wounds of the eye in general is to remove every kind of extraneous substance, which might impede the cure. Hence, the necessity of observing whether the instrument with which the wound has been inflicted, or any part of it, is lodged in the eye. When this is the case, the foreign body should be quickly extracted, or else no recovery of the organ can take place. But, says Beer, this is more easily said than done; for in many instances, it is very difficult to find and remove the fragments of instruments, on account of the great delicacy of the organ, the irritability and alarm of the patient, and the bleeding from the part. However, the attempt must be made with the greatest gentleness possible; and Beer particularly advises a fine elastic whalebone probe to be used, instead of a silver one, for the purpose of detecting the fragment. He also sanctions making an incision, for facili-

tating the finding of the extraneous substance, provided it is certainly lodged, and cannot otherwise be traced. This author attaches great importance to the fulfilment of this first indication in all wounds of the eye, and relates a case, to which he was called sixteen years ago, where a piece of tobacco pipe had been driven so forcibly and deeply at the external canthus between the eyeball and orbit of a young student, aged 19, and of delicate make, that the eye was immediately pushed out of its socket, and, on Beer's arrival, it lay with the cornea quite against the nose. Its very position led Beer to suspect, that some extraneous body was lodged in the orbit, and, notwithstanding the assurances of all the bystanders to the contrary, and the patient's being affected with violent spasms, the part was examined with a fine flexible whalebone probe, by which means, a piece of the pipe, nearly an inch in length, was felt, and immediately extracted with a pair of forceps. Scarcely had this substance been removed, when the eyeball was spontaneously drawn back into the orbit, though with the cornea still turned towards the nose, and the twitchings of the muscles also instantly ceased; but the eye was blind, and had but a very faint perception of light. By very careful treatment, the eyesight was restored in five weeks; but, the eye could not turn towards the temple, owing to the considerable injury, which the external straight muscle had sustained. With the aid of electricity, the power of rotating the eye about half its natural extent outwards was in the end regained, and the remaining infirmity resisted every method deemed worthy of trial. (*Beer, B. 1, p. 146.* See also the article *Exophthalmia*.)

Fragments of broken instruments are not the only kind of extraneous substances, which may lodge in the wounded eye; for, as Beer observes, when the injury is extensive, contused, and lacerated, there may be splinters of bone, or pieces of membrane, cellular substance, muscle, &c. so detached as to be quite incapable of reunion, on which account, this author sets them down as foreign bodies requiring to be taken away. However, I conceive, that, with respect to the soft parts, the advice here delivered should be received with much limitation.

Wounds of the eye, like those of most other parts of the body, may be healed either by direct union, or a slower process, in which suppuration, the filling up of the chasm, by granulations, and the gradual but not complete approximation of its edges to each other, are the most conspicuous effects. Clean incised wounds may be cured in the first way, (see *Cataract*;) and lacerated, contused wounds, or such as are attended with loss of substance in the second. But, whichever plan be attempted, the eye must be kept quiet, and excluded from the air and light, with a light suitable bandage. As in wounds and chymical injuries of the eyeball itself, not admitting of reunion, the eyelids, when closed, completely cover the wounded part, the application of dressings to it be-

comes both unnecessary and impracticable, and all that can be done is to drop frequently into the eye a mucilaginous collyrium, and cover the organ with a light bandage, which will not make any hurtful pressure. In simple contusions of the eye, unaccompanied with wound, Beer deems a bandage the only requisite application; but, when these accidents are conjoined with effusion of blood, he recommends the use of spirituous aromatic fomentations, with the view of promoting absorption.

In healthy individuals small punctures of the eye, made with instruments like needles, and perforating only the conjunctiva, or cornea, but not reaching the deeper textures of the organ, are generally followed by no serious consequences, even when all the aqueous humour is voided. It is only necessary to keep the eye quiet, and the air and light excluded from it by means of a light compress, suspended over it from the forehead. Under this treatment, such punctures are so firmly closed in twenty-four hours, without any opacity, that the chambers are nearly filled again with aqueous humour, and the intolerance of light, which was only the effect of the loss of that fluid, is entirely removed.

In large clean cut wounds of the eye, whether accidental or made in the extraction of the cataract, the prognosis must be very cautious, and the treatment conducted with the utmost care; for, says Beer, it too readily happens, that, though the wound is not important in itself, its effects become from the least mismanagement highly dangerous to the eye. Hence, when the patient is known to be either an individual not likely to take proper care of himself, or one too much alarmed about the fate of his eye, the prognosis should be very guarded, even where the constitution is of the best description, because a violent and dangerous attack of ophthalmia is apt to ensue, and destroy the eye, sooner than effectual succour can be administered. On the other hand, when the patient is steady and intelligent, and the case is properly treated, the prognosis is very favourable.

In considerable cuts of the eye, it is only possible to promote their union with a suitable bandage, and by effectually preventing all motion of the eye and eyelids, which is best accomplished, when the sound as well as the injured eye is covered, and the patient kept quiet in bed until the sides of the wound have grown together. (*Beer, B. 1, p. 164.*)

As cases of deeply penetrating wounds of the eyeball itself, Beer enumerates the punctures made in the depression and reclinatio of the cataract, and in every mode of forming artificial pupil; and lacerations of the conjunctiva with ears of corn, pointed pieces of iron, splinters of wood, &c. In these cases, the prognosis, he says, is always very favourable, when the patient can put himself under all the conditions which the treatment requires, and his constitution is good. The first thing here to be carefully fulfilled, is the removal of any fragments of the instrument, or body, with which the injury has

been inflicted, and it should be recollected, that, in these cases, minute splinters, which are scarcely discernible, frequently lodge in the conjunctiva, and, if not immediately traced and removed, produce the very worst consequences. By the weapon being suddenly withdrawn, pieces of the conjunctiva are sometimes nearly torn away, and hang from the eye; these Beer directs to be cut off with scissors. The best applications, he says, are either lukewarm mucilaginous lotions, or, (when blood is effused under the conjunctiva,) vinous, spirituous collyria. To these cases, he thinks fomentations scarcely applicable. When the quantity of blood, effused in the loose cellular texture under the conjunctiva, is very considerable, he recommends scarifications, but, where this practice does seem likely to answer, and vinous spirituous collyria are ineffectual, some of the liquor ammoniæ should be added to them. When any fragment of the instrument has been overlooked, and remains in the part, either a copious suppuration ensues, and the fragment is at length detached, or else, in a patient of inferior sensibility, a soft, spongy, readily bleeding, pale-red excrescence is formed all round the extraneous body, and sometimes even projects between the eyelids. Here, according to Beer, the first requisite step is to cut away the fungus with a knife, so as to reach the irritating fragment under it, and then the rest of the excrescence may be removed by touching it with the tinctura thebaica, or vinous tincture of opium.

With respect to lacerated wounds of the cornea, they either penetrate the anterior chamber, or not. They are all of them attended with more or less concussion, laceration, stretching, and partial contusion of the delicate anterior textures of the eyeball; a consideration, as Beer observes, materially affecting the prognosis. When, in such injuries of the cornea, inflammation and suppuration cannot be prevented, or the discharge is protracted, an obvious scar is always the consequence, which, when situated in the centre of the cornea, is a serious impediment to vision. Every endeavour should therefore be made to unite the wound by the first intention; and the best chance will be afforded by treating the eye precisely in the same manner as after the extraction of the cataract. (See *Cataract*.) And, when fortunately the plan succeeds, the flow of the aqueous humour out of the eye ceases in about 36 or 48 hours, and the anterior chamber becomes distended again; but, the site of the injury continues visible for some time afterward. The speck, however, ultimately disappears, though much sooner in young healthy subjects, than in the aged and feeble. When the opacity does not go off of itself, Beer finds a collyrium, containing some of the lapis divinus, (see *Lachrymal Organs*), and the vinous tincture of opium, the most effectual means of dispersing it. Through large wounds, penetrating the cornea near its edge, a fold of the iris is apt to protrude, and, when it does, it should be re-

placed, which can only be effected without mischief to the eye by gently rubbing the upper eyelid, and then letting a strong light suddenly strike the organ. In this case, the employment of instruments is considered by Beer highly objectionable. When the iris is not immediately reduced, it as well as the cornea is attacked with inflammation, and soon becomes firmly adherent to the edges of the wound. (See *Iris, Prolapsus of the*.)

Large wounds penetrating the eyeball, and reaching to the iris, are always of a very serious nature, even though the latter part may have received only a prick, or cut, because as the injury has been produced by accident, and not by art, the wound of the iris cannot be free from all laceration and contusion. It is incredible, says Beer, what extensive injuries the iris will bear in healthy individuals at its pupillary and ciliary edges, especially when produced by very sharp instruments; nay, rents may happen at both its edges, without any ill consequences, if the constitution be favourable; a proof of which fact is seen in the two common methods of forming an artificial pupil, viz. the excision of a piece of the iris, and the detachment of the iris from the ciliary ligament, as practised both by Schmidt and Scarpa. But, according to Beer, all violent pressure, or actual contusion, particularly when it affects the portion of this organ between its two circles, cannot be borne even in the best constitutions, and the least grievous consequence is inflammation, soon followed by a partial or complete closure of the pupil, or suppuration in the eyeball. When the instrument, causing such injury, passes to the iris through the cornea, as is mostly the case, and the wound in the latter tunic is extensive, the torn iris is frequently pulled between the edges of the wound, at the moment when the weapon is withdrawn, and protrudes in a lacerated state. In this case, Beer recommends the torn projecting piece of the iris to be cut away with scissors close to the wound in the cornea, when the rest, he says, is generally retracted within the eye. Thus an adhesion of the iris to the cornea, termed *synechia anterior*, may often be prevented, which, when the lacerated iris is suffered to hang out of the cornea, is inevitable, surrounded by a large opaque cicatrix.

Some violent blows on the eye, though they cause no wound, are attended with such a concussion of the anterior hemisphere of the organ, that more or less of the iris is instantaneously separated from the part of the ciliary ligament, where the force is most vehement. The consequence of this accident is either a double pupil, or the natural pupil closes, and the artificial one remains open. Such injuries may be produced by the lash of a whip, or a horse's tail, (a common accident in the narrow streets of Vienna) or the thrust of any bluntish weapon against the outer part of the cornea; and they are purposely inflicted in the method of forming an artificial

pupil, recommended both by Schmidt and Scarpa.

Wounds which enter the eye through the sclerótica near the cornea, usually produce a considerable effusion of blood in the chambers of the aqueous humour; but Beer thinks that there is never any necessity for making an opening for its discharge at the lower part of the cornea, except when it is so considerable as completely to hide the iris, at the same time that the eyeball is affected with very painful tension and hardness. In all wounds of the iris, it is likewise proper to follow the same treatment as applies to penetrating wounds of the cornea, with this difference, that when the effusion of blood in the chambers of the eye is considerable, the action of the absorbents should be promoted by the immediate employment of vinous aromatic collyria, and afterward warm spirituous lotions.

Wounds of the eyeball, affecting the corpus ciliare, are set down by Beer as extremely dangerous, independently of the inflammation, which quickly follows. However, such injuries are most serious when they consist in a real contusion, or laceration of the corpus ciliare, which can hardly take place without a severe concussion, or actual disorganization of the retina, and laceration of the principal ciliary nerves and vessels. Hence, besides an effusion of blood in the chambers of the aqueous humour, a partial or complete amaurotic blindness is instantly produced, and the iris, in the vicinity of the place where the instrument entered, is so retracted towards the margin of the cornea, that neither of its circles can be seen. In cases of this description, it also frequently happens, says Beer, that the patient, or the person who inflicted the wound, suddenly and roughly pulls the weapon out of the eye again, and together with it a part of the corpus ciliare, which is then to be regarded as an extraneous substance, and immediately cut off. With respect to the prognosis and treatment, the observations already made on these topics, in reference to wounds of the iris, are here quite applicable, excepting that as the effused blood is less copious than in the latter cases, there can never be here any necessity for letting it out by a depending opening in the cornea.

Wounds of the eye, affecting the crystalline lens, are not unfrequently followed by the formation of a cataract, and so are blows on the eye, which may be supposed to produce this effect by destroying some of the minute nutrient vessels naturally connecting the capsule with the lens. (Beer, B. 1, p. 218.) The treatment of these accidents resembles that of injuries of the iris, except that the surgeon has rarely any extravasation of blood to deal with. However, when the lens has slipped into the anterior chamber, Beer recommends its immediate extraction through an incision in the cornea, in order to prevent the eye from being destroyed by a violent attack of traumatic inflammation and suppuration. Nor when

inflammation has come on, should this measure be postponed, as Beer has constantly found the disorder lessen, after the lens has been taken out.

Considerable wounds of the eye, attended with loss of the vitreous humour, are described by Beer as of a very serious nature; but they rarely take place accidentally, being almost always the consequence of a surgical operation. Accidental injuries of this kind are generally combined with so large or complete a discharge of the vitreous humour, and with such mischief to the organization of the eye, that the consequence is a loss of the eyeball, or such a dwindling of it, that the fissure of the eyelids becomes nearly closed. According to Beer's experience, injuries of the foregoing kind, arising from accident, are mostly produced by the horns of cows. On the contrary, the effusion of the vitreous humour in operations upon the eye, he observes, is seldom followed by the loss of the eye. Kortum, in his Manual on the Diseases of the Eye, adverts to some instances which he had seen, or fancied that he had seen, where *the whole of the vitreous humour was lost*, and yet the eyesight afterward became as strong as if no such accident had happened. On the other hand, Beer has never met with any of these fortunate cases; but has always found the sight to be seriously impaired when the quantity of vitreous humour lost has amounted to nearly its half, and that complete blindness was the result when the loss much exceeded that quantity. He conceives also, that Kortum had probably seen but few cases of this nature, and therefore might have been mistaken, as to the proportion of the vitreous humour discharged, which to the inexperienced seems larger than it really is, and he cautions surgeons not to promise too much in cases of this description. (B. 1, p. 222.) See *Cataract*.

Considerable injuries of the eyeball, complicated with a concussion, bruise, or actual wound of the retina, produce, either gradually or immediately, an amaurosis, which is almost always incurable. When the concussion of the retina is less violent, and does not affect every part of this texture, it may occasion only an amaurotic weakness of sight. In worse cases, the surgeon may think himself very successful if he can prevent the figure of the eye from being destroyed by the subsequent inflammation, all idea of the recovery of the eyesight being out of the question. The treatment is the same as that commonly adopted after operations for the removal of an opaque lens (see *Cataract*;) but there is one particular circumstance, sometimes attending injuries of the retina and ciliary nerves, claiming notice, viz. violent vomiting; a symptom which Beer says may even attend contusions of the sclerótica and of the ciliary nerves and retina, without any wound. Injuries of the ciliary nerves, he observes, are denoted by a very peculiar appearance; for, near the injured part, the iris is drawn up

so close to the edge of the cornea, that its colour can scarcely be seen. When the surgeon is consulted in a case of this kind, though some inflammation may have commenced, the prognosis is yet favourable, in regard to the preservation of the eye; for a gentle opiate will relieve the vomiting when merely a nervous effect, not depending upon the loaded state of the gastric organs; but, if the case be of this last description, the *primæ viæ* should first be emptied. However, when a traumatic inflammation is completely established, before the treatment is begun, the eye is generally destroyed, as the repeated and violent vomiting cause a great determination of blood to the head and eyes, and increase of the inflammation; an effect which the opiates, given for the relief of the vomiting, also tend to produce.

Beer has seen two cases in which the eye was pricked with a needle near the insertion of the external straight muscle into the sclerotic; in both instances, the punctures were so small, that they would scarcely have been found, had not the patients known their situation exactly by the pain, and they were then only perceptible with a magnifying glass. The punctures were soon followed by a convulsive rolling of the eyeball, and afterward by trismus, which continued severe in one patient a day and a half, and in another two days, but yielded to large doses of musk and opium given at short intervals, the warm bath, and the application of warm poultices containing hyosciamus.

As chymical injuries of the eye produce an actual loss of substance, they are even more serious than common mechanical lesions. However, chymical injuries of little extent are generally repaired with tolerable facility and expedition. Quietude of the organ, and moderating the outward noxious effects by lukewarm mucilaginous applications, either in the form of fomentations, or eye waters, are the only requisite measures. If the cornea itself be hurt, as frequently happens when boiling hot fluids strike the eye, a kind of vesicle arises on the injured part, which becomes more and more white. The vesicle either bursts of itself, or subsides without breaking. In both cases, the production of the conjunctiva, of which the cyst of the vesicle is composed, shrivels up, and peels off, a new membrane of a similar nature being regenerated underneath. An opaque speck is frequently apprehended; but, says Beer, if the surgeon will merely avoid being too much in a hurry to open the vesicle, and not disturb the work of nature by applying various remedies to the eye, there will be no danger of such an occurrence.

More extensive chymical injuries of the eye, which at first are not in themselves very severe, frequently become dangerous, in consequence of care not being taken to prevent the influence of external stimuli. To this class of cases belongs the accidental sprinkling of the eye with boiling fluids, or

strongish mineral acids. And even in these examples, says Beer, the prognosis is not unfavourable, and a complete recovery may be effected when the treatment is conducted according to the directions already given with respect to such accidents in general. While this author approves of cutting away any substance which is dead and partially detached, he strongly cautions surgeons not to remove the thin layer of the conjunctiva, nor to puncture any vesicle which may form.

When the burning or corrosion is not limited to the conjunctiva of the eyeball, but extends to the lining of one or both eyelids, Beer recommends covering the injured parts with mucilaginous applications, and mildly astringent ointments, containing tutty, or the white oxide of lead. In these cases, keeping the eye perfectly motionless must be hurtful, as it tends to promote the formation of adhesions, either between the eye and eyelids, (*Symblepharon*) or between the eyelids themselves. (*Anchyloblepharon*.)

Extensive, deeply penetrating, chymical injuries of the eyeball, Beer describes as being almost always followed by more or less impairment of the functions of the organ, or of some of its particular textures, because such accidents never happen without a loss of substance. Thus a part, or the whole, of the cornea may be entirely destroyed, as in injuries caused by quicklime; and, frequently, adhesions between the eye and eyelids, or between the two latter parts, cannot be prevented by any kind of skill. (*Beer*.) These serious degrees of mischief, as the same author observes, are mostly occasioned by slaked or unslaked lime, concentrated mineral acids, fire, &c. Unslaked lime, especially when extensively diffused over the eye by the immediate application of water, not unfrequently produces a sudden destruction of the whole of the cornea, which is changed into a grayish, pappy substance, capable of being removed from the subjacent iris with a camel-hair pencil. Such an annihilation of texture, however, is generally restricted to particular points, or the surface of the cornea. Wherever this membrane has been so much decomposed that a manifest depression is directly perceptible in it when inspected sideways, a snow-white shining speck must be expected to be the consequence. Slaked lime never operates upon the cornea with so much violence, usually causing (as Beer states) only a superficial corrosion, or a coagulation of the lymph between the layers of the cornea. Nor are mineral acids, even when concentrated, generally so destructive to the cornea as quicklime; first, because, as fluids, they do not long remain in contact with the eye; and secondly, because the immediate mixture of the tears with them weakens their operation; whereas it only increases that of unslaked lime. The local treatment here consists in carefully removing every particle of the hurtful substance, afterward dropping frequently into

the eye lukewarm mucilaginous decoctions or collyria, or covering the injured place with a mild cerate, and excluding the air and light from the eye. Every endeavour must also be made to prevent the formation of adhesions between the injured surfaces.

In very severe burns of the eyeball, of course, all idea of restoring its functions is out of the question. The violence of the injury is the greater, the more numerous the vesicles are upon the conjunctiva, and the more the eyeball and the iris are incapable of motion. Here the only indication is to moderate the inflammation, and avert such additional mischief, as might otherwise be produced by it. With this view, the eye should be kept at rest, and excluded from the light and air. According to Beer, the most common injuries of the eye, partaking both of a mechanical and chymical nature, are those caused by mortar, or the accidental touching the eye with hot curling irons. When the mortar contains no particles of quicklime, it often occasions, at particular points of the cornea, very white specks, which Beer describes as being composed of coagulated lymph, and admitting of dispersion. He even declares, that when the whole of the cornea is in this state, its transparency may be restored by proper treatment, as has been frequently exemplified to the gentlemen attending his clinical lectures. (*B. 1, p. 234.*) The pricking of the eyeball with a red-hot needle, and the stinging of it by bees, wasps, and other insects, are also both chymical and mechanical injuries. Whether the sting be left in the skin of the eyelid, or in the conjunctiva, or not, a considerable inflammatory swelling immediately takes place; and, if the sting be lodged, and not now taken away, the inflammation spreads, and the eye itself is endangered. In two cases, where the stings of bees were left in the skin of the upper eyelid, Beer has known gangrene arise in the short space of a day and a half, and the patients were saved with great difficulty. The treatment of such cases consists in immediately extracting the sting, if lodged, and applying folds of linen over the eye, wet with cold water.

After noticing the destructive effects of burning substances, the explosion of gunpowder, and fulminating silver, on the eye, (cases in which, when the functions of the organ are annihilated, the only indication is to diminish the subsequent inflammation and its consequences,) Beer inquires, what is the reason why the slightest mechanical, or chymical, injuries of the eye, in an apparently healthy subject, are sometimes followed by an immoderate degree of inflammation, and even the loss of the organ from suppuration? It is, says he, an observation made by Schmidt, that there are some eyes, which the greatest bunglers may abuse for hours at a time, without being spoiled, their powerful organization defying all such unskilful disturbance; while other eyes are met with, which the most skilful opera-

tors can hardly touch, without inducing a destructive degree of inflammation and suppuration. It was to this peculiar idiosyncrasy that Schmidt applied the term *vulnerability* (*Verwundbarkeit*.) Patients of this habit are said to possess an exceedingly fine soft skin, with a reddish polish upon it, and their cheeks are not only red, but exhibit a network of very minute vessels, which seem as if injected. Such individuals appear as if they were in the bloom of health; and, says Beer, in some respects they are really so. When their spirits are raised by the slightest causes, their complexion is universally reddened; but the least fear turns them as pale as a corpse. Their skin is described as being uncommonly irritable, sensible of every impression, and attacked with an erysipelatous redness, whenever any fatty substance touches it. In such habits, the utmost caution is necessary whenever the eyes have been injured, and the prognosis should be reserved. And, when an operation is to be done on their eyes, Beer recommends the previous exhibition of opium, and the application of a blister to some part of the skin, at a considerable distance from them. As a prophylactic measure, he also directs regular friction of the surface of the body.

In severe ophthalmies, particularly those which affect the eyeball itself, all mental emotions, anger, joy, &c. should be avoided. Hence, no talkative nor quarrelsome persons should be suffered to remain with the patient; and noisy children ought to be kept away from him. The apartment should be ventilated at least once a day, without the patient being exposed to any current of wind. All touching of the eye, or rubbing it with the bed-clothes during sleep, must be strictly prohibited. Stimulating, spicy food, spirituous drinks, and great bodily exercise are likewise to be forbidden. In the list of things which have a hurtful effect, Beer also includes all exertions of the lungs, every kind of disturbance, an atmosphere impregnated with tobacco-smoke, &c.

Having fulfilled the first general indication by removing, if possible, every kind of irritation acting upon the eye, the *second general indication* specified by Beer as proper in the first stage of ophthalmia, is to be observed, which is to moderate, according to the degree of inflammation, the agency of several things to the effect of which the organ is naturally subjected. Thus, the inflamed eye should not be exercised, even though the eyeball itself may not be immediately inflamed; and the operation of the light and air should be diminished partly by green silk eye-shades, and partly by window-blinds. Attention to this rule is still more necessary, when the eyeball itself is affected. With respect to the exclusion of light, it is to be well remembered, that it is only advisable, as Dr. Vetch observes, in the very early stage of inflammation, the eye becoming more irritable and less manageable, when the access of a moderate degree of light is afterward prevented. (*Vetch on Diseases of the Eye, p. 16.*)

The *third general indication*, mentioned

by Beer, as proper in the first stage of ophthalmia, when the disorder threatens to extend to the whole organ, and to bring on a febrile disturbance of the system, is to counteract these effects by covering the eye with folded linen wet with simple cold water, or vinegar and water; and having recourse to leeches, or when the nature of the case allows, to scarifications. (B. 1, p. 242.) Here, however, it merits particular notice, that, Beer, in expressing a general preference to cold lotions in the first stage of ophthalmia, differs from Richter, Scarpa, and Mr. Travers, (*Synopsis of the Diseases of the Eye*, p. 250.) all of whom, in the painfully acute stage, recommend tepid emollient applications.

With regard to leeches, also, the late Mr. Ware objected to their being put on, or very near the eyelids, as they sometimes cause a considerable swelling of these parts, and increase, instead of lessening the irritation. In ordinary cases, his method was to apply three on the temple, about an inch and a half from the outer part of the orbit. Scarpa recommends applying the leeches to the vicinity of the eyelids, especially about the inner canthus, on the vena angularis, where it joins the frontal, deep orbital, and transverse vein of the face. Beer prefers nearly the same situation, as that specified by Scarpa, viz. the inner canthus, immediately below the under eyelid; and he forbids the application of leeches above either canthus, as likely to produce a disagreeable ecchymosis in the cellular membrane of the upper eyelid. The number of leeches, and the time, which they should be allowed to suck, he thinks, ought to depend upon the severity of the inflammation. According to Beer, when this mode of bleeding is to be of any service, the patient will experience a considerable abatement of the throbbing pain, tension, &c. in the affected eye. Hence, when any of the leeches fall off prematurely, the bleeding from the bites is to be kept up, with a sponge dipped in warm water, until such relief is felt. In the acute stage, Beer considers the abstraction of blood by means of scarifications rarely admissible. (B. 1, p. 243.) Mr. Travers also sets down scarifications of the conjunctiva as mostly objectionable in the acute stage; though highly beneficial in the chronic, where the lining of the eyelids is thickened and over vascular; and a considerable discharge of blood may be thus obtained, if the operation be briskly done with a sharp lancet, and the lower lid kept everted, and fomented. The same gentleman states, that cupping has a decided superiority over leeches, but that both are well adapted to relieve local congestion. Yet, he deems these methods too indirect to answer as substitutes for the lancet, where it is desirable to make the system "sustain and feel a reduction of power," in which case blood must be taken from a vein, or the temporal artery. (*Synopsis*, &c. p. 249.) While inflammation of the conjunctiva is described by Dr. Vetch, as not much affected by bleeding, unless the quantity of blood taken away be

such as to occasion syncope, he states, that the abstraction of blood, in quantities proportioned to the violence of the symptoms, more especially, by means of cupping and leeches, has for the most part sufficient control over the various states and individual symptoms of sclerotic inflammation. In some obscure cases of what this author terms amaurotic inflammation, he has seen great benefit derived from the application of leeches to the septum nasi, and he represents their being put directly on the conjunctival lining of the eyelids, as being sometimes more advantageous than on the adjacent integuments, the orifices bleeding with great freedom. (*On Diseases of the Eye*, p. 15.)

If some of the above remarks are correct, scarifications are rather too boldly praised by the late Mr. Ware, as applicable to the acute stage of ophthalmia. But, supposing the first violence of the attack past, his recommendation of the practice either in the vascular and turgid state of the lining of the eyelids, or in the eversion of the lower one from a similar cause, seems perfectly unobjectionable. When the upper eyelid was very œdematous, and its thickness prevented the application of proper remedies to the eye, Mr. Ware also thought a few punctures near the ciliæ useful, by causing a discharge of bloody serum, and a quick subsidence of the swelling. And he speaks of the excision of a piece of the excessively tumid lining of each eyelid, in cases of ophthalmia with eversion, as having afforded great and speedy relief. (*Ware on Ophthalmia*, &c. p. 39.)

The fourth general indication, enumerated by Beer, is that, which has for its objects a diet and regimen suited to the state of the case, after it has attained a degree, in which its effects begin to be felt throughout the system. When therefore the plan is to be rigorously practised, the patient's ordinary diet is to be reduced, and he is to be allowed only vegetable food, cooling drinks, water, weak lemonade &c. And not merely the eye itself is to be kept at rest, but the whole body.

Should the disorder be further advanced, and attended with a great deal of inflammatory fever, the observance of the foregoing indications will not suffice for checking the inflammation and preventing suppuration, unless the fifth indication, laid down by Beer, be fulfilled, which is to employ such remedies as operate upon the whole constitution. 1. Purgative and gently aperient medicines, which will empty the bowels well, and lessen the determination of blood to the head and eyes. 2. Clysters, which are useful on the same principles. 3. The frequent exhibition of the nitras potassæ. 4. General bleeding, the efficacy of which will much depend upon the blood being voided in a full stream. Beer seems to prefer opening a vein on the foot; but, in England, the most experienced practitioners generally open a vein in the arm, and sometimes the temporal artery. The blood, as Beer remarks, should be allowed to flow until the hard small pulse rises and becomes plainly softer; for, otherwise the

operation will be completely useless. Also, when in these cases, general bleeding is no longer indicated, the employment of leeches will yet be advantageous, and afterward, scarifications may be practised, which, at any earlier period, would have aggravated all the inflammatory symptoms.

By strict attention to the five above explained indications, either without precipitation, or too much delay, the first stage of ophthalmia, even when in its most violent degree, may be certainly checked and resolved; and all suppuration avoided, so that the eye may be restored to a perfectly sound state again, provided the patient, previously to the attack, was quite healthy, and of course the affection of the eye a genuine idiopathic inflammation. (Beer, B. 1, p. 246, 247.)

Respecting the *prognosis* and *indications* in the second stage of ophthalmia in general, and of idiopathic cases in particular, Beer offers many interesting remarks. He observes, that when ophthalmia has reached its second stage, which may be known by circumstances already referred to in the preceding columns, it must be clear, that the above indications are no longer valid, and the fulfilment of them would destroy the eye.

In the second stage, every thing which has a tendency to produce further weakness of the eye must be avoided, or suppuration will be the consequence: the first indication, therefore, specified by Beer, is to let the eye be cautiously exposed according as its tendency will allow, to its wonted stimuli again. 1. By letting fresh, dry, and, if possible, a warmish air, have free access to the organ. 2. By exposing the eye to as much light (not of a reflected description) as can be borne, not only without difficulty, but with pleasure. 3. By moderately exercising the organ, especially in the inspection of agreeable diversified objects; a plan, which is of infinite service, when the eyeball itself has been affected.

The second indication, proposed by Beer in the second stage of ophthalmia in general, is to apply tonic remedies, particularly those of a volatile kind, to the eye, which are to be discontinued in the event of suppuration. 1. Beer praises the application of well-warmed linen compresses, which, if necessary, may be sprinkled with camphor; or, in urgent cases, he uses little bags of aromatic herbs and camphor; a practice, in which I am disposed to think surgeons here will have little or no confidence. 2. However, when the eye is too irritable to bear the application of bags of aromatic substances, Beer sanctions the employment of poultices made of bread crum and warm herbs, or the pulp of a roasted apple. But, this experienced author is very particular in qualifying his approbation of moist applications with a caution, that they must never be allowed to become completely cold on the eye, whereby they would do more harm in a quarter of an hour, than any good, which may have been attained in many hours by their previous use. Hence, Beer employs poultices

only in cases of necessity. In this country, "when the extreme vascular congestion and excessive sensibility are reduced, and the inflammation tends to become chronic, the use of cold lotions, of a slightly tonic quality, is substituted with great advantage for ablu-tions of warm water. The sulphates of alum and zinc are the best." (Travers, Synopsis, &c. p. 252.) The employment of astringents also agrees with the advice delivered by Richter and Scarpa. Here then we find a point on which Beer differs from the generality of writers; but, nothing is clearer to me, than that his alarm about the ill effect of cold upon the eye in the second stage of ophthalmia is only the fruit of some theories, which he entertains, and not of impartial experience. 3. When there are small ulcers, or pustules, on the eyeball itself, Beer assures us, that great benefit is derived from dropping between it and the eyelids a tepid solution of the lapis divinus, the composition of which is elsewhere described (see *Lachrymal Organs*), and bathing the eye with the same application, to which a little of the vinous tincture of opium is added. Should this remedy fail in checking the progress of the ulcers, or pustules, Beer recommends the addition of acetate of lead. 4. And, says the same author, when no decided amendment is produced, within twenty-four hours, the suppurating points must be touched once or twice a day, according to the urgency of the danger, with a camel-hair pencil, dipped either in a watery solution of opium, or the vinous tincture of opium. In the worst cases, he even directs Hoffman's balsam, vitæ, naphtha, or the Peruvian balsam to be mixed with the vinous tincture of opium.

But, Beer observes, that when these remedies have been too precipitately employed, and any granulations, or excrescences form, the treatment must be less active, and then these new productions will frequently recede of themselves; but, if they should not do so, they may be removed with burnt alum, or caustic. (B. 1, p. 252.)

The third rule, laid down by Beer, in the treatment of the second stage of ophthalmia, cautions the practitioner not to apply the caustic or the knife, to any of the morbid changes, which either originate during the first stage, and continue in the second, or make their first appearance at the period of suppuration, as, for instance, opacities of the cornea, eversion of one or both eyelids, &c. However, as exceptions to this advice, Beer adverts to the treatment of new-growths under the circumstances above specified, and to that of abscesses of the eyeball, where the matter is of an unhealthy quality, and so copious as to make an opening advisable, which practice, however, as a general one, he condemns. The other morbid changes, already alluded to, the practitioner must endeavour to remove simply by proper treatment of the second stage. (Beer, B. 1, p. 254.)

Beer's fourth rule in the treatment of the second stage of ophthalmia in general, and of

idiopathic ophthalmia in particular, when the suppurative process is extending itself, and threatening to impair the health, is, 1st. To allow the patient such food as is both easy of digestion, and of a very nutritious quality, and even a moderate quantity of wine and spirituous drinks, if he has been accustomed to them. 2dly. To direct the patient to keep his eye exposed the greater part of the day, in a fresh, dry, and (if possible) mild air, and take just exercise enough in various ways to produce a slight degree of fatigue. 3dly. When the eye itself is affected with suppuration, and the sight is either thereby much impaired, or quite lost, and, of course, the patient very unhappy and depressed, Beer considers it highly beneficial to let his spirits be improved by society.

The fifth rule, or general indication in the second stage, laid down by Beer, refers to the necessity of supporting the constitution, when the suppurative process is attended with a general febrile disturbance. For this purpose, he recommends, 1st. The exhibition of calamus aromaticus, naphtha, and camphor. 2dly. If they prove ineffectual alone, they are to be joined with other tonics, especially bark. 3dly. The warm bath, which, in consequence of the sympathy between the skin and eyes, is particularly efficacious. 4thly. Rubefacients, applied not far from the eye; means, which are exceedingly beneficial in the second stage of ophthalmia. (B. 1, p. 257.)

As an appendix to these general remarks, delivered by Beer, on the general treatment of ophthalmia in its first and second stages, I annex the sentiments of some other writers, as either confirming, or rendering questionable, some of his statements.

According to Scarpa, when bleeding and other evacuations have been practised, the next most useful measure is the application of a blister to the nape of the neck. He observes, that the skin here and behind the ears, has a stronger sympathy with the eyes, than any other part of the integuments. On the other hand, the late Mr. Ware preferred blistering the temples, and says, "When the leeches have fallen off, and the consequent hemorrhage has ceased, I would advise a blister of the size of half a crown to be applied on the temples, directly over the orifices made by the leeches, and I have found, that the sooner the blister has followed the bleeding, the more efficacious both have proved." He adds, that when ophthalmia is very violent, and resists common methods, the most beneficial effects are sometimes produced by the application of a blister large enough to cover the whole head. (P. 43, 44.)

With respect to blisters, another modern writer particularly objects to their being applied near the eye, or on the temples, "where they never fail to prove injurious." There is (says he) "but one exception to this, as a general rule; for, it would seem, that blisters applied to the external surface of the palpebræ, in cases of purulent ophthalmia, tend considerably to diminish the puru-

lency and chemosis." (*Velch on Diseases of the Eye*, p. 17.)

In the second stage of acute ophthalmia, the vinous tincture of opium (the tinctura thebaica) has been very extensively used, as a topical application. In common cases, two or three drops may be insinuated between the eyelids and globe of the eye, twice a day; but, in other instances, attended with more sensibility, once at first will be sufficient. The late Mr. Ware, who brought this application into great repute, found, that introducing two, or three drops, of this medicine at the inner canthus, and letting them glide gradually over the eye, by gently drawing down the lower eyelid, proved equally beneficial, and less painful than letting them fall directly upon the eyeball. Immediately the application is made, it usually creates a copious flow of tears, a smarting, and a sense of heat in the eyes; which inconveniences, however, soon cease, and the eyes become clearer, and feel decidedly improved. But, notwithstanding every exaggeration, unbiassed surgeons are now fully convinced, that the vinous tincture of opium is a proper application only when the inflammatory action has been previously diminished by bloodletting, aperient medicines, and blisters, and when the action of the vessels has been weakened by the continuance of the disease. Nor is any doubt entertained, that the late Mr. Ware went much too far, when he recommended the vinous tincture of opium, as a most effectual application in every species and stage of the disorder, from the most mild and recent to the most obstinate and inveterate. (P. 51. Scarpa has seen the necessity of limiting the use of the remedy in question, and has expressly pointed out, that it is useful only when the violence of the pain, and the aversion to light, have abated. Indeed, Mr. Ware himself, a little before sanctioning its employment in all cases, has acknowledged, that, in certain instances, in which the complaint is generally recent, the eyes appear shining and glossy, and feel exquisite pain on exposure to the light, no relief at all was obtained. (P. 48, 49.) Mr. Travers has remarked, that "there are inflammations, which assume a chronic character in their commencement, evidently depending on a state of atony, of very partial extent, void of pain, and scarcely possessing any sign of inflammation, except the congestion of the vessels, or, if any, so feebly marked, as to encourage us to disregard them in the treatment. In such cases, a single stimulus will often restore the healthy action at once. The vinous tincture of opium has acquired a nostrum-like importance from its restorative operation in such cases; a virtue, I believe, not proper to it. A drop or two of the zinc, or the lunar caustic solution, or water impregnated with calomel, or a minute portion of the citrine ointment, or any other stimulant, would do as much." (*Synopsis*, &c. p. 252.)

Whenever the patient can easily bear a moderate degree of light, Scarpa directs all

coverings to be removed from the eyes, except a shade of green, or black silk. A brighter light should be gradually admitted into the chamber every day, so that the eyes may become habituated, as soon as possible, to the open daylight; for, as Scarpa truly states, nothing has a greater tendency to prolong and increase the morbid irritability of the eyes than keeping them unnecessarily long in a dark situation, or covered with compresses and bandages.

Dr. Vetch has such a dislike to the plan of covering the eye, that he never suffers a shade to be worn, conceiving that, in conjunctival inflammation, it always does a great deal of harm by preventing a free exposure of the eye to a temperate atmosphere. (*On Diseases of the Eye*, p. 17.)

Besides the common remedies for inflammation, there are some very powerful means, which may be employed for the relief of particular states of ophthalmia with great effect. Thus, as the latter author has observed, by means of hyosciamus, belladonna, and stramonium. (See *Belladonna*) the important structure of the iris may be secured from injury, at the same time that other measures are adopted for checking the inflammation. Such medicines may even be applied, as a mechanical force, for detaching any recent adhesion. (*Op. cit.* p. 18.)

The uses of the argenti nitratum are also very extensive: "the slightest application of it in substance (says D. Vetch) can often remove the highest degree of morbid sensibility to light, and instantaneously restore quietude to the organ; it can prevent incipient changes, and obviate advanced ones; and may also be used in solution, as a valuable sedative."

The mention of so stimulating and active a substance as the nitrate of silver having a sedative effect may excite surprise; but the fact is unquestionable, and well illustrated in the treatment of several diseases. (See *Cornea and Iris*.) As another modern writer correctly states, it is remarkable that even the weaker forms of medicated lotions irritate, and none more than such as contain opium. The relief, afforded by anodyne fomentations in general, is very various. "I have known them (says Mr. Travers) objected to as painful, and patients inquire if they might not substitute warm water for the aqueous solution of opium and infusions of poppy and hemlock. The same observation applies especially to painful herpetic cutaneous affections, and acutely irritable ulcers. Upon these a solution of opium often acts as a stimulant, and augments pain, while the lunar caustic solution as often assuages it." At the same time, Mr. Travers admits, that exceptions occur, and that he has met with cases, "in which no other application than the aqueous solution of opium could be borne." He has also known the vapour of laudanum afford the most marked relief to the irritability to light accompanying strumous ophthalmia. (*Synopsis of the Diseases of the Eye*, p. 251.)

According to Dr. Vetch, it is impossible,

in cases of conjunctival ophthalmia, to possess an application of greater efficacy, than the undiluted liquor plumbi subaceticis, for altering the morbid and purulent state of that membrane; he also describes nicotiana, externally employed as a narcotic and astringent, as being of singular service in lessening the pain, and tumefaction. (P. 19.) However, the discordance among the best writers, about the effects of favourite local applications, would lead me to enjoin rather attention to the leading principles of the treatment, than confidence in the superior efficacy of any particular drug or composition. As also the local applications should vary in the different stages of purulent ophthalmia, no single one will always be right. Dr. Beer had delivered no observations of greater importance, than his condemnation of Bates's camphorated lotion, and his praise of other styptic stimulating applications, his remarks would be of little value; but, as he has pointed out the different stages of purulent ophthalmia in a very correct manner, and adapted his remedies to these various states of the disease, his information comprehends scientific principles, and becomes peculiarly interesting. The same praise belongs also to Dr. Vetch's observations on purulent ophthalmia, who, in some points, both of the description of the complaint and its treatment, has surpassed Beer.

Of the different Kinds of Ophthalmia. Beer's classification is very comprehensive. According to the situations, in which ophthalmic inflammation first originates, he proposes a general division of it into three forms, as suggested by some of the older writers; viz. inflammation of the eyelids, or blepharophthalmitis; inflammation of the parts between the orbit and globe of the eye; and, lastly, inflammation of the eyeball itself, or ophthalmitis. He observes, however, that these distinctions seem to assign a considerable extent to the original seat of the affection; for the expression, inflammation of the eyelids, can only denote a case, in which the disorder begins at once in all the parts composing the eyelids. In the same way, inflammation of the parts between the eyeball and orbit appears to signify, that all those parts constitute the original sphere of the complaint; while inflammation of the eyeball seems to denote that the disorder has begun at once in all the textures, of which this organ is composed. But, fortunately, as Beer remarks, the extent of the original seat of genuine idiopathic inflammation of the eye is but seldom thus considerable; being mostly restricted to particular textures, from which it first spreads further only when neglected, or injudiciously treated. Hence, certain subdivisions of the complaint are necessary; and, accordingly, Beer subdivides inflammation of the eyelids, first, into the erysipelatous, or blepharophthalmia erysipelatosa, which commences in the integuments of these parts. Secondly, into that, which originates at the edges of the palpebre, in the conjunctiva lining these parts, and the

Meibomian glands, and which Beer denominates *glandular inflammation of the eyelids* or *blepharophthalmitis glandulosa*; a case, described by writers under an infinite number of names, and often confounded with complaints of a totally different nature. Thirdly, when the effects of the inflammation are confined to a small portion of the eyelid, it constitutes the disease, termed the *inflammatory stye*, or *hordeolum*, which Beer says is rarely a simple inflammation, but complicated with a scrofulous habit; a proposition, which, I think, will not receive any credit in England. Fourthly, as there is one more form of inflammation of the eyelids, Beer gives it the name of the *erysipelatous swelling of the cornea of the eye*, or *anchyrops erysipelatosus*, which affects the skin of the inner canthus, immediately over the lachrymal sac. The name, here suggested, expresses precisely the seat of the inflammation, and, as Beer thinks, will tend to prevent the case from being mistaken for inflammation of the lachrymal sac. *Inflammation of the parts in the orbit* comprehends, first, *inflammation of the lachrymal gland*; secondly, *inflammation of the lachrymal sac*, a disorder, which begins in the lachrymal sac and nasal duct, and generally extends with great rapidity over all the excreting parts of the lachrymal organs; and, thirdly, *inflammation of the caruncula lachrymalis*, or the *encanthis inflammatoria*.

In the same way, inflammations of the eyeball admit of a classification, which is of the highest practical importance, first, into the *erysipelatous inflammation of the sclerotic conjunctiva*, the *ophthalmitis erysipelatosus*, which denotes that form of the disorder, which is first entirely confined to the membrane connecting together the eyelids and eyeball. Secondly, into *inflammation of the outer textures of the eyeball*, the *ophthalmitis externa*, originating in the cornea and sclerotic. Thirdly, into *inflammation of the innermost textures of the eyeball*, the *ophthalmitis interna*, which has two forms highly necessary to be recollected in practice; for the inflammation may begin immediately in the retina choroides, the membrane of vitreous humour, &c. and spread from these textures to all the rest of the eyeball, being named *true internal inflammation of the eyeball*, or *ophthalmitis interna vera*, and thus discriminated from another case, which is originally seated in the iris, the adjoining corpus ciliare, the lens, and its capsule, and afterward extends from these parts to the more deeply situated coats, and to the texture of the vitreous humour. This last form of internal inflammation of the eyeball is named both by Schmidt and Beer, *iritis*. The classification then embraces a view of the different forms of ophthalmia, as modified by constitutional causes, as the effect of contagious and infectious diseases, measles, small-pox, &c.; and as a complication of certain cachexiæ, like gout, rheumatism, and scurvy.

Although I have thus given a brief delineation of Beer's classification of ophthalmic

inflammations, it is not my design in the subsequent columns, to enter into a full consideration of every particular case, above enumerated; first, because the limits of this work will not permit me to do so; and secondly, because some of these cases have been already considered in other parts of the work. (See *Lachrymal Organs*.)

Common Inflammation of the Eyelids. This form of disease is said by Beer to affect the upper much more frequently, than the lower eyelid, because the former obviously has a larger surface exposed to injuries from without; nor does the complaint always spread to the latter. From the margin of the eyelid, a very red, tense, painful swelling arises, attended with heat, throbbing, and a great deal of tenderness, when touched. It gradually extends over the whole eyelid; but seems to be plainly bounded by the edge of the orbit. The motion of the eyelid is always more or less obstructed, and, at length, when the inflammation has reached its greatest degree, it is completely prevented. Nor is there any difficulty in comprehending why, when the inflammation has become severe, the eye should be excessively dry, and every attempt on the part of the patient to move the eyelid should be productive of considerable pain, and of a sensation, as if some sharp extraneous substances lay under the lid; for at this period, the palpebral conjunctiva is already severely inflamed, and, consequently, the secretion of mucus from the Meibomian glands is immediately stopped by the inflammation itself, while that of the tears is interrupted partly by the extension of the inflammation to the sclerotic conjunctiva, and partly by the effect of the sympathetic connexion existing between the conjunctiva of the eyelid, and that of the eyeball. To this last cause, viz. sympathy, Beer refers the supervening dryness and shrivelling up of the lachrymal papillæ, as well as the apparent closure of the puncta lachrymalia, and the uneasy dry state of the edges of the eyelids. Hence, also, the dryness of the adjacent nostril, and a very disagreeable smell of dust obliging the patient to sneeze repeatedly, which act is constantly attended with a great increase of pain in the swelling, a transient shooting of it to the eye and head, and a sensation as if flashes of light were elicited within the eyeball; a kind of hallucination, technically named *photopsia*. As the original seat of the inflammation is already extensive, one may readily understand, says Beer, why the affection in its first stage, particularly when neglected, or badly treated, should frequently give rise to some febrile disturbance of the system.

In the second stage of the case, or that of suppuration, which follows when the inflammation is violent and not soon dispersed, matter forms with the annexed train of symptoms. The redness suddenly increases very much, the eyelid becoming of a brownish red, and lastly of a purplish red colour. The swelling becomes more prominent, and presents a conical eminence, either in the

middle of the eyelid, or close to the outer or inner canthus. The pain is irregular, and of a stinging, burning kind, a throbbing being felt only in the deeper part of the tumour. At length, the swelling becomes somewhat softer, and less sensible at its most projecting point. The secretion from the Meibomian and lachrymal glands, which in the first stage of the disorder was suppressed, is now quite re-established, but more copiously, than in the healthy state. During sleep, a quantity of mucus accumulates between the edges of the eyes, and glues them together. An extraordinary sensation of cold and heaviness is felt all about the eye. Ultimately the most prominent point of the swelling presents a pale red colour, followed by a yellowish livid tinge. As the abscess is now completely formed, the fluctuation of the matter can be plainly felt. (Beer, B. 1, p. 269, &c.)

According to the same author, nothing very particular is known respecting the causes of the preceding form of ophthalmic inflammation, and, with the exception of blows, he has not been able to discover the precise circumstances which give rise to it.

With regard to the prognosis, if the treatment be neglected, or injudicious, the inflammation may suddenly become so violent, as to produce in weak subjects gangrenous mischief. But, when the case is properly managed in its first stage, the second, or that of suppuration, never ensues; yet, says Beer, the curative measures must be decisive, and valuable time not wasted on trifling means, although due regard must be paid to the constitution. When the inflammation subsides favourably, it leaves no vestiges of it behind, and even the redness, which is the latest in disappearing, completely goes off in a few days, and the function of the eyelid becomes perfect again.

If gangrene and sloughing take place, the outer coverings of the eyelid are destroyed, and the consequences are an incurable eversion of the part. (See *Ectropium*) or a hare-eye, (see *Lagophthalmus*.) When suppuration happens favourably, the abscess sometimes breaks very well of itself on the upper eyelid; but, according to Beer, this does not readily occur on the lower one, nor without the formation of sinuses, which sometimes run quite into the orbit. After the abscess has burst, or been opened, the part heals up with great celerity in favourable constitutions, but slowly in others; vermilion granulations arise from the bottom of the cavity, and a cicatrix follows which is scarcely perceptible. When the abscess is very large, however, and bursts of itself, the upper eyelid continues for some time very much weakened. If the collection of matter be neglected, or wrongly treated, or the subject be unhealthy, or the disease be aggravated by the effects of a damp atmosphere, hurtful food, severe mental trouble, wet poultices, or too long confinement of the matter, then, says Beer, fistulae are apt to be produced, sometimes complicated with necrosis of the bone, the certain effects of which are some perma-

nent and mostly incurable disease of the eyelid, and impairment of its functions: 1st. A closure of the lachrymal canals, with a permanent stillicidium. 2. A complete obliteration of the same tubes, with an incurable stillicidium. 3. A prolapsus of the upper eyelid, from distention of the skin by the long confinement of the matter. 4. Inversion of the edge of the eyelid, from a shrinking of its cartilage. 5. Eversion of the eyelid, and hare-eye, from loss of skin. (Beer.)

As, in this species of inflammation, says the same author, the organ of sight cannot well be affected, unless the disorder afterward extend itself very much, the exclusion of air and light is here but of little use. Linen compresses, well wet with very cold water, or vinegar and water, are to be applied; and, while the complaint is local, leeches are to be used; but, if the constitution be threatened with febrile symptoms, then Beer urges the necessity of venesection, low diet, purgatives, and general antiphlogistic measures. (B. 1, p. 275.)

In the second stage, with the exception of a few points, Beer states, that the case is to be treated like any other common abscess. When the matter is situated in the middle of the upper eyelid, not far beneath the skin, the abscess may be allowed to burst of itself, especially, if the patient have a great dread of the knife. But, if the matter lie near the outer, or inner canthus, it should be let out with a lancet as soon as its fluctuation is quite distinct, the incision being made in the direction of the fibres of the orbicular muscle. When fistulae, or gangrene, have already taken place, the treatment should be like that, which is applicable to the same kind of mischief in most other parts of the skin.

Erysipelatous Inflammation of the Eyelids usually affects both these parts together, very seldom only the upper one, and never the lower alone. When also both are affected, the disorder always presents itself in the greatest degree in the upper eyelid. A pale, yellowish red, seemingly transparent, shining swelling arises from the edges of the eyelids, and rapidly extends itself, without any determinate boundary, the faint red colour being gradually lost upon the eyebrow above, and not unfrequently upon the cheek below. When the inflamed part is gently touched, the redness disappears, but only for a moment. At length, the swelling towards the margins of the eyelids becomes exceedingly soft, and feels like a vesicle that has been raised by a blistering plaster. The pain is inconsiderable, not attended with throbbing, but rather with a sense of heat and stiffness; when the part is slightly touched, the patient experiences a lancinating sensation in it. Its temperature is not much increased. The secretions from the Meibomian glands, lachrymal gland, and mucous membrane of the nostrils, are much augmented.—In a strong subject, the disorder, if genuine and idiopathic, is not productive of any constitutional disturbance; but, in bad

habits, and weak females and children, it is sometimes attended with fever. However, when the complaint partakes of the phlegmonous character, and is badly treated, the general symptoms are occasionally very severe at the change from the first to the second stage, and the case may then terminate in a gangrenous kind of suppuration. In irritable, delicate children, says Beer, when the disease spreads over the face, the case requires the most skillful treatment for the prevention of a disastrous termination.

In strong persons, the second stage of this disorder rarely ends in a manifest suppuration: but there is rather an exudation of lymph, which becoming dry, forms very small, delicate, branny scales, in the composition of which the desquamated cuticle has also a considerable share. In other instances, vesications of various sizes are formed on the erysipelatous surface, and burst, and discharge a fluid, which is converted into yellowish scabs.

According to Beer, the skin of the eyelids is particularly prone to erysipelatous inflammation, which is therefore more easily induced in it, than in the integuments of other parts. Beer considers the sudden effect of a cold blast of air, or of very cold water, upon the skin of the eyelid, while in a state of free perspiration, as the most common cause of its being attacked with erysipelas, particularly in weak subjects. He states, however, that the complaint may be occasioned by the stings of bees, wasps, and other insects; accidents, which when the stings are not extracted, are liable to be followed by a violent and dangerous general inflammation of the eyelid, not unfrequently extending in a perilous degree to the eyeball itself. (*B. 1, p. 281.*)

With regard to the prognosis, no other case of ophthalmic inflammation so frequently subsides without the aid of surgery as this, provided the constitution be healthy and strong; and, when the complaint is resolved in its first stage, the vestiges of it afterward are as little as those consequent to common inflammation of the eyelids.

The second stage, however well treated, is followed for a long time by a peculiar sensibility of the skin to the impression of cold damp air, and a strong propensity to relapses. If, when the cuticle peels off, a patient of weak constitution sit in a current of damp cold air, or try to wash away the scales and scabs with cold water, Beer states, that an œdematous affection of the eyelid will be produced, which is often very obstinate, and apt to occasion a temporary inversion of the ciliæ (*Trichiasis*), or a similar state of the edge of the eyelid (*Entropium*). And, he observes, that when from neglect, or bad treatment, an erysipelatous inflammation of the eyelid terminates in suppuration, the abscess is not like a common one, but the matter rapidly makes its way out through several openings in the already partially disorganized skin, and, in general, this state is followed by ill-conditioned tedious ulcerations, whereby a good deal of skin is

always destroyed. Under these circumstances, all those consequences may be produced, which have been described as liable to take place from the second, or suppurative stage, of common inflammation of the eyelid. Gangrene and sloughing may even occur, when erysipelas of the eyelids is brought on by the unremoved sting of an insect, and efficient treatment is delayed.

The treatment, recommended by Beer in the first stage, consists in the application of cold water, and he remarks, that exposure of the part for a time to a cool, moist, but, in other respects, pure atmosphere, will often suffice for the removal of the complaint. When, however, the disorder increases, and assumes a phlegmonous character, the directions given for the treatment of blepharophthalmitis, are to be followed.

In the second stage of erysipelas of the eyelids, Beer praises the good effects of a mild, dry air, of an equal temperature, and recommends covering the parts with a light bandage, under which are to be put well warmed linen compresses, which, for weak persons, should be sprinkled with camphor; or he directs the eyelids to be covered with bags of aromatic herbs; generally a very favourite plan with Beer, whenever he objects to moist applications. In such individuals, he observes, that the cure is promoted by keeping up the function of the skin with gentle diaphoretic medicines, with which, when the debility is very great, camphor should be joined. Should an abscess form, the same treatment is proper as in the second stage of common inflammation of the eyelids, or (what Beer calls) blepharophthalmitis.

Glandular Inflammation of the Eyelids, or the Blepharophthalmitis Glandulosa, as Beer terms it, is considered by this author as the disease, of which all the various cases of purulent ophthalmia are only modifications, which he describes under the names of *idiopathic catarrhal ophthalmia*; *idiopathic catarrhal-rheumatic ophthalmia*; and *blepharo-blennorrhœa*, or *ophthalmo-blennorrhœa*. The two latter terms comprehend the purulent ophthalmia of infants, the Egyptian ophthalmia, the gonorrhœal ophthalmia, &c.

Glandular Inflammation of the Eyelids, Beer knew very well was so far a defective term, that it seemed to imply merely an affection of the Meibomian and mucous glands of those parts, whereas he means to express by this name the kind of inflammation, of which all the cases, usually called in this country *purulent ophthalmias*, are varieties and modifications, and in which the conjunctiva is also particularly affected.

Acute suppurative inflammation of the conjunctiva, divisible into the mild and severe forms, as proposed by Mr. Travers, appears, perhaps, a better name (*Synopsis, &c. p. 96, &c.*) Dr. Vetch, who also prefers the general term *conjunctival inflammation*, observes, that from many internal and external causes, the membrane of the conjunctiva is liable to become the seat of inflammation, more especially that portion of it, which gives

a lining to the inner surface of the eyelids. The disease, in its general nature, he says, differs little from that which is met with in other parts having a similar surface, as the nose, the fauces, the bronchial cells, and the urethra; but, the continuation of the membrane forward upon the anterior portion of the eye, and the consequent liability of the inflammation to affect this important organ, attach much interest to all the circumstances, capable of producing it. (*Velch on Diseases of the Eye*, p. 148.) In the common glandular inflammation of the eyelids, described by Beer, which seems to me to correspond to the more moderate forms of *purulent ophthalmia* met with in this country, either the whole, or only that part of the edges, which is near one, or both canthi, is affected with a very red, hardish, sensible swelling, attended with a violent annoying degree of itching. This swelling, Beer observes, does not extend far over the outside of the eyelid upwards, or downwards, at most, not more than a few lines; but it spreads over the palpebral conjunctiva, especially when neglected, or badly treated, and the constitution is weak. This, he says, can only be discovered when the eyelid is everted. The further the swelling extends over the inside of the eyelid, the more is the motion of the part obstructed, not on account of any want of power in the orbicular muscle, but from the fear of the pain, with which every attempt to move the eyelid is accompanied. The itching, which continually distresses the patient, more or less, is often succeeded by an irritating, burning kind of pain, which is particularly experienced when the eyelids are moved, and hence, the patient is obliged, as it were, to keep his eye closed. While the inflammation is restricted to the edges and conjunctiva of the eyelids, and the Meibomian glands situated under it, though the secretion from these glands is entirely stopped, that from the lachrymal gland is much augmented, and consequently, the disease is associated with a true *epiphora*, which is seriously aggravated whenever the eye is exposed to a strong light. As, under these circumstances, the tears are not properly blended with the Meibomian secretion, they must of course be very irritating to the eye and its surrounding parts, and less fitted for properly lubricating its surface. Hence, the pain now becomes burning, and not unfrequently the cheek, over which the tears run, is excoriated. As soon as the inflammation of the eyelids spreads further, and begins to affect the sclerotic conjunctiva, the effusion of tears ceases the eye becomes preternaturally dry, and the patient constantly thinks that he feels sand under the eyelids, which sensation is rendered almost intolerable by any motion of the eye, or eyelids. Children and women have so great a dread of this painful feel, that much persuasion is often requisite to induce them to let the eye be properly examined. If the glandular inflammation of the eyelids attain a considerable degree, the lachrymal papillæ

shrink, and the puncta seem closed, which is particularly the case when the disorder begins at the inner canthus.

In the *second stage* of the complaint, Beer describes the itching, burning sensation, and dryness of the eye, as undergoing a remarkable diminution, as either the canthi, or the whole extent of the edges of the eyelids, become more and more moist, and smeared with mucus, an increased secretion of a puriform sebaceous fluid from the Meibomian glands being the first symptom, denoting the commencement of the second stage of the inflammation. As this mucous secretion is not mixed with an adequate quantity of tears, it inspissates in the form of white, thin, delicate layers, which, from time to time, cover the cornea, and make the patient very apprehensive of becoming blind, as the flame of a candle in the evening, and other objects appear to him more or less concealed by a dense mist. When, under these circumstances, however, the eyelids are repeatedly and briskly moved, or the eye is wiped, these appearances soon go off, the flakes of mucus being removed from the cornea. These accumulations of thickened mucus, Beer remarks, are apt to be most frequent and troublesome some time after a meal; and the eyelids become so firmly glued together during sleep with yellowish crusts, that, when the patient awakes in the morning, it is not till after a great deal of washing and bathing of his eyes with warm water, that he is able to open them again. The above described change in the quantity and quality of the secreted matter, as already mentioned, indicates the *first period of the second stage*; for Beer wishes it to be particularly noticed, that here, as in all inflammations of mucous membranes, the second stage of the disorder has three periods, as will be presently seen, to which the practitioner cannot be too attentive.

This morbid secretion of a mucous sebaceous matter does not continue long unattended with other effects; and, very soon, the peculiar appearances of suppuration are seen, at the same time that the conjunctiva of the eyelids becomes more considerably swelled, and a discharge takes place not only from the canthi or margins of the eyelids, but from the whole of the thickened villous surface of the palpebral conjunctiva, and which discharge is distinguishable at first view from the mucus, which, at an earlier period, accumulated in much smaller quantity only between the edges of the eyelids, and at the canthi. It is now no longer white, but yellow, completely like pus, with which it is in reality blended, and so viscid is it, that the crusts which collect on the eyelids in the nighttime cannot be removed, without pulling the eyelashes away with them. Sometimes, says Beer, at the moment of suppuration, minute pustules, which are scarcely distinguishable, form either at the canthi, or along the edges of the eyelids, and are soon burst by the constant friction of the parts. These pustules indicate the second, or suppurative period of the second

stage of the case, when either merely the canthus, or the whole of the margin of the eyelid, constantly becomes excoriated, and secretes mucus and purulent matter, the sore fretted places smarting so severely on exposure to the air, particularly to such as contains a large proportion of carbonic acid gas and nitrogen, that the patient is afraid of opening his eye. When the patient neglects himself, and continues in an unhealthy atmosphere, these excoriations of the skin, occurring in the suppurative stage, are always more extensive; nay, they sometimes spread over the lower eyelid, and down the cheek.

At length, after the excoriations have lasted, perhaps, several weeks, the suppurative process is checked and suppressed, either by surgical treatment, or accidental favourable circumstances, as change of regimen, the weather, climate, &c., and then the excoriations immediately diminish. However, a morbid secretion from the Meibomian glands still continues, making the third period of the second stage, and is apt to become habitual, if not rectified by art, or removed by the effect of accidental favourable circumstances, when it changes into a thin serous discharge, and then terminates.

Beer refers the causes of *glandular inflammation of the eyelids*, or *simple purulent ophthalmia*, to the immediate operation of various stimuli acting chymically upon the edge of the eyelid, where it is covered with a very delicate cuticle, and upon the exposed follicles of the glands of the eyelid towards the inner canthus. Hence, says he, when many men are living together in a polluted, noxious air, impregnated with extraneous substances, this form of inflammation is found to occur even in the strongest constitutions with such frequency, that it seems as if it were epidemic. And, according to Beer, the principal cause of the disease will be found to be in the atmosphere, and the next most frequent occasion of it, he observes, is uncleanness, as washing the eyes with foul water, &c. At the same time, this experienced oculist seems aware that this explanation would not of itself be always quite satisfactory; for, he adds, that although, under the above circumstances, no constitution, no sex, nor age, is spared, there must be some particular condition which is conducive to the disorder, or at all events, to its more rapid and severe course, and the quick extension of the inflammation in certain individuals, which condition Beer supposes must depend either upon weakness of constitution, or upon excessive irritability, or as he terms it, *vulnerability* of the whole surface of the body. Beer makes no mention of the effect of damp nocturnal air in warm countries in giving origin to purulent ophthalmia, so much insisted upon by Assalini and Dr. Vetch, but, which doctrine, in reference to the origin of purulent ophthalmies in England, I think completely fails; and what is still more worthy of notice, Beer never attempts to explain the propagation of the disease by its infectious

nature. It is observed by Dr. Vetch, that the history of all diseases, originating from some particular impression received from the atmosphere, but capable, when formed, of propagating themselves by contagion, is rendered particularly difficult; because the same circumstances, which favour the communication by contagion, produce also a predisposition to be acted upon by the more general causes existing in the atmosphere. The principal cause which gives force and opportunity to the action of contagion, is the crowding individuals together into too limited spaces. The same circumstance Dr. Vetch has seen give a predisposition to diseases of an epidemic, but not a contagious nature; and hence he infers, that it may produce the same predisposition to diseases which are both contagious and atmospheric. "The appearance of ophthalmia among the crews of ships and in barracks was often met with long before the late destructive and virulent disease (presently to be described.) In the army, such an ophthalmia has extended to whole regiments, without any appearance of the disease among the inhabitants of the neighbourhood; and while the free intercourse which subsists among the men, as to washing in the same water, using the same towels, and sleeping more than one in a bed, readily accounts for the rapid extension of the disease in the same corps, yet the excessive crowding together of men will often of itself engender inflammation of the conjunctiva." (*Vetch on Diseases of the Eyes*, p. 171.) I believe, with respect to the causes of all purulent ophthalmies, our present knowledge will permit us to venture no further than the tenor of the preceding observations, which is, that they originate epidemically, but probably multiply both in this manner, and by the infectious matter of the disease being inadvertently applied in various ways to the eyelids of other persons. This species of inflammation of the eyelids is rarely met with by the surgeon in its first stage, because only very timorous patients then seek medical advice, and most individuals, who feel in other respects well, relieve themselves by washing the eyes with cold water, and applying cold poultices, made of bread crum softened in water. Besides, when the disease is not very severe, it frequently subsides of itself, as in a favourable constitution, a better air is sometimes capable of restoring the healthy state of the eye. If, however, the disease at its very commencement should be violent, or attack an individual of very weak habit, Beer states that it may immediately affect, not only the Meibomian glands, but the perichondrium of the cartilage of the eyelid, and produce an incurable entropium, which is also sure of taking place when the case is neglected, and followed by deeply extending ulcerative mischief. When the complaint is strictly idiopathic, it never brings on any general indisposition, except by improper treatment it should happen to be converted into a violent inflammation of the whole eyelid,

or what Beer terms a complete *blepharophthalmitis*; which he says, only happens in weak subjects, and women and children, whose skin is in a very irritable state, or when a person of apparently good constitution remains under the influence of circumstances which tend to augment the inflammation, as for instance, exposed to the air of a stable, privy, &c. in which event, Beer describes the inflammation of the eyelids as being quite of a peculiar description.

As for the prognosis in the second stage, Beer observes, that, if the excoriations at the suppurative period should spread all over the edges of the eyelids, and compel the patient to keep his eye incessantly shut, a partial adhesion of the eyelids to each other (*anchyloblepharon*) may be the result. Also, when at either of the periods of the secretion of mucus, or at that of suppuration, the patient is content with merely softening with warm water the thick matter glueing the eyelids together, so as just to be able to open his eye; and does not completely free the eyelashes from the crusts, clusters of the hairs will project inwards, (see *Trichiasis*) whereby a secondary inflammation of the conjunctiva of the eyeball will be excited, which, Beer says, should be carefully discriminated from a mere extension of the glandular inflammation of the eyelid. Such a trichiasis, he observes, may easily become incurable, when the edge of the eyelid is seriously injured by the depth of the excoriations. But, if the suppurative process be restricted chiefly to the canthus, especially the outer one, (which case, according to Beer, is not unfrequent in old, debilitated subjects, of a relaxed constitution) and if the excoriations should deeply penetrate the commissure of the eyelids this may be completely destroyed, and the lower eyelid everted.

As the state of the atmosphere, uncleanness, crowded and close places, &c. are considered by Beer to be the principal causes of the glandular inflammation of the eyelids, or simple purulent ophthalmia, one of the most important indications, in the first stage of the disorder, seems to him to be the removal of these hurtful circumstances. And, he declares, that, if immediate attention be not paid to such indication, it will be quite impossible to prevent a dangerous increase of the disorder. A cool fresh air, and bathing the eye with cold water, or a weak lotion of vinegar and water, Beer represents to be means, usually adequate to stifle this inflammation in its birth. In the second stage, he says, the indication is entirely different.

But, also in the beginning of this stage, and even at its second period, namely that of suppuration taking place, the disorder, according to Beer, seems for a short time to be benefited by the employment of cold water, but the consequences are rendered by such treatment a great deal worse; for a fresh, much more extensive inflammation of the same kind again takes place. At the first period of the second stage, viz.

while the secretion is a pure mucous and sebaceous matter, Beer says, that it is absolutely necessary to employ such external means, as are calculated to promote the action of the veins and absorbents. For this purpose, he recommends the following collyrium: *R. Aq. rosæ ℥iv. Hydrarg. oxymur. gr. j. vel. gr. dimidium. Mucil. sem. cydon. ℥j. Tinct. opii vinos. ℥j. Misce.* This eyewater is to be used lukewarm from four to six times a day, and the eye afterward carefully and completely dried. No eye, in this state, he says, will bear more than the proportion of one gr. of the oxymuriate of quicksilver, and only seldom more than half a grain.

But, as soon as the suppurative period commences, attended with excoriations, gentle astringents, like the liquor plumbi subacetatis, in a solution of the lapis divinus (See *Lachrymal Organs*) should be added to the above lotion, for which they may at length be entirely substituted. And, when the suppurative period has terminated, but a morbid secretion of mucus yet obstinately continues, and threatens to become habitual, recourse should be had, without the least delay, to one of the following eyesalves, a bit of which, about the size of a small pea, Beer directs to be smeared once a day over the edges of the eyelids. *R. Butyr. recentis insulsi ℥ss. Hydrargyri nitrico-oxidi gr. x. Tutia ptt. gr. vj. Misce.* This ointment, he says, will sometimes answer; but, that it is mostly necessary to use Janin's salve, composed as follows: *R. Butyri recentis insulsi ℥ss. Hydrargyri præcipitati albi gr. xv. Boli albi ℥j. Misce.*

According to Mr. Travers, the mild acute suppurative inflammation of the conjunctiva is not attended with that excessive swelling of the eyelids, that intense pain, nor that profuse secretion, with which the vehement acute form of the disease is characterized. In the treatment, he directs a solution of alum to be early substituted for emollient fomentations, which he recommends to be freely used during the acute period. Simple purging and abstinence, he says, are generally sufficient to allay the febrile irritation, which is moderate. Topical bleedings, and blisters, kept open on the back of the neck, are also stated to be of great efficacy. "When the pain and irritability to light subside, and the discharge becomes gleety, the conjunctiva pale and flaccid, tonics, especially the extract of bark and the acids, do great good." (*Synopsis, &c. p. 264.*)

Catarrhal ophthalmia, so called by Beer, is described by him as a species of glandular inflammation of the eyelids, attended with a simultaneous affection of the mucous membrane of the nose, trachea, &c. brought on by particular states of the weather, and attacking so many persons at once, as to appear epidemic. The prognosis and indications are the same as those in common glandular inflammation of the eyelids, with this exception, that attention must be paid to the affection of other organs, and both at the first and second periods of the second

stage, such remedies given as operate powerfully on the mucous membranes and skin, and, in general, during the second stage, an equal warm temperature, and gentle diaphoretics, with camphor, are highly beneficial.

Severe Purulent Ophthalmia.—The *Blepharoblenorrhœa*, and *Ophthalmoblenorrhœa*, of Schmidt and Beer; including the *ophthalmia neonatorum*; the *Egyptian ophthalmia*; the *gonorrhœal ophthalmia*, &c., on which varieties, however, I shall annex to this account some further particulars, as they relate to each of these cases individually, because, though the following history contains an excellent general description of the severe forms of suppurative inflammation of the conjunctiva, it leaves unexplained some of the circumstances on which its varieties depend.

The vehement acute suppurative inflammation of the conjunctiva is described by Mr. Travers as being sudden in its attack; a feature, in which it particularly differs from the milder cases usually met with in schools. (See *Lloyd on Scrofula*, p. 321.) It is accompanied with most severe darting pains; and the upper eyelid is sometimes in a few hours prolonged upon the cheek, owing to the infiltration and enormous swelling of the tissue, connecting the conjunctiva to the tarsus. (*Travers, Synopsis*, &c. p. 265.)

According to Beer, the modification of glandular inflammation of the eyelids, here to be considered, consists entirely in the rapid extension of the inflammation and suppuration, the disorder affecting, ere it is suspected, not only the whole of the conjunctiva of the eyelid, but also that of the eyeball, and the sclerotica and cornea. The swelling of the palpebral conjunctiva is described by Beer as being unusually great; at first, soft, somewhat elastic, smooth, and readily bleeding; but, afterward, in the second stage, hard and granulated, or, as another writer says, it "becomes preternaturally vascular, thickened, and scabrous, or forms fleshy eminences." (*Travers, Synopsis*, &c. p. 96.) The first stage is rapidly over. At the first period of the second stage, the secretion both of mucus and pus is surprisingly copious. First, the mucus is whitish and thin; but, as soon as the suppurative process begins, it becomes yellowish and thick, and when an attempt is made to open the eyelids, it gushes out with such force, and in so large a quantity, as frequently to cover, in an instant, the whole cheek. Sometimes, this mixture of mucus and matter contains light-coloured streaks of blood; but, in worse cases, these streaks are dark and brownish, or else a thin ichor is discharged, in which case, the progress of the disease is so rapid, that the eye can seldom be saved. The swelling of the conjunctiva of the eyelids, especially of that of the upper one, always increases during the first period of suppuration, and, when the discharge is more ichorous, the membrane is more granulated, so that if the eyelid be opened carelessly, or during the child's crying, fits of pain, &c. the whole tumefied conjunctiva of

the upper eyelid is immediately thrown outward, in the form of ectropium, and it is sometimes difficult, and even impracticable to turn the part inward again, especially, when the conjunctiva is already changed into a hard sarcomatous substance. While the swelling at the inner surface of the eyelids continues to increase, their outer surface, particularly that of the upper one, becomes reddened; but the redness is dark-coloured, inclining to brown, and when the child cries, to blue. In children, the whole cheek on the affected side is very often swelled, and sometimes the mucous membrane of the lachrymal sac and even of the nose, participates in the effects of the disorder. Sometimes, at first, only one eye is affected, and the other is afterward attacked. And, according to Beer, just before the period of suppuration, it is by no means uncommon for rather a profuse bleeding to take place from the eye; an event, which though it seriously alarm the parents of the child, or an adult patient, is hailed by the experienced surgeon as a favourable omen; for, in such cases, the suppuration is generally very mild, and not of a destructive kind, and the swelling of the conjunctiva of the eyelids, as well as that of the sclerotic conjunctiva, if already present, soon undergoes a remarkable diminution after such hemorrhage, which often recurs two or three times. When during the first, very short and transient stage, the inflammation extends also to the sclerotic conjunctiva, this membrane forms a pale-red, soft, irregular swelling, all round the cornea, which at length seems so buried, that at the period of the mucous secretion, its centre can hardly be discerned; and, when suppuration begins, both mucus and pus are discharged from the conjunctiva of the eyeball in profuse quantity, particularly accumulating over the cornea, and not unfrequently drying into a thick pellicle, when long detained in the eye. Hence, the case looks as if the whole eyeball, or at least, all the cornea, were in a state of complete suppuration. At length, the tumefied conjunctiva of the eyeball becomes sarcomatous, though never in such a degree as that of the eyelids. When the suppurative period ceases, and with it the most urgent danger to the eye, the secretion of mucus alone continues, as at the first period of the second stage, the swelling of the conjunctiva of the eyelids, and of the sclerotic conjunctiva, when this has also been affected, diminishes, and the disorder ends in an increased effusion of tears, or true epiphora. When the effects of the suppuration upon the conjunctiva of the eyeball are more severe, the corneal production of this membrane in the most favourable cases is raised from the subjacent cornea, and so opaque, that the eyesight is lost, or at all events seriously impaired, until the transparency returns, which is sometimes late, especially when efficient treatment is not put in practice. Should the suppuration be very deep, the cornea, which always turns whiter and whiter, pre-

sents near the edge of the swelling of the conjunctiva an arrangement, similar to that of the leaves of an old book, and at length seems converted into a mass of purulent matter, which projects more and more out of the depression in the swelled conjunctiva, and then bursts in its centre either quickly and with very violent pain, or slowly without any suffering, an oval hole being left, behind which the yet transparent crystalline lens appears, included in its undamaged capsule. At this period, adults can often see very plainly, and fancy their recovery near at hand, or, at least, all danger over. Already, however, every part of the cornea has been more or less perforated by ulceration, the iris protrudes through all these apertures, so as to form what has sometimes been named the *staphyloma racemosum*. In a very short time, not exceeding a few hours, the capsule of the lens is affected, and bursts like the cornea, when it is discharged either with, or without, a portion of the vitreous humour. At length, the suppuration subsides, and with it the protrusions of the iris, the opening in the cornea becoming closed with a brown, or bluish, opaque flat cicatrix. But, if in this destructive form of suppuration, nothing is done for the relief of the disease, the whole eyeball suppurates, the eyelids become concave instead of convex, and the fissure between them closes for ever. In adults of feeble constitutions, when the case is not properly treated, but particularly in weak children, this excessively violent form of conjunctival inflammation and suppuration spreads with such rapidity, that a considerable general disturbance of the system is occasioned. Indeed, according to Mr. Travers, in the common course of this vehement form of conjunctival suppurative ophthalmia, the system sympathizes; chilliness is succeeded by a hot and dry skin; and the pulse is frequent and hard. Yet, it is particularly pointed out by the army surgeons, that one peculiarity of the Egyptian purulent ophthalmia is its being generally attended with little constitutional disturbance. When the above-described annihilation of the eyeball takes place, it always creates violent general indisposition in unhealthy weak children, and even leaves adults for along while afterward in an impaired state of health.

According to Beer, who appears to have no idea of infection being concerned, the particular cause of this unfortunate extension of idiopathic glandular inflammation of the eyelids, both in infants and adults, frequently depends altogether upon the foul atmosphere, in which they are residing, and hence, says he, the disorder is, as it were, endemic in lying-in and foundling hospitals, where the air is much contaminated by effluvia, from the lochia, the crowding together of many uncleanly persons, dirty cloths, &c. The unjustifiable folly of exposing the eyes of new-born infants to every degree of light; a tedious labour, in which the child's head is detained a long while in the vagina; and roughly washing the eyes after

birth with a coarse sponge; are other circumstances, supposed by Beer to be conducive to the origin of the complaint, in new-born infants. The reality of many of these causes I regard myself with a great deal of doubt; and as for his conjecture, that sprinkling cold water on the head in baptism, while in a state of perspiration, may produce the complaint, it is too absurd to need any serious refutation. The disorder, he says, is always more rapid and perilous in new-born infants than adults; (*B. 1, p. 318*.) a remark which does not agree with the statements usually made, if the Egyptian ophthalmia, as seen in the army, be comprehended. It is observed by Mr. Travers, that the highly contagious nature of the suppurative ophthalmia, whether in the mild, or vehement acute form, is sufficiently proved. For one person, affected with this disease above three months old, he thinks at least twenty are attacked under that age. "The mother is the subject of fluor albus, or gonorrhœa, and the discharge is usually perceived about the third day." (*Synopsis, &c. p. 97.*) Some further observations on the causes of some of these severe modifications of glandular inflammation of the eyelids will be introduced, after the prognosis and treatment have been considered. This will be the more necessary, as the propagation of the disorder by infection is here entirely overlooked.

According to Beer, whenever an idiopathic inflammation of the glands of the eyelids attains the severe forms, exhibited in the purulent ophthalmia of infants, the Egyptian ophthalmia, and gonorrhœal ophthalmia, the prognosis must naturally be unfavourable, and this in a greater degree, the more the inflammation and suppuration have extended to the eyeball itself. The cases are still more unpromising, when they happen in poor, half-starved, distressed individuals, whom it is impossible completely to extricate from the circumstances, which either cause, or have a pernicious effect upon the disease. Should an incidental ectropium not be immediately rectified, says Beer, it will continue until the end of the second stage, and even frequently longer, so as to require particular treatment. When at the period of suppuration, merely the layer of the conjunctiva, spread over the cornea, is destroyed, the prognosis, in respect to the complete recovery of the eyesight, is favourable, although it takes place but slowly. If the effects of the disease at this period should be deeper, yet the cornea not destroyed, only rendered flat and somewhat opaque; or, if the cornea should be ulcerated only at a very limited point; there will remain in the first case, an opacity of the cornea; but, in the second, a partial adhesion of the iris to the latter membrane (*synechia anterior*) is apt to follow, with a more or less extensive cicatrix on the cornea, covering in a greater or lesser degree the lessened and displaced pupil, and thus diminishing, or preventing vision. When, during the inflammation

and suppuration, a considerable part, or the whole of the iris adheres to the cornea, and this is not penetrated by ulceration, the result, in the first case, is a *partial*, in the second, a *complete staphyloma* of the cornea, which does not fully develop itself, until towards the decline of the second stage of the ophthalmoblenorrhœa. If the inflammation should spread to the textures of the eyeball itself, so as to produce severe constitutional disturbance, the eye wastes away in the midst of the profuse discharge, the eyelids sink inwards, and the fissure between them becomes permanently closed. (Beer, B. 1. p. 319.)

Beer notices the opinion of the celebrated Schmidt, which was, that the ophthalmoblenorrhœa, or purulent ophthalmia involving the sclerotic conjunctiva, always has a fixed duration of a month, in new-born infants, and of six, eight, or twelve weeks, in very weak individuals. Beer acknowledges the correctness of this opinion, only in cases where the surgeon has to deal with a completely formed ophthalmoblenorrhœa, and not in a more recent case, or one in which the disease is chiefly confined to the inside of the eyelids. (*Blepharo-blenorrhœa*.) When the disorder is met with in the first period of the second stage, or it is confined to the palpebral conjunctiva and Meibomian glands, and truly idiopathic, Beer asserts, that its course may be restricted by efficient treatment to a few days, as he has often proved in the establishment for foundlings at Vienna.

It is further remarked by Beer, that, in this modification of genuine idiopathic glandular inflammation of the eyelids, the indications have something peculiar in them. If, by chance, the surgeon meet with the disease in its first stage, it will be most benefited by the application of folded linen wet with cold water; and sometimes a brisk purge of jalap and calomel, and putting a leech over the lachrymal sac at the inner canthus, will promote the subsidence of this dangerous species of ophthalmia. The case, however, rarely presents itself for medical treatment thus early, and, in hospitals, Beer says, *antiphlogistic treatment is, on this account, hardly ever indicated.*

With some exceptions of importance, the treatment, advised by Beer, for the second stage of these severer forms of purulent ophthalmia, resembles that proposed by him for the second stage of simple glandular inflammation of the eyelids, or the milder varieties. These more severe kinds of purulent inflammation of the eye, implied by blepharo-blenorrhœa and ophthalmoblenorrhœa, he says, should never be viewed and treated merely as local disorders; but that, both in children and adults, internal remedies should be exhibited, particularly volatile tonic medicines. In cases, where the cornea is already attacked by a destructive ulcerative process, manifold experience has convinced him, that bark, combined with naphtha, and the tincture of opium, is the only means of saving the eye; but, that if

the suppuration be confined to the eyelids, the decoction of calamus aromaticus with naphtha and opium will mostly answer. When, on the supervention of suppuration, the pain in the eye and neighbouring parts is excessively severe, Beer assures us, that friction with a liniment of opium will give great relief. In new-born infants, the maternal milk of right quality will mostly do more good, than internal medicines: but if the case be very urgent, and the child feeble, Beer thinks volatile medicines may sometimes do good.

With respect to particularities made necessary in the local treatment by the modified nature of the inflammation, Beer offers the following information. First, in new-born infants, or very young children, the oxymuriate of mercury cannot be used without danger, though blunted with mucilage; and even in adults, it should be employed in these cases with great circumspection. Secondly, the mucus and purulent matter should not be allowed to remain long under the eyelids, as such lodgment is found to promote the destruction of the layer of the conjunctiva situated on the cornea; but, at the same time, Beer thinks, that leaving any water on the eyes, after cleaning them, and letting it become cold there, will have quite as pernicious an effect. Hence, he is very particular in directing all the mucus and purulent matter to be wiped away from the eye with a bit of fine sponge moistened with a warm mucilaginous collyrium, but not so wet as to let the fluid drop out of it; or when they are very copious, and in large flakes, he even recommends them to be washed away by means of Anel's syringe; but, he says, that every part about the eye should be immediately afterward well dried with a warm napkin, and then covered with a warm camphorated compress. Thirdly, during the suppurative period, according to Beer, common tincture of opium, or the vinous tincture is the best local application, the parts being smeared with it twice a day, by means of a fine camel-hair brush. It is only in a few instances, that a small proportion of the laxis divinus (see *Lachrymal Organs*), mixed with the mucilaginous collyrium, can be endured. Beer declares, that he has never seen any good produced by Bates's camphorated lotion, which was so highly praised by the late Mr. Ware. Fourthly, when the suppurative period has terminated, the mucous secretion again becomes white and thin, as at the very commencement of the second stage, but it is always more copious; now is the time, (as in the last stage of simple glandular inflammation of the eyelids) when the topical use of mercury, joined with styptics, especially in the form of an eye-salve, is indicated. Fifthly, if an eversion of the upper eyelid should happen from washing the eye carelessly, or the mere crying of the infant, in consequence of the thickened granulated state of the palpebral conjunctiva, the position of the eyelid must, if possible, be immediately rectified; for afterward, this cannot be done. In order to

avoid this ectropium, the eyelids should never be opened while the child is crying, or in any way agitated; for, at such periods, the thickened scabrous conjunctiva will suddenly protrude, and cannot be kept back. Beer says, that the eyelid should be replaced in the manner directed by Schmidt. (*Ophthalmol. Bibl.* 3. B. 2, *Stuck*, p. 149.) The surgeon having smeared the ends of the thumb and forefinger of each of his hands with fresh butter, is to take hold of the everted cartilage of the eyelid at the outer and inner canthus, draw it slowly a little upwards, and then suddenly downwards. Thus, the thickened conjunctiva, if not too fleshy and granulated, may be quickly reduced, and the ectropium removed. But, if the swelling of this membrane should be already very considerable, and have begun to be hard and studded with excrescences, the thumbs should be placed so as to compress rather the middle of the eyelid. However, if the ectropium cannot be at once removed, it is to be treated, after the termination of the second stage of the purulent ophthalmia, as a sequel of this disorder. (See *Ectropium*.)

In the ophthalmia-blennorrhœa the alteration of the sclerotic conjunctiva is said by Beer to be very different from chemosis; a remark, which is strictly correct, inasmuch as ordinary chemosis is not attended with that change in the surface of the sclerotic conjunctiva, which fits it for the secretion of pus. But, if we are to understand by chemosis, a copious effusion of lymph in the loose cellular substance between the conjunctiva and the eyeball, this state must be admitted as one of the usual effects of severe purulent ophthalmia.

"It is after this morbid condition, which is characteristic of the suppurative ophthalmia (says Mr. Travers) that the conjunctiva forms fungous excrescences, pendulous flaps, or hard callous rolls protruding between the palpebræ and globe, and everting the former, or, if not protruding, causing the turning of the lid over against the globe. The tarsal portion takes on from the same cause the hard granulated surface, which keeps up incessant irritation of the sclerotic conjunctiva, and at length renders the cornea opaque." (*Synopsis*, &c. p. 98.)

The treatment recommended by Mr. Travers for the vehement acute suppurative inflammation of the conjunctiva consists in a very copious venesection, by which, he says, the pain is mitigated, if not removed; the pulse softened; and the patient sinks into a sound sleep and perspires freely. The high scarlet hue and bulk of the chemosis are sensibly reduced, and the cornea is brighter. The blood-letting, if necessary, is to be repeated, and the patient briskly purged, every dose of the opening medicine being followed by a tea-spoonful of a solution of emetic tartar, so as to keep up a state of nausea, perspiration, and faintness. When the discharge becomes thin, gleet, and more abundant, the swelling of the eyelid subsides, the conjunctiva sinks and becomes pale and flabby, the pain and febrile

irritation are past, and the cornea retains its tone and brightness, Mr. Travers considers the case safe, and states, that the prompt exhibition of tonics, with the use of cooling astringent lotions, will prevent its lapsing into a chronic form. "But if, when the lowering practice has been pushed to the extent of arresting acute inflammation, the patient being at the same time sunk and exhausted, the cornea shows a lack lustre and raggedness of its whole surface, as if shrunk by immersion in an acid, or a gray patch in the centre, or a line encircling, or half encircling its base, assuming a similar appearance, the portion so marked out will infallibly be detached by a rapid slough, unless by a successful rally of the patient's powers, we can set up the adhesive inflammation, so as to preserve *in situ* that which may remain transparent." (*Synopsis*, &c. p. 266.) Here we find some approximation of practice, between Mr. Travers and Professor Beer; but it is almost the only point, in which any resemblance can be found in their modes of treatment.

The granulated, or fungous state of the palpebral conjunctiva, produced by purulent ophthalmia, sometimes demands particular treatment after the original disease is subdued. If such state of the eyelid be not rectified, it often keeps up a "gleety discharge, irritability to light, drooping of the upper lid, a pricking sensation as of sand in the eye, and a preternaturally irritable and vascular state of the sclerotic conjunctiva; with these are frequently combined opacities of the cornea." (*Travers*, *op. cit.* p. 271.) The affection, as conjoined with opaque cornea, is particularly noticed by Dr. Vetch, who describes the disease of the palpebræ as consisting, at first, in a highly villous state of their membranous lining, which, if not treated by appropriate remedies, gives birth to granulations, which in process of time become more deeply sulcated, hard, or warty. Along with the villous and fleshy appearance of the lining of the eyelids, there is a general oozing of purulent matter, which may at any time be squeezed out by pressing the finger on the part. The diseased structure is highly vascular, and bleeds most profusely when cut. It possesses, as all granulated surfaces do, a very great power of growth or reproduction. Dr. Vetch has seen many cases in which it has been removed with more zeal than discretion, twenty or thirty times successively, without this disposition to reproduction having suffered any diminution. Indeed, he assures us, that the operation was very unfavourable to the ultimate recovery of the part; "a new surface is produced of a bright velvety appearance, much less susceptible of cure than the original disease, and which, even if at length healed, does not assume the natural appearance of the part, but that of a cicatrized surface," not attended with a return of the transparency of the cornea. It is satisfactorily proved, by the observations of Dr. Vetch, that this diseased state of the inner surface of the eyelid was not only known to

Rhases, and other old practitioners, under the names of sycosis, trachoma, scabies palpebrarum, &c. but that its treatment by the actual cautery, excision, and friction, was also recommended by them. The honour of having introduced the preferable mode of cure with escharotics, Dr. Vetch assigns to St. Ives. No substances appear to Dr. Vetch more effectual for this purpose than the sulphate of copper and nitrate of silver. He says, that they should be pointed in the form of a pencil, and fixed in a port-crayon. They are to be applied, not as some have conceived, with the view of producing a slough over the whole surface, but with great delicacy, and in so many points only, as will produce a gradual change in the condition and disposition of the part. As long as any purulency remains, Dr. Vetch states, that the above applications will be much aided by the daily use of the liquor plumbi subacetatis. When the disease resists these remedies, and the surface is hard and warty, he applies very minute quantities of finely levigated powder of verdigris, or burnt alum, to the everted surface, with a fine camel-hair pencil, but carefully washes them off with a syringe before the eyelid is returned. The caustic potassa, lightly applied to the more prominent parts of the diseased surface, will also answer. (See *Vetch on Diseases of the Eye* p. 73, &c.) Mr. Lloyd also gives his testimony in favour of the superiority of the nitrate of silver, which he has employed in the form of a saturated solution for restoring the healthy state of the inner surface of the eyelid. (*On Scrofula* p. 328.) Others, however, still adhere to the practice of excision, which, as already observed, was followed by the ancients, and revived of late years in England by Mr. Saunders, who did with scissors what Sir W. Adams and others have subsequently performed with a knife or lancet. Mr. Travers, I may observe, is also one of the advocates for the excision of the granulations and hardened excrescences of the conjunctiva. If there be a nebula of the cornea, with a plexus of vessels extending to it, these are then divided, near the edge of the cornea, in the manner recommended by Scarpa. Mr. Travers afterward applies a solution of the sulphate of copper, the liquor plumbi subacetatis, or the vinous tincture of opium. One remark which he makes tends very much to confirm the general advantage of the practice inculcated by Dr. Vetch; for, it is observed, "the application of the bluestone, or of the lunar caustic, is often useful in preventing the regeneration of the granulations after their excision." (*Synopsis*, &c. p. 272.) My friend, Mr. Lawrence, whose experience in diseases of the eye is very considerable, lately informed me, that he finds caustic the sure mode of permanently removing the granulated fungous state of the inner surface of the eyelid, and that, when the granulations are cut away, they are frequently reproduced; a fact on which Dr. Vetch has particularly insisted.

Egyptian Ophthalmia. One of the best accounts of this disease, as it appeared in the army, is that delivered by Dr. Vetch. Although there can be no doubt that the disorder, in all its general characters, closely corresponds to the severe form of acute suppurative inflammation of the conjunctiva, as described by Beer; yet there are some peculiarities with which it appears to have been characterized. Thus, one thing noticed in the Egyptian ophthalmia, but not in other purulent ophthalmies, is, that the first appearance of inflammation was observable in the lining of the lower eyelid. (Peach, in *Edinb. Med. and Surgical Journ.* for January, 1807. *Vetch, on Diseases of the Eye*, p. 196.) According to the latter writer, the feeling of dirt, or sand, rolling in the eye is a symptom requiring particular attention, as its accession is a certain index of the disease being on the increase. It is subject to exacerbations and remissions, the attacks always taking place in the evening, or very early in the morning. The first stage of the disease is said by Dr. Vetch to be characterized by its great and uniform redness, without that pain, tension, or intolerance of light, which accompanies most other forms of ocular inflammation; and, in particular, that in which the sclerotic coat is affected. From the very beginning of the complaint, there is a disposition to puffiness in the cellular texture between the conjunctiva and the globe of the eye, often suddenly swelling out into a state of complete chemosis, and at other times making a more gradual approach to the cornea. While effusion is thus taking place upon the eye, œdema is likewise going on beneath the integuments of the eyelids. This enormous tumefaction of the eyelids is said to be generally contemporaneous with the complete formation of chemosis; entropium is produced, and the integuments of the two eyelids meet, leaving a deep sulcus between them. When the external swelling begins, the discharge, which was previously moderate, and consisted of pus floating in a watery fluid, changes into a continued stream of yellow matter, which, diluted with the lachrymal secretion, greatly exceeds in quantity that derived from any gonorrhœa. Although, says Dr. Vetch, the tumefaction may be, at first, farther advanced in one eye than the other, it generally reaches its greatest height in both about the same. The patient now begins to suffer attacks of excruciating pain in the eye; a certain indication of the extension of the mischief. "An occasional sensation, as if needles were thrust into the eye, accompanied with fulness and throbbing of the temples, often precedes the deeper seated pain." This last is often of an intermitting nature, and a period of excruciating torture is succeeded by an interval of perfect ease. Sometimes the pain shifts instantaneously from one eye to the other, and is seldom or never equally severe in both at the same time: and sometimes, instead of being in the eye, it occurs in a circumscribed spot of the head, which the patient de-

scribes by saying, he can cover the part with his finger. Sooner or later, one of these attacks of pain is terminated by a sensation of rupture of the cornea, with a gush of scalding water, succeeded by immediate relief to the eye in which this event has happened, but generally soon followed by an increased violence of the symptoms in the other. At length the attacks of pain become shorter, and less severe, though they do not cease altogether till after the lapse of many weeks, and even months. During this stage of the disease, according to Dr. Vetch, there is seldom the slightest alteration of the pulse, unless the lancet have been freely employed. The patient's general health is little impaired, his appetite continues natural, but sleep almost totally forsakes him.

As the pain abates, the external tumefaction also subsides, and a gaping appearance of the eyelids succeeds, their edges, instead of being inverted, now becoming everted. This is what Dr. Vetch designates as the third stage of the disease.

After the swelling of the second stage has subsided, the eyelids are prevented from returning to their natural state by the granulated change of the conjunctiva which lines them; and an eversion of them now occurs in a greater or lesser degree. (*Vetch on Diseases of the Eye*, p. 196, 202.) Among other interesting remarks, made by the same author, he states, that there is no reason to warrant the idea, that the ulceration ever proceeds from within outwards. He observes, that, when any large portion of the cornea sloughs, an adventitious and vascular membrane is often produced, which finally forms a staphyloma. "In some few cases, (says he) I have seen the lens and its capsule exposed, without any external covering whatever, and, for a short time, the patient saw every thing with wonderful accuracy; but, as soon as the capsule gives way, the lens, and more or less of the vitreous humour, escape, the eye shrinks, and the cornea contracts into a small horn-coloured speck." This total destruction of the globe of the eye is said generally to ensure the other, and renders it less liable to be affected by future attacks of inflammation.

A few years ago, an ophthalmia, supposed to be of the same nature as the Egyptian, though milder, like that which has generally been observed in schools, occurred to a great extent in the Royal Military Asylum at Chelsea, and Mr. McGregor, the surgeon of that institution, has favoured the public with an excellent description of the disease, and some highly interesting facts and reflections upon the subject. In the Military Asylum the symptoms of this species of ophthalmia generally made their appearance in the following order: "A considerable degree of itching was first felt in the evening; this was succeeded by a sticking together of the eyelids, principally complained of by the patient on waking in the morning. The eyelids appeared fuller externally than

they naturally are; and on examining their internal surface this was found inflamed. The sebaceous glands of the tarsi were considerably enlarged, and of a redder colour than usual. The caruncula lachrymalis had a similar appearance.

"In 24 or 30 hours after the appearance of the above-mentioned symptoms, a viscid mucous discharge took place from the internal surface of each eyelid, and lodged at the inner canthus, till the quantity was sufficient to be pressed over the cheek by the motions of the eye. The vessels of the tunica conjunctiva, covering the eyeball, were distended with red blood, and the tunica conjunctiva was generally so thickened, and raised, as to form an elevated border round the transparent cornea. This state was often accompanied with redness of the skin round the eye, which sometimes extended to a considerable distance, and resembled, in colour and form, very much what takes place in the cow-pox pustule, between the 9th and 12th days after inoculation.

"When the purulent discharge was considerable, there was a swelling of the external eyelids, which often prevented the patient from opening them for several days. The discharge also frequently excoriated the cheeks as it trickled down. Exposure to light caused pain. When light was excluded, and the eye kept from motion, pain was seldom much complained of.

"These symptoms, in many, subsided, without much aid from medicine, in 10, 12, or 14 days, leaving the eye for a considerable time in an irritable state. In several, however, the disease continued for a much longer time, and ulceration took place on the internal surface of the eyelids, and in different parts on the eyeball. If one of those small ulcers happened to be situated on the transparent cornea, it generally, on healing, left a white speck, which, however, in the young subjects under our care, was commonly soon removed. In some few instances, an abscess took place in the substance of the eyeball, which, bursting externally, produced irrecoverable blindness." (*P. McGregor, in Trans. of a Society for the Improvement of Med. and Chirurgical Knowledge*, Vol. 3, p. 38—40.)

When the local symptoms had prevailed two or three days, some febrile disturbance occurred; but, except in severe cases, it was scarcely observable.

Mr. McGregor considered this ophthalmia to be of the same nature as that which has raged with such violence in the army at different periods, since the return of our troops from Egypt in 1800, 1801, and 1802. However, he has found that its consequences have not been so injurious to children as to adults; for, out of the great number of children that were afflicted with the disease at the Military Asylum, only six lost the sight of both eyes, and twelve the sight of one eye. (*Op. cit.* p. 49.) On the other hand, Dr. Vetch informs us, that, in the second battalion of the 52d regiment, which consisted of somewhat more than 700 men, 636

cases of ophthalmia were admitted into the hospital between August, 1805, and August, 1806; and that, "of this number, fifty were dismissed with the loss of both eyes, and forty with that of one." And, as Mr. McGregor observes, it is a melancholy fact, as appears from the returns of Chelsea and Kilmainham Hospitals, that 2317 soldiers were, on the 1st of December, 1810, a burthen upon the public from blindness, in consequence of ophthalmia. The cases, in which only one eye was lost, are not here included.

The attacks of the disease appear to be much more frequent, severe, and obstinate, in hot, sultry weather, than in cold or temperate seasons. (*P. McGregor, op. cit. p. 37, 54, &c.*)

This gentleman also observed, that the ophthalmia was more severe and protracted in persons having red hair, or a scrofulous habit, than in others. The right eye was more frequently and violently affected than the left. In females the symptoms are greatly aggravated for some days previous to the catamenia; but, on this evacuation taking place, they are quickly lessened. Mr. McGregor further remarks, that the measles, cow-pox, and mumps, go through their course as regularly in persons affected with this species of ophthalmia, as when no other disease is present; a circumstance which, with some others, proves that the disorder is entirely local. (*P. 54, 55.*)

With respect to the causes of the *Egyptian Purulent Ophthalmia*, much difference of opinion has prevailed, and, indeed, there was a time when the disease was regarded by the majority of army surgeons, who alone had opportunities of judging of it, as not being in reality contagious, but dependent upon local epidemic causes; the irritation of sand; peculiarity of climate, &c. The late Mr. Ware even doubted the propriety of calling this ophthalmia *Egyptian*, and he contended that a disease precisely similar in its symptoms and progress had been noticed long ago in this and other countries; and that, in Egypt, several varieties of ophthalmia prevail. He preferred calling the disease the *Epidemic Purulent Ophthalmia*. On the other hand, Sir W. Adams conceives, that it ought rather to be called *Asiatic Ophthalmia*, as recent investigations prove that it prevails in the greater part of Asia, and was long ago described by Avicenna. (*Graefe, Journ. der Chir. 1 B. p. 170.*)

That there has been long known in this country an infectious species of purulent ophthalmia cannot be doubted. The case, described by many surgeons, as proceeding from the sudden stoppage of gonorrhœa, or the inadvertent application of gonorrhœal matter to the eyes, which disorder will be presently noticed, is certainly an infectious purulent ophthalmia. It is also admitted, that it resembles Egyptian ophthalmia, by the intensity and rapidity of its symptoms; but the latter case is strongly characterized by the quickness with which it causes, especially in adults, opacities or ulcerations of the cornea; the long continued irritability

of the eyes after the subsidence of inflammation; but, more particularly, its very infectious nature, by which it spreads to an extent, that has never been observed with regard to any other species of purulent ophthalmia. There have been epidemic ophthalmias of other kinds, which have been known to affect the greater part of the population of certain districts and towns in England. The celebrated ophthalmia, which happened at Newbury, in Berks. some years ago, is an instance, that must be known to every body. But I know of no purulent inflammation of the eyes, which ever spread to a great extent in England, before the return of our troops from Egypt.

The reflections and observations of Mr. McGregor, as well as those of Dr. Vetch, and Dr. Edmondstone, I think, leave no doubt of two facts: first, that this ophthalmia was at all events brought from Egypt; and secondly, that it is infectious, but only capable of being communicated from one person to another by actual contact of the discharge. "If (says Dr. Vetch) any belief were entertained by the officers of the British army, during the first expedition to Egypt, that the disease was contagious, it was of a nature very vague and indefinite. Combined as its operations necessarily must be in that country with other exciting causes, there would be more difficulty in the first recognition of the fact. But, the continuance of the complaint with the troops, after their departure from the country, could scarcely fail to lead to the obvious conclusion of its possessing a power of propagation. Before the disease reached this country, the opinion of its being contagious was adopted by many. Dr. Edmondstone, in the account which he published of the disease, as it appeared in the regiment, to which he was surgeon, after its return to England, first made the public acquainted with the fact of the disease being communicable. In an account of the Egyptian ophthalmia, as it appeared in this country, printed in the early part of 1807, I first established, that the communication of the disease was exclusively produced by the application of the discharge from the eyes of the diseased to those of the healthy." (*Vetch on Diseases of the Eye, p. 178.*)

The opinion that the disease is ever communicated from one person to another, through the medium of the atmosphere, is at present nearly abandoned. During the whole time that Dr. Vetch had the management of the ophthalmic hospitals, there never was an instance of any medical officer contracting the disease, although exposed to what might be supposed to be the greatest concentration of any contagion that could arise in the worst stage of the complaint. Two orderlies only contracted the disease, and both in consequence of the accidental application of the virus. However, Sir W. Adams maintains, that he has seen many cases which prove, that the disorder, like small-pox, may spread contagiously, without any kind of inoculation. (*See Graefe's Journ. B. 1. p. 174.*) That the disease may also be

partly propagated by epidemic causes in certain places, I think as certain and clear, as that there must be a cause for the first commencement of the disorder in situations where infection by contact is out of the question. And, as Dr. Vetch has observed, "from whatever cause inflammation of the conjunctiva may originate, when the action is of that nature, or degree of violence as to produce a puriform or purulent discharge; the discharge, so produced, operates as an animal virus, when applied to the conjunctiva of a healthy eye. Considering the various modes, by which such a contact must inevitably occur in the usual relations of life, it must be obvious, that wherever ophthalmia prevails, whether it be the effect of local conditions of the soil, or of the atmosphere, naturally or artificially produced, this contagious effect must sooner or later mix, or unite its operation with that of the more general and original one; and hence, without regard to this property of the disease, its occurrence must often remain inexplicable, and at variance with the more general cause existing in external circumstances. And further, as the disease, produced by infection, is of a nature more violent and malignant, than that produced by the impression of atmospheric causes, it will, in every instance of extensively prevailing ophthalmia, occasion two different forms of disease, which, as long as they are considered as one and the same, will produce, according as the one or the other predominates, very discordant results." (*Vetch on Diseases of the Eye*, p. 175.)

Mr. McGregor relates three cases, which prove, that the matter, after its application, produces its effects in a very short time. I shall only cite the following example:—On the 21st of October, 1809, about four o'clock, P. M. Nurse Flanneily, while syringing the eyes of a boy, let some of the lotion, which had already washed the diseased eyes, pass out of the syringe into her own right eye. She felt little or no smarting at the time; but, towards nine o'clock the same evening, her right eye became red, and somewhat painful, and when she awoke next morning, her eyelids were swelled, there was a purulent discharge, pain, &c. (*Op. cit.*, p. 51.)

The late Mr. Ware, though he admitted, that the infection was brought into this country from Egypt by the troops, conceived that the same disease also sometimes arose from the matter of gonorrhœa being applied to the eyes, and that it had been prevalent in this country before the return of the army from Egypt. He thought, however, that the infection was generally communicated by contact. Mr. Ware observes, some of the worst cases of the purulent ophthalmia of children have happened in those whose mothers were subject to an acrimonious discharge from the vagina at the time of parturition. Some of the worst forms of the purulent ophthalmia in adults have occurred in those, who, either shortly before the attack of the ophthalmia, or at that very time,

laboured either under a gonorrhœa, or a gleet. Mr. Ware does not mean to impute every purulent ophthalmia to such a cause; but, in the majority of adults, whom he has seen affected, if the disorder had not been produced by the application of morbid matter, from a diseased eye, it could be traced to a connexion between the ophthalmia and disease of the urethra. Other causes, Mr. Ware acknowledges, may contribute to aggravate, and perhaps produce the disorder, and the purulent ophthalmia in Egypt has been attributed to a great number. The combined influence of heat and light, of a burning dust continually raised by the wind, and of the heavy dews of the night, may powerfully tend to excite inflammations of the eyes. Yet something more must operate in causing the malignant ophthalmia now under consideration; for the same causes operate with equal violence in some other countries, besides Egypt, and yet do not produce the same effect; and, in this country, (says Mr. Ware) the disorder prevailed during the last summer, to as great a degree, and upon as great a number of persons within a small district of less than a mile, as it ever did in Egypt; and yet, beyond this space, on either side, scarcely a person was affected with it. The disorder was certainly brought into this country by the soldiers who returned from Egypt, and was probably communicated from them to many others. Now, as the action of the atmosphere alone cannot account for the spreading of the disease, &c. Mr. Ware is led to believe, that this particular disorder is only communicable by absolute contact; that is, by the application of some part of the discharge, which issues, either from the conjunctiva of an affected eye, or from some other membrane secreting a similar poison, to the conjunctiva of the eye of another person. In schools and nurseries, in consequence of children using the same basins and towels, as others who had the complaint, the disease has been communicated to nearly twenty in one academy. Hence, Mr. Ware censures the indiscriminate use of those articles, in schools, nurseries, hospitals, ships, and barracks. (P. 14, 15.)

That in Egypt the origin of the disease cannot rightly be imputed to the effect of the sand and hot winds of the country, is clearly proved; 1st. Because, if this were the case, the disease would not be most prevalent in the autumnal season, during the inundation of the Nile. 2dly, The inhabitants of the Delta would not be more subject to it, than the Bedouin Arabs, who live on the sands of the desert. Not only the Bedouin Arabs, says Dr. Vetch, remain free from the disease, but Europeans, who are not particularly exposed to the night air, are also safe from its attacks. "The nature of military duty prevented our soldiers from using this precaution, and in a particular manner they became victims to the complaint. The men suffered more in proportion to the officers of the English army; &c."

the latter enjoyed a better, though often an incomplete defence from the coldness and dampness of the night; and officers, employed in strictly military duty, suffered more than those attached to the civil departments." (*Vetch on Diseases of the Eyes*, p. 157.) And Assaïni remarks, that if the dust or sand were the sole cause of ophthalmia, we ought to be exempted from the disease, where the cause does not exist. The contrary, however, was the case in the Delta, and principally on the cultivated borders of the Nile, during its inundations. *When we were exposed to the air during the night, we were immediately attacked with ophthalmia*, though the dust and sand were then under water. Larrey also imputes the origin of the disease to the cold damp nocturnal air, after the great heats of the day. (*Graefe's Journ. B.1, p. 179.*)

Whoever reads the account of the Egyptian ophthalmia, as given by Mr. McGregor and Dr. Vetch, will be convinced that the disorder is only communicable from one person to another by the application of the infectious matter to the eyes. Probably, the common mode of propagation is the inadvertent use of the same towels, or even merely touching the same articles, which have been in the hands of infected persons, who must be supposed occasionally to apply their fingers more or less to the eyelids. In this last way, the commencement of the disease may be accounted for in regiments upon their entering into barracks, which have been quitted by other infected soldiers. "Flies, in warm weather, (says Mr. McGregor) are seen in great numbers surrounding patients labouring under ophthalmia; and I much suspect are very frequently the medium by which the disease is communicated." (*P. 54.*) The matter is observed to be most infectious, when the disease is in an acute state.

Dr. Vetch adverts to two important questions connected with the history of the Egyptian ophthalmia. The first relates to the length of time which the disease has, at different periods, lain dormant, and especially between the return of the troops from Egypt, and the breaking out of the disease in the 52d regiment. An explanation of this fact is attempted by supposing, that the complaint exists, and is liable to a renewal of its infectious quality, long after the eye seems to have recovered its natural and healthy appearance. Perhaps, it would be as well to be content with the fact, that, in crowded barracks, under particular circumstances, soldiers, who have once had the disease, are very liable to relapses. The other question is, why has the disease produced such ravage in the army in England, and not in that of France? It is well known, that the French soldiers in Egypt suffered as much as our own troops from the affection, and great numbers of them returned to France with the disease in a chronic form. "In many (says M. Roux) the influence of their native climate has sufficed for the removal of all vestige of the disorder. On

the contrary, in others, it has continued in a chronic state, either attended with the loss of one, or of both eyes; and many of our invalids remain with the affliction. But, it has not been found, that these soldiers, who returned from Egypt, have ever communicated a contagious ophthalmia, either in regiments, in which many of them have been incorporated; or in invalid houses, where others have obtained their retirement; or in the individuals belonging to the different classes of society. Such is the objection that has been made, and may always be again urged, against the opinions and observations of the English, respecting the Egyptian ophthalmia." (*Roux, Voyage faite à Londres en 1814, ou Parallèle de la Chir. Angloise, &c. p. 49.*)

Baron Larrey, who admits that the disease may be communicated by application of the matter, argues, that it is not contagious in any other way, because, in Egypt, for want of sufficient hospital room, patients with this and other diseases were mixed together, without the ophthalmia being propagated to any of the patients, who were careful to avoid the above mode of infection. (*Graefe's Journ. B. 1, p. 179.*) Larrey, however, need not have used this reasoning with us, because it is a mistake in him to suppose, that the disease is here commonly regarded as communicable through the medium of the atmosphere. While, however, English surgeons chiefly explain the extension of the disease by the infectious nature of the discharge when applied to the eyelids, and Larrey admits that the matter is thus infectious, the latter, as well as Roux, assures us, that none of the healthy soldiers, who came home with the blind invalids from Egypt, were attacked with this species of ophthalmia. A great number of those invalids were received in the hospital of the guards at Paris, and treated there without any of the other patients being infected. (*Graefe's Journ. loc. cit.*) On my return from the Mediterranean through France in 1802, I saw many of the French troops in a town between Marseilles and Lyons, with bad eyes, contracted in Egypt, associating with other soldiers, whose eyes were perfectly healthy, and living in the same barracks; a proof, that the French soldiers, with the exception of climate, or some other protecting cause, were placed apparently in circumstances, in which the disease here made such extensive ravages. This is a point which I humbly conceive, is not at all solved by Dr. Vetch's belief, that the difference is explicable by the French troops being sent into the field; for, in fact, the soldiers with diseased eyes were in barracks, or hospitals, as well as our own troops.

But, notwithstanding it seems proved, that the discharge from the eyes in the Egyptian ophthalmia is so actively infectious in England, it appears from an experiment, made by Mr. Mackesy, that its application may sometimes be made to a healthy eye, without the disease following as a matter of certainty.

This gentleman, who was surgeon to the 62d regiment, applied to his own eyes linen impregnated with matter discharged from the eyes of patients in the fully formed stage of the disease, and even allowed some of the matter to pass under the eyelids; yet the complaint was not communicated. (See *Edinb. Med. and Surg. Journ.* Vol. 12, p. 411.)

One of the most material circumstances in which the practice of English surgeons differs from that of foreign practitioners in cases of severe purulent, and especially Egyptian ophthalmia, is the freedom and boldness, with which the former attack the disease in its first stage. Mr. Peach recommends taking away at once as much as 60 ounces of blood; (*Edinb. Med. and Surg. Journ.* for January, 1807) and Dr. Vetch lays great stress on the striking benefit of bleeding the patient till syncope is produced. "When inflammation has its seat in the sclerotic coat, (says this gentleman) general blood-letting may for the most part be dispensed with, and even when employed to the greatest extent, the same benefit does not ensue. In the purulent inflammation of the conjunctiva, however, although some good may be derived from depletion, yet a perfect command over the disease depends less on lowering the system, than on the temporary cessation of arterial action by syncope, which it becomes the object of the operation to produce. This practice, besides its efficacy, will accomplish the cure with a much less expenditure of blood, than is occasioned by the repeated bleedings generally had recourse to, where this method of rendering one equal to the cure of the complaint has been neglected. Some time before the approach of faintness, the redness of the conjunctiva for the most part disappears; but this is no security against the return of the disease, if the flow of blood be stopped, without deliquium animi succeeding." (*Vetch on Diseases of the Eye*, p. 206.) The attacks of a painful sensation, as if gravel were in the eye, are considered by this gentleman as a proof of the disease increasing, and are regarded by him, in the early stage of the disease, as a better indication of the necessity for bleeding, than the appearance of the eye itself.

With respect to applications, Dr. Vetch speaks very highly of the beneficial effects produced in the beginning of the case by dropping into the eye the undiluted liquor plumbi subacetatis, which, he says, diminishes the discharge, lessens the inflammation, and is incapable of doing harm in any stage of the disease. He places great confidence in the salutary results of a free exposure of the eye to the atmosphere; and speaks in high terms of the good derived from applying at night to the eye an infusion of tobacco, two drachms of the leaves to eight ounces of water. "It possesses (says Dr. Vetch) the valuable properties of acting as a powerful astringent, restraining the purulent discharge, and diminishing the oedema,

or external swelling of the palpebrae; at the same time, that its narcotic qualities often relieve the pain and the perpetual watchfulness, which the largest doses of opium cannot subdue." (P. 211.) Bleeding, however, is the "sheet anchor," and the only means of preventing the destruction of the cornea, whenever attacks of pain in the eye, or orbit, denote the unsubdued state of the disease. (P. 212.) When the disease shifts its violence from one eye to the other, and is of long duration, Dr. Vetch recommends cupping, and the eye to be more carefully cleaned by the injection of tepid water, or any gentle astringent lotion, and afterward wiped dry. When the discharge continues acrid and scalding, he directs blisters to be applied to the nape of the neck, and behind the ears. He wishes it to be distinctly kept in mind, that the time for the employment of bleeding, with the view of saving the eye, is during the first stage, or early part of the second; and when ulceration of the cornea has commenced, the case is to be treated on the principles applicable to sclerotic inflammation.

With regard to the plan of diminishing inflammatory action by medicines which excite nausea and sickness, instead of having recourse to the lancet, Dr. Vetch states, that, in soldiers, it does not answer so well, and in the end proves more debilitating.

As soon as the external oedema of the eyelids subsides, and they begin to be everted, Dr. Vetch begins the cure of the granulations and general villosity, by a very light and careful application of the argenti nitratum. The everted portion is then to be returned, and secured in its place with a compress and bandage. This method is to be repeated every time the eye is cleaned, and, in the course of a fortnight, the tendency to ectropium will be removed (P. 229.)

Assalini found venesection, all emollient applications, and eyewaters, hurtful. He first purged his patients, and then introduced into their eyes a few drops of a solution of the lapis divinus, (see *Lachrymal Organs*), to which was sometimes added a small quantity of the acetate of lead. He speaks favourably of leeches, and sometimes he put a small blister on the temple, or behind the ears. (See *Manuale di Chirurgia*; Milano, 1812.)

Perhaps the best mode of putting an immediate stop to the Egyptian ophthalmia, when it prevails extensively in a regiment in garrison, or barracks, is to put the men actually affected into a detached hospital, at a considerable distance from the rest of the corps, which should be dispersed as much as possible in separate billets and villages. Purulent ophthalmia is a disease which makes great head only when large numbers of persons are either exposed together to the epidemic causes, which first give birth to it, or to the causes which occasion the disease to be communicated from one individual to another, as when soldiers are crowded together in the same building, using the same towels and water, &c. Notwithstanding the

reports of Roux and Larrey prove, that the disease did not spread in the French army, after the return of uncured soldiers from Egypt to France, though these were freely mixed with their comrades in hospitals and barracks the same security did not extend to the British troops lately in the latter country, who at one time were threatened with a very extensive renewal of the Egyptian ophthalmia among them, but which was wisely checked by attention to the principles above specified, and in which Dr. Grant, the head of the medical department of that army, had the greatest confidence.

In the cases under Mr. McGregor, local applications were found most advantageous. During the inflammatory stage, however, this gentleman also had recourse to antiphlogistic means, spare diet, bleeding, neutral salts, &c. The topical treatment was as follows: Leeches were freely and repeatedly applied near the eye. But while there was much surrounding redness, instead of leeches, which created too much irritation, fomentations, with a weak decoction of poppy-heads, and a little brandy, were used. A weak solution of acetate of lead, and sulphate of zinc, had mostly a good effect when applied to the eye. The vinous tincture of opium did not answer the expectations entertained of it. But of all the remedies, the ung. hydrarg. nitrat. was found most frequently successful. It was applied by means of a camel-hair pencil, and at first weakened with twice its quantity of lard. The red precipitate, well levigated, and mixed with simple ointment, sometimes answered when the ung. hydrarg. nitrat. failed. Well levigated verdigris, and a quack medicine, called the golden ointment, proved also sometimes efficacious. (P. 41—43.) According to Mr. McGregor, blisters behind the ears, and upon the neck, are useful; but hurtful when put nearer to the eye. In cases where the disease seems to resist antiphlogistic means, and ulceration has commenced on the external surface of the cornea, this gentleman approves of discharging the aqueous humour by a puncture, as advised by Mr. Wardrop.

When the violence of the inflammation has subsided, Mr. McGregor recommends the use of Bates's camphorated water, diluted with four, five, or six times its quantity of water. But the astringent collyrium, from which he saw most good derived, was a solution of the nitrate of silver, in the proportion of half a grain to every ounce of distilled water. In some cases, it may be used stronger.

Tepid sea-water sometimes proved serviceable in removing the relics of the complaint. (P. 56 &c.)

The late Mr. Ware was in favour of bleeding; but he rarely carried it to the extent which has been done in the army. In weak persons, instead of repeated venesection, he preferred topical bleeding, either from the vein that passes on the side of the nose, or by means of five or six leeches put on the temple. Sometimes he thought it better to scarify the inside of the lower eyelid with

the point of a lancet, carried along parallel to, and very near the margin of this part. He objects to pricking the eyelid in an infinite number of places, as very painful, and likely to increase the irritation. The lancet (he says) never need be applied more than twice, and rarely more than once; and, perhaps, less pain will be occasioned by making the incision with the edge, rather than the point of the lancet. After taking away blood, Mr. Ware says, a large blister on the head, or back, is often useful. Anodynes should be given, with occasional purgatives, and an antiphlogistic regimen. (*Ware on Purulent Ophthalmia*, 1808. p. 26, &c.)

As a local application, Mr. Ware preferred the aqua camphorata, which was used exactly in the same way, as will be described in speaking of his method of treating the purulent ophthalmia of children. When the inflammation was very great, he only put four or five grains, instead of eight, of the sulphate of copper to eight ounces of water. He usually employed the lotion cold, especially in children; but in adults, in whom the general fever and local inflammation were considerable, he was obliged to use it warm. In cases of great pain and swelling, it should be very weak, less often applied, and sometimes only warm water injected. In such circumstances, Mr. Ware also sanctioned fomenting the eye with a flannel, or sponge, wet with a hot decoction of poppy-heads, or mere hot water. When the cornea threatens to burst, this gentleman approves of opening it, in order to discharge the aqueous humour, by making an incision in a place where the scar will not obstruct vision, as first suggested by Mr. Wardrop.

Purulent Ophthalmia of Infants. Dr. Vetch describes the external appearances of this case as not materially different from those of the purulent ophthalmia of adults; but, he states, that its nature is considerably modified by the more delicate texture and greater vascularity of the parts affected, and the more intimate connexion, subsisting between the vessels of the conjunctiva and those of the sclerotic coat. Hence, he says, the inflammation is sooner communicated to this coat, and sloughing and ulceration of the cornea occur earlier in infants, than adults. When the oedema ceases, the inner surface of the palpebræ becomes sarcomatous, and this diseased surface, when the eyelids are opened, forms an exterior fleshy circle, beyond which the relaxed conjunctiva of the eye comes forward as a second; and often the caruncula lachrymalis adds still farther to the valvular appearance, which the part presents. (*On Diseases of the Eye*, p. 256—258.)

According to the late Mr. Ware, the principal difference between the purulent ophthalmia in infants and that in adults, consists in the different states of the tunica conjunctiva: in the former, notwithstanding the quantity of matter confined within the eyelids is often profuse, the inflammation of the conjunctiva is rarely considerable, and whenever the cornea becomes impaired, it is rather

owing to the lodgment of such matter on it than to inflammation; a statement, which appears to me very questionable. But, in the purulent ophthalmia of adults, the discharge is always accompanied with a violent inflammation, and generally with a tumefaction of the conjunctiva, by which its membranous appearance is destroyed, and the cornea is made to seem sunk in the eyeball. (*Ware on Epidemic Purulent Ophthalmia*, p. 23.) In children, the affection of the eyes is occasionally accompanied with eruptions on the head, and with marks of a scrofulous constitution. (See *Ware*, p. 138, &c.) The only inference to be drawn from this fact is, that scrofulous, as well as other children, are liable to this disorder of their eyes.

The following is the treatment recommended by Mr. Ware. If the disease be in its first stage, the temporal arteries are to be opened, or leeches applied to the temples, or neighbourhood of the eyelids, and a blister put on the nape of the neck and temples. The child should be kept in a cool room, not covered with much clothes, and if no diarrhoea prevail, a little rhubarb or magnesia in syrup of violets should be prescribed.

A surgeon, however, is seldom called in before the first short inflammatory stage has ceased, and an immense discharge of matter from the eyes has commenced. Of course, (says Mr. Ware,) emollient applications must generally not be used. On the contrary, astringents and corroborants are immediately indicated, in order to restore to the vessels of the conjunctiva and eyelids their original tone, to rectify the villous and fungous appearance of the lining of the palpebræ, and thus finally to check the morbid secretion of matter. For this purpose Mr. Ware strongly recommends the *aqua camphorata* of Bates's Dispensatory: *R. Cupri sulphatis, bol. armen. āā ℥iv. Camphoræ, ℥j. M. & f. pulvis, de quo projice ℥j. in aquæ bullientis ℥iv. amove ab igne, et subsidant fœces.* Mr. Ware, in his late *Remarks on Purulent Ophthalmia*, 1803, observes, that he usually directs the *aqua camphorata* as follows: *R. Cupri sulphatis, bol. armen. āā gr. viij. Camphoræ gr. ij. Misce, et affunde aquæ bullientis ℥viij. Cum lotio sit frigida, effundatur limpidus liquor, et sæpissimè injiciatur paululum inter oculum et palpebras.* This remedy possesses a very styptic quality; but, as directed in Bates's Dispensatory, it is much too strong for use before it is diluted; and the degree of its dilution must always be determined by the peculiar circumstance of each case. Mr. Ware ventures to recommend about one dram of it to be mixed with an ounce of cold clear water, as a medium or standard, to be strengthened or weakened as occasion may require. (P. 143.) The remedy must be applied by means of a small ivory or pewter syringe, the end of which is a blunt-pointed cone. The extremity of this instrument is to be placed between the edges of the eyelids, in such a manner, that the medicated liquor may be carried over the whole surface of the eye. Thus the matter will be entirely washed away, and enough of the styptic medicine left behind to interrupt and diminish

the excessive discharge. According to the quantity of matter, and the rapidity with which it is secreted, the strength of the application, and the frequency of repeating it, must be regulated. In mild recent cases, the lotion may be used once or twice a day, and rather weaker than the above proportions; but, in inveterate cases, it is necessary to apply it once or twice every hour, and to increase its styptic power in proportion; and when the complaint is somewhat relieved, the strength of the lotion may be lessened, and its application be less frequent.

"The reasons for a frequent repetition of the means just mentioned, in bad cases, are, indeed, of the most urgent nature. Until the conjunctiva is somewhat thinned, and the quantity of the discharge diminished, it is impossible to know in what state the eye is; whether it is more or less injured, totally lost, or capable of any relief. The continuance or extinction of the sight frequently depends on the space of a few hours: nor can we be relieved from the greatest uncertainty in these respects, until the cornea becomes visible." (*Ware*, p. 145.)

This author condemns the use of emollient poultices, which must have a tendency to increase the swelling and relaxation of the conjunctiva. If poultices are preferred, he particularly recommends such as possess a tonic or mild astringent property; as one made of the curds of milk, turned with alum, and an equal part of the unguentum sambuci, or axungia porcini. This is to be put on cold, and frequently renewed, without omitting the use of the injection. (*Ware*, p. 147.)

When the secreted matter is glutinous, and makes the eyelids so adherent together, that they cannot be opened, after being shut for any length of time, the adhesive matter must be softened with a little fresh butter mixed with warm milk, or by means of any other soft oleaginous liquor, after the poultice is taken off, and before using the lotion. (P. 147.)

If the eversion of the eyelids only occurs when the child cries, and then goes off, nothing need be done in addition to the above means. When, however, the eversion is constant, the injection must be repeated more frequently than in other cases: the eyelids put in their natural position, after its use; and an attendant directed to hold on them, with his finger, for some length of time, a compress dipped in the diluted *aqua camphorata*. (P. 148.)

In some cases, when the inside of the eyelids has been very much inflamed, the tinctura thebaica, insinuated between the eye and the eyelids, has been useful. If, after the morbid secretion is checked, any part of the cornea should be opaque, the unguentum hydrargyri nitrati, melted in a spoon, and applied accurately on the speck, with a fine hair pencil; or Janin's ophthalmic ointment, lowered and used in the same manner, may produce a cure, if the opacity be not of too deep a kind. When the local disease seems to be kept up by a bad habit, alteratives should be exhibited, particularly the

black sulphuret of mercury, or small doses of calomel.

The treatment, recommended by Dr. Vetch, is as follows: if the inflammation has not extended to the conjunctiva of the eye, its further progress may be checked by removing the infant to a healthy atmosphere, and washing the eye with any mild collyrium. Leeches are commended throughout the whole course of the complaint. On the first accession of the tumefaction, the best effect will often be produced by the application of a small portion of ointment, composed of lard, or butter 3vj. and x gr. of the red nitrate of mercury, without any wax. As the purulency advances, the liquor plumbi subacetatis, he says, will be found not less serviceable, than in other instances of purulent ophthalmia. For promoting the separation of any slough, he recommends a solution of the nitrate of silver; and for curing the relaxed state of the conjunctiva, a solution of alum, or of the sulphate of copper. (*On Diseases of the Eye*, p. 260.)

The *Purulent Ophthalmia arising either from suppression of gonorrhœa or from the inadvertent conveyance of gonorrhœal matter to the eyes*, is said to produce rather a swelling of the conjunctiva, than of the eyelids, which is followed by a discharge of a yellow greenish matter, similar to that of clap. The heat and pain in the eyes are considerable; an aversion to light prevails, and, in some instances, an appearance of hypopion is visible in the anterior chamber of the aqueous humour. When the complaint proceeds from the second cause, it is described as being less severe, than when it arises from the first. However, by such gentlemen, (*Ware, Travers, &c.*) as have seen unequivocal instances of purulent ophthalmia excited in the second way, the disease is said to be remarkable for its violence and intensity. The reality of cases of purulent ophthalmia from the application of gonorrhœal matter to the eyes, seems supported by such a mass of evidence, that I believe the fact must be admitted. Yet, from some statements, lately published by Dr. Vetch, it would appear, that the frequency of this mode of infection must be very much lessened by the circumstance of the matter taken from the urethra, not being capable of communicating the disease to the eyes of the individual, by whom such matter is secreted, though probably capable of doing so to the eyes of another person.

In the same way, the urethra cannot be affected by the application of matter taken from the purulent eyes of the individual, on whom the experiment is made. At least, of these circumstances, there is a negative proof in some facts recorded by Dr. Vetch. "In the case of a soldier, received in a very advanced stage of the Egyptian ophthalmia, in whom destruction of the cornea had to a certain extent taken place, I took occasion to represent the possibility of diverting the disease from the eyes to the urethra, by applying the discharge to the latter surface. Accordingly, some of the matter taken from the

eyes, was freely applied to the orifice of the urethra. No effect followed this trial, which was repeated on some other patients, all labouring under the most virulent state of the Egyptian disease, and in all the application was perfectly innocuous. But, in another case, where the matter was taken from the eye of one man, labouring under purulent ophthalmia, and applied to the urethra of another, the purulent inflammation of the urethra commenced in thirty-six hours afterwards, and became a very severe attack of gonorrhœa. From the result of these cases, (says Dr. Vetch) I could no longer admit the possibility of infection being conveyed to the eyes from the gonorrhœal discharge of the same person. Some time after this, the improbability, or rather impossibility of this effect, was rendered decisive by an hospital assistant, who conveyed the matter of gonorrhœa to his eyes, without any affection of the conjunctiva being the consequence." (*See Vetch on Diseases of the Eye*, p. 242.) Hence, this gentleman is led to refer the connexion, between gonorrhœa and ophthalmia, in the same person, to peculiarity of constitution; but the theories on which this opinion rests, my limits will not allow me to examine.

If it be actually true, that, in adults, a species of purulent ophthalmia does originate from the sudden suppression of a gonorrhœa, are we to consider the complaint so produced as a metastasis of the disease from the urethra to the eyes? This ophthalmia does not regularly follow the suppression of gonorrhœa; nay, it is even a rare occurrence: also, when it is decidedly known, that the purulent ophthalmia has arisen from the infection of gonorrhœa, namely, in those instances in which the matter has been incautiously communicated to the eyes, it appears that such an affection of these organs, so produced, is different from the one alluded to, inasmuch as it is slower in its progress, and less threatening in its aspect. When the eyes are affected, the disease of the urethra is not always suspended. (*Vetch on Diseases of the Eye*, p. 239.) Hence, there is good reason for supposing that no metastasis takes place in this species of purulent ophthalmia, supposed to be connected with a suppressed gonorrhœa: but, we must be content with inferring that, if it really has such a cause, it originates from a sympathy, prevailing between the urethra and eyes, and, that the difference of irritability, in different people, is the reason, why it is not an invariable consequence of the sudden stoppage of a gonorrhœa.

The injection of warm oil, the introduction of a bougie into the urethra, and the application of cataplasms to the perinæum, with a view of renewing the discharge from the urethra, form the outline of the practice of those who place implicit reliance in the suppression of gonorrhœa being the cause of the complaint. The rarity of the occurrence; the frequency of the sudden cessation of the urethral discharge; the possibility of an ophthalmia arising, as well at this

particular moment, as at any other, totally independent of the other complaint; cannot fail to raise in a discerning mind a degree of doubt concerning the veracity of the assigned cause. Besides, admitting that there is a sympathy between the urethra and eyes, how are we to ascertain whether the suppression of gonorrhœa be the cause or the effect of the ophthalmia, supposing that the one ceases and the other commences about the same time? Actuated by such reflections, I am induced to dissuade surgeons from adopting any means calculated to renew a discharge of matter from the urethra. When the purulent ophthalmia, in adult subjects, is decidedly occasioned by the actual contact, and infection of gonorrhœal matter, applied accidentally to the eyes, no one has recommended this unnecessary and improper practice.

The first indication in the treatment of the disease from either cause, is to oppose the violence of the inflammation, and thus resist the destruction of the eye and opacity of the cornea. A copious quantity of blood should be taken away both topically and generally; mild laxatives should be exhibited, and a blister applied to the nape of the neck, or temples. The eyes ought to be often fomented with a decoction of white poppy-heads, and warm milk repeatedly injected beneath the eyelids. To prevent the palpebræ from becoming agglutinated together, during sleep, the spermaceti cerate should be smeared on the margins of the tarsi every night.

When the heat and pain in the eyes, and febrile symptoms have subsided; when an abundant discharge of pus has commenced; all topical emollients are to be relinquished, and a collyrium of Aq. rosæ ℥x. containing Hydrarg. oxy. mur. gr. j. used in their place. Scarpa states, that in the ophthalmia, originating from the inadvertent communication of the matter of gonorrhœa to the eyes, applications, in the form of ointment, such as the ung. hydrarg. and Janin's salve, to which might be added the ung. hyd. nitrat. avail more, than fluid remedies.

Inflammation of the Eyeball in general. From cases in which the eyelids are at first chiefly affected, I pass to the consideration of inflammation, as commencing in the eyeball itself. As Beer remarks, fortunately it is only very seldom, that the whole of the organ is at once attacked with genuine idiopathic inflammation, without any part of its texture being spared. Although this kind of ophthalmia is far more frequent than common inflammation of the orbit, it is much more rare than the same disorder of the eyelids. For the most part, healthy inflammation of the eyeball has a limited point of origin, from which it spreads, sometimes quickly, sometimes slowly over the whole organ. During an exceedingly violent, tense, throbbing pain, affecting not only the eye itself, but extending to all the surrounding parts, the bottom of the orbit and within the head, the white of the eye becomes suffused with

an uniform redness, which, on attentive examination, is found to be seated not only in the conjunctiva of the eyeball, but also in the sclerotica, and to exhibit at first a very fine vascular network, which, as the redness grows more intense, assumes the appearance of scarlet cloth, forming all round the cornea an uniform circular prominent fold, which has a very firm feel, and is so tender, that, when touched in the gentlest manner, the patient cries out with agony. The circumference of the cornea continues to be more and more covered by this increasing swelling of the conjunctiva, until at length only a portion of its centre remains visible. At the same time, the pupil is very much contracted; the iris motionless; and though vision is nearly or entirely lost, the patient is seriously disturbed by fiery appearances before the eye. When the iris is naturally gray, or blue, it turns greenish, and when brown, or black, it becomes reddish. Every movement of the eyeball and upper eyelid is suspended, and the orbit feels to the patient, as if it were too small, which, Beer says, is in reality the case, because the whole of the eyeball, and not merely the conjunctiva, is enlarged, so as to project like a lump of raw flesh further and further between the edges of the palpebræ, and completely fill every part of the orbit. While the eyeball enlarges, the cornea always loses its transparency, and the inflammation spreads to the eyelids, the lower one at last becoming everted by the excessive and firm tumefaction of the parts behind it, and the upper one presenting the most unequivocal marks of phlegmonous inflammation. The secretion of tears and mucus is now entirely suppressed, and of course, the eye preternaturally dry. At the very commencement of this violent form of ophthalmia, the constitution is disturbed by a severe attack of inflammatory fever, and irritable patients are not unfrequently seized with delirium.—Here, says Beer, terminates the first stage of this very dangerous disorder.

When the disease is left to itself, suppuration comes on, attended with fever and constant shiverings; the swelling of the sclerotic conjunctiva undergoes a remarkable increase, and assumes a dark red colour, at the same time that it becomes softer. The pain becomes irregular, throbbing, and, when the eye or eyelids are touched, of a lancinating description. As a morbid secretion now begins to take place from the Meibomian glands, the swelled conjunctiva has a more moist appearance. The upper eyelid has a purple hue, and, on account of the continually increasing size of the eyeball, is pushed further and further outward. The portion of the cornea, still discernible in the middle of the protuberant conjunctiva, acquires a snowy whiteness, which afterward changes to yellow. The patient feels an oppressive sense of heaviness in the orbit, and a disagreeable kind of coldness all round the eye. At length the throbbing and ten-

sion are so agonizing, that the patient often expresses a wish to have the eyeball extirpated. If no effectual treatment be adopted, the eye now bursts, and a mixture of matter and blood, together with the scarcely perceptible remains of the lens and vitreous humour, is discharged with considerable force to some distance in front of the patient; an occurrence sometimes termed *rhexis*, or *rhagma oculi*. From this moment, the pain all at once subsides into a very moderate feel of burning in the eye; and suppuration goes on, until all the textures of the organ are annihilated, the orbit has an empty appearance, and the closed eyelids sink into a concavity. Thus ends, as Beer observes, the second stage, after much tedious and general indisposition. But, he remarks, that the course of the case is quite different, when it has been wrongly treated in its first stage with stimulants, or exposed to the ill effects of tobacco smoke, the drinking of spirits, improper diet, immoderate exercise, &c.; for, under the operation of these unfavourable circumstances, the second stage may commence with dreadful gangrenous mischief, every vestige of the organization of the eye disappearing, and the parts at length sphacelating, while large abscesses form around, and, unless efficient medical aid be promptly given, the patient loses his life.

With respect to the causes of such an attack of the whole eyeball at once by common inflammation in a healthy subject, they must be of an exceedingly violent description, such as injuries produced by gunpowder, burns, and lesions either of a mechanical kind, or acting both chymically and mechanically together, a subject already fully treated of in the foregoing columns.

The following are the observations which Beer delivers on the prognosis: While, in the first stage of this dangerous form of ophthalmia, the eyesight yet remains, and the eyeball itself is not enlarged, if the patient can be properly taken care of, some hope may be entertained of dispersing the inflammation so favourably, that, with the exception of a weakness of sight, of longer or shorter continuance, no ill effects will be left. It is manifest, however, that under these circumstances, the surgeon should not be too bold in promising a perfect cure; for, the very commencement of such an inflammation of the whole eyeball, even when the disorder is purely idiopathic, is unavoidably attended with some risk, not only of permanent blindness, but of the eye itself being destroyed in the most painful manner; and, when things turn out rather better, a tolerably favourable termination of the case is uncommon. But, as soon as the power of seeing is quite lost, the pupil nearly closed, and the eyeball prodigiously swelled, it will be fortunate, if the inflammation can be resolved, so as to preserve the shape of the organ; for the restoration of the eyesight is entirely out of the question. But, besides the irremediable loss of vision, the disorder under these circumstances always

produces a greater or lesser closure of the pupil, which, however, has no share in causing the blindness.

In the second stage of the case, of course, the hope of restoring vision is quite past, and if the eyeball itself, and not merely the conjunctiva, has been considerably swelled in the first stage of the case, the chance of preserving the natural shape of the organ extremely unpromising. But, when the eye bursts, the latter desideratum is impossible. If the first stage should have been so violent as to have induced gangrene, the practitioner will have enough to do in preventing sphacelus, and death, the danger of which is considerable, on account of the intimate connexion between the eye and parts in the orbit, and the brain and its membranes.

In the first stage, antiphlogistic treatment, in the general sense of the expression, is indicated, and the case is not to be regarded merely as a local disorder. However, with respect to topical bleedings, the surgeon, says Beer, should be more active, than in other examples of ophthalmia, and, after copious venesection and the use of leeches have produced some relief, the protuberant conjunctiva, round the cornea, should be deeply scarified with a lancet. If, in the first stage, delirium come on, as it sometimes does during the violence of the inflammatory fever, Beer directs one of the external jugular veins to be opened: or blood might be taken from the temporal artery.

In the second stage of the case, when the re-establishment of vision is quite impossible, and the objects are to endeavour to keep the eye of a good shape, and quickly lessen the suppuration, warm emollient poultices, and particularly those made of apples, are the applications, on which Beer bestows his praises. This topical treatment is to be assisted with internal means, as explained in the preceding pages, because the disorder is attended with a general disturbance of the constitution. When matter is fully formed, and its fluctuation can be distinctly felt, Beer approves of opening the abscess with a lancet; for, it is only by this means, that the annihilation of the eyeball can be prevented. If the eye has already burst, the preservation of its form is no longer possible, and, according to Beer, both the topical and general treatment should be partly of a tonic description. When gangrenous mischief has occurred, the practice ought to conform to the principles explained in the article *Mortification*.

External Ophthalmia. Inflammation of the Outer Coats of the Eye. Ophthalmia Externa Idiopathica, of Beer. The modifications of this common species of ophthalmia, as the latter author observes, have a variety of names applied to them, as *ophthalmia levis*, *ophthalmia angularis*, *taraxis*, and sometimes *chemosis*, and *ophthalmia sicca*. Together with a preternatural dryness of the eye, and a sensation, as if the eyeball were compressed on every side, the white of the eye becomes covered with a general redness,

which, though it affect both the sclerotica and the conjunctiva, will be found on attentive examination to be much more considerable in the former, than the latter membrane, in which only a delicate plexus of blood-vessels is at first perceptible. The motions of the eye and eyelids are not absolutely prevented; yet, the patient never moves these parts except when he is actually obliged to do so, as every motion of them, if not actually painful, occasions a good deal of annoyance. Though the cornea cannot be said to become opaque, its clearness is always much diminished, and this change is the greater, the redder the white of the eye appears. These effects, which occur almost simultaneously, are followed by pain, which increases every moment, at first extending over the whole eyeball, and then to the surrounding parts, and to the top of the head. As the pain grows more severe, every movement of the eyeball and palpebræ becomes more distressing, the dryness of the eye greater, and the redness of the sclerotic conjunctiva augments, either more slowly, or quickly, according to the degree of inflammation until the network of blood-vessels, which was at first distinguishable, entirely disappears, and the conjunctiva looks like a piece of red cloth, quite concealing the sclerotica, and forming round the cornea a very painful, firm, uniform circular projection. Thus, the cornea seems as if it lay in a depression, with its margin partly covered by this inflammatory swelling of the conjunctiva. At the period, when the protuberance of the latter membrane takes place, the cornea itself always becomes less and less clear, and of a reddish gray colour, so that neither the iris nor the pupil can be any longer distinguished, and the power of vision is reduced to a faint perception of light. The pain, which was that of heaviness and tension, now becomes of a throbbing description, and the eyelids, which now begin to participate in the effects of the inflammation, are no longer capable of covering properly the swelled conjunctiva. The eyeball and eyelids are perfectly motionless; and, if an attempt be made by the patient to move them, the efforts of the muscles may be perceived, but still no movement of the parts intended is performed. The orbit feels as if it were too small for the eye, and the constitution suffers a severe attack of inflammatory fever. Thus, says Beer, does the first stage of this form of ophthalmia gradually rise to its highest degree, to which he applies the name of *true chemosis*.

However, it is observed, that idiopathic external ophthalmia does not always become so violent, as for instance, when the complaint has been excited merely by the lodgment of some small foreign body under the eyelids; for though in such a case the conjunctiva and sclerotica are both reddened together, yet even when no aid is afforded, if no other sources of greater irritation are present, the redness does not readily increase so as quite to conceal the sclero-

tica, or to be attended with an inflammatory swelling all around the cornea. This milder form of external ophthalmia has sometimes received the name of *taraxis*. It is the *mild acute ophthalmia* of Scarpa, characterized, as this author says, by redness of the conjunctiva and lining of the eyelids, an unnatural sensation of heat in the eyes, uneasiness, itching, and shooting pains, as if sand were lodged between the eye and eyelids. At the place where the pain seems most severe, Scarpa remarks, that some blood-vessels appear more prominent and turgid than other vessels of the same class. The patient keeps his eyelids closed; for he feels a weariness and restraint in opening them, and by this means he also moderates the action of the light, to which he cannot expose himself, without increasing the burning sensation, lancinating pain, and effusion of tears. If the constitution be irritable, the pulse will be a little accelerated, particularly towards the evening; the skin dry; and sometimes slight shiverings, and nausea and sickness take place.

According to Scarpa, mild acute ophthalmia is often the consequence of a cold, in which the eyes, as well as the pituitary cavities, fauces, and trachea, are affected. It is not unfrequently occasioned by change of weather, sudden transitions from heat to cold, the prevalence of easterly winds, journeys through damp unhealthy, sandy countries, in the hot season of the year, exposure of the eyes to the vivid rays of the sun, draughts of cold air, dust, &c. Hence, it does not seem extraordinary, that it should often make its appearance as an epidemic, and afflict persons of every age and sex. As additions to the list of remote causes, authors enumerate the suppression of some habitual evacuation, as bleedings from the nose, or piles, the menses, &c. a disordered state of the *primæ viæ*, worms, dentition, &c.

Between Beer and some late writers, there is either one point of difference in their descriptions of external ophthalmia, or else they mean different cases; for while Beer represents the redness as affecting the sclerotica at first more than the conjunctiva, other writers describe the affection of the sclerotica as generally secondary, when it happens at all; for according to modern observations, it is not *unavoidably* either an attendant upon, or an effect of simple inflammation of the conjunctiva.

As the second stage of external ophthalmia comes on, the symptoms vary, according to the degree of the complaint in its first stage; but when what Beer calls a *true chemosis* is produced, the following are described by him as the usual appearances. The circular prominent fold of the conjunctiva round the cornea, becomes of a dark red colour, and the swelling increases, but it becomes softer and less painful. The hardly visible portion of the cornea, situated in the depression formed by the circular protuberance of the conjunctiva, seems at first perfectly white, and afterward yellowish, being the seat of more or less purulent

matter. Though the swelled conjunctiva is every where moistened with a thin whitish mucus, this secretion, says Beer, is never so copious as to run over the face, as in the case of ophthalmoblenorrhœa. In this stage, the lower eyelid is turned somewhat outwards, in consequence of its lining becoming more swelled. While suppuration is taking place in the cornea, attended with the febrile symptoms which usually accompany the formation of acute abscesses, little collections of matter sometimes occur at different points of the conjunctiva, and after they have burst, a probe may easily be passed rather deeply into them, without any particular pain. (Beer, B. 1, p. 412.) The suppuration continually advancing, the swelling of the conjunctiva, and of the whole eyeball now diminishes, the effects of the inflammation penetrate deeply into the organ, and the structure of the eye is so altered as not to be cognizable, the part shrivelling up, as Beer says, into a motionless, whitish mass. However, according to this author, these deep effects of suppuration are sometimes produced only in a certain part of the eyeball, especially when the chemosis is the consequence of an external injury, and in this circumstance, the rest of the circumference of the globe of the eye exhibits its natural organization, while in the part above alluded to, there is a funnel-like depression, attended with a considerable diminution in the size of the organ.

But, says Beer, when an idiopathic external inflammation of the eye has only attained the milder degree, expressed by the term *taraxis*; as, for instance, when the complaint is principally owing to the lodgment of some mechanically, or chymically irritating substance under the eyelids, the redness of the conjunctiva and sclerotica undergoes a remarkable increase on the accession of the second stage; the first of these membranes becomes somewhat swelled; the pain is lancinating and irregular; and the secretion of tears unusually profuse; but at the point where the extraneous substance lodges, an open superficial suppuration occurs, and according to Beer, the case both in the first and second stage, is generally accompanied with no febrile symptoms.

In the first stage, Beer represents the prognosis as very favourable, provided the disorder does not exceed that degree, to which the name of *taraxis* is applied; for with the aid of proper treatment, the inflammation, when of a healthy kind, may be soon so favourably removed, as not to leave a vestige of it behind. If the cause of the disorder be not greater than a moderate injury or wound of the eye, any traces of the lesion, which are perhaps still remaining, will disappear as soon as the inflammation subsides. On the other hand, when this kind of ophthalmia presents itself in the form of *true chemosis*, the prognosis is serious, and must be made with great reserve, especially when the patient is of a

weak irritable constitution, a child, very stubborn and unmanageable, or incapable of following strictly the advice which he receives from his medical attendant; for, under these circumstances, it will not be in the power of the latter to prevent the complaint from advancing unremittingly to its second stage, in which event the ill consequences of suppuration will be incalculable. But if these unfavourable conditions are not present, though the genuine idiopathic chemosis may really have attained a violent, and almost its highest degree in the first stage, not only the eye may be saved by prompt and judicious treatment, but also the eyesight; nor will the result be different, even when the cornea continues for some time deprived of its transparency, and the power of vision impaired by a slight varicose affection of its conjunctival covering. These effects, says Beer at length completely disappear, less in consequence of the aid of medicine, than of a proper regimen, the uninterrupted enjoyment of a fresh, dry air, &c.

The prognosis in the second stage, is under very different circumstances; for, as Beer observes, though the inflammation in the first stage may really not exceed that degree which is implied by the term *taraxis*, yet if any suppurating point, occasioned by some slight preceding injury, be not efficiently treated, or if there be any loss of substance, already produced by the injury itself, a more or less opaque, white cicatrix is apt to remain on the cornea, and cause a permanent impediment to vision in a degree determined by the situation and extent of the opacity. And in addition to this risk it is to be remembered, that if the suppurating point be entirely neglected, or erroneously treated, the cornea or sclerotica may be penetrated by ulceration, and in the first case, a prolapsus of the iris, an adhesion of this organ to the cornea, (*synechia anterior*), a disfigurement of the pupil, or an irregularity of the cornea, be produced; while, in the second, the consequences may be a partial wasting away of the eyeball, attended with loss of sight, and of the natural shape of the part. (Beer, B. 1, p. 417.)

Beer further observes, that when this species of ophthalmia presents itself in its first stage in the form of *true chemosis*, the prognosis in the second stage is very unfavourable; for when the cornea is generally pervaded by suppuration, the eyesight, and, in some degree, the form of the eyeball, are for ever lost, and it will be lucky, if the case can be brought to a conclusion with the mere destruction of the cornea. But when the matter points at once in several places of the conjunctiva, round the cornea, all idea of preserving the shape of the eye sufficiently for the application of an artificial eye is out of the question, and the surgeon will be very successful, if he can now check in moderate time the suppuration, which continues with a good deal of general indisposition. An extraordinary relaxation of the conjunctiva of the lower eyelid,

and a consequent ectropium, are the least disastrous effects of the abscesses of the eye thus produced. Lastly, Beer remarks, that when chemosis is in the second stage, that is to say, attended with suppuration of the eye, it rarely happens, under the most favourable circumstances, that the eyesight and shape of the organ can be preserved entirely free from permanent injury. (*B. 1, p. 418.*)

Let us next consider the treatment of idiopathic external ophthalmia in its modifications of simple inflammation of the conjunctiva, mild acute ophthalmia, or taraxis, and severe acute ophthalmia, with chemosis.

According to Mr. Travers, simple inflammation of the conjunctiva unconnected with injury of the eye, and neither depending upon any established disorder of the system, nor modified by a scrofulous diathesis, may be easily and speedily reduced, even in its most acute form, by bleeding, and some brisk doses of purgative medicine. (*Synopsis of the Diseases of the Eye, p. 247.*) For the relief of mild acute ophthalmia, Scarpa recommends low diet, gentle purging with small repeated doses of antimonium tartarizatum, the removal of any extraneous body lodged under the eyelid, and frequently washing the eye with a warm decoction of mallow leaves, and covering it with a very soft emollient poultice, included in a fine little muslin bag. Mr. Travers also expresses his decided preference to a tepid application in the painfully acute stage of inflammation, and considers simple warm water generally better than medicated lotions, like the aqueous solution of opium, or infusions of poppy and hemlock.

When the disease presents itself in its first stage, in the mild form of taraxis, says Beer, it usually runs its course, quite uncomplicated with any general indisposition, and may be cured by moderate antiphlogistic treatment, in which, indeed, since the eyeball itself is affected, particular attention must be paid to lessening the action of the light and air upon the organ. But when a true chemosis is present, every antiphlogistic means must be promptly and rigorously put in practice, internal as well as external remedies being employed, and besides common measures, the conjunctiva, round the cornea, is to be scarified; a proceeding never necessary in the case of taraxis. Such scarifications, Beer observes, have a wonderful effect when practised at the proper period, after venesection and topical bleeding with leeches have been fully put in execution, and when the cuts are made deep, so as to produce immediately a copious discharge of blood. "By means of such scarifications (says he) I have seen the inflammation and all its threatening effects recede, as it were, before my face, when no material relief could be effected by other measures." (*B. 1, p. 419.*)

According to the late Mr. Ware, there cannot be, in chemosis, an easier or more effectual remedy than aether. A few drops

are to be poured into the palm of the hand, and diffused over it, which may be immediately done by pressing the other hand against it. The hand is then to be applied to the eye, and kept so close to it that the spirit, as it evaporates, may insinuate itself into the part affected, and act on the extravasated blood, so as to disperse it. In a few instances of chemosis, in which the swelling and inflammation have been considerable, this gentleman found the following application of singular service: *R. Interiorum foliorum recentium Lactucæ Sissilis ℥iij. Coque cum aq. pur. ℥ss. in balneo marie pro semihora; tunc exprimatur succus, et applicetur paululum ad oculos et ad palpebras sæpe in die.* (*Ware, p. 54.*) As these applications are not noticed by the generality of modern writers, I infer, that the superior efficacy imputed to them by the late Mr. Ware, is not such as to obtain the confidence of all other ophthalmic practitioners.

General and local bleeding, and, if chemosis be present, scarifications having been put in practice, the treatment is to be continued by administering purgatives of the mildest description, and, after their operation, applying blisters, according to the directions given in a preceding part of this article. In the first stage of severe acute ophthalmia, Scarpa considers topical emollient applications to the eye most beneficial, such as mallows boiled in new milk; bread and milk poultices; or the soft pulp of a baked apple; all included in fine little muslin bags. Remedies of this description should be renewed at least every two hours. The patient should be directed to observe perfect quietude, and to lie with his head in an elevated position. To keep the eyelids from adhering together in the night-time, the spermaceti cerate is proper. When ophthalmia is accompanied with a violent pain in the head, the late Mr. Ware recommended a strong decoction of poppy-heads to be applied as a fomentation. (*P. 51.*)

Under the preceding plan of treatment, the first stage of severe ophthalmia commonly abates in about a week. The burning heat and darting pains in the eyes, and the febrile disturbance of the constitution subside. The patient is comparatively easy, and regains his appetite. The eyes become moist again, and can now be opened without experiencing vast irritation from a moderate light. In this state, notwithstanding they may continue red, and the conjunctiva swelled, all evacuations are to be left off, as well as the use of topical emollients, for which latter astringent, corroborant collyria are to be substituted. Scarpa recommends the following application: *R. Zinci sulphatis gr vj. Aquæ distillatæ ℥vj. Mucil. sem. cydon. mali ℥j. Spiritus vini camphor guttas paucas. Misce et cola.* This collyrium may be injected with a syringe, between the eye and eyelids, once every two hours; or the eye may be bathed in it by means of an eye-cup. Such persons as cannot bear cold applications to the eye, must have the same kind of collyrium a little

warmed; but as soon as the irritability is lessened, it may be used cold.

Scarpa then speaks of the good effects produced in the second stage of ophthalmia by the application to the eye of two or three drops of the vinous tincture of opium, once or twice a day; a subject already considered in the foregoing columns. The utility of letting the eye be habituated to the light, as soon as it can bear it, is next strongly commended; a rule of great importance, but on which I need not here dwell, because it has been already insisted upon in the general observations.

When idiopathic external ophthalmia has terminated in suppurations of little extent, Beer speaks highly of the benefit derived from a solution of the lapis divinus, (see *Lachrymal Organs*) containing the liquor plumbi subacetatis, or from smearing the suppurating points with a little laudanum. In worse cases, Beer states, that, when such local treatment is combined with the internal exhibition of bark and naphtha, and a diet and regimen conducive to the support of the system, its efficacy is very great. And here, says he, it is worth observing, that while the solution of the lapis divinus is of great service in the second stage of *true chemosis*, it is more or less detrimental in the kind of chemosis which accompanies purulent ophthalmia, especially if not blended with mucilage, and, even when thus qualified, it cannot be endured by weak and irritable subjects, affected with the latter complaint; a fact not observed in other instances of chemosis. (*B. 1, p. 420.*) To Mr. Ware's use of æther in chemosis, I have already adverted.

When pustules, or abscesses in the swelled conjunctiva point round the cornea, a free outlet to the matter must be immediately made in each of them with a lancet; for, if this be not done, as Beer observes, the matter will spread extensively, and the eyeball be in danger of being destroyed. For an account of the method of treating the eversion of the lower eyelid, sometimes remaining as a consequence of the disorder, see *Ectropium*.

Inflammation of the Sclerotica. Scleritis.—The modern attempts to class ophthalmias, according to the texture of the eye first or chiefly affected, promises, I think, to lead to clearer views of the subject, and sounder practice. One circumstance, particularly adverted to, both by Dr. Vetch and Mr. Travers, in inflammation of the sclerotica, is the appearance of a vascular zone at the margin of the cornea. By the latter gentleman, this effect is ascribed to the particular distribution of the vessels. "Branches from the straight vessels of the conjunctiva, penetrate the sclerotica obliquely towards the margin of the cornea, and the long ciliary vessels pass in sulci of this membrane to the plexus ciliaris at the root of the iris. At the interior border of the sclerotica, where the annulus ciliaris is adhering closely to this tunic, the ciliary communicate with the muscular branches, and being in deep-

seated inflammation fully injected with red blood, the condensation of colour gives the well-known and remarkable appearance of a vascular zone at the margin of the cornea." (*Synopsis, &c. p. 126.*) According to Dr. Vetch, only a few interspersed trunks are posteriorly observed, "which do not affect the natural appearance of the intermediate space, but these, diverging as they come forwards, produce a zone more or less complete, of minute hair-like vessels, distinguished by their rectilinear direction, and their uniform concentration towards the margin of the cornea; their colour advances with the progress of the disease, from that of a delicate pink, or damask rose, to a deeper hue, and imparting a faint blush to the part immediately surrounding it." (*On Diseases of the Eye, p. 27.*) There appears, however, to be a good deal of variety in the symptoms of scleritis; for rheumatic inflammation of the eye, described by Professor Beer and Mr. Wardrop, as particularly affecting the sclerotica in common with other fibrous membranes, is not noticed by these authors as characterized by the red zone round the edge of the cornea. Indeed, instead of there being posteriorly only a few interspersed trunks, Mr. Wardrop states, "that (in rheumatic ophthalmia) the blood-vessels are generally *equally* numerous over the whole white of the eye, passing forwards in nearly straight lines from the posterior part of the eyeball, and advancing close to the cornea; but neither passing over it *nor* leaving the pale circle around it, which is so striking when either the choroid coat or iris is inflamed. If the vessels be closely examined, the general redness will be found produced more from numerous small ramifications than a few large trunks." (*Med. Chir. Trans. Vol. 10, p. 3.*) However, as if there must be no harmony on this subject, Beer describes the blood vessels, in rheumatic ophthalmia, not as being *equally* numerous over the whole white of the eye, but as being in some places collected in larger numbers or clusters, and he differs again from Mr. Wardrop, in describing the redness as coming on with considerable intolerance of light, (*Lehre von den Augenkr. B. 1, p. 397—398.*) while the latter author distinctly mentions, that "the eye does not seem to suffer from exposure to light." (*Med. Chir. Trans. Vol. 10, p. 6.*) I can only reconcile these accounts by concluding, that sclerotic inflammation, like that of other textures of the eye, has stages and modifications which account for these seeming contradictions. And, with respect to the vascular zone round the edge of the cornea, it would appear, at all events, to belong to iritis, as well as sclerotic inflammation. The vessels of the sclerotic coat are observed by Dr. Vetch to follow the motion of the eye, and he says, that they may, by this circumstance, be distinguished from those of the conjunctiva, "the vessels of the latter, independent of their darker colour, their more tortuous form, and varying size, have likewise a more longitudinal direction, and as they proceed

from the angles of the orbit, they form radii of a larger circle. The distinction between the inflamed vessels of the conjunctiva and the sclerotica, (says Dr. Vetch) I consider to be, therefore, obvious; but, *that any difference can be observed in the arrangement, or appearance of the vessels of the latter, sufficiently distinct to indicate the peculiarity of the exciting cause, or specific nature of the case, is more than I have been able to perceive.* The general character, as it arises out of the structure of the part, will be found the same, whether the cause be gout, rheumatism, or syphilis. The vessels, such as I have described them, will always be most observable on the upper portion of the eye, as it is in that place that the inflammation is most intense, except when its locality is affected by any external exciting cause, in which case it will be greatest near the injured part." (*On Diseases of the Eye*, p. 29.)

While Dr. Vetch describes the vessels of the conjunctiva as exhibiting in sclerotic inflammation a darker colour than that of the vessels of the sclerotic coat itself, Mr. Travers represents the vessels of the *latter membrane*, which pursue a straight course to the margin of the cornea, as having a somewhat darker hue than the areolar vessels upon the loose portion of the conjunctiva.

It should be mentioned, however, that by sclerotic inflammation Dr. Vetch signifies inflammation of the eye itself, as contrasted with conjunctival inflammation; but, how far this will account for the differences, above pointed out, between his description and that of Mr. Travers, I am not prepared to say. According to Mr. Travers, ordinary inflammation of the sclerotica is secondary, that is to say, this membrane is usually affected only as intermediate to the conjunctiva and the other tunics. However, he has occasionally observed, in a recent ophthalmia, a turgescence of the vessels, which pursue a straight course to the cornea, unaccompanied with any affection of the iris, and so slight a vascularity of the loose conjunctiva, that he was disposed to regard the case as a primary scleritis. The inflammation, he says, is not acute, and the motions of the eyeball are painful. It sometimes accompanies, and sometimes follows rheumatic inflammation. If continued, it presents the vascular zone and a pupil contracted, or drawn a little to one side. It is often seen in company with eruptions, or sorethroat, of a pseudo-syphilitic character, or is secondary to gonorrhœa. (*Travers, Synopsis, &c.* p. 123.)

The practice recommended by this gentleman, is as follows: obtuse pain in the eyeball, he says, may be materially relieved by blood-letting, and by antimony and ipecacuanha with opiates. Mercury is stated to have much less power over this case, than iritis. In general, the patient is seriously reduced, and very irritable, from suffering, rheumatic inflammation in the elbow, knee, or ankle; a state, to the production of which the previous use of mercury has commonly contributed. But though such is

stated to be the case, the moderate and cautious employment of this mineral is set down as generally indispensable in the treatment. And in the interval of the mercurial action, the nitric acid is alleged often to be of great service. The preparations of mercury preferred by Mr. Travers in these cases, are the oxymercurate in doses of one 1-12 or 1-8 of a grain, and the hydrargyrus cum creta, in doses of from five to ten grains, twice or thrice a day. As auxiliaries for allaying irritation, he prescribes the pulv. ipecac. comp. hemlock, hyosciamus, and the extract of sarsaparilla, either dissolved in the decoction, or taken solid. (*Vol. cit.* p. 289.)

On rheumatic inflammation of the eye, a few observations will be hereafter inserted. *Idiopathic Inflammation of the Internal Textures of the Eyeball, or Internal Ophthalmia in general.* According to Beer, internal inflammation of the eye does not always originate in one particular texture, but, in some instances, commences in the retina, choroides, &c.; while, on other occasions, its principal seat is in the iris, from which membrane it quickly extends itself to the corpus ciliare, and the crystalline lens and its capsule, or else in another direction to the sclerotica, cornea, &c. These differences in the seat of the disorder obviously depend upon the way in which the exciting causes have operated; for, when they are such as immediately affect the retina only, the inflammation must have its origin in this texture, as when the disorder is produced by the effect of the sudden entrance of any very strong vivid or reflected light into the organ. This case Beer denominates *ophthalmia interna idiopathica, proprie sic dicta*.

The exciting causes, however, may not affect directly the retina, and parts immediately next to it, but may operate chiefly upon the iris, in which event, this part is the chief seat of the inflammation, and the complaint is named both by Schmidt and Beer, *iritis idiopathica*. This form of inflammation, Beer says, is seen after the extraction of the cataract, and accidental injuries of the eye, where the weapon, with which they were produced, has either penetrated directly to the iris, and more or less caused it, or roughly entered the eyeball near the ciliary edge of this membrane, without actually wounding it. (*Lehre von den Augenkrankh.* B. 1, p. 421.)

Symptoms of the first stage of idiopathic internal ophthalmia, properly so called. While a very uneasy sensation of general constriction and tension affects the whole eyeball, and soon changes into an obtuse, deep throbbing pain, increasing every instant, and quickly propagating itself over the eyebrows to the top of the head, as Beer observes, the power of vision gradually declines, and, at the same time, the pupil, which previously loses its clear shining blackness, contracts without being deprived of its circular figure, or drawn out of its natural position, until, at length, it is so completely closed, that the iris seems as if it had no aperture whatever. But long before this perfect closure of the pupil has taken place, the power of seeing is entirely

gone, though after the faculty of perceiving the external light is extinguished, fiery appearances, which trouble the patient seriously, are seen at each pulsation of the blood-vessels within the eye. As the development of these symptoms is going on, the iris evidently loses its natural colour, becoming, as Beer says, greenish, when it was gray, or blue; and reddish, when it was brown, or black. In consequence of the iris swelling, and projecting towards the cornea, the anterior chamber becomes considerably diminished. Immediately the least mark of the swelling of the iris is seen, together with a moderate degree of contraction of the pupil, the whole sclerotica assumes a pink-red colour; a plexus of innumerable blood-vessels is seen in the conjunctiva; and the cornea loses a good deal of its natural brilliancy, without being actually opaque. The latter symptoms of this form of ophthalmia are attended with manifest general indisposition, and intolerable headach. Sometimes in the first stage of the case, the pupil, though much lessened, is not absolutely closed, but thickish and if examined with a magnifying glass, it has a red ish-gray appearance, and the power of vision, notwithstanding the continuance of the aperture, is quite lost. (Beer.)

Symptoms in the second stage. According to the same author, while the eye is suffering very irregular throbbing pain, attended with a sensation of heaviness and cold in the eye, an increase of the redness of the conjunctiva, severe constitutional disturbance, and constant shivering, there is suddenly formed at the bottom of the anterior chamber a collection of matter which above presents a horizontal line, but on every inclination of the head sideways, changes its position. This matter continues to accumulate more and more, until it not only reaches the pupil, but fills the whole of the anterior chamber, constituting the case termed *Hypopium*. If the disease be left to itself, says Beer, the matter collects in such quantity, that the cornea is rendered more prominent, and afterward conical, very like an abscess, ultimately bursting during an aggravated attack of pain, when the eye shrinks, and the sufferings gradually cease. This kind of hypopium Beer names *true*, in order to distinguish it from the case, in which the matter passes into the anterior chamber out of an abscess in the cornea, and which he terms a *false* hypopium. When, at the end of the first stage, the pupil is not entirely closed, one may discern in the second stage, at the period of matter presenting itself at the bottom of the anterior chamber, (though not easily with the unassisted eye) whitish filaments, extending from the edge of that opening towards its centre, produced by the coagulable lymph effused in the aqueous humour, the secretion of which was interrupted in the first stage, but now commences again. And, continues Beer, one may perceive, with a good magnifying glass, a very delicate cobweb-like membrane, which, when the matter collected lies over the pupil, and remains for a good while unabsorbed, at length becomes quite yel-

low, the matter being really encysted by it in the form of a small lump, which remains in the pupil, and partly projects into the anterior chamber, forming the case, which Beer denominates a *spurious purulent cataract*, to which the edge of the iris is so closely adherent, that sooner than a separation could be effected, the whole of the iris would be torn in pieces. When the pupil has been completely closed in the first stage, these effects of course cannot take place.

Beer remarks, with respect to the causes of this form of ophthalmia, that, as there are not many circumstances which can produce it, the case belongs rather to the less frequent kinds of inflammation of the eye. As predisposing, he mentions plethora and irritability of the eyes, occasioned by little exercise of them. Experience has convinced him, however, that by far the most usual cause of this internal ophthalmia is an extraordinary, long-continued straining of the eye in the inspection of small microscopic objects in a strong reflected light.

Respecting the prognosis, it is remarked by Beer, that this is not unfavourable, when the inflammation of the eyeball is moderate, proper treatment can be immediately employed, the pupil is not yet very much contracted, and the power of seeing not considerably impaired. But if the power of vision should seem as if it were abolished, the prognosis is extremely uncertain. And if the pupil should close after the entire stoppage of vision, no hope can be entertained of the recovery of the sight; for if the pupil open again on the subsidence of the inflammation, it will yet continue very small and motionless, and the eye blind. When the case is mistaken in its first stage, and neglected or erroneously treated, Beer says, it changes into a very perilous general inflammation of the whole eyeball; a disorder already considered.

In the second stage the prognosis is always unfavourable; for the eyesight has always been already destroyed at the end of the first one, and the only expectation of the practitioner can now be to preserve the shape of the eye, while as speedy a cure as possible is put to the suppuration. If the case has been so mismanaged in its first stage, that a violent inflammation of the whole eyeball is inevitable, and traces of chemosis are already present, the chances of the figure of the eye being lost in the second stage are still greater, and as Beer observes, the surgeon will be fortunate, if he can now prevent a frightful morbid change of the organ.

In the treatment of the first stage, Beer describes the indications as being exactly the same as in common ophthalmia, except that no scarifications are necessary, unless the case change into a violent inflammation of the whole eyeball. However, great promptitude in the application of proper curative measures is here particularly called for, as the least delay is apt to cause either a total loss of sight, or at least a serious impairment of it. (Beer.)

With few exceptions, the treatment of the second stage is also like that of ophthalmia
